**Springer Handbook
of Medical Technology**

Springer Handbook provides a concise compilation of approved key information on methods of research, general principles, and functional relationships in physics and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes will be designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Preface

This Springer Handbook is an overview of the expanding and exciting field of medical technology in which the reader will find a modern presentation of the relevant aspects of research, design, manufacturing, and application of different medical devices. The following components: Basics, Functional Diagnostics Devices, Monitoring, Medical Imaging, Therapeutic Devices, Rehabilitation, Medical Information Processing, Telemedicine, Equipment and Tools cover the major aspects of this field.

The handbook was compiled to be an indispensable resource for professionals working directly or indirectly with medical systems and appliances. Just as importantly, it was organized for graduate and postgraduate students in hospital management, medical engineering, and medical physics.

Medical technology has a long and productive tradition of developing medical devices, and innovative approaches to solve critical problems in medicine, biology, and environmental sciences. Hence, biomedical engineering is a rapidly developing field, which exemplifies multidisciplinary approaches such as biotechnology, microsystems technology and telematics. Biomedical engineers develop devices and systems which ultimately contribute to the identification, treatment, abatement and monitoring of diseases and to the compensation of disabilities. The use of modern diagnostic methods enables the early and safe identification of numerous diseases and improving therapeutic outcomes. Using engineering methods to address medical problems will foster additional breakthroughs in clinical treatment and management.

The transfer of ideas from basic research and prototyping to the final medical product, including the

methodological questions of application requires continued cooperation between teams. The result of the interaction of basic and clinical medical sciences, information technology, engineering, materials science, and cell biology will open up undreamed-of possibilities in diagnostics and therapy. Challenges include 4-D imaging, e.g. for beating heart diagnostics, coupling of microsystems to neurons, e.g. neural prostheses, the application of new biomaterials with surface modifications at the nanoscale, e.g. for the fabrication of a lifelong stable joining of hip prostheses, and the computer modeling of a virtual patient for the verification of diagnosis and direction of therapy.

Protection of patients, cost reduction and the consideration of progress in medicine as well as the technological state-of-the-art are significant challenges for the development of medical products. Hopefully this Springer Handbook will assist in the continued development of new medical products that will enhance the well being of patients.

The editors would like to thank the authors for their fruitful, successful and collegial cooperation. It was a pleasure for us to collect views from the different fields of medical technology and bring them together in the handbook. Special thanks to Dr. Werner Skolaut, Senior Manager Springer Handbooks, and Dr. Thomas Ditzinger, Senior Editor Engineering/Applied Sciences, from Springer publishing for their time, help and kind support.

About the Editors

Rüdiger Kramme, Graduate Engineer, studied Biomedical and Hospital Engineering as well as Economics in Gießen and Freiburg, Germany. After his studies, he acquired several years of professional experience in sales, marketing and human resources development in the medical device industry for consumer and investment capital goods. Since 1993 he is working for the German Federal State of Baden-Württemberg and the German Federal Armed Forces, where he is involved in planning and project development of University Hospitals and Military Medical Facilities in Germany and abroad. He is a lecturer for Medical Engineering at the University of Applied Sciences in Gießen, Germany. Rüdiger Kramme has authored numerous scientific publications in magazines and books, and is the founder and editor of the Springer standard work *Medizintechnik*, which will be published in its fourth edition in 2011, as well as the Springer Dictionary *Technische Medizin*.

Klaus-Peter Hoffmann received his Doctorate degree in Biomedical Engineering from the University of Technology in Ilmenau, Germany, in 1987. He is currently Professor of Biomedical Engineering at the University of Applied Sciences in Saarbrueck, and Head of the Department of Medical Engineering and Neuroprosthetics at the Fraunhofer Institute for Biomedical Engineering in St. Ingbert. His main research interests include methods and devices of Clinical Neurophysiology especially Neuromonitoring and saccadic eye movement as well as the use of Microsystems in medicine especially sensors and actuators for Neuroprostheses. He is also active in the field of cognitive technical systems. He has coordinated various European and national research projects, has published more than 200 journal papers, conference papers and book chapters. He is member of several scientific societies as well as in the advisory board of the journal *Das Neurophysiologie-Labor*. Since 2004, Professor Hoffmann has led the Expert Group Neuroprosthetics in the Initiative Micromedicine of the German Association for Electrical, Electronic & Information Technologies (VDE). He is also member of the Technical Committee on Cardiopulmonary Systems of the IEEE Engineering in Medicine and Biology Society.

Robert Pozos, Professor of Biology at San Diego State University, has been actively engaged in numerous studies utilizing various biomedical technologies to study human performance in extreme environments. His expertise extends to motor control studies in which he has two patents dealing with quantification of fatigue generated during typing using dynamic finger force measurements. His current studies deal with the quantification of surface electromyographic signals during various athletic events utilizing wifi technology. In addition he is continuing his studies that combine the use of NIRS measurements with EMG signals during movement.

Prashant Tathireddy

University of Utah
Electrical and Computer Engineering
Salt Lake City, UT 84112, USA
e-mail: p.tathireddy@utah.edu

Rachel Toomey

University of Dundee
Institute for Medical Science and Technology
1 Wurzburg Loan, Dundee Medipark
Dundee, DD2 1FD, UK
e-mail: r.toomey@dundee.ac.uk

Iasonas F. Triantis

Sensors Systems and Circuits Research Group
Department of Electronic and Electrical
Engineering
University College London
London, WC1E 7JE, UK
e-mail: i.triantis@ee.ucl.ac.uk

Jakub Trzebinski

Imperial College London,
South Kensington Campus
Institute of Biomedical Engineering
London, SW7 2AZ, UK
e-mail: jakub.trzebinski09@imperial.ac.uk

Friedrich Ueberle

Hamburg University of Applied Sciences
Department of Life Sciences/Biomedical
Technology
Lohbrügger Kirchstr. 65
21033 Hamburg, Germany
e-mail: friedrich.ueberle@haw-hamburg.de

Hans-Peter Uhlig

Österreicher Str. 69a
01279 Dresden, Germany
e-mail: cu-uhlig@t-online.de

Jörg Vienken

Fresenius Medical Care
Else Kroener Str. 1
61342 Bad Homburg, Germany
e-mail: joerg.vienken@fmc-ag.com

Udo Voges

Karlsruher Institut für Technologie
Institut für Angewandte Informatik
Hermann-von-Helmholtz-Platz 1
76344 Eggenstein-Leopoldshafen, Germany
e-mail: udo.voges@kit.edu

Birgit Wacker

Philips Healthcare
Hewlett-Packard Str. 2
71034 Böblingen, Germany
e-mail: birgit.wacker@philips.com

Golam Abu Zakaria

Hospital of the University of Cologne
Department of Medical Radiation Physics
Wilhelm-Breckow-Allee 20
51643 Gummersbach, Germany
e-mail: zakaria@kkh-gummersbach.de

Christian Zapf

Siemens AG – Healthcare Sector
Imaging and Therapy – SYNGO
Hartmannstr. 16
91052 Erlangen, Germany
e-mail: christian.zapf@siemens.com

Frank Zgoda

Laser- und Medizin-Technologie GmbH
Fabeckstr. 60–62
14195 Berlin, Germany
e-mail: f.zgoda@LMTB.de

Loredana Zollo

Università Campus Bio-Medico di Roma
Laboratory of Biomedical Robotics and
Biomicrosystems
Via Álvaro Del Portillo, 21
00128 Rome, Italy

Contents

List of Abbreviations	XXXVII
------------------------------------	--------

Part A Medical Technology Basics

1 Technology in Medicine: Its Role and Significance in Terms of Health Policy	
<i>Rüdiger Kramme, Heike Kramme</i>	3
1.1 A Short History	3
1.2 Early Breakthroughs of Medical Technology	3
1.3 Analog to Digital	4
1.4 Health Policy	5
1.5 New Key Areas	5
1.6 Innovation Versus Financial Resources	6
2 Medicine Is More Than Applied Technology for Human Beings	
<i>Giovanni Maio</i>	7
2.1 Technology Suggests Feasibility and Controllability	7
2.2 Technology Knows No Bounds	8
2.3 Technology Is Unable to Answer the Question of Meaning	9
2.4 Technology Alone Does Not Make Medicine Humane	9
References	10
3 Hygiene in Medical Technology	
<i>Heinz-Michael Just, Eckhard Roggenkamp, Annette Reinhardt</i>	11
3.1 Background	12
3.2 Causes of Infection	13
3.3 Vaccinations	13
3.4 Disinfection Methods	14
3.5 Sterilization Methods	21
3.6 Hygiene of Noninvasive Technology Equipment	25
3.7 Hygiene of Invasive Technology Equipment	26
3.8 Practical Examples	26
3.9 Regulations	31
References	33
4 Technical Safety of Electrical Medical Technology Equipment and Systems	
<i>Rüdiger Kramme, Hans-Peter Uhlig</i>	35
4.1 General Information Regarding the Safety of Technical Systems	36
4.2 Attaining Safety in Medical Institutions	36
4.3 Minimum Requirements for ME Equipment	37

4.4	Areas Used for Medical Purposes	40
4.5	Electrical Systems According to the Nature of the Connection to Earth	42
4.6	Protection Against Shock Currents	42
4.7	Power Supply	44
4.8	Power Sources for Safety Purposes with Accumulators	44
4.9	Final Circuits and Plug Sockets	45
4.10	Static Electricity	45
4.11	Electromagnetic Compatibility	46
4.12	Conclusions	47
	References	47
5	Quality Management in Medical Technology	
	<i>Albrecht Malkmus</i>	49
5.1	Objectives of a Quality Management System	49
5.2	Elements of a Quality Management System	54
5.3	Organization of a Quality Management System	54
5.4	Implementation of a QMS	56
5.5	Product Quality	57
5.6	Concluding Remarks	57
	References	58
6	Usability of Medical Devices	
	<i>Ulrich Matern, Dirk Büchel</i>	59
6.1	What Is Usability?	59
6.2	Usability in Medical Technology – Obligation or Opportunity?	60
6.3	Usability in Medical Technology – Why?	61
6.4	Development of Usable Devices – How Is this Done?	62
6.5	Testing of Usable Devices – How Is this Done?	64
6.6	Assessment of Usability	67
6.7	Usability Development, Testing, and Assessment – An Example	67
	References	70
 Part B Functional Diagnostics Devices		
7	Basic Diagnostics in Cardiology	
	<i>Rüdiger Kramme</i>	75
7.1	Electrocardiography	75
7.2	Electrocardiograph Equipment Technology and PC ECG	76
7.3	ECG Methods	79
7.4	Lead Systems	80
7.5	Methodological Notes	83
7.6	The Diagnostic Value of the ECG	83
7.7	Complications	84
7.8	Technical Safety Aspects of ECG Systems	84
7.9	Long-Term ECG	84

7.10	Long-Term ECG Systems	85
7.11	Computer-Based Assessment	85
7.12	Heart Rate Variability and Heart Rate Turbulence	87
7.13	Indications for Long-Term Electrocardiography	87
7.14	The Significance of the Long-Term ECG	87
7.15	The Exercise ECG	88
7.16	Equipment Technology	88
7.17	Reduced Exercise ECG Leads	89
7.18	Automatic ST Measuring Programs	90
7.19	Exercise Test.....	90
7.20	Methodological Notes	93
7.21	The Diagnostic Value of Ergometry.....	93
7.22	Indications	93
7.23	Abort Criteria and Safety Measures	93
7.24	Technical Safety Aspects.....	94
7.25	Notes on Planning.....	94
	Further Reading	94
8	Pulmonary Function Testing	
	<i>Rolf M. Schlegelmilch, Rüdiger Kramme</i>	95
8.1	Spirometry	95
8.2	Advanced Cardiopulmonary Function Testing.....	105
	References	116
9	Devices and Methods in Clinical Neurophysiology	
	<i>Klaus-Peter Hoffmann, Ursula Krechel</i>	119
9.1	Basics	119
9.2	Electroencephalograph.....	129
9.3	Electromyograph	138
	Further Reading	157
10	Sleep Diagnostic Systems	
	<i>Klaus-Peter Hoffmann, Robert S. Pozos</i>	159
10.1	Function and Application	159
10.2	Sleep Diagnostics, Sleep Laboratories, and Sleep Apneas	160
10.3	Technology	162
10.4	Sleep Diagnostic Procedures.....	165
10.5	Signal Recording and Signal Processing	166
10.6	Fields of Application	171
10.7	Methodical Instructions	172
10.8	Medical Significance of Sleep Diagnostics	173
10.9	Therapy	175
10.10	Safety Aspects	176
10.11	Planning Advice	176
	Further Reading	176

11 Nystagmography	
<i>Klaus-Peter Hoffmann, Eduardo Fernandez</i>	179
11.1 Application	179
11.2 Eye Movements	180
11.3 Technology and Methods	181
11.4 Methods	184
11.5 Signal Recording and Signal Processing	187
11.6 Medical Significance	187
11.7 Safety Aspects	188
11.8 Spatial Planning	188
References	189
12 Audiometry	
<i>Sebastian Hoth</i>	191
12.1 Physical, Technical and Physiological Bases of Audiometry	191
12.2 Behavioral Audiometric Assessment	200
12.3 Objective Audiometric Assessment	212
12.4 Technical Hearing Devices	228
References	242
13 Measurement Techniques in Ophthalmology	
<i>Albert J. Augustin</i>	245
13.1 Measurement of Intraocular Pressure	246
13.2 Optical Coherence Tomography (OCT)	247
13.3 Laser-Scanning Tomography with the Heidelberg Retina Tomograph (HRT)	249
13.4 Nerve Fiber Polarimetry with GDx	251
13.5 The Rostock Cornea Module (Confocal Laser Microscope)	252
13.6 Automatic Refractometry	252
13.7 Visually Evoked Potential (VEP)	253
13.8 The Ganzfeld ERG (Ganzfeld Electroretinogram)	254
13.9 Pattern Electroretinography (Pattern ERG, PERG)	257
13.10 Multifocal ERG (mfERG)	259
13.11 Electrooculograms (EOG)	260
13.12 Adaptometry	261
13.13 Aberrometry (Wavefront Analysis)	261
13.14 Keratometry	263
13.15 Retinoscopy or Skiascopy	263
13.16 Ultrasound	263
13.17 Corneal Topography	265
13.18 The Orbscan	265
13.19 Scheimpflug Examination	267
13.20 Fluorescence Angiography of the Retina (Sodium-Fluorescein)	267
13.21 Fluorescence Angiography of the Retina (Indocyanine Green)	269
13.22 Visual Field Measurement (Perimetry)	269
13.23 Exophthalmometry	271
References	271

14 Functional Force Assessment of Skeletal Muscles	
<i>Paul A. Iaizzo, William K. Durfee</i>	273
14.1 The Need for Skeletal Muscle Force Assessment	273
14.2 Manual Muscle Strength Testing	275
14.3 Advanced Muscle Assessment Methods	278
14.4 Stimulated Muscle Force Assessment	279
14.5 Stimulated Muscle Force Assessment in Animal Models	283
14.6 Conclusion	285
References	285
Part C Medical Imaging	
15 Digital Radiography	
<i>Lothar Heuser</i>	291
15.1 Historical Background	291
15.2 From Analog to Digital Image	292
15.3 Digital Imaging Systems in Radiology	296
15.4 Digital Image Processing	305
15.5 Image Communication and Archiving	307
References	309
16 Computed Tomography	
<i>Thorsten M. Buzug</i>	311
16.1 Background	311
16.2 Milestones of Computed Tomography	313
16.3 Computed Tomography Technology	318
16.4 Image Reconstruction	323
16.5 Scan Planning and Applications	329
16.6 Dose	335
16.7 Special System Designs	338
References	341
17 Ultrasound Diagnostics	
<i>Rudolf Götz, Frank Schön</i>	343
17.1 Basic Physical Principles	344
17.2 Visualization of the Blood Flow and Vascular System	348
17.3 Equipment Technology	350
17.4 Three-Dimensional Ultrasound (3-D, Real-Time 3-D)	360
17.5 Operation of an Ultrasound Unit	367
Further Reading	367
18 Medical Infrared Imaging	
<i>Gerald C. Holst, Thorsten M. Buzug</i>	369
18.1 Background	369
18.2 Infrared System Design	370
18.3 Infrared Physics	372

18.4	IR Imaging in Medical Applications.....	373
18.5	Specific Applications.....	374
18.6	Limitations of IR Imaging in Medical Applications.....	377
18.7	Summary.....	377
	References	378
19	Endoscopy	
	<i>Martin Leonhard, Klaus-Martin Irion</i>	379
19.1	Basics.....	380
19.2	Endoscopes and Endoscopic Accessories.....	382
19.3	Integrated Operating Theaters.....	391
19.4	Medical Applications.....	393
19.5	Tissue Differentiation.....	394
19.6	Further Future Developments.....	398
	References	402
20	Cone-Beam Computed Tomography and Navigation	
	<i>Dirk Schulze, Gerhard Hoffmann</i>	405
20.1	Technical Background of Dental Digital Volume Tomography.....	405
20.2	Areas of Application of Dental CBCT.....	408
	References	413
21	Interventional Radiology – Angiography	
	<i>Doris Pommi</i>	417
21.1	Definition of Digital Subtraction Angiography.....	417
21.2	Application Range for Angiography.....	419
21.3	Advantages of Interventional Radiology Procedures.....	420
21.4	Trends of Development.....	420
	Further Reading	421
22	Near-Infrared Spectroscopy (NIRS)	
	<i>John McNulty, Michael Born, Robert S. Pozos</i>	423
22.1	NIRS – Technical.....	423
22.2	NIRS Technology: Engineering Aspects.....	425
22.3	Instrumentation and Equipment.....	427
22.4	New Developments: Multidepth Differential Approach.....	430
22.5	Clinical Application and Study of NIRS.....	431
22.6	Does Skin Blood Flow Affect NIRS Measurements?.....	433
22.7	Future of NIRS.....	436
	References	437
23	Magnetic Resonance Imaging	
	<i>Wolfgang R. Nitz</i>	439
23.1	History of MRI.....	439
23.2	MRI – System Components.....	441

23.3	MRI – Basic Principles and Applications.....	446
23.4	MRI – Safety- Relevant Aspects	453
23.5	MRI – Pictures of the Future	456
	References	458
24	Magnetic Particle Imaging	
	<i>Jörn Borgert, Bernhard Gleich, Thorsten M. Buzug</i>	461
24.1	Introduction	461
24.2	A Brief History of Magnetic Particle Imaging.....	462
24.3	How Magnetic Particle Imaging Works	463
24.4	From Data to Images – Reconstruction	468
24.5	Beyond General Purpose Systems – Special Geometry	470
24.6	Putting MPI to Use – Applications	472
	References	474
25	MR-Guided Interventions and Surgery	
	<i>Andreas Melzer, Erwin Immel, Rachel Toomey, Fabiola Fernandez-Gutierrez</i>	477
25.1	MRI Basics.....	478
25.2	MRI Image Guidance for Interventions and Surgery in Comparison with CT and Ultrasound	479
25.3	MR Systems Design and Setup for Interventions and Surgery	479
25.4	Instruments for Interventional and Intraoperative MRI	482
25.5	MR-Applicable Endoscopic Instrument Systems.....	482
25.6	Instrument Representation and Tracking in MRI.....	483
25.7	MR-Guided Robotics and Navigation.....	485
25.8	Hybrid Multimodal Imaging for MR-Guided Diagnosis and Therapy..	491
25.9	Therapeutic MR-Guided Imaging.....	493
25.10	MR-Guided Delivery of Implants	494
25.11	Conclusions.....	498
	References	498
26	Devices and Materials in MRI	
	<i>Gregor Schaeffers, Andreas Melzer</i>	503
26.1	MR Safety.....	504
26.2	Interactions in the MR Environment.....	504
26.3	Examples of MR Artifacts Caused by Medical Devices.....	510
26.4	Evaluation of MRI Artifacts of Implants	512
26.5	MR Safety Labeling	514
26.6	Interpretation of MR Labeling	517
26.7	Discussion.....	518
	References	519

Part D Therapeutic Devices

27 Long-Term Ventilators for Intensive Therapy

<i>Thomas Peyn</i>	525
27.1 Tasks of the Ventilator	525
27.2 Function and Components of a Long-Term Ventilator	526
27.3 Technical Implementation	529
27.4 Controlling the Ventilator	530
27.5 Ventilation Procedures	531
27.6 Ventilation Extras and Special Functions	540
27.7 Patient Monitoring and Alarm Limits	543
27.8 Weaning Strategy and SmartCare/PS	543

28 Defibrillators and ICD Systems

<i>Rüdiger Kramme</i>	545
28.1 Defibrillator Technology	546
28.2 Therapeutic Intervention	549
28.3 Methodological Notes	550
28.4 Complications	551
28.5 Technical Safety Aspects	551
28.6 Implantable Cardioverter-Defibrillators	551
References	556

29 Laser Systems

<i>Frank Zgoda</i>	557
29.1 History of the Laser	558
29.2 Physics and Technology	558
29.3 Application Methods	564
29.4 Biophysical Effects on Tissue	564
29.5 Laser Types in Medicine	567
29.6 Fields of Use	571
29.7 Safety Aspects	574
29.8 Future Prospects	577
References	577

30 Inhalational Anesthesia Devices

<i>Erich Siegel</i>	579
30.1 Anesthesia Devices in General Anesthesia	579
30.2 Functional Principle, Medical Aspects	580
30.3 Functional Principle of the Main Components	582
30.4 Safe Operation Prerequisites	594
Further Reading	595

31 Extracorporeal Blood Purification Systems

List of Abbreviations

μ TAS	micro total analytical system	APOD	adaptive probe off detection
1-D	one-dimensional	APm	mean arterial pressure
2-D	two-dimensional	AR	augmented reality
3-D	three-dimensional	AR	automated refractometer
3-D CSI	three-dimensional chemical shift imaging	ARM	Aspen return monitor
4-D	four-dimensional	ART	algebraic reconstruction technique
		ASB	assisted spontaneous breathing
		ASD	atrial septal defect
		ASHA	American Speech and Hearing Association
A			
A-mode	amplitude mode	ASICS	application-specific integrated circuit
A/D	analogue/digital	ASL	arterial spin labeling
AAA	abdominal aortic aneurysm	ASSR	auditory steady-state response
AAL	ambient assisted living	ASTM	American Society for Testing and Materials
AAMI	Association for the Advancement of Medical Instrumentation		
ABI	auditory brainstem implant	AT	adaptive tripole
ABLB	alternate binaural loudness balance	ATC	automatic tube compensation
ABR	auditory brainstem responses	ATMP	advanced therapy medicinal product
AC	air conduction	ATP	antitachycardic pacing
AC	alternating current	ATP	adenosine triphosphate
ACC	American College of Cardiology	ATPD	ambient temperature and pressure, dry
ACD	absolute claudication distance	ATPS	ambient temperature and pressure, saturated
ACT	activated clotting time		
ADC	analog-to-digital converter	ATS	American Thoracic Society
ADHD	attention-deficit/hyperactivity disorder	AV	atrioventricular
ADL	advanced distributed learning	AVC	automatic volume control
ADSL	asymmetric digital subscriber line	AWIGS	advanced workplace for image guided surgery
ADT	admission, discharge, and transfer		
AEC	automatic exposure control		
AED	automated external defibrillator		
AEP	auditory evoked potential		
AEP	acoustic evoked potential		
AGC	automatic gain control	B	
AGC/i	input-controlled automatic gain control	B-mode	brightness mode
AGC/o	output-controlled automatic gain control	B2B	business-to-business
AGIT	Arbeitsgemeinschaft Informationstechnik	BAHA	bone-anchored hearing aid
AHA	American Heart Association	BANG	bis acrylamide nitrogen gelatin
AI	artificial intelligence	BAR	billing and accounting request
Aix	augmentation index	BART	breathing-adapted radiotherapy
ACF	autocorrelation function	BC	bone conduction
ALL	acute lymphatic leukemia	BCI	brain-computer interface
ALS	amyotrophic lateral sclerosis	BCM	body composition monitor
AMFR	amplitude modulation following response	BER	bit error ratio
AMI	alternate mark inversion	BERA	brainstem electric response audiometry
AMI	auditory midbrain implant	BERA	brainstem evoked response audiometry
AMIGO	advanced multimodality image-guided operating room	BF	body floating
		BGA	blood gas analysis
AML	acute myeloic leukaemia	BGO	bismuth germanate
ANSD	auditory neuropathy spectrum disorder	BILD	binaural intelligibility level difference
AP	anaesthetic proof	BIS	bispectral index
APD	auditory processing disorder	bit	binary digit
		BL	blended learning
		BMLD	binaural masking level difference

BOLD	blood oxygenation-dependent imaging	CGM	continuous glucose monitoring
BPEG	British Pacing and Electrophysiology Group	CGMS	continuous glucose monitoring system
BPH	benign prostate tissue	CGS	centimeter-gram-second
BPS	battery-supported power supply	CI	cochlear implant
BSE	bovine spongiform encephalopathy	CI	confidence interval
BSN	body sensor network	CIC	completely in the canal
BTB	bridge to bridge	CIM	ceramic injection molding
BTD	bridge to decision	cIONM	continuous intraoperative neuromonitoring
BTE	behind the ear	CIRS	computer integrated radiology system
BTPS	body temperature and pressure, saturated	CJD	Creutzfeldt–Jakob disease
BTR	bridge to recovery	CL	comfortable stimulation level
BTT	bridge a patient to transplantation	CLT	color lookup table
BVAD	biventricular assist device	CMCT	central motor conduction time
BfArM	Bundesinstitut für Arzneimittel und Medizinprodukte	CML	chronic myeloid leukemia
Bipol-TUR	bipolar transurethral resection	CMOS	complementary metal–oxide–semiconductor
C		CMRR	common mode rejection ratio
		CNAP	continuous noninvasive arterial pressure
		CNC	computer numerically controlled
		CNCA	Certification and Accreditation Administration of the Peoples Republic of China
CABG	coronary artery bypass grafting	CNS	central nervous system
CAD	computer-aided diagnosis	CNT	carbon nanotube
CAD	coronary artery disease	CNV	choroidal neovascularizations
CAL	computer-assisted learning	CNV	contingent negative variation
CAM	computer-aided manufacture	CO	cardiac output
CAP	contention access period	CPA	continuous positive airway
CAPD	central auditory processing disorder	CPAP	continuous positive airway pressure
CAS	compressed analog stimulation strategy	CPK	creatine phosphokinase
CAS	computer-aided surgery	CPOE	computerized physician order entry
CAT	computerized axial tomography	CPP	cerebral perfusion pressure
CBCT	cone-beam computed tomography	CPU	central processing unit
CBF	cerebral blood flow	CQC	China Quality Certification Centre
CBI	computer-based instruction	CQM	contact quality monitor
CBIR	content-based image retrieval	CR	computed radiography
CBT	computer-based training	CROS	contralateral routing of signals
CBV	cerebral blood volume	CRT	cardiac resynchronization therapy
CCC	China compulsory certificate	CRT	cathode-ray tube
CCD	charge-coupled device	CSCL	computer-supported cooperative/collaborative learning
CCITT	Comité Consultatif International Téléphonique et Télégraphique	CSCN	customer support clinical network
CCR	continuity of care record	CSCW	computer-supported cooperative work
CCU	camera control unit	CSF	cerebrospinal fluid
CCU	coronary care unit	CSMA-CA	carrier sense multiple access with collision avoidance
CCU	critical care unit	CSSD	central sterilization supply department
CD	compact disc	CT	computer tomograph(y)
CD-ROM	compact disc read-only memory	CTA	CT-angiography
CDA	clinical document architecture	CTG	cardiotocography
CDC	Center for Disease Control	CTI	computed tomography imaging
CDM	central display and control module	CTV	clinical target volume
CE	contractile element	CUNY	City University of New York
CEN	Comité Européen de Normalisation	CVC	central venous catheter
CENELEC	European Committee for Electrotechnical Standardization	CVD	cardiovascular disease
CERA	cortical electric response audiometry		
CF	cardiac floating		
CFP	contention-free period		

CVD congenital vascular disorder
 CVP central venous pressure
 CW continuous wave
 CWRUVA Case Western Reserve
 University/Department of Veterans
 Affairs

 EOG electrooculogram
 EOG electrooculography

EP	electropolished
EP	evoked potential
EPR	electronic patient record
EPSP	excitatory postsynaptic potential
ER	enhanced reality
ERA	electric response audiometry
ERB	equivalent rectangular bandwidth
ERD	event-related desynchronization
ERG	electroretinography
ERG	electroretinogram
ERP	early receptor potential
ERP	event related potential
ERS	European Respiratory Society
ERS	event-related synchronization
ERV	expiratory reserve volume
ESC	European Society of Cardiology
ESD	electrostatic discharge
ESWL	extracorporeal shock wave lithotripsy
ESWT	extracorporeal shock wave treatment
ESWT	extracorporeal shock wave therapy
ETL	echo train length
ETO	ethylene oxide
ETSI	European Telecommunications Standards Institute
EUG	ectopic pregnancy (Extrauterin gravidität)
EUS	endosonographic
EUTox	European Uremic Toxin Working Group
EVC	expiration volume capacity

F

FA	flip angle
FAEP	brainstem auditory evoked potentials (frühe akustisch evozierte Potentiale)
FBP	filtered back-projection
FCC	US Federal Communications Commission
FDA	US Food and Drug Administration
FDI	Fédération Dentaire Internationale
FDL	flashlamp pumped dye laser
FDRC	full dynamic range compression
FEL	free-electron laser
FEM	finite element method
FES	functional electrical stimulation
FET	FES therapy
FFE	fast field echo
FFP	field free point
ffs	form/fill/seal
FFT	fast Fourier transformation
FHN	Fitzhugh–Nagumo
FINE	flat interface nerve electrode
FIR	far-infrared
FIV1	forced expiratory volume in 1 s
FLAIR	fluid-attenuated inversion recovery
FLASH	fast low-angle shot
FMD	fibromuscular dysplasia

FMEA	failure modes and effects analysis
fMRI	functional magnetic resonance imaging
FMT	floating mass transducer
FO	formaldehyde
FOV	field of view
FP	Framework Programme
FRC	functional residual capacity
FSE	fast spin echo
FSK	frequency shift keying
FSM	Frederick S. Mikelberg
FSP	fine structure processing
FT	Fourier transformation
FTIR	Fourier transform infrared
FVC	forced vital capacity
FWHM	full width at half maximum
FoV	field of view

G

GA	genetic algorithm
GCP	good clinical practice
GEDV	global end-diastolic volume
GEF	global ejection fraction
GIF	graphics interchange format
GM	gray matter
GMDS	Society for Medical Informatics, Biometry and Epidemiology
GMG	Law on the Modernization of Healthcare
GOx	glucose oxidase
GPU	graphics processing unit
GRAPPA	generalized autocalibrating partially parallel acquisition
GRE	gradient echo
GS	general supply
GSDOM	German Society of Dental, Oral and Craniomandibular Sciences
GSM	Global System for Mobile Communications
GSR	galvanic skin response
GTV	gross tumor volume
GTWM	Georgia Tech Wearable Motherboard
GUI	graphical user interface

H

hcg	human chorionic gonadotropic
HCV	hepatitis C virus
HD	hemodialysis
HDD	hard-disc drive
HDF	hemodiafiltration
HDR	high-dose rate
HEMO	hemodialysis
HF	hemofiltration
HF	high frequency
HFCS	high-frequency current-switching
HFITT	HF-induced interstitial tumor therapy

HH	Hodgkin and Huxley	IHS	inspiratory help system
HI	hypopnea index	iIONM	intermittent intraoperative neuromonitoring
HINT	hearing in noise test	ILR	implantable loop recorder
HIS	hospital information system	ILV	independent lung ventilation
HL	hearing level	IMAT	intensity-modulated arc therapy
HL	hearing loss	IMRT	intensity-modulated radiotherapy
HL7	Health Level 7	INA	instrumentation amplifier
HLD	high level disinfection	IOERT	intraoperative electron radiation therapy
HLM	heart–lung machine	IOL	intraocular lens
HMD	head-mounted display	IOM	Institute of Medicine
HME	heat and moisture exchanger	IONM	intraoperative neuromonitoring
HMEF	heat and moisture exchange filter	IOP	intraocular pressure
HPC	health professional card	IP	intellectual property
HR	heart rate	IPPV	intermittent positive pressure ventilation
HRT	Heidelberg Retina Tomograph	IPSP	inhibitory postsynaptic potential
HTX	heart transplant	IQ	installation qualification
HU	Hounsfield unit	IR	infrared
HV	Vickers hardness	IRFI	infrared functional imaging
Hb	hemoglobin	IRMA	image retrieval in medical applications
Hbt	hemoglobin concentration	IROG	infrared oculo-graphy
HpD	hematoporphyrin derivative	IRV	inspiratory reserve volume
		ISDN	integrated services digital network
		ISE	ion-selective electrode
		ISF	interstitial fluid
		ISFET	ion-sensitive field effect transistor
		ISM	industrial, scientific, and medical
		ISO	International Standardization Organization
		IT	information technology
		ITBV	intrathoracic blood volume
		ITGV	intra-thoracic gas volume
		ITS	initial transmission slot
		ITU	International Telecommunication Union
		IVC	inspiration vital capacity
		J	
		jnd	just noticeable difference
		K	
		KIT	Karlsruhe Institute of Technology
		KV	health insurance (Krankenversicherung)
		L	
		LAN	local area network
		LAP	left atrial pressure
		LASER	light amplification by stimulated emission of radiation
		LCA	Leber's amaurosis
		LCD	liquid-crystal display
		LDA	linear discriminant analyzer
		LDH	lactate dehydrogenase
IC	inspiratory capacity		
IC	integrated circuit		
ICD	implantable cardioverter-defibrillator		
ICD	International Classification of Diseases		
ICD	implantable cardioverter–defibrillator		
ICD	initial claudication distance		
ICG	impedance cardiogram		
ICG	indocyanine green		
ICP	intracranial pressure		
ICSD	International Classification of Sleep Disorders		
ICSPE	International Commission for the Standardization of Ergometry Application		
ICT	information and communication technology		
ICT	information and computer technology		
ICU	intensive care unit		
ICW	intracellular water		
ID	identification number		
IDE	investigational device exemption		
IDEFIX	identification of dental fixtures		
IEC	International Electrotechnical Commission		
IEGM	intracardial electrogram		
IFOV	instantaneous field of view		
IG	insertion gain		
IGRT	image guided radiotherapy		
IGV	intra-thoracic gas volume		
IHC	inner hair cell		
IHE	integrating healthcare enterprises		

LDR	low-dose rate
LED	light-emitting diode
LF	low frequency
LFP	local field potential
LGN	lateral geniculate nucleus
LI	laser iridotomy
LITT	laser-induced thermotherapy
LLLT	low-level laser therapy
LLT	laser lithotripsy
LMS	learning management system
LOINC	logical observation identifiers names and codes
LPRT	low-power, real-time protocol
LSHD	light spot hydrophone
LTP	low-temperature plasma sterilization
LUT	look-up table
LVAD	left ventricular assist device
LWIR	long-wavelength infrared
LiDCO	lithium ion dilution

M

M-mode	motion mode
MAC	media access control
MAEP	middle latency auditory evoked potential
MAP	mean arterial pressure
MARS	adsorbent recirculating system
MC	microcontroller
MCS	mechanical circulatory support
MCSS	mechanical circulatory support system
MDCT	multidetector computed tomography
MDD	medical device directive
MDM	manage document message
MDR	medium-dose rate
MDS	move during scan
MDS	myelodysplastic syndrome
MDX	dystrophic mice
ME	medical electrical
ME	medical engineering
MEA	multielectrode array
MEDARPA	medical augmented reality for patients
MEDDEV	medical device
MEG	magnetoencephalography
MEMS	microelectromechanical system
MEP	motor evoked potential
MEQ	modified essay question
mfERG	multifocal ERG
MFI	micro flex interconnection technique
MFT	multifrequency tympanometry
MHLW	Ministry of Health, Labor and Welfare
MIB	medical information bus
MICS	medical implant communication service
MIP	maximum-intensity projection
MIS	minimally invasive surgery

MITOS	multimodality image-guided diagnosis and therapy setup
MLC	multileaf collimator
MLEM	maximum-likelihood expectation maximization
MLRA	middle latency response audiometry
MMN	mismatch negativity
MMS	multimedia message service
MMT	manual muscle testing
MOD	magneto-optical disc
MOG	magnetooculography
MPDA	microphotodiode array
MPE	maximum permissible exposure
MPI	magnetic particle imaging
MPI	master patient index
MPPS	modality performed procedure step
MPR	multiplanar reconstruction
MPS	magnetic particle spectrometer
MPS	maximum physical frame size
MR	magnetic resonance
MRI	magnetic resonance imaging
MRS	MR spectroscopy
MRSA	methicillin-resistant staphylococcus aureus
MRT	magnetic resonance tomography
MRT	minimum resolvable temperature
MRgFUS	MR-guided focused ultrasound
MS	multiple sclerosis
MSCT	multislice computer tomography
MSLT	multiple sleep latency test
MT	movement time
MTF	modulation transfer function
MTT	mean transit time
MUAP	motor unit action potential
MUP	motor unit potential
MV	minute volume
MVCT	megavoltage computer tomography
MVP	MedBiquitous virtual patient
MWIR	mid-wavelength infrared
MWT	maintenance of wakefulness test
Mb	myoglobin
MetHb	methemoglobin
Mi	mechanical index

N

NA	numerical aperture
NAA	<i>n</i> -acetyl-aspartate
NAL	National Acoustics Laboratories
NAS	network attached storage
NASPE	North American Society of Pacing and Electrophysiology
NBG	NASPE/BPEG generic pacemaker code
NBI	narrowband imaging
NBP	noninvasive blood pressure

NCIGT	National Center for Image Guided Therapy
nCPAP	nasal continuous positive airway pressure
NCV	nerve conduction velocity
NDIR	nondispersive infrared
NDT	nondestructive testing
NE	neutral electrode
NEDT	noise equivalent differential temperature
NET	noise equivalent temperature
NETD	noise equivalent temperature difference
NFD	nephrogenic fibrosing dermopathy
NFI	nerve fiber indicator
NIBP	noninvasive blood pressure
NICU	neonatal intensive care unit
NIHL	noise-induced hearing loss
NIP	needle image plate
NIR	near-infrared
NIRS	near-infrared spectroscopy
NIV	noninvasive ventilation
NMES	neuromuscular electrical stimulation
NMR	nuclear magnetic resonance
NN	nearest neighbor

Technology

1. Technology in Medicine: Its Role and Significance in Terms of Health Policy

Rüdiger Kramme, Heike Kramme

New avenues in diagnosis and therapy are today increasingly being opened up as a result of sophisticated and advanced technology, and at the forefront of this are evolutionary developments in existing technology. Many medical devices and pieces of equipment are developing at lightning speed as a result of digital technologies, which enable new medical concepts, strategies, and visions to be implemented faster than ever before. This means that developments which previously took a decade to implement are now being introduced at a rate of one a year. Technology thus not only has a dynamic interrelationship with medicine; it influences and shapes modern medical science on the

basis of new technical possibilities. First-class health care would be inconceivable without progress and innovation in the field of medical technology.

1.1 A Short History

Medicine (from the Latin *ars medicīna*, *the art of healing*) and technology (from the Greek, meaning *skill, craft*) have inspired and fascinated mankind since its early beginnings. Technical instruments and devices have always had their place in medicine. Acupuncture needles are known to have been used in Far Eastern medicine since approximately 2500 BC. Hippocrates (460–370 BC), the founder of scientific medicine in the Western world and a prominent doctor of his time, was already using a proctoscope to inspect his patients' intestines. He also gave descriptions of a variety of instruments and apparatuses for the treatment of

wounds. These included, for example, apparatuses with weights and straps which, in the case of an arm fracture, positioned the broken bones in relation to one another, straightened them, and simultaneously immobilized them. As striking evidence from archeological digs in the buried town of Pompeii has shown, sophisticated instruments and devices for surgical interventions were already being used in the Roman Empire (from 63 BC onwards). The vision aids known as glasses, on which many of us rely, are not an achievement of the 20th century but had already been invented by a craftsman at the end of the 13th century.

1.2 Early Breakthroughs of Medical Technology

The first major breakthrough in medical technology and boom in modern medicine took place around the turn of the 20th century with Röntgen's discovery of

x-rays in 1895. Although the nomenclature of the electrocardiograph (ECG) – which is still in use today – had already been decided by Einthoven in 1895, use

of the first clinically viable ECG was not possible until 1903. In 1896, Riva-Rocci introduced the method of noninvasive palpatory measurement for determining blood pressure. The electroencephalogram (EEG) was first recorded in 1924 by Berger using a string galvanometer. Other milestones in medical technology were the invention and introduction of the artificial kidney (1942), the heart–lung machine (1953), hip-joint prostheses (1960), artificial cardiac valves (1961), and the first clinical patient monitoring devices (around 1965). Criteria which had already been used for classification in the USA were developed for measurement and standardization of the ECG according to the Minnesota

Code around 1960. In the early 1940s, the construction of the first electronic computer ushered in a new era, and a new technology was born which was to revolutionize medical technology once more: data processing and information technology. This new technology overshadowed all the technological developments which went before it. If a modern calculator were equipped with electronic components (e.g., transistors) from 40 years ago, that calculator would require a power of 6000 W, provided by an electricity supply and emitted to the surroundings as heat. A weight of 50 kg and cube edges approximately 1 m in length would more likely suggest an oven than a calculator.

1.3 Analog to Digital

The radical change in technology from analogue to digital opened up new dimensions in medical technology: the computer tomograph (CT), which generates cross-sectional images of the body, was developed by Hounsfield and Cormack, and a prototype was installed and tested in a hospital in 1971. In 1977, Mansfield found success with a breakthrough for medical applications of magnetic resonance tomography using the magnetic resonance method, and the human thorax was imaged for the first time without the use of x-rays. Unique and sophisticated possibilities in diagnosis were introduced by a large-scale medical technology system which is used in nuclear medicine: the positron emission tomograph (PET). As an imaging system, the PET enhances the diagnostic range because it enables representations of physiological and metabolic processes in the human body to be determined both quantitatively and on a location-dependent basis. Molecular imaging with hybrid PET/CT scanners offers a view of things which had previously not been visible. However, other hybrids such as ultrasound and magnetic resonance imaging also not only have the advantage that they offer an image quality which is much more precise and accurate in every detail when compared with other imaging methods, but they can also be used without any exposure to radiation. It has so far been possible to reduce the radiation dose for a full body scan to as little as 40% compared with older systems.

As a result of the increasing integration of computer-based systems in x-ray technology, imaging methods are being redeveloped in ever shorter time cycles. The rapid growth of the spectrum of clinical

applications and the continuous further development and implementation of new technologies have not only led to an altered and extended range of indications for these methods. Furthermore, imaging technologies are increasingly being developed as a complete solution, such as hybrid systems for interventional radiology or integrated IT solutions (picture archiving and communication system (PACS), radiology information system (RIS), etc.) which aim to optimize processes and thus increase efficiency in hospitals. The increasing interconnectedness of technology will change the health system.

To outline the progress and development of all the devices and achievements in medical technology would be to go beyond the scope of this book. Although medical technology is in most cases not original but rather adopts technological developments from fields such as electronics, optics, precision engineering, and plastics technology among others, and these developments are only thought of as being part of medical technology when applied to living creatures, medical technology has nevertheless established itself as a field, and medical care today would be unthinkable without it. This fact reveals the real significance of medical technology:

Medical technology devices and equipment (including in the laboratory and research field) are individual or interlinked instruments, apparatuses, machines, appliances, and auxiliary devices, and any necessary equipment which is used because of its function for the identification (diagnosis), treatment (therapy), observation (monitoring), and prevention (prophylaxis) of illness in humans.

1.4 Health Policy

The aim of health policy must be to provide human, modern, high-performance, efficient, and people-orientated medical care both in hospitals and on an ambulatory basis, with the focus on the patient. In the future, diagnosis and therapy will be adjusted according to the genetics of the patient, and technical solutions will be orientated towards the interaction between diagnosis and therapy. Another trend is that of orientation towards disease patterns. This aspect is even more important, because the risks of acute illnesses will increase as a result of ageing society. Investment in health care should provide benefits, not only in terms of administration at the level of individual hospitals and clinics but also in terms of national economics.

The development of medical technology as an essential part of health care is in permanent interaction with the changes in social lifestyles. The significance of medical technology in terms of health policy is therefore essentially based on the following points.

- The quality and security of medical care as a result of continuous modifications and improvements to diagnostic and therapeutic options and promotion of medical and technological research, and furthermore with broad application and extension to large population and patient groups using equipment-based mass screening (e.g., within the scope of illness prevention).
- Shortening the duration of illness or the length of hospital stay, which will reduce costs and therefore bring about associated benefits in terms of national economics.
- Relieving staff from time-consuming routine jobs.
- Meeting the expectations and demand level of the population in terms of the quality of the processes and of the results in health care.

Future developments in technical medicine must be geared towards the additional demands of health care as a result of limited resources.

1.5 New Key Areas

A key area of technology in health care of the 21st century is telematics, which has the potential to bring

- Medical technological diagnosis and therapy with high cost-savings potential, using environmentally friendly equipment and systems.
- Further development of minimally invasive procedures with the aim of reducing morbidity rates and convalescence times.
- Miniaturized compact systems, which are less time and cost intensive in terms of installation and servicing.
- User-friendly and operationally reliable design, which substantially avoids faulty operation. Invasive techniques will increasingly be replaced by less invasive and/or noninvasive techniques, such as disintegration of kidney and gall stones using a lithotripter instead of surgical intervention, endoscopic minimally invasive interventions instead of conventional surgery, three-dimensional (3-D) echocardiography to show complex malformations of the heart, pathomorphological changes in the mitral or tricuspid valve, and atrial or ventricular septal defects instead of the complex and high-risk procedure of cardiac catheterization, and imaging the coronary vessels using magnetic resonance imaging instead of contrast angiography or diagnosis by cardiac catheterization.

It is becoming apparent that the boundaries between diagnosis and therapy are becoming increasingly blurred by the use of current technological solutions such as interventional radiological or endoscopic procedures, for example.

Where operative interventions in traditional surgery were performed using a scalpel and surgical instruments, in the foreseeable future these will to a large extent be replaced by the *light and sound* of noninvasive surgery. Successful high-energy ultrasound operations on the brain have already been achieved in the field of neurosurgery, meaning not only that there are new methods of treatment opening up but that there is even talk of a paradigm shift in neurosurgical therapy. Neurosurgical treatment by means of ultrasound in the case of psychiatric disorders, such as affective psychoses, for example, should also be possible in the future.

enormous advantages to all those involved in health care but will also mean that health care organizations

are faced with many new organizational, technological, and legal requirements. In the future, hospitals will be centers of telemedicine applications. Telemedical communication and systems – that is to say all IT applications in the health care system which are provided via public or long-distance communications networks – enable large amounts of data to be transferred quickly,

meaning that physical distance is no longer an obstacle. This is also a reason for the fact that increasingly great importance is placed on telemedicine internationally. These endeavors are aimed at developing a uniform platform for telematics, so that use of modern telecommunications and information technology will improve the quality of care and economic efficiency in the future.

1.6 Innovation Versus Financial Resources

Today, limited financial resources in hospitals mean that it is only rarely possible to introduce and exploit every technical innovation and possibility. It is therefore imperative for the user to evaluate any investment decisions on a commercial and performance-related basis (e.g., by process-orientated technology assessment, which takes account primarily of criteria such as performance, effectiveness, and efficiency). Particularly with respect to the advantages of a real investment, it is important that it is not emotional but rather rational criteria which are at the fore in the decision-making process. One of the key questions is whether there are limits to technical progress, and where these limits might lie. Assessment of technological possibilities with respect to their benefits for patients requires an understanding of modern technology and its limits. Frequently, the aim of medical technological manufacturers and suppliers is to provide medical technological products and medical data-processing systems which are better and more technically perfect every time. The result is that, these days, the functions of many medical technological products go far beyond the needs and possible uses for them. Users – who are usually not technophiles – will pay for something extra that they cannot use. Numerous sophisticated products are perhaps technically perfect but are rarely tailored to suit a need. There is a lot which is fea-

sible technologically, but equally it is obvious that humans can barely control this technology, as in the case of the complexity of various software interfaces, which are no longer completely understood even by highly qualified technicians. This means that the technical possibilities are frequently beyond the ability of many users to use them. Uncritical enthusiasm for technology can therefore very quickly turn into technophobia.

However, to do nothing or to make do without innovations and to cling to outdated technical products is not a solution either. In the future, the service provided to customers in hospitals or in a doctor's practice will itself become a product with greater potential for differentiation than the quality and technical performance of medical technological products. The innovations in medical technology which will also be indispensable in the future must have a *human dimension* and be tailored to suit a need. This will inevitably be embedded in the area of tension between technical and scientific knowhow, market orientation, and orientation towards individual customers. From the point of view of the user, virtually all products are becoming increasingly similar. Good customer service will be another factor in the success of medical products: the focus must increasingly be on the demand for products and not just supplying them *on offer*.

2. Medicine Is More Than Applied Technology for Human Beings

Giovanni Maio

Medicine owes many of its undeniable achievements to technological developments; without the elaboration of technologies, medicine would have been unable to devise or apply many methods of treatment which are, indisputably, a blessing for mankind. And yet, curative science has sometimes been dazzled by the alliance between medicine and technology. Medicine has been taken in by technology to such an extent that it has lost sight of what characterizes it as curative science and what constitutes its actual essence. Technology is not just a method to be chosen, but also a programme. Ethical reflections on the relationship

	References	10

between medicine and technology are presented in this chapter.

From the very moment when medicine presents a purely technical solution to the crisis of falling ill, medicine has not only chosen a method, but has devoted itself to a certain view of the world

and humankind. If the relationship between medicine and technology is to be understood adequately, these basic preconceptions about humanity must be contemplated.

2.1 Technology Suggests Feasibility and Controllability

Despite the uncertainty that still remains, a system that backs technology alone assumes a high degree of controllability of the system. In this case, that which is incalculable merely represents a challenge to the developer to perfect technology to make it controllable. If technology is now used to heal the ill, and as a central instrument at that, this engineer's way of thinking also infiltrates how physicians think. In other words, physicians who rely fully on technology are under the tacit assumption that the problems faced by medicine are generally problems that can be solved using technology. If a problem remains, however, technology is to blame for not being sophisticated enough, according to this credo. This way, it is assumed that basically everything is feasible and that all problems faced by mankind can be solved using technology. The reproductive-medicine

complex is one example of coupling treatment with technology. Reproductive medicine, in particular, which increasingly regards itself as a market-oriented service industry, equates remedy with the application of technical instruments; it responds to many persons' crisis of meaning by offering technical solutions. What is more, reproductive medicine implicitly declares the technical solution to be the only possible response to the challenge arising from involuntary childlessness. Medicine that regards itself in this way does not only create an offer, but also establishes standards that those who are confronted with involuntary childlessness are virtually unable to avoid [2.1]. In particular, however, reproductive medicine comprehended in this way fails to make use of the opportunity of making couples aware of the potential of alternative life

concepts at a sufficiently early stage. Such an absolutization of the technical solution leads to a continuation of infertile couples being dependent on the technical solutions offered by medicine, rather than making them aware that a crisis of meaning can also be overcome by giving life a new meaning, a meaning that may arise by opening up new prospects of life [2.2]. It is the example of reproductive medicine, in particular, that highlights the fact that humane medicine is more than about just being technically adept. It is equally important to invest in good consultation, in a good conversation which should, in particular cases, also include touching upon the potential failure of technology. Technology suggests feasibility –

as can be clearly seen using reproductive medicine as an example – and puts the *victims* of technology in a situation where they are unable to escape from the resulting technical imperative. Thanks to technology, every woman has the opportunity to fall pregnant, and if they still remain infertile, they just have not invested enough or have not had a sufficient number of attempts. It hardly occurs to the majority of physicians, nor, secondarily, to many couples, that the technical solution may not be the adequate one. Thus, technology creates a maelstrom, a feasibility maelstrom, which can only be resisted with difficulty. This aspect must always be taken into consideration with every new technology.

2.2 Technology Knows No Bounds

Technology has no boundaries; it progresses into uncharted territory, it never shies away from the new, nor does it spare the essence of being; technology is always oriented towards change and dynamism. With such a basic concept, however, technology ensures that there is no longer such a thing as a reasonable boundary within medicine, and that there is no state that might not undergo technical optimization or change. Research on embryos is one example of this. Here, in particular, it can be seen that technical methods are considered almost blindly without thinking about morally tenable boundaries. There are grounds here for criticizing the basic approach of using an inherently problematic technical means for an undeniably good cause. The fact that the destruction of embryos was at all taken into account as an option is the actual core of the ethical problem, which is that, in their basic approach, the natural sciences and technology grasp blindly at methods simply because they are technically feasible or simply because they are required to make promises come true. Offering such options alone creates a problematic denial of any boundaries whatsoever. It is like asking a counterpart a certain question that simply should not be asked, no matter what the situation is, because it is, for example, an unreasonable demand. In the same way, there should be certain methods in technical research and development that one simply does not select, because they are bound to offend the feelings of far too many people, and should therefore be regarded as unacceptable. Consequently, the basic problem that research on embryos has to face only arose because research methods were chosen blindly from the start, and, from the very begin-

ning, no respect was shown for the fact that merely the request of sacrificing embryos is an unreasonable demand for many people – and this is just one example representing many more. We need only think of cloning techniques, the creation of chimera, and so on. In this case, technicians cannot retract and deny any responsibility. Moreover, simply by selecting their methods, technicians assume responsibility, and this responsibility must become apparent prior to the development so that no *blind* mechanization occurs, but a mechanization on a humane scale. And this humane scale must also take boundaries into consideration, and must bear in mind that certain processes are inherently problematic. If they are still selected, despite being aware of these problems, presenting the whole of society with a fait accompli, this could signify a heavy burden in certain constellations.

And yet, it is not only the moral boundary that developers of technology defy without further reflection – the denial of the boundary itself is the basic problem of technical development. Technology knows no point at which it could be said that it is perfect now as it is; technology, i. e., those who work on technical products, are always anxious to surpass existing technology with one that is even faster, even more sophisticated, even smaller or even more comprehensive. This attitude towards endless development is based on the lack of a notion about the ideal state and on a glorification of efficiency. The credo is: the faster, the better; the more, the better, and so on. Admittedly, this credo may be useful when dealing with certain utensils. In the context of medicine, however, the credo cannot be generalized in all cases.

What about the discussion on enhancement? This is precisely where the esteem for *more and more* reaches its limits and where *less is more* makes sense [2.3]. The human being is not a machine that operates better the faster it runs; humans need efficiency as much as they crave leisure, they need to achieve their goals quickly, but also need changes in their lives, and resistance to be

able to mature at all. Accelerating everything – human beings included – does not automatically mean that human beings are doing themselves a favor. With regard to humanity, offering less, decelerating or back-peddaling is often more conducive to reaching the goal, provided, of course, that humanity finds fulfilment is the desirable goal rather than rapid production.

2.3 Technology Is Unable to Answer the Question of Meaning

Technology knows only purpose-rational thinking, and if technology is proclaimed as the solution for mankind, the human being will primarily be regarded as a body machine within such thought. Technology does not ask about meaning, about the superior sense; indeed, it cannot ask what is meaningful, because it lacks the tools to assess the answer to this question – since the question of meaning cannot be expressed in figures and values. With regard to technology in the context of medicine, this aspect is particularly precarious. As a result of technology's triumph, medicine has sometimes fallen victim to an absolutization of the natural sciences and technology, with the grave consequence that medicine is time and again inclined to define not only what is proper but also what is good via the natural sciences. That which takes place as an applied natural science and technology in the course of the self-image of medicine is equating functionality with the good, equating natural scientific properness with what is good for mankind. In

this context, organic functionality is occasionally seen as a value in itself; in other words, functionality should always be restored. Secondly, the loss of functionality is per se interpreted as something negative or even as a failure on the part of medicine under this natural scientific dictum. Both conclusions, however, are inherently problematic. First of all, trying to restore functionality by all means may be problematic if sight of the whole picture is lost. Concerning the superior sense, restoring functionality cannot be equated with the creation of meaningfulness; for example, organs can be restored but the treatment may be senseless regardless. The more medicine becomes specialized and regards itself as a natural science, the more it sometimes treats organs and x-ray photographs, blood gases, and laboratory values, but by doing this does not automatically treat the human being. Precisely this, then, becomes a serious problem if medicine sees itself only as a technically oriented specialist medicine.

2.4 Technology Alone Does Not Make Medicine Humane

Bearing all this in mind, it should become apparent that it is not a matter of demonizing technology. Technology per se is not the problem of modern medicine. The problem starts when the importance of technology is overestimated, i. e., when it is assumed that existential questions arising from a patient falling ill can only be solved by technological means. The central criticism is therefore not directed at technology itself, but at the thought that technology is the one and only solution. Medicine that categorically rejects technology is doomed to failure, because in this case, it often fails to exploit the potential of being able to assist. Medicine, however, that relies solely on technology and ignores everything else will equally fail. For this reason, humane medicine has to focus on implementing technology, whilst al-

ways bearing in mind that human beings need more than effective technology to recover. The art of healing is to precisely recognize where technology would be a good solution for human beings and where it is merely an apparent solution. This art of healing requires a pronounced practical power of judgement in a more comprehensive sense, and not only technical expertise.

The technical credo in modern medicine overlooks the fact that physicians often successfully bring about a cure by a good relationship in which technology has to be embedded. Technology without a relationship will generally achieve little. Great importance is attached to the technical aspect, whereas the human relationship is often completely ignored. This change in priorities represents the greatest challenge mechanized medicine has

to face. The more technology is used as a substitute for a relationship, the more this will lead to the loss of a curative culture. Consequently, as long as we do not expect more from technology than it is actually able to solve, and avoid using it as a substitute for everything, the sick will rightly hope that they will regain their health if possible or find comfort and meaning when there is no further chance of a cure. As long as medicine wishes to see itself as a curative science and not as a repair service, it will have to invest the same amount of energy

in comforting the suffering and giving their life new meaning as in technical development.

Hygiene in M

3. Hygiene in Medical Technology

Heinz-Michael Just, Eckhard Roggenkamp, Annette Reinhardt

The application of new technologies in medicine leads to therapeutic and diagnostic advancements, yet also causes risks for patients to acquire health-care associated infections. In this chapter precautions to prevent the transmission of infectious agents from inanimate medicotechnical sources are shown.

Disinfection and sterilization processes are described in detail aside with requirements for cleaning equipment used for noninvasive and invasive technology on the patient (Sects. 3.4–3.7). Targeted measures with focus on technical means for preventing the four most important device-related infections are pointed out in practical examples (Sect. 3.8). Furthermore special attention is given to dialysis departments because of high risk of infection both for patients and staff and to the special processing of medical devices that have been used on patients with proven or strongly suspected Creutzfeld–Jacob disease (CJD) respectively its new variant (vCJD).

Finally technical regulations and standards focused on German and European circumstances give an overview of what must be observed by manufacturers and users of medical devices (Sect. 3.9).

Technology is increasingly finding its way into medicine. Many diagnostic and therapeutic advance-

ments have only become possible as a result of corresponding technical processes and further developments.

3.1 Background

The significance of hygiene becomes clear when we realize that even many years ago almost half of all infections contracted by patients in hospital were associated with medicotechnical measures or were (partly) caused by them [3.1]. Medical progress uses increasingly complicated and sophisticated technical facilities and equipment, the use and preparation of which also endangers employees.

It is difficult to obtain reliable data which is more or less representative from Germany, because to date there is no central collection point for this purpose. An indication can be gained by drawing on observations which are based on data from the Trade Association for Health and Welfare in Hamburg [3.2]. According to these observations, infectious diseases represent the second largest group after dermatosis with a frequency of 7.3%, but their numbers increase to one-third in the case of those occupational diseases for which compensation is awarded for the first time. The data do not show what percentage of the cases of dermatosis can also be attributed to technical use in the widest sense, such as handling of detergents and disinfectants.

Hygiene measures in the context of medical technology devices must therefore pursue the goals of

1. Protection of employees during handling,
2. Protection of patients during use of these devices *against the transmission of germs*, which can lead to
 - a) Contamination,
 - b) Colonization, or
 - c) Infection.

The measures that are necessary in individual cases to achieve these goals depend on several factors.

3.1.1 Employee Protection

When using these devices on patients, the rule is to act such that the risk of coming into contact with the patient's germs is kept to a minimum. This is achieved by providing appropriate briefing regarding correct handling before a medical technology device is used for the first time. Hygiene guidelines govern which protective measures are necessary and when, but these protective measures are also dependent on the illness of the patient, the suspected bacterial colonization, and the possible transmission path. When dealing with medical

technology devices in the course of reprocessing, maintenance, and repair, the employee can himself monitor whether the equipment is already visibly contaminated on the outside or components are dirty, for example. He/she must in particular have been instructed by the operator regarding whether the device has been used immediately beforehand for a patient with a contagious disease or with certain germs.

In such cases, disinfectant preliminary cleaning must be carried out before maintenance or repair is begun. Disinfection as a first step is also always necessary when handling of the device is linked with an increased risk of injury. Where reprocessing work is concerned, processes should be used in which the devices are cleaned and disinfected by machine, and this should be done with the application of heat and in one process. Under some circumstances, certain protective clothing (e.g., gloves) is sensible or even compulsory.

3.1.2 Patient Protection

How the medical technology device is used on the patient is crucial to the necessary measures. A pacemaker implanted in the patient must be and remain sterile and pyrogen-free during insertion. Disinfectant pretreatment is sufficient for medical equipment with only external (skin) contact, and in the case of equipment which stands at the bedside next to the patient, cleaning is generally sufficient. However, if parts of a piece of equipment which is situated remotely from the patient come into contact with sterile areas of the patient (e.g., tube systems which convey blood in a dialysis machine or in cardiac surgery equipment), then this system component must of course satisfy the same criteria as an implanted device. The same also applies when equipment is used to introduce fluids or medication into sensitive (e.g., lungs in the case of machine-assisted artificial respiration) or sterile regions of the body (e.g., infusion apparatus) [3.3–5].

The text which follows explains the principles of targeted hygiene measures and demonstrates, with reference to examples, how the risks can be recognized and which risk-based measures are necessary. Reference is made to sets of regulations which must be observed, although it is the duty of the person responsible for the area in question to adapt the catalog of measures to new scientific findings and recommendations in the course of regular training. General guidelines which are not

orientated towards practical use, the specific risk of infection, and the path of infection are often expensive, as

they require a lot of personnel and time, but are rarely effective.

3.2 Causes of Infection

Requirements for an infection to develop are an infectious agent, a person susceptible to infection, and contact which enables the germs to colonize the individual such that an infection can develop. This multitude of requirements makes it clear that there is no reason to live in general fear of microorganisms, be they bacteria, viruses or fungi. Bacteria colonize our skin and mucous membranes and are an important part of our body's defenses. Over 40 different species can be isolated from our nasopharyngeal cavity, and there are up to 10^{12} germs living in every gram of feces.

The natural bacterial colonization present in the skin of every human being can be divided into *permanent* and *temporary*. Permanent germs are always present, whereas temporary germs are acquired and therefore change according to what the person has been handling or what work he/she has been carrying out. Washing the hands eliminates the majority (> 90%) of this acquired *contamination* but leaves the permanent bacterial colonization undisturbed. Disinfecting the hands or skin should completely eliminate acquired germs, but it also has an adverse effect on the permanent skin colony.

The skin and mucous membranes are mechanical barriers which, when they are not damaged, prevent microorganisms from penetrating into our bodies. This explains why damage to the skin and mucous membranes is always accompanied by an increased risk of infection, whether that be in the form of a local, superficial infection (pustule, abscess) or whether it be in the

form of a widespread infection – usually occurring in immunocompromised patients – of the soft tissue (ulceration, gangrene), which can also result in sepsis with high fever.

In many fields, our body has also developed further defense mechanisms, such as the acid mantle of the skin, microorganism-killing enzymes in secretions and excretions (e.g., tear fluid), and special structures in our blood whose primary role is to eliminate intruders. These include the white blood cells which *eat up* and digest bacteria (phagocytose), and so-called antibodies which help blood cells identify structures in the body which they should destroy. These specific antibodies are formed in the lymphatic tissue of our body following such *stimulation*. Stimulation of this kind may be due to contact with the infectious agent itself (*natural immunization*) or may be as a result of vaccination (*artificial immunization*, see later).

If a germ nonetheless manages to attach to skin or mucous membranes, then the first important step has been successful. If this *colonization* persists, although it does not result in illness, the patient or member of staff would become an (undetected) source of further transmission, in case the germ in question is a problematic germ (infectious agent, multiresistant bacterium). However, if in the second step the germ is able to deploy its pathogenic properties and the person affected is not immune, then this would lead to an *infection* which, depending on the state of health of the affected individual, can result in an illness which varies in its severity.

3.3 Vaccinations

One of the most important measures for protecting against infections is vaccination. The vaccinations which are recommended and constantly updated by the Standing Committee on Vaccination (Ständige Impfkommision – STIKO) at the Robert Koch Institute (RKI) [3.6] are of particular importance for employees in the health care system. The vaccinations in category S (standard vaccinations with general

application = standard vaccinations) are the vaccinations for infants and children and should be given to all employees in the health care system and, if necessary, should be regularly boosted. These include important vaccinations against such as tetanus, poliomyelitis, and diphtheria. Depending on the field of activity, so-called *indicated vaccinations* (category I) may also be added, such as vaccinations against hep-

atitis A and B, influenza, and varicella. The point of contact for questions regarding personal vaccine pro-

tection and work-related requirements is generally the occupational health officer.

3.4 Disinfection Methods

3.4.1 Basics of Disinfection

Like sterilization (Sect. 3.5), disinfection also has the aim of preventing transmission of pathogens. Complete freedom from germs (sterility) is not guaranteed, however. Disinfection of equipment and materials is always sufficient if, although the aim is to prevent transmission of microorganisms which are capable of multiplying, the body physiologically speaking has a certain level of self-protection in these areas as well as in other areas of the human body which have colonies of germs (e.g., the gastrointestinal tract). Obligate pathogens (those which always cause illness) must not be present on disinfected items, however.

When using disinfectants and disinfection processes, both the respective microbiological spectrum of activity and the field of use must be taken into consideration. Thermal disinfection processes, where they can be used, must always be given precedence over chemical disinfectants and disinfection processes. Provided they do not contain any other special directions, chemical disinfectants are usually only suitable for killing vegetative bacteria and fungi.

Before they come onto the market, disinfectants are tested for their antimicrobial action by means of microbiological analysis. There are standardized methods for this, whose results also determine whether a substance will be included in the list of substances permitted by

the Robert Koch Institute in accordance with the German Infection Protection Act [3.7].

3.4.2 Disinfection Processes

Thermal processes are only suitable for thermostable objects, while *chemical* processes are also suitable for thermolabile objects and surfaces.

A distinction is made between the fields of use for chemical disinfection, as follows:

- Disinfection of hands, skin, and mucous membranes
- Disinfection of surfaces
- Disinfection of instruments.

Disinfection of Hands, Skin, and Mucous Membranes and Disinfection of Surfaces

Disinfection of hands, skin, and mucous membranes and disinfection of surfaces can only be carried out in the form of chemical disinfection, with various germicidal substance groups being used (Table 3.1). When selecting a substance, the purpose for which it will be used and the required strength of its effect as well as the required scope of its effect are crucial in this selection. Appropriate definitions should be regulated in area-specific or process-specific *hygiene plans* based on the corresponding KRINKO (Kommission für Krankenhaushygiene und Infektionsprävention) recommendation [3.8].

Table 3.1 Advantages and disadvantages and fields of use of the most common active substances in disinfectants

Active substance	Advantages	Disadvantages	Field of use
Alcohols	Fast-acting, no residues, low toxicity, pleasant odor	Not sporocidal, combustible/explosive, expensive	Hand disinfection, skin disinfection, small surfaces
Iodine/iodophosphorus compounds	Does not irritate mucous membranes, fast-acting	Allergies possible, naturally colored, (side-effects on thyroid?)	Skin disinfection, mucous membrane disinfection, hand disinfection
Formaldehyde/aldehyde	Broad spectrum of activity, biodegradable	Irritant, allergenic, moderately toxic, (carcinogenic?)	Surfaces, instruments, disinfection of rooms
Quaternary ammonium compounds	Good detergent action, low odor, low toxicity	Gaps in effectiveness, inactivated by soap and protein	Disinfection of surfaces in special areas (kitchen)
Peracids/peroxides	Broad spectrum of activity, fast-acting	Inactivated by protein, corrosive, irritant, unstable	Surfaces, instruments
Phenols	Low impact because of environment	Gaps in effectiveness, barely biodegradable	Disinfection of excretions, otherwise obsolete

Disinfection of Instruments

Instruments and equipment can be disinfected thermally, thermochemically, or else purely chemically. The choice of the process is dependent on the suitability of the material for certain types of disinfection, on the local conditions (infrastructure), and if applicable, on certain requirements. The most reliable option is mechanical thermal disinfection in special washer-disinfectors, because it is only when exposed to appropriate temperatures that the desired reduction in germs is guaranteed with sufficient certainty. The machines report faults in the program sequence, which means that it is not possible to remove items inadvertently before the disinfection process is complete, and errors are for the most part ruled out. Purely chemical processes, such as immersion in solutions, etc., are in contrast susceptible to errors in processing and require a high degree of reliability on the part of the staff performing the process.

3.4.3 Chemical Disinfecting Agents

The most common active substances in disinfectants, their advantages and disadvantages, and their fields of use are reproduced in Table 3.1. In the rarest cases, commercial disinfectants contain only one active substance, but they frequently consist of mixtures of active substances in order to achieve the most optimum antimicrobial action possible.

3.4.4 Carrying out Manual Disinfection

Selection of Disinfectants

Disinfectants are usually selected on the basis of the Network for Applied Hygiene (Verbund für angewandte Hygiene, VAH) list. However, in so doing it is necessary to bear in mind that, in addition to the field of use, the concentration, and the application time (which are dependent on one another), the necessary scope of activity is also ensured. Where there is any doubt, reference must be made to appropriate expert advice. A further important source of information, in particular from the point of view of occupational health, is the material safety data sheets according to 91/155/EEC – amended by 2001/58/EEC – for the disinfectants in question. With regard to material compatibility and effectiveness, particular care must be taken with materials which contain rubber and plastic.

Exposure Time

The maximum period during which the substance has its intended effect can be gathered from the relevant data

sheets. If the solution becomes visibly dirty, however, then it should be replaced immediately. If a combination of detergents and disinfectants is used, the exposure time is generally only 24 h.

Sequence: Disinfection and Cleaning

In the case of instruments where there is a risk of injury, disinfection must be carried out *prior* to cleaning. In other cases, disinfection is performed *with or after* cleaning.

Procedures

Disinfectants for treating surfaces and instruments are provided by manufacturers in the form of a concentrate in various packaging sizes, from sachets to large packs, and must be made up to the appropriate usage concentration by the user by adding water. To avoid foam formation when preparing a disinfectant solution, water is added first and then the disinfectant. The solution is prepared by hand by means of dosing aids or using mixing equipment. The advantage of using mixing equipment is the automatic dosing of the disinfectant.

Disinfectants must only be used for the stated purpose and must not be mixed with detergents without prior testing, because this can result in a loss of effectiveness of the disinfectant (follow the information from the manufacturer). It becomes necessary to change the disinfectant solution when the exposure time stated by the manufacturer has been reached or when the solution becomes visibly dirty.

Effectiveness may be impaired in tubes and pipes with narrow lumen, e.g., as a result of air bubbles or impurities. It is therefore necessary to ensure that the item to be disinfected is completely submerged, that there are no bubbles, and that all surfaces are completely and thoroughly wetted.

All items should be disassembled as far as possible. Instruments should be immersed in the solution with care to prevent damage.

Cost-Saving Hints

The following options can be used for cost savings:

- It is often sufficient to carry out cleaning instead of disinfection prior to subsequent sterilization. Exceptions: Only pointed, sharp items must be disinfected prior to cleaning.
- Where feasible from a time perspective, low concentrations should be selected with a longer application time.

- If possible, make do without additional detergents, because a disinfectant solution with added detergent must be changed daily.
- Contaminate the solution as little as possible with organic materials, so that it is not necessary to change the solution before the end of the exposure time.
- Wipe down items instead of immersing them.

Pouring Away

To protect drainage systems against corrosion, care must be taken to ensure that the solution is diluted sufficiently before it is poured away. Disinfectants for treating instruments are generally provided with corrosion inhibitors. High concentrations can nevertheless be problematic for drains. The municipal wastewater bylaws must also be taken into account. Disinfectant concentrates are considered hazardous substances, and their disposal requires special supervision.

Personal Protection

When preparing the solution, immersing/removing items, and emptying and cleaning the bowl, gloves (disposable or household gloves) and protective clothing (waterproof apron) must be worn. If there is a danger of splashing, protective goggles and a face mask must be worn. Bowls filled with disinfectant must be covered to minimize evaporation into the surrounding air. Disinfectant solutions must always be made up with cold water (no warmer than lukewarm) for the same reason. Disinfectant concentrates must not be stored above eye level. The workplace-specific regulations to protect staff should take into account the relevant technical regulations (the German Technical Regulations for Biological Agents, TRBA, and the Technical Regulations for Hazardous Substances, TRGS) (Bundesanstalt für Arbeitsschutz und Arbeitsmedizin, BAuA).

Special Circumstances

There may be undesired effects on materials if unsuitable disinfectants are used. The chemical resistance of the items must therefore always be taken into account. Where there is any doubt, enquiries should be made to the instrument manufacturer.

3.4.5 Physical Disinfection Processes

With physical disinfection processes, a distinction is made between thermal and thermochemical disinfection processes.

Thermal Disinfection Processes

In thermal disinfection processes, pathogens are rendered harmless as a result of the influence of heat. The higher the temperature and the longer the application time, the more effective the process is. In practical applications, a distinction is made between *dry heat* and *damp heat*, depending on the presence or absence of free water. Only *damp heat* is of significance for combating hospital infections. When using a treatment with *damp heat*, a distinction is made between two processes:

1. Rinsing with hot water (washer-disinfectors) and
2. Treating with steam (steam disinfection process).

Washer-disinfectors

Washer-disinfectors are devices in which instruments, anesthesia accessories, laboratory materials (glassware and the like), and other thermostable items are processed by machine.

The series of standards DIN EN ISO 15883 specifies the performance and device requirements for washer-disinfectors.

Depending on the design, a distinction is made between washer-disinfectors with one processing chamber and devices with multiple processing chambers, so-called batch washer systems.

Washer-disinfectors are available in a front-loading design (loaded and unloaded in the same area) or in a through-loading design with two doors (separated into a *clean* and *dirty* side).

Batch washer systems (multichamber systems) consist of multiple washing chambers and drying chambers through which the items to be treated are passed on loading trolleys. The loading trolleys differ according to the items to be treated. Sensors on the loading trolleys allow the control unit in the system to identify what items are on the trolley and to automatically select the correct processing program, which means that operating errors as a result of incorrectly selected programs, temperatures, and times are ruled out.

The disinfection process which runs in each case is usually thermochemical or thermal. An ultrasonic cleaning tank can be added to the system as an additional feature for precleaning of heavily soiled items.

Different processing steps are performed in each chamber. Special tanks with the appropriate detergents are assigned to each chamber. The detergent solution is collected in the tanks and reused for the next processing batch. Because not all of the detergent solution is recaptured, some of the solution must be supplemented.

The exact dosing of the detergent is done using dosing pumps which are controlled via contact water meters. The contents of the processing tank must be emptied and refilled every working day.

Owing to their relatively high throughput rate, batch washer systems are predominantly used in central sterile supply departments.

Carrying out Machine Cleaning and Disinfection

To achieve a good cleaning and disinfection result, the way in which the machine is loaded is of crucial importance. It is important to ensure that all items are disassembled as far as is possible and that hollow parts are inserted with the opening pointing downwards. Fluid must also flow through the interior of instruments with long or narrow cavities, such as metal catheters, metal suction apparatus, special needles, etc. Special loading trolleys must be used for this.

In the case of use of detergents or combined disinfectants and detergents, the information provided by the manufacturer (application time, concentration, and temperature) must be followed precisely.

Only the correct dosage will ensure a perfect disinfection and cleaning result while providing the greatest possible protection of the material. Underdosing of alkaline detergents involves the risk that pitting may occur, as this is avoided at pH values of above 10.5. When using acidic detergents, corrosion may occur as a result of chlorides in the water, and this can only be precluded by using demineralized water.

In the case of machine cleaning, all residues from the cleaning phase must be reliably removed in the rinsing phase, as otherwise stains and discolorations may appear on the surgical instruments. Additional use of a suitable neutralizing agent can support this process and improve the result of rinsing.

Documentation

In the course of quality assurance, when processing medical equipment it is necessary for the process-relevant processing steps of the individual batches to be documented with direct assignment to the relevant items to be treated.

Inspections and Maintenance

Disinfection measures in cleaning equipment are only effective if maintenance and inspection of these machines are not neglected. The necessary inspection and maintenance are specified in the operating instruction, which should be issued by the manufacturer. Maintenance

should be carried out at least once a year by trained specialists.

Tests

The ordinance regarding the installation, operation, and use of medical devices (German Medical Devices Operator Ordinance – Medizinprodukte-Betreiberverordnung, MPBetreibV) states the requirement that medical devices must be processed using suitable, validated processes such that reproducible success is ensured and the safety and health of patients, users, and third parties are not endangered. The KRINKO recommendation [3.9] likewise requires validated processing of medical devices.

Specific information about carrying out the validation and the subsequent periodic tests is set out in DIN EN ISO 15883-1 – Washer-disinfectors – General Requirements, Definitions, and Tests, and in the guideline from the German Society for Hospital Hygiene, the German Society for Sterile Supply, and the Working Group Instrument Preparation for routine monitoring of machine washer-disinfectors for thermolabile medical devices.

Validation is a documented process for providing, recording, and interpreting the results necessary to show that a process constantly produces the desired quality which conforms with the given specifications. For washer-disinfectors (WD), the validation consists of installation qualification, operating qualification, and performance qualification, performed for devices which have documented proof from the manufacturer of compliance with the requirements of DIN EN ISO 15883.

The installation qualification is performed to ensure that the WD and accessories have been properly supplied and installed and that the supply of operating media satisfies the special requirements. The tests and inspections which are to be carried out for the installation qualification must be defined and performed, and the results documented.

Tests and inspections which must be carried out are:

- Testing the scope of supply and delivery (in the case of existing installations, testing the stock)
- Loading trolleys/baskets, cartridges, and also plugs/adapters
- Installation plan, instructions for use
- Testing the connections and supply of media, and comparing them with the installation plan
- Electricity
- Water (cold/warm/demineralized)
- Steam

- Wastewater
- Exhaust air/ventilation.

The operating qualification is carried out to ensure that the WD and the supply of media comply with the manufacturer's specifications and the requirements set out in DIN EN ISO 15883. The tests and inspections which are to be carried out for the operating qualification must be defined and performed, and the results documented. In the performance testing, the specified washer-disinfector programs are tested for reference loading, and the results are documented. When observing the regulations, it should be ensured that results are obtained which can be reproduced at any time. Any reference loading must cover instruments with contamination which is typical of operation as well as critical design features. Reference loading is always operator specific and must be documented. A requirement for the performance qualification is specification and documentation of the necessary programs with the corresponding process flows. The description of the process must also include the preconditions for cleaning. The process description must be documented in detail, including precise information about the chemicals. The following tests are performed as part of the performance qualification.

Testing the Cleaning. The cleaning is tested using two different methods. Test instruments (hemostats after Crile) with defined test soiling in accordance with DIN EN ISO 15883 and instruments which are actually soiled following use are used. Every program used must be tested. The test instruments are removed from the WD using gloves following the cleaning phase and prior to the disinfection phase.

The results of the cleaning process are first evaluated visually, and these findings are documented. The test instruments must be visibly clean. The test instruments must then be tested for protein residues using a protein detection method which is at least semiquantitative. In practice, detection of protein residues using the Biuret method has proven successful. Testing of the instruments which are actually soiled is carried out in the same way.

Assessment. The limit value is that all test instruments must neither reach nor exceed the protein content of 100 µg protein per ml eluate. If this limit is exceeded, then the WD is immediately shut down. The guide value is a maximum of 50 µg protein per ml eluate for a test instrument, at which no measures are necessary.

Testing the Disinfection. The disinfection is tested using thermoelements which are distributed in the disinfection chamber at critical locations and which record the temperature profile during processing. The resulting temperature graphs show whether the temperature necessary for killing microorganisms was present at all locations in the chamber. The A_0 value can be calculated from the temperature graph in accordance with DIN EN ISO 15883. The A_0 value of a disinfection process with damp heat is a measure of the rate at which microorganisms are killed, given as a time in seconds at a temperature of 80 °C applied to the medical item by the process.

The A_0 value which must be achieved depends on the nature and quantity of the microorganisms on the contaminated medical device and on the subsequent use. In the case of crucial medical devices and medical devices which are or may be contaminated with heat-resistant viruses such as hepatitis B, the A_0 value must reach 3000. This corresponds to an application time of 5 min at a temperature of 90 °C or an application time of 50 min at a temperature of 80 °C.

An A_0 value of 600 is used in the case of noncritical medical devices which can only come into contact with undamaged skin. This corresponds to an application time of 1 min at a temperature of 90 °C or an application time of 10 min at a temperature of 80 °C.

In addition to the thermoelectric measurements (A_0 concept), biological indicators can also be used to make statements about the killing of microorganisms. Biological indicators are germ carriers which are contaminated with a blood/germ mixture which has a defined resistance to the disinfection process in question. The Robert Koch Institute stipulates the use of contaminated screws and tubes for testing thermal disinfection processes in washer-disinfector machines. Meanwhile, equally good biological indicators are available which allow testing which is easier for the user.

The performance qualification must be repeated annually. When the programs or process chemicals are changed or new medical devices are introduced which have to be processed differently, the performance qualification must be carried out once more.

Decontamination Systems

Decontamination systems have in the past been used first and foremost for cleaning and disinfection (decontamination) of bed frames and accessories. Requirements regarding hygiene, economic considerations, and occupational safety requirements (TRBA 401 hazard due to skin contact) have led to decontamination sys-

tems increasingly being used for other articles in the field of medicine as well, such as transport trolleys, containers (e.g., for medications, medical devices, sterile articles, and meals), operating theater shoes, transporting containers for small conveyor systems, and similar items.

A decontamination system consists of a decontamination chamber, which receives the items to be treated, and an apparatus compartment, which contains the units and components necessary for operation. The systems are generally constructed with a two-door design.

The items to be treated are pushed into the decontamination chamber on the *dirty side* (in some cases using special loading trolleys). Combined cleaning and disinfection of the items to be treated is carried out in the first phase using a separate nozzle system by means of a recirculation pump. The temperature of the decontamination agent solution and the decontamination period can be set and changed on the control panel, making it possible to optimally adapt the process quickly and simply to the items being treated. The decontamination agent solution is supplied from a heated storage tank.

Following the decontamination process, the items being treated are sprayed with a rinsing agent solution to remove residues of the decontamination agent solution and ensure fast and spotless drying. During the drying time, a ventilator extracts the damp warm air from the interior of the compartment, while at the same time sucking in fresh air from the clean side. The decontamination agent solution is pumped back into the storage tank via a recirculation pump, so that only about 20 l of water is required for each batch.

With regard to the requirements, operation, and testing of the effectiveness of decontamination systems, reference should also be made to DIN standards 58955 section 1–7.

Steam Disinfection Processes

Steam disinfection processes are preferably used to disinfect bedding (mattresses, laundry, and textiles) but also for waste which needs to be disinfected. Simultaneous use of these systems for disinfecting waste as well can be considered to be problematic because of the offensive smell and risk of contamination of the apparatus. With appropriate separation, however, joint use of the apparatus to disinfect both bedding and waste is also perfectly feasible.

The items to be disinfected are subjected to the effect of saturated steam in the steam disinfection apparatus. To ensure that all surfaces to be disinfected

are exposed to unobstructed steam, the air must be removed from the disinfection chamber and from the items.

A distinction of steam disinfection processes can be made depending on the procedure:

1. Steam flow process, and
2. Fractionated vacuum process (vacuum–steam–vacuum (VSV) process).

Steam Flow Process (Range of Action, ABC: Sect. 3.4.6). In the steam flow process the air is forced out of the chamber and the items to be disinfected using saturated steam. The disinfection temperature is 100–105 °C, with an application time of at least 15 min. For porous items, the application time may be more than 1 h. The steam flow process is suitable for disinfecting waste which contains sufficient water, e.g., microbiological cultures.

Fractionated Vacuum Process. The process (Fig. 3.1) is characterized by:

1. Removal of the air from the chamber and the items to be disinfected by repeated evacuation alternated with influx of saturated steam
2. Disinfection with saturated steam
3. Drying of the disinfected items by evacuation.

To perform this process, steam which is largely free of air and foreign gases is necessary (cf. DIN EN 285). The disinfection chamber must be vacuumtight. The fractionated vacuum process is mainly used to disinfect porous items such as mattresses, blankets, and waste.

3.4.6 Application Times and Ranges of Action

The application times and ranges of action are presented in Table 3.2. In the list of disinfectants and disinfection processes tested and approved by the Robert Koch Institute [3.7], the ranges of action are identified by letters; these are:

- A – suitable for killing vegetative bacteria, including mycobacteria, as well as fungi, including fungal spores
- B – suitable for inactivating viruses
- C – suitable for killing spores of the anthrax pathogen.

Fig. 3.1 Diagram of the fractionated vacuum process

Table 3.2 Application times and ranges of action of disinfection processes

Temperature (°C)	Duration (min)	Range of action
75	20	A, B (except viral hepatitis)
105	1	A, B
105	5	A, B, C

Higher temperatures and longer application times are sometimes used for disinfecting waste. Approved processes can be found in the RKI list. The requirements, operation, and testing of the effectiveness of steam disinfection apparatus are laid down in the DIN standards 58949 section 1–7.

3.4.7 Comparison of Chemical and Physical Disinfection Processes

Disadvantages of Chemical Disinfection

- Gaps in effectiveness, contamination
- (Primary) bacterial resistance
- Adaptation (biofilm formation)
- Possible distribution of germs in the hospital (central units)
- Dependence on concentration, temperature, and pH
- Decomposability, loss of effectiveness

- Inactivation by soap and protein
- Limited ability to penetrate organic material
- Risk of decontamination
- Disinfectant residues in the material (e.g., rubber)
- Material corrosion
- Health effects for staff and patients
- Pollution of the workplace and environmental damage
- High costs
- Increase in the volume of refuse.

Advantages of Physical Disinfection Processes

- Lower costs
- Lower impact on the environment
- Higher degree of reliability
- Automated operation possible
- Cleaning, disinfection, and drying in one process
- No toxicity and no allergization
- Testing for effectiveness.

3.5 Sterilization Methods

3.5.1 Sterilization Processes

- Physical processes
- Steam sterilization
- Hot air sterilization
- Physicochemical processes
- Ethylene oxide gas sterilization
- Formaldehyde gas sterilization
- H₂O₂ low-temperature plasma sterilization.

Physical Processes

Steam Sterilization. Sterilization with the aid of saturated and compressed steam, also sometimes referred to as damp heat, is the most reliable sterilization process and, because of its simple handling, is the most important process for sterilizing medical devices.

The principle of steam sterilization is based on the transfer of thermal energy to the contaminated surfaces as a result of condensation of compressed steam. Energy is released through condensation of the steam on the items to be sterilized, which causes irreversible damage to microorganisms.

The pressure and temperature of steam are dependent on one another; for example, compressed, saturated steam at a temperature of 121 °C has a pressure of 2 bar (1 bar = 105 Pa), while at a temperature of 134 °C it has a pressure of 3.2 bar. In practice, two standard conditions are used:

- 121 °C with application time of 15 min
- 134 °C with application time of 3 min (only for correspondingly heat-resistant items).

Pathogen Resistance to Damp Heat. The resistance of germs to damp heat is classified into four levels (Table 3.3).

A complete effect of the steam on the items to be sterilized is only possible if the air has been removed from the chamber and from the items which are to be sterilized. Processes for removing the air from the items to be sterilized include:

1. Fore-vacuum process. In the fore-vacuum process (Fig. 3.2), the air is removed from the sterilizer chamber using a vacuum pump. The process features the following operating phases:
 - Single evacuation of the sterilizer chamber to pressure of 20–70 mbar
 - Admission of steam until the operating pressure has been reached.

The fore-vacuum process is not suitable for sterilizing porous items (e.g., laundry) in sterilization containers with a filter or valve in the lid of the sterilization container.
2. Fractionated vacuum process. The fractionated vacuum process (Fig. 3.3) features operating phases such as:
 - Evacuation to pressure < 130 mbar (1 mbar = 100 Pa), repeated several times
 - Alternated with influx of steam to a pressure which is below or above atmospheric pressure
 - Admission of steam until the operating pressure has been reached.

The fractionated vacuum process is suitable for all sterilization items in packaging approved for steam sterilization.

According to the German Medical Devices Operator Ordinance § 4, medical devices must be sterilized us-

Fig. 3.2 Fore-vacuum process

Table 3.3 The four levels of resistance of germs to damp heat

Level of resistance	Temperature (°C)	Application time	Pathogens recorded
I	100	Seconds to minutes	Vegetative bacteria, fungi including fungal spores, viruses, protozoa
II	105	5 min	Bacterial spores with a lower level of resistance, e.g., anthrax spores
III	121 or 134	15 min or 3 min	Bacterial spores with a higher level of resistance
IV	134	Up to 6 h	Bacterial spores with a high level of resistance

Fig. 3.3 Fractionated vacuum process

ing suitable, validated processes, such that reproducible success of these processes is ensured and the safety and health of patients, users, and third parties are not endangered. Validation serves to prove the effectiveness of the sterilization process under the operating conditions present in the location where the equipment is installed, with the items which are to be sterilized in routine operation, in the appropriate packaging, and with the loading model used. Validation consists of commissioning and performance qualification. DIN EN 554 and DIN 58946-6 have been replaced by DIN EN ISO 17665-1. Validation according to DIN EN ISO 17665-1 consists of installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ).

In the installation qualification, evidence must be found that the device equipment, documentation, operating media, and installation comply with the standard. It must also be demonstrated that the device is in good working order, and that there is no leakage of the operating media or in the equipment.

In the operational qualification, evidence must be provided that the sterilizer is able to perform the specified sterilization programs.

In the performance qualification, all sterilization items and the types of packaging used must be recorded and commissioned. The sterilization parameters of the resulting commissioned items are then measured and assessed in the sterilizer using physical test methods.

In addition to the physical test methods, DIN EN ISO 17665 also approves microbiological testing. Thermoelectric tests cannot be performed on medical devices (e.g., instruments for minimally invasive surgery). In this case, there is the option of contaminating the instrument directly with test germs or using suitable medical device simulators as per DIN 58921. The results must be documented in the validation report.

Documentation. As part of the quality assurance in the central sterilization supply department (CSSD), the sterilization batches must be documented. This is done firstly by recording the process-relevant sterilization parameters (pressure, temperature, and time) and secondly by testing each batch using a suitable chemical indicator in a special test specimen. Using a label with the batch number on ensures that the item to be sterilized is assigned to the batch. Once sterilization has taken place, the parameters are checked, and the batch is released and documented.

Hot Air Sterilization. Hot air sterilization is sterilization by dry heat. Because dry air is a poor thermal conductor, relatively high temperatures and long application times (e.g., 180 °C for 30 min sterilization time) are necessary to ensure reliable sterilization. Table 3.4 presents the sterilization times for hot air sterilization.

Germs, spores, and viruses are killed as a result of protein coagulation. The sterilization effect is strongly dependent on the preparation of the items to be sterilized. The items to be sterilized must be clean and dry (evaporatively cooled).

The following must be taken into consideration when loading the sterilizer.

- It must be possible for air to flow unhindered around all of the items.
- The direction of the air flow must be taken into account.
- Larger items can create a slipstream.
- The items to be sterilized must not be stacked in blocks.

Larger sterilizers must be equipped with forced air circulation equipment (ventilator). Because of their unreliable operation, hot air sterilizers should only be used to a very limited degree. Their fields of use are:

- Glass (laboratory)
- Metal
- Porcelain.

Suitable packaging materials are:

- Metal cases
- Glass bowls
- Aluminium foil.

Note that textile and paper packaging are not suitable.

Physicochemical Processes

Ethylene Oxide Sterilization. Sterilization with ethylene oxide must only be used if the item to be sterilized cannot be sterilized using any other process [3.10].

Table 3.4 Sterilization times for hot air sterilization

Sterilization temperature (°C)	Sterilization time (min)
160	120
170	60
180	30

According to the German Ordinance on Hazardous Substances and the TRGS 513, since 1 January 1995, ethylene oxide (EO) may only be used in validated, fully automatic sterilizers, in which an automated degassing program follows the sterilization program, with the sterilizer remaining locked until the program is finished.

Substance Properties. Ethylene oxide is a colorless, sweet-smelling, highly flammable gas, which can form explosive mixtures with air. It is toxic and can cause cancer and inheritable damage. A maximum allowable concentration (MAC value), in the sense of harmless concentration, can therefore not be given. The technical reference concentration (TRC value) for the breathing air in the workplace is 1 ppm-vol. EO irritates the eyes, the respiratory organs, and the skin. It is classified as hazardous to water (water hazard class WHC 2).

How It Works. Its good ability to penetrate cells makes it possible for various vital biochemical components in the metabolism of microorganisms, such as DNA, proteins, vitamins, and enzymes, to be exposed to EO. The alkylation reaction of proteins with EO kills the microorganisms.

The effectiveness of EO is influenced by various parameters. The relative humidity of the gas mixture is optimally 33% at a temperature of 55 ± 3 °C. Because the materials to be sterilized and their packaging absorb water to different degrees depending on how the sterilization chamber is loaded, relative humidity of 100% is in practice aimed for at the beginning of the sterilization process. Water loss due to vacuum and absorption then results in a reduction in the relative humidity. This initially high humidification should in practice prevent the relative humidity from dropping below the limit value of 33% which is necessary for reliable EO sterilization.

Adsorption and Desorption. Ethylene oxide binds to surfaces of solids (is adsorbed) depending on the material. With regard to EO sterilization this means that residues adhere to the materials following EO exposure. A relatively long degassing or desorption time is therefore necessary for the treated items following sterilization. These may contain a maximum

residual concentration of 1 ppm EO before use on patients [3.11]. As already mentioned above, in accordance with TRGS 513, the desorption process must be performed in the sterilization chamber, which is automatically locked, after sterilization has ended. Reloading of the sterile items directly after sterilization into so-called ventilation cabinets is not permitted.

Exhaust Air from EO Sterilization Systems. A mass flow of 2.5 ppm EO (according to the German Technical Instructions on Air Quality Control, TALuft) must not be exceeded in the exhaust air from the system. Methods used for reducing the EO concentration are listed here.

- **Combustion.** This must be supported using auxiliary gas firing. The consumption of fuel gas is ≈ 0.5 m³/h. In the process, EO is fully converted into carbon dioxide and water.
- **Catalytic reaction.** The necessary temperature of the catalyst is reached by supplying energy in the form of steam or electrical energy. It is virtually impossible to achieve complete decomposition of the EO.
- **Gas wet scrubbing process (only for pure EO).** The firm VIG provides a process in which the EO is bonded with a washing agent. Using diluted sulfuric acid in water, the EO is converted to ethylene glycol. The EO is disposed of completely, and there is no need to supply exhaust air.

Sterilization Processes

Vacuum Process. This process involves working with 100% EO in the vacuum range. After evacuation to below absolute pressure of 55 hPa and humidification of the sterilization chamber, the EO flows into the chamber, and the items to be sterilized are treated at an operating temperature of 50–60 °C for between 1 h and 6 h. The application time is essentially determined by the process parameters of EO concentration, pressure, humidity, and temperature. The pressure range is kept below the lower explosive limit of EO. The sterilization chamber is then purged and ventilated multiple times.

Overpressure Process. Following a pre-vacuum and humidification, sterilization is performed in the overpressure range using a gas mixture of 6% EO and 94% CO₂. As in the vacuum pressure process, the application time is essentially determined by the process parameters of EO concentration, pressure, humidity, and temperature. The inert gas (mostly carbon dioxide) helps to avoid explosion. After the sterilization phase, multiple vacuum and ventilation phases take place alternately to

achieve desorption of the EO from the sterile items. The desorption time is generally 8–10 h.

Requirements for Sterilizers. The requirements for reliable sterilization are described in detail in DIN 58948 and DIN EN 1422. According to the German ordinance for minimizing hazardous substances, care should be taken to ensure that sterilizers work with gas mixtures of 6% EO and 94% CO₂ and that the risks for staff, patients, and the environment are therefore reduced.

Requirements for Operating Staff. According to TRGS 513, operating staff must demonstrate knowledge of the subject through an approved course.

Formaldehyde Gas Sterilization

Substance Properties. Formaldehyde (FO) is a colorless, pungent-smelling gas with a broad spectrum of biocidal activity. It is toxic, allergenic, suspected to cause cancer, combustible, and can form explosive mixtures with air. With the exception of its allergenicity, the potential for danger in the areas just mentioned is lower than in the case of ethylene oxide, but it is also less effective. The maximum allowable concentration (MAC value) is 0.5 ppm. Formaldehyde is commercially available as a 30–50 weight percent solution (formalin).

Adsorption and Desorption. Formaldehyde is adsorbed by the surfaces of solids. With regard to FO sterilization, this means that residues remain on materials following FO exposure. After the sterilization phase, the FO residues adsorbed on the sterile items are removed by purging with air and steam (desorption). The extent of adsorption and desorption is dependent, among other things, on the type of material of the solids. Experiments looking at its desorption behavior have shown that the residues on sterilized products can often be removed relatively easily, but that the residues in the sterilization packaging are many times higher in comparison. FO-sterilized items stored in poorly ventilated spaces can lead to the MAC value for formaldehyde being reached in the air of the room. Storage locations in which sufficient dilution and aeration are guaranteed must accordingly be selected.

Process Sequence

1. Ventilation and humidification, often using a fractionated vacuum process. The FO sterilization process is not able to penetrate to the same extent as the EO sterilization process. To achieve sufficient penetration in the process, the FO sterilization pro-

cess may only be performed using the fractionated vacuum process.

2. Sterilization, at a constant, low vacuum and high atmospheric humidity (at least 60%); i. e., formaldehyde and steam are used for sterilization in combination at temperature of 60–75 °C.
3. Desorption: purging and ventilation using steam/air scrubbing; i. e., the chamber and the items being sterilized are purged in 15–20 changes in pressure with air or steam.

Requirements for Sterilizers. Sterilizers must comply with the requirements of DIN 58948.

Requirements for Operating Staff. According to TRGS 513, operating staff must demonstrate knowledge of the subject through an approved course.

H₂O₂ Low-Temperature Plasma Sterilization (LTP)

Field of Use. Because of their well-known problems in respect of residues, there are considerable restrictions on operation of conventional gas sterilizers (ethylene oxide/formaldehyde) (German Ordinance on Hazardous Substances, TRGS 525). No harmful residues of the active substance are to be expected in the case of H₂O₂ LTP sterilization, which is based on the active substance H₂O₂, i. e., hydrogen peroxide plasma, and whose chamber temperature is 45 °C.

Active Principle. The active substance used is hydrogen peroxide (H₂O₂). In a vacuum it is evaporated, diffused through the sterilization packaging, and then excited by radiofrequency to form hydrogen peroxide plasma. Hydroxyl and hydroperoxy radicals form in the plasma, which inactivate the microorganisms. After the radiofrequency field is switched off, the radicals lose their high levels of energy and recombine to form water and oxygen [3.12, 13].

Process Sequence

First Phase: Vacuum. The sterilization chamber is evacuated to residual pressure of ≈ 1 mbar (1 mbar = 100 Pa). The radiofrequency generator is then switched on, and an air plasma is generated. The chamber is then ventilated and evacuated once more to prepare for the injection. The air plasma allows any residual moisture to be dried for better preparation for loading.

Second Phase: Injection. At room temperature, 1.8 ml H₂O₂ is injected into the chamber and evaporated at

pressure of ≈ 11 mbar. A short period of ventilation then follows. This ensures that the active substance penetrates quickly into the lumina.

Third Phase: Diffusion. The H_2O_2 diffuses into the items being sterilized. A vacuum is generated once again before the plasma phase.

Fourth Phase: Plasma. The pressure in the chamber is reduced to 0.7 mbar, and the plasma phase is begun by means of radiofrequency in the MHz range. The hydrogen peroxide vapor is thereby ionized, i. e., converted into gas plasma. This consists, among other things, of highly reactive hydroxy and hydroxyl radicals, which bond with functional building blocks of microorganisms, thus causing them irreversible damage. Phases 2–4 are carried out twice, the so-called first and second halves of the cycle.

Fifth Phase: Ventilation/Pressure Equalizing. Following completion of the 10 min plasma phase, the gas residues in the chamber and in the sterile items are removed harmlessly by fractionated air purging and active carbon filtering. The vacuum is equalized. When atmospheric pressure is reached, the cycle is ended and the door can be opened.

Process Duration. When fully loaded, the process lasts for 75 min. Smaller loads sometimes mean shorter process times.

Information for Use. Because of the way in which it works, this process can be used for sterilization of

thermolabile items, but with certain restrictions [3.14]. Users of this process should draw up a list of all the thermolabile items which must be sterilized and then decide which items this process can be used for. A so-called positive list of articles which are approved for sterilization is issued by the manufacturer.

Based on comprehensive tests, open plastic tubes with internal lumen > 3 mm and up to 200 mm in length can currently be sterilized. Tubes with internal lumen < 3 mm must be provided with a diffusion amplifier before sterilization. Catheters which are closed at one end cannot be reliably sterilized.

The disadvantages of this process should be discussed very specifically: hydrogen peroxide vapor is strongly adsorbed by materials containing cellulose. Plasma sterilization therefore cannot be used for items to be sterilized which contain cellulose or for instruments in packaging containing cellulose. All packaging materials must be free from cellulose and are currently only available from the operating company. Packaging bags, for example, are also on average three times more expensive than similar products for steam sterilization. Containers for instruments, such as those which are available for steam sterilization, are only in the development stages. The instruments must be completely dry before loading the plasma sterilizer. In the case of organic contamination of the surface, the effect of plasma sterilization is restricted considerably, but this is also the case with all surface sterilization processes.

Inspection and Testing for Effectiveness. Test systems with biological indicators in accordance with ISO 14937 must be used to test effectiveness.

3.6 Hygiene of Noninvasive Technology Equipment

This category includes all equipment and technical measures which are used for diagnosis and therapy but which are not inserted into the patient. These may be electrocardiogram (ECG) electrodes, ultrasonic transducers or monitors by the patient's bed or in function-testing departments, and they may equally be small conveyor systems, ventilation technology or processing machines.

3.6.1 Equipment Used on the Patient

These must be included in regular cleaning. If the equipment does *not* come into contact with the patient,

then cleaning – often only of the accessible surfaces – is usually sufficient. Environmentally friendly detergents should be given preference for this, and it is also important to bear in mind material compatibility and area-specific regulations (e.g., explosion protection).

Where such equipment is in areas with increased requirements in terms of sterility (e.g., operating theaters) or in isolation rooms (infectious patients, patients with multiresistant colonized bacteria, immunosuppressed patients), disinfectant cleaning must be stipulated. The disinfectant used must be suitable for the field of use (disinfectants for treating surfaces or instruments) and

must comply with requirements in the scope of its effect. When used in areas with increased requirements in terms of sterility, *all* potential pathogens should be covered, and when used in isolation areas, substances are preferred which act very quickly *against the known pathogens* with a long-lasting effect.

Equipment or equipment parts which come *into contact with the patient* must be cleaned carefully prior to use in accordance with the guidelines and must always be disinfected if there are corresponding regulations (e.g., after use on patients with multiresistant germs) or if, despite proper cleaning, there is still a risk of infection, e.g., in the case of severely immunocompromised patients for whom even harmless environmental germs can become a threat.

3.6.2 Equipment Not Used on the Patient

Initially, the same requirements apply for this equipment as for use outside a hospital. It must be maintained according to its intended purpose and regularly cleaned. Different requirements may be necessary when the equipment is used in *areas with increased requirements in terms of sterility*, and, when necessary, these increased requirements should be governed by in-house guidelines. If, as a result of use, the equipment/unit is contaminated with material from the patient, then disinfectant cleaning is recommended, and if the material is from an infectious patient then disinfectant cleaning is a requirement. For certain equipment (e.g., air-conditioning units, cleanroom benches), special reg-

ulations may need to be taken into account (see below).

3.6.3 Repair and Maintenance

Equipment which is handed in for repair and maintenance to relevant departments should have been given at least basic cleaning beforehand. Equipment parts which have been in contact with patients/patient material must only be disinfected before being worked on if they are visibly dirty, or if it can be assumed that it is contaminated with germs which should be prevented from spreading in the hospital (multiresistant germs), which can lead to infections in the maintenance staff, or which are subject to special regulations by law (German Infection Protection Act). These also include germs such as hepatitis and tuberculosis pathogens, and other similar pathogens.

Whether this pretreatment is carried out by the user, somebody in another position (processing unit) or the maintenance department itself may depend on the structure of the organization and also on the size of the hospital. It is therefore recommended that the procedure and the respective responsibility are set down in writing and that *hygiene plans* are used to regulate who has to do what, when, and in particular precisely how, and in what sequence. This should in any case be agreed upon together with the person responsible for hygiene (hygiene officer/infection control nurse) and possibly also with the member of staff responsible for occupational health and safety.

3.7 Hygiene of Invasive Technology Equipment

This includes all equipment, equipment parts, and technical measures which are used for diagnosis or therapy and which in the process are inserted *into* the patient. These may either be instruments or equipment which are used in the patient *without* penetrating the skin or mucosa (e.g., bronchoscope, oesophageal arteriography, suction aspirator), in which case there may be intentional (biopsy) or unintentional damage to the mucosa, or they may be instruments or equipment which are designed for use *with* or *after* penetration of the barrier of

the skin/mucosa (e.g., biopsy forceps, arthroscope, and vascular catheter).

Disinfectant measures are usually sufficient for the first group, whereas a sterilization process is obligatory for the second group (see above).

Here, too, the following general *rule* applies: Primarily use thermal disinfection (washing) processes, and only consider thermochemical or even purely chemical processes when the materials are not compatible with thermal disinfection processes.

3.8 Practical Examples

Targeted measures to prevent transmission of germs and infections must be adapted to the pathogen, the group

of people, and the hazard potential. Vaccination alone may be sufficient, or specific disinfection or steriliza-

tion measures or even isolation of the patient may be necessary. The route of transmission plays a crucial role in this (Table 3.5).

The German Infection Protection Act, which has been in force since 1 January 2001 and has replaced the

old Federal Contagious Diseases Act, takes into consideration these findings but also takes into account the effects of technology in the changing world of medicine by stipulating in § 23 that infections acquired in hospitals must be continuously recorded, even those which

Table 3.5 Types of infection transmission and their features and protective measures (after [3.15])

Type of transmission	Features	Examples	Protective measures
Airborne transmission	Microorganisms attached to particles in the air with size of $<5\ \mu\text{m}$, movement over a relatively long period of time therefore possible	<ol style="list-style-type: none"> 1. Reasonable suspicion of or confirmed tuberculosis 2. Measles 3. Varicella/disseminated herpes zoster 4. HIV patients with cough, fever, and opaque pulmonary infiltrates, provided TB cannot be ruled out 	<ol style="list-style-type: none"> 1. Isolation in a single room (door and windows closed), cohort isolation potentially possible 2. Respiratory protection when entering the room if open-lung TB is identified or there is strong clinical suspicion 3. In the case of certain diseases (measles, varicella) nonimmune people should not enter the room; if unavoidable, only with respiratory protection
Droplet transmission	Microorganisms attached to particles $>5\ \mu\text{m}$ (these droplets are created when speaking, coughing, and sneezing)	<ol style="list-style-type: none"> 1. Bacterial diseases: <i>H. influenzae</i> (type B) infections, meningococcal infections, multiresistant pneumococcal infections, diphtheria, pertussis, mycoplasma pneumonia infections 2. Viral diseases: influenza, mumps, rubella, parvovirus infections 	<ol style="list-style-type: none"> 1. Single room, cohort isolation if necessary; if not possible a distance of at least 1 m should be kept between the infectious patient and other patients or visitors 2. Mouth and nose protection required when working close to the patient ($<1\ \text{m}$ distance)
Contact transmission	Direct contact (touching) or indirect contact (secondary, e.g., via contaminated surfaces) with epidemiologically important pathogens in the case of infected or colonized patients	<ol style="list-style-type: none"> 1. Infectious diarrheal diseases 2. <i>C. difficile</i> enteritis 3. Respiratory infections in children (bronchiolitis, croup) 4. Multiresistant pathogens such as Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA), Vancomycin-resistant <i>Enterococcus faecium</i> (VRE) (except multiresistant TB) 5. Abscess or secreting wounds which cannot be covered 	<ol style="list-style-type: none"> 1. If possible single room; cohort isolation if necessary 2. Gloves and gowns depending on the pathogen and site of the infection (follow infection control recommendations) 3. Disinfect hands on leaving the room

are particularly influenced by technical factors (*device related*):

- *Postoperative* wound infections
- *Ventilator associated* pneumonias
- *Catheter-related* septicemias
- *Catheter-related* urinary tract infections.

Because these are also the four most common health-care acquired infections in hospitals and the measures required by law make an important contribution to sensible quality management, the following practical examples are limited to these infections and demonstrate the vital contribution that technology can make here.

3.8.1 Postoperative Wound Infections

The pathogens for postoperative wound infections either originate from the patient himself (germs in the skin or mucous membranes) or are introduced into the patient from outside during surgery as a result of a lack of hygiene. Before many surgical procedures, hair removal up to now is still carried out using a razor (medicotechnical measure). If this is done on the evening before the procedure, then the bacteria from skin flora have time overnight to migrate deep into the skin via the microscopic cuts in the skin which are unavoidably caused during shaving to cause inflammation there. The result is a significantly higher risk of developing surgical site infection. It is therefore recommended either not to shave at all and to simply cut the hair short using hair trimmers, or to shave immediately before the surgery and thus immediately before the skin is disinfected (see also KRINKO recommendation for the prevention of postoperative infections in the operating field [3.9]).

Further important measures for the avoidance of postoperative wound infections which are proven in their effectiveness and which relate to technical means are: sterile instruments, sterile implants, reliably sterilized equipment parts which are required for surgery (suction apparatus, counter with connection cable, etc.), correctly functioning air-conditioning units, sufficient vacuum in the case of reprocessed reusable drainage equipment, etc. [3.16].

3.8.2 Ventilator-Associated Pneumonias (VAP)

Pneumonia is the second most common overall infection in hospitals and is the most important in the case of intensive care patients. It is seen as the primary or secondary cause in 30–50% of deaths. With respect

to diagnosis related groups (DRGs), it is also significant that health-care associated pneumonia increases the length of hospital stay by an average of 11.5 days. The main risk factor for developing health-care associated pneumonia is mechanical ventilation.

According to the KRINKO evidence criteria, orientated towards the criteria of the Centers for Disease Control and Prevention (CDC) [3.17], the following technically relevant points are important for targeted prevention [3.17–20].

1. Oral intubation is better than nasal (development of maxillary sinusitis); in the case of long-term artificial respiration prefer tracheotomy.
2. Use sterile or disinfected tracheal tubes.
3. Clean all equipment and tools thoroughly before disinfection and sterilization.
4. Do not carry out routine sterilization or disinfection of the circulation system of ventilators and anesthetic apparatus.
5. Do not change ventilator breathing circuits more frequently than every 48 h, including tubes and expiratory valves and also nebulizers and steam humidifiers, provided the equipment is only used for one patient (according to recent studies an interval of 7 days between changing is even possible).
6. Do not use atmospheric humidifiers, which form aerosols (= atomizer), if sterilization/disinfection and sterile water are not used on at least a daily basis.
7. Use sterile (not distilled or nonsterile) water for rinsing the processed equipment and tools which are used on the respiratory tract after they have been chemically disinfected.
8. Do not reprocess equipment and tools which have been manufactured for single use, unless there is data to show that reprocessing does not pose any threat to the patient and is cost-effective and that the functionality of the equipment and tools is not altered.
9. Sterilize or disinfect ventilation breathing circuits and humidifiers between use on different patients.
10. Do not use bacterial filters between the humidifier reservoir and the inspiratory tube.
11. Do not change the respiratory tube routinely if the system is connected to an heat and moisture exchange (HME) or heat and moisture exchange filter (HMEF), provided it is only used on one patient.
12. Change tubes between patients, including nose clamps or masks, which are used to supply oxygen from a wall outlet.
13. Sterilize atmospheric humidifiers which are used in inhalation therapy, e.g., for tracheostomy patients,

or disinfect between patients and every 24 h when used on the same patient.

14. Sterilize or disinfect portable spirometers, oxygen probes, and other respiratory tools which are used on various patients between uses.
15. Anesthetic equipment: clean and then sterilize or thermally/chemically disinfect the reprocessable parts of the respiratory circuit (such as the endotracheal tube or mask, inspiratory and expiratory tube, Y-piece, bag valve mask, humidifier, and tube) between use on different patients and observe the relevant manufacturer's instructions.
16. Pulmonary function testing: sterilize or disinfect reusable mouthpieces and tubes between different patients or in accordance with the manufacturer's instructions.

3.8.3 Catheter-Related Septicemia

Most cases of septicemia acquired in hospitals are the result of using a vascular catheter. The most important points to avoid resulting infections are checking of the indication for access, selection of the correct catheter and the correct access site, aseptic placement of the catheter, and aseptic dressing change. The technical component is comparatively low here and covers the following points [3.21]:

1. Change IV tubes including the three-way valves only every 72 h (every 24 h when blood/blood products or lipid solutions are administered), except where there are signs of infection.
2. When choosing transducers (pressure sensors), preference should if possible be given to disposable items (as opposed to reusable equipment).
3. The transducer, the tube system, and the rinse solution must be changed at least every 96 h.
4. All components of the blood pressure monitoring system must be sterile (including the calibration apparatus and the rinsing fluid). The entire pressure system (tube lines, transducers, and rinse solution) must be handled aseptically.
5. Reusable pressure systems must be processed and sterilized taking into account the manufacturer's instructions.
6. If preparation of mixed infusions in areas close to patients is unavoidable, then it must be done under controlled aseptic conditions.

In past years it has been increasingly common to reprocess certain expensive intravascular catheters within

the hospital or to have them reprocessed by external providers (see later). This practice is currently the subject of controversial debate for very many different reasons (German Medical Devices Act, costs, bovine spongiform encephalopathy (BSE)). In this context, reference should in particular be made to the recommendations of the German Commission for Hospital Hygiene and Infection Prevention at the RKI [3.21] and [3.9] with the explanations from the RKI and the final report of the vCJD taskforce: variant Creutzfeldt–Jakob disease (vCJD), epidemiology, identification, diagnosis, and prevention, with particular consideration of minimizing the risk of iatrogenic transmission via medical devices, particularly surgical instruments [3.22]. Reference is further made to specific literature [3.23–26].

3.8.4 Catheter-Related Urinary Tract Infection

Urinary tract infections make up more than 40% of all infections acquired in hospital and, as the starting point for urosepsis, are responsible for up to 15% of cases of septicemia. Up to 80% of these urinary tract infections are found in patients with urinary catheters, which emphasizes their significance. Technically relevant aspects of targeted prevention are as follows:

- Urinary catheters should only be placed if medically necessary and only for as long as is absolutely necessary; an indication as part of nursing care must be rejected.
- Only sterile, permanently sealed urine drainage systems with an antireflux valve should be used (i. e., without disconnection to empty the bag) [3.27, 28].

3.8.5 Dialysis

Because of the high risk of infection both for patients and also for staff, dialysis departments deserve special attention. The risks of infection are:

1. For the patient:
 - a) Infections via the vascular access
 - b) Bloodborne infections
 - c) Contamination of the dialysate and dialyzer.
2. For the staff:
 - a) Through infected dialysis systems
 - b) Infections via blood and dialysate.

In comparison with peritoneal dialysis, hemodialysis is more significant from a technical viewpoint

and is the basis for the following explanations. However, some of the requirements also apply to peritoneal dialysis.

If drinking water is used for dialysis, it must undergo additional processing because it contains bacteria and pyrogens, even if chlorinated. The processes used for this are ion exchange (water softening), active carbon filtering, distillation, and reverse osmosis. However, it must be borne in mind that particularly the first process mentioned can provide waterborne bacteria (mainly *Pseudomonas* spp. and other Gram-negative bacteria such as acinetobacter and enterobacter) but also mycobacteria, which are present in water and are described as *atypical*, with good opportunities to multiply. Subsequent ultrafiltration to remove bacteria and bacterial toxins is therefore considered essential [3.29].

Although reverse osmosis is currently the most optimum processing method, it is still necessary to take into account that, even with this method, there may be microbial contamination of the membrane, and germs may find their way in if there are leaks. Once the dialysate is added, this forms a mixture which, because of its composition, is a good culture medium for waterborne bacteria. Various countries have therefore suggested guidelines for the assessment of dialysis water (Table 3.6).

To prevent contamination of hemodialysis equipment and supply apparatus, the following technical requirements are deemed necessary [3.30]:

- No open reservoirs for water and processed dialysis fluid
- No open reservoirs for concentrates
- Small line cross-sections in supply lines
- Route lines as a closed circular pipeline; avoid dead spaces (only for clean water)
- Complete disinfectability of the line system
- Pipe disconnection when disposing of the dialysis fluid to prevent retrograde microbial contamination.

In accordance with the hygiene guideline which is an appendix to the 2006 Dialysis Standard [3.31], dialysis equipment (hemo- and peritoneal dialysis) used

must comply with the regulations of the German Medical Devices Act and must be maintained, operated, cleaned, and disinfected in accordance with the manufacturer's instructions (instructions for use, technical manual) [3.30]. Due to this required disinfection after each patient, the formerly required separation into a so-called *yellow* (for infectious patients) and *white* (for noninfectious patients) region is now obsolete. The operator is responsible for ensuring that all parts which come into contact with the used dialysate or even with the patient's blood are treated as potentially infectious and that the equipment is disinfected after each dialysis treatment.

This can be done by [3.29]:

- Sterilization with steam at a temperature of 121 °C, provided this is technically possible from a material point of view (equipment with stainless-steel tanks)
- Disinfection using hot water (90–95 °C for 20 min); citric acid is automatically added during the process to prevent deposits in the equipment
- Thermochemical disinfection (for ecological reasons, preferably with peracetic acid, possibly also with formaldehyde or glutaraldehyde or with sodium hypochlorite).

Dialyzers have been regularly reprocessed in the past. Figures for the USA show that the proportion of dialysis centers reprocessing their equipment rose from 18% in 1976 to 82% in 1997 [3.32], and corresponding processing guidelines issued by the Association for the Advancement of Medical Instrumentation (AAMI) were adopted by official authorities [3.33]. The percentage then dropped to 62% by 2002. The literature describes infectious complications through to outbreaks in the course of reprocessing dialyzers, without being able to prove causality beyond doubt [3.34]. For quality assurance purposes it is therefore necessary to ensure that effective processes are used, which are currently based on thermochemical disinfection. The hygiene guideline which is an appendix to the 2006 Dialysis Standard – written by the German Commit-

Table 3.6 Guidelines for assessment of dialysis water in various countries

	Dialysis water (generally permeate)		Dialysis fluid	
	(CFU/ml)	Endotoxin	(CFU/ml)	Endotoxin
AAMI (USA 2004)	≤ 200	2 EU/ml	≤ 2000	2 EU/ml
European Pharmacopoeia (2008)	≤ 100	≤ 0.25 IU/ml	No information	No information
Swedish Pharmacopoeia (1997)	< 100	< 0.25 IU/ml	< 100	
Japanese Society for Dialysis Therapy (2008)	< 100	< 0.05 EU/ml	< 100	0.05 EU/ml

tee for Clinical Nephrology in collaboration with the Association of German Nephrology Centers run by the German Society of Nephrologists in Private Practice and also with the German Society of Pediatric Nephrology, in agreement with the German Commission for Hospital Hygiene and Infection Prevention – likewise points to the requirements for a processing method with appropriate validation and stresses that the German Committee for Nephrology currently does not favor reuse of dialyzers and tube systems, despite the financial ramifications [3.30]. Tests to monitor clean water and dialysis fluid must be performed and documented at least twice a year [3.30, 35]. The relevant water-conducting systems (e.g., closed circular pipelines) must be fitted with suitable sampling points.

The following procedure is considered necessary to test the microbiological quality of the water [3.35]:

- Disinfect hands before each sample is taken
- Use sterile glass bottles with a screw closure for collecting the sample; to test for endotoxins use pyrogen-free containers made from polystyrene
- Draw off ≈ 100 ml in each case
- *Demineralized water*
 - From the closed circular pipeline at the bedside
 - Aseptic sampling (disinfected adapter, at least twice a year)
- *Basic bicarbonate*
 - Only if it is taken as a concentrate from a closed circular pipeline at the bedside (not from canisters or cartridges)
 - Aseptic sampling (disinfected adapter)
 - Once a month
- *Dialysis fluid*
 - Sample taken from the dialyzer
 - Before the start and after the end of dialysis
 - Every 6 months

3.9 Regulations

3.9.1 Technical Regulations for Hazardous Substances

- TRGS 513. Fumigations with ethylene oxide and formaldehyde in sterilization and disinfection systems (edition June 2008).
- TRGS 525. Handling of hazardous substances in facilities for human medical care (as of May 1998

- *The assessment is performed according to the following guidelines*

- In the processed water and in the dialysis fluid before the beginning of dialysis: 100 CFU/ml.

In an ISO standard [3.36] which appeared in 2009 and in which the quality of fluids for hemodialysis is formulated as an international standard, requirements, and limit values for the chemical constituents and impurities in water, concentrate, and dialysis fluid are listed in addition to microbiological quality standards. The operator of specialist dialysis departments is responsible for monitoring of microbiological water quality and also for chemical monitoring.

3.8.6 Creutzfeldt–Jakob Disease

After medical devices have been used on patients with a proven or strongly suspected case of Creutzfeldt–Jakob disease (CJD) or its new variant (vCJD), special processing procedures are necessary [3.22, 25]. According to the currently favored prion theory, particular significance is attributed to the cleaning which takes place during processing, because proteins must primarily be removed. For disinfectant processing, 1–2 M sodium hydroxide (NaOH), 2.5–5% sodium hypochlorite (NaOCl), or 4 M guanidinium thiocyanate (GdnSCN) is currently recommended [3.22].

Instruments which cannot be steam-sterilized are then subsequently processed with aldehyde disinfectant and finally rinsed with 70% alcohol (e.g., endoscope) and gas-sterilized.

Instruments which can be steam-sterilized undergo chemical decontamination before then being subjected to machine processing at 93 °C, and are finally autoclaved at 134 °C for 1 h.

The relevant appendices to the RKI guideline must be observed [3.22].

BArbBl. no. 5/1998, p. 58, currently undergoing revision).

- TRGS 401. Hazards due to skin contact (as of June 2008).
- TRBA/TRGS 406. Sensitizing substances for the airways (as of June 2008).
- TRBA 250. Technical regulations for biological agents (as of February 2008).

3.9.2 Standards

The importance of standards has been re-evaluated as a result of Directive 93/42/EEC about medical devices and the correspondingly harmonized German Medical

Table 3.7 Standards for the (minimum) standard for medical devices ►

Type of standard	Source
DIN	German standard

4. Technical Safety of Electrical Medical Technology Equipment and Systems

Rüdiger Kramme, Hans-Peter Uhlig

Medical electrical (ME) equipment and systems are used primarily in medical institutions such as doctors' surgeries, dental surgeries, medical centers, outpatient clinics, rehabilitation clinics, sanatoriums, health clinics, nursing homes for the elderly, homes for the disabled and those with learning difficulties, and hospitals and clinics. According to the regulations and standards for electrical systems, suitable rooms – areas used for medical purposes – must be present in these institutions in which *mains-operated* ME equipment can be operated. Many questions emerge concerning the use of this equipment, on the one hand relating to the safety of patients and those operating the equipment, and on the other hand relating to the smooth operation of this apparatus. The main risks posed by these pieces of ME equipment and ME systems may be of electrical, mechanical or thermal nature. Other possible potential risks are ionizing radiation, explosion or fire as outlined in this chapter.

What is meant by risks and hazard? *Risks* in an operational process are components of the working system which can damage the life or health of operating staff or patients. These risks are energy sources or are connected to them. When this energy is greater than the electrical resistance of the human body or an affected body part, the energy is of a damaging nature. The damaging force is derived from the ratio of energy to body resistance. A *hazard* is described as the possibility of humans encountering risks in space and time. To provide safe medical workplaces, it is therefore necessary to clarify how and under what

operating conditions humans encounter risks and the risk of injury occurs, and what successful safety measures (protection objectives) are or should be in use to guard against this [4.1]. The largest proportion of possible hazards result from ME equipment and ME systems for diagnosis, therapy, and monitoring. The commonest causes of an electrical accident can be attributed to malfunctioning protective devices, defective insulation on cables and wires, defective or missing protective covers on equipment and plug connectors, and missing, disconnected or interchanged protective earths.

4.1 General Information Regarding the Safety of Technical Systems

The current state of science and technology which has been achieved in principle makes it possible to develop and build technical products and systems which are very safe. Absolute safety nevertheless does not exist, either in life or in technology. The important thing is therefore to ascertain the justifiable residual risk in each individual case, then to consciously live with this risk [4.2].

DIN 31000 general guidelines for the safety design of technical products (*Allgemeine Leitsätze für das sicherheitsgerechte Gestalten technischer Erzeugnisse*), dated 03/1979, forms the basis for the content of safety standards and VDE (Verband der Elektrotechnik, Elektronik und Informationstechnik, Association for Electrical, Electronic and Information Technology) specifications. In DIN 31000 part 2, dated 12/1987, which was unfortunately withdrawn in 2005, *borderline risk* is described as the greatest risk relating to a certain technical process or condition that is still considered justifiable. Safety is defined according to DIN VDE 31000 part 2 as a circumstance in which the residual risk remains below a defined borderline risk. The level of risk is formed as an abstract variable from the product of the extent of damage and probability of damage occurring [4.3]. The temporal and content-based limit on safety resulting from this is achieved through the description of appropriate requirements or measures.

The measures which ensure safety are divided into three classes according to DIN 31000 part 1 (three-class theory).

1. *Direct safety engineering* includes measures which provide safety mainly through constructive, planning-related engineering of products and systems and their parts.
2. *Indirect safety engineering* is understood as meaning the application of safety-related means, e.g., locking mechanisms.
3. *Indicative safety engineering* is produced by guidelines regarding the conditions for risk-free use – e.g., in operating instructions and on signs – when direct and indirect safety engineering do not, or do not completely, achieve their goal.

In the case of all of the safety-engineering measures mentioned, use of the products and systems according to their intended purpose is a precondition. The *first-fault philosophy*, described in DIN VDE 0752 supplementary sheet 1, dated 03/2003, forms an important foundation when assessing hazard situations. The findings of the international standardization on the subject of safety, such as the contents of IEC 300-3-9, dated 12/1995 (Dependability Management; Part 3: Application Guide; Section 9: Risk Analysis of Technological Systems), can also be used [4.2]. The possible consequences of first faults are virtually ruled out by protective measures and by scheduled testing and maintenance. Suitable monitoring devices must immediately discover any *first faults* which might occur.

4.2 Attaining Safety in Medical Institutions

In Germany there are very comprehensive regulations, provisions, standards, and guidelines which apply to the planning, installation, refurbishment, and testing of electrical systems in medical institutions. The same applies to the development, manufacture, and operation of ME equipment and ME systems. The crossovers or points of intersection between these documents are unfortunately not defined but are instead fluid. So, for example, different provisions and standards for ME equipment contain important requirements regarding the planning and installation of electrical systems.

Provisions and standards in principle contain only the minimum requirements, and there is not always conformity between them. In addition, they do not always reflect the state of the art, because in many cases technological developments move at a faster rate than revision of these documents is carried out. Each individual project must therefore be checked both with regard to observance of the statutory and normative minimum requirements and with regard to additional requirements. The required safety can in principle only be achieved if the overall system, consisting of the physical structure and technical systems as well as the ME equipment, is safe.

The safety of the system consisting of electrical system/ME equipment is essentially described by the protection objectives [4.2].

- Protection of patients and staff from shock currents and from the risks of power failure or of poor-quality voltage or frequency
- Safety of the interface between the ME equipment and the electrical system, in particular when using equipment for vital purposes

- Safety of the escape and emergency routes
- Protection from fires and their effect on the system of electrical installations and ME equipment over a required period of time
- Safety as a result of using reliable technology
- Safety as a result of using all of the system components according to their intended purpose
- Safety as a result of operation in accordance with regulations and regular maintenance.

4.3 Minimum Requirements for ME Equipment

DIN EN 60601-1 (classified as VDE 0750-1) Medical electrical equipment: General requirements for basic safety and essential performance (*Medizinische elektrische Geräte; Allgemeine Festlegungen für die Sicherheit einschließlich der wesentlichen Leistungsmerkmale*), dated 2007 (which replaces the 1996 edition), is the basic standard in this series and describes the general requirements for ME equipment. All approved ME equipment in Germany must be built and tested according to the standards of the DIN EN 60601 series. The basic standard DIN EN 60601-1 is evaluated here based mainly in connection to the electrical system. The protection classes I and II are approved for mains-operated ME equipment.

In *protection class I*, all nonactive parts of the ME equipment are connected to the protective earth (PE). The equipment housing is composed of metal and is likewise connected to the PE. In the event of a fault to frame or earth fault internally in the equipment (e.g., insulation fault) between an active conductor and the PE, a protective device is triggered in the equipment and/or in the electrical system and the electrical circuit affected is disconnected. During a fault situation, a contact voltage occurs between the housing of the equipment and other earthed components.

The definition of ME equipment in protection class I which is given in DIN 60601-1.

The equipment in *protection class II* is double insulated (all-insulated). A fault can only occur between active conductors or an active conductor and the neutral conductor (N). No contact voltage to earth occurs during a first fault to frame or earth fault.

The definition of ME equipment in protection class II which is given in DIN EN 60601-1.

Another category is made up mostly by *battery-operated ME equipment* which does not rely on mains electricity. As in mains-operated ME equipment of protection class II, with regard to protection against shock currents, this equipment is not dependent on the installed protective measures.

Equipment in class AP (anaesthetic proof (low risk)) must comply with the requirements regarding construction, labeling, and accompanying documentation to avoid ignition sources in explosive mixtures of inhalational anesthetic agents with air.

Equipment in class APG (anaesthetic proof, Cat. G (high risk)) must comply with the requirements regarding construction, labeling, and accompanying documentation to avoid ignition sources in explosive mixtures of inhalational anesthetic agents with oxygen or nitrous oxide.

A distinction is also made between ME equipment according to the *insulation classes of the applied parts*.

- Insulation class B: The applied part is connected to earth. External application to the patient. Provides protection against electric shock by taking into account the fault current. Not suitable for direct application to the heart.
- Insulation class BF: The applied part is insulated from the ME equipment (no connection to earth). External application to the patient, higher-quality protection against electric shock than in insulation class B. Not suitable for direct application to the heart.
- Insulation class CF: The applied part is insulated to a high level from the ME equipment (no connection to earth). External and intracardiac application

Ser. no.	Consumables	Applied for	Medical area of group	Protection against electric shock					Power supply

Table 4.1 Requirements of the electrical system for ME equipment

to the patient, higher-quality protection against electric shock than in insulation class BF. Suitable for direct application to the heart.

DIN EN 60601-1 applies accordingly to the safety of ME equipment.

Prerequisites for this are performance of risk management processes, use of the equipment according to its intended purpose, and compliance with the instructions from the manufacturer. The following are considered to be first faults for ME equipment.

1. Break in the protective earth.
2. Break in a power supply cable.
3. Occurrence of an external voltage at applied parts with code letter “F”.
4. Occurrence of an external voltage at signal input or output parts.
5. Failure of an electrical component.

The rated voltage may be a maximum of 250 V for handheld ME equipment. For ME equipment and ME systems which are operated on direct current or single-phase alternating current, the maximum value is 250 V at a power limitation of 4 kV A. For ME equipment and ME systems operated on polyphase current, the upper limit of the rated voltage is 500 V.

The tolerance of the nominal voltage for ME equipment is $\pm 10\%$ and that of the mains frequency is ≤ 1 Hz. According to the standards which apply to electrical systems, other values may also occur in this case (Sect. 4.7).

The protective earth of the equipment must be checked regularly. A limit value of 0.1Ω is permitted

between the PE of the plug and exposed metal parts (housing) for equipment with a permanently connected power supply cord, and of 0.2Ω for equipment with a removable power supply cord.

The collateral standard DIN EN 60601-1-1 stipulates that, when using portable multiple sockets, it must be possible to connect the ME equipment of an ME system to a multiple socket only with the aid of a tool. Multiple sockets of this kind are available factory-built in accordance with DIN EN 60601-1-1. Alternatively, the portable multiple socket must be electrically isolated (e.g., isolating transformer).

It is worth noting that electrically wired toroidal transformers are frequently used as isolating transformers. There is no proof of safety from first faults for this arrangement. The same applies to the supply of entire ME systems from one power socket. Complete power failure is possible at any time.

The conclusion is that the safest kind of power supply is the supply of ME systems from fixed single power sockets, especially for vital purposes, being connected to an information technology (IT) system.

Some of the requirements for ME equipment in DIN EN 60601-1 which have been mentioned have a direct or indirect bearing on the electrical system. Some additional requirements for the electrical system can be found there [4.2].

Table 4.1 summarizes the various applications of ME equipment such that the most important requirements can be recognized at the interface with the electrical system and additional requirements can be defined.

4.4 Areas Used for Medical Purposes

Medical examinations and treatments must be carried out in appropriate rooms, areas used for medical purposes, regardless of where these rooms are. It may be a hospital, medical center or health center, an outpatient clinic or a private doctor’s practice. The use of medical procedures requires the areas used for medical purposes to be divided into the groups 0, 1 or 2 (DIN VDE 0100-710).

There are specific hazards caused by the possible condition of patients, such as unconsciousness, or the nature of the medical examination or treatment, e.g., an operation. A patient’s skin resistance can be compromised as a result of medical interventions, and a patient’s cognitive ability or the body’s defenses can

be impaired or limited as a result of medical treatment. It is mandatory that the required classification and division of the areas used for medical purposes into groups be carried out – generally by the representative of the purchaser (= planner) together with the medical and technical staff (= operators). An essential basis for the decision regarding which group a room is allocated to (Table 4.2) is the nature of the contact between the applied parts of the ME equipment and the body of the patient. In areas belonging to group 1, invasive examinations and therapies can even be performed, but no examinations or therapies can be performed directly on the heart. A power failure with a maximum duration of 15 s can be dangerous

Table 4.2 Normative criteria for the classification of rooms in groups

Group 0	Group 1	Group 2
Consulting rooms	Medical and dental practice rooms	Surgery preparation rooms
Surgery consulting rooms	Surgical outpatient clinics	Operating theaters
Dressing rooms	Rooms for home dialysis	Recovery rooms
Wards	Wards	Intensive care units
Massage rooms	Rooms for hydrotherapy	Special baby care units
Fitness rooms	Endoscopy rooms	Endoscopy rooms
OT adjoining rooms	Rooms for minimally invasive surgery	Rooms for minimally invasive surgery
Respiratory chambers	Angiography rooms	Angiography rooms
	Cardiac catheterization laboratories (investigation)	Cardiac catheterization laboratories (investigation and treatment)
	CT rooms	
	Magnetic resonance imaging (MRI) rooms	
	Electrocardiography (ECG) rooms	
	Electroencephalography (EEG) rooms	
	Delivery room	

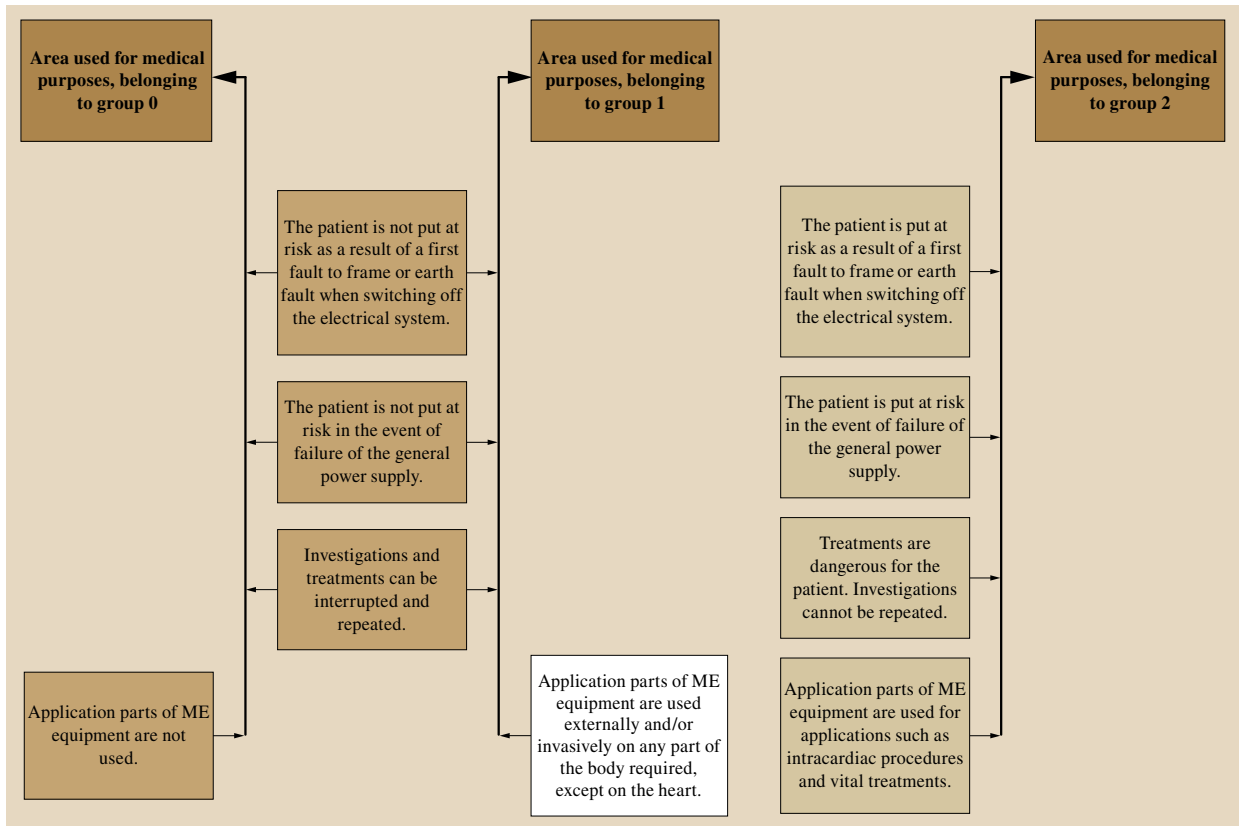

Fig. 4.1 Examples of the allocation of rooms to groups

in this situation, however. Classification in group 2 and the use of a battery-supported power supply for safety purposes (BPS, previously PS) should therefore be considered.

In group 2, the criteria applied are *intracardiac or open-heart treatments or examinations* (in addition, consider DIN 57753-2) and *essential examinations and*

treatments. The additional description of the electrical conditions in DIN VDE 0100-710 for classification into groups should help in making the decision (Fig. 4.1). All criteria which are important for the safety of the patient must always be consulted when selecting the group. Where there is any doubt, the decision should be made to choose the higher level of safety [4.2].

4.5 Electrical Systems According to the Nature of the Connection to Earth

Consistent application of the terre neutre séparé (TN-S) system in accordance with DIN VDE 0100-100 and DIN VDE 0100-710 within a building is of fundamental importance for the effectiveness and the proper application of protective measures in the electrical system, in particular of measures to protect against shock currents and against electromagnetic interference (external voltages). In this system, the neutral conductor and the protective earth (PE) are conducted separately in the entire building and are only connected to one another at one point, e.g., in the low-voltage main distribution

board. As a result, only fault currents but no operating currents can continue to flow in the protective earth. In normal operation, small, unavoidable fault currents occur in the protective earth of the final circuits, in particular small inductively and capacitively induced fault currents and those induced by insulation resistances. These currents can be several amps in the protective earth of the building's main distributor. In the case of fault to frame or earth faults, relatively high fault currents of up to several kA may briefly occur in final circuits until the protective device is triggered [4.2].

4.6 Protection Against Shock Currents

In areas used for medical purposes belonging to groups 1 and 2, according to DIN VDE 0100-710 an agreed limit of the *contact voltage* (DIN VDE 0100-200) of $U_L \leq 25$ V applies, which must be observed. *Examinations and treatments performed directly on the heart* are an exception. A maximum contact voltage of 10 mV is applicable in this case, in accordance with DIN 57753 part 2 of 02/1983 (VDE guideline 0753-2 part 2/02.83). In the event of a fault, a low value of this kind cannot be achieved purely by physical means via the protective earth by means of measures in the electrical system. For this reason, ME equipment in protection class I can in this case only be operated at the medical IT system (DIN VDE 0100-710). The flexible additional potential equalization cables must be connected without fail. With interventions of this kind, measures must also be carried out on the medical side, such as the use of ME equipment with applied parts of insulation class CF. Under the conditions mentioned, risks caused by leakage currents are extremely unlikely. Leakage currents (Fig. 4.2) and their effects are limited in terms of the electrical system by the application of the medical IT system and by the additional potential equalization.

Protection against the effect of leakage currents is achieved in terms of equipment by using ME equipment in protection class II and by limiting the patient leakage current (Table 4.3).

The *additional potential equalization* in every area used for medical purposes is the most important fundamental protective measure in the areas used for medical purposes belonging to groups 1 and 2. In the areas belonging to group 2, in accordance with DIN VDE 0100-710, additional connector bolts for the additional potential equalization according to DIN 42801 are installed in the patient environment (DIN VDE 0100-710, DIN EN 60601-1-1). The flexible potential equalization cables to be connected there, which establish an additional direct connection between the PE of the permanently installed system and the housings of the ME equipment, serve the purposes of

- equalizing potential differences between the ME equipment in the patient environment,
- preventing failure of the protective earth in equipment in protection class I (first-fault safety), and

Fig. 4.2 Patient and operator connected to ME equipment (after [4.4]). The various equipment parts form capacitors C with the safety-related insulation which is situated between them, and the patient leakage current and housing leakage current flow via these capacitors. In equipment belonging to protection class I, the earth leakage current also flows via the protective earth. (A–a Insulation mains part/exposed metal parts, B–a Insulation mains part/applied part, B–d Insulation applied part/mains part)

- ensuring that the required contact voltage at the housing of equipment in protection class I is maintained.

These cables are of great importance for protecting against shock currents and must always be connected when equipment in protection class I is used [4.2].

Further *important protective measures* against shock currents include

- Protection by automatic disconnection according to DIN VDE 0100-410*

The electrical circuits of power sockets must be disconnected by the associated protective device within 0.3 s in the event of a fault (zero-impedance short circuit). In accordance with DIN VDE 0100-410 of

Table 4.3 Maximum permissible leakage currents from ME equipment according to DIN EN 60601-1

Type	Type B	Type BF	Type CF
Earth leakage current (mA)	0.5	0.5	0.5
Housing leakage current (mA)	0.1	0.1	0.1
Patient leakage current (mA)	0.1	0.1	0.01

2007, this protective measure may only be used for power sockets of up to 20 A when the power socket is monitored (in this regard see the German government safety organization regulation BGV A3). In all other situations, 2 shall apply.

- Protection by automatic disconnection of the power supply using residual current protective devices (RCD) release current $I_{\Delta N} = 30$ mA*

This protective measure is prescribed for power sockets in areas in groups 1 and 2 if there is no risk to the patient. ME equipment for vital purposes must not be connected here.

- Protection by notification of insulation faults in the medical IT system*

Where ME equipment is used for vital purposes or for investigations which cannot be repeated, the equipment must be supplied from a medical IT system. In accordance with DIN VDE 0100-710, power sockets of this type are only installed in areas belonging to group 2. Here, the medical IT system constitutes the preferred protective measure. Owing to the limitation of power in the IT isolating transformers to a maximum of 8 kV A, however, it cannot always be used universally.

The *medical IT system* forms an isolated and locally restricted network. The conductive housing of the ME

equipment in protection class I is connected to the protective earth. When only one first fault to frame or earth fault occurs, only the housing leakage current emerges as a fault current and there is no disconnection. This ensures that a piece of ME equipment which is vital for the examination or treatment will not fail and can continue to be operated until the treatment is complete. The medical staff are notified of this. Protection against overload is not permissible. The overloading of the IT isolating transformer is communicated to the medical staff via a monitoring device. The causes of the overload

must be determined and remedied because otherwise the isolating transformer can be destroyed.

The power sockets of the medical IT system must be accordingly labeled or designed such that they are unmistakable when several systems are present in one room according to the type of earth connection. The intention of this is to prevent ME equipment which must be supplied from the medical IT system from being inadvertently connected to power sockets of the TN-S system. There are no normative guidelines for such color coding.

4.7 Power Supply

A safe power supply is another important criterion for safe operation. The following forms of power supply are available for areas used for medical purposes.

- *General supply* (GS) via a house connection or a high-voltage feed from a distribution system operator (DSO);
- *Power supply for safety purposes* (PS) via power generation units with internal combustion reciprocating piston engines;
- *Battery-supported central power supply for safety purposes* (BPS).

When supplying safety-relevant consumers in areas belonging to group 2, it is necessary to switch between these power supplies (power sources and mains networks). The requirements for this switching can be found in DIN VDE 0100-710 under several sections. Considering these normative sources, the following switching devices are necessary in the subdistributors for the supply to areas in group 2.

- Switching between a PS and GS feed.
In this case, the voltage of the outer conductor of the first cable (PS) is monitored. If the first cable fails,

continued supply to the consumers mentioned under 710.564.4 and 5 must be guaranteed within 15 s, provided this supply is fed from a subdistributor.

- Switching between a PS and BPS feed.
In this case, the voltage of the outer conductor of the first cable (PS) is monitored. If the first cable fails, continued supply to the ME equipment must be guaranteed within 0.5 s. If the BPS is used in continuous operation and the first cable is supplied with power from the BPS, the voltage provided is uninterruptible.

The stability and quality of the supply voltage is an important criterion for a safe power supply. When the standards for the power socket are observed, in individual cases the nominal voltage of the mains electricity can deviate by 14% below the nominal voltage. When supplying the mains from a power generation unit, in the case of certain load changes deviations of ± 1 Hz from the permissible tolerance band for the ME equipment are possible. On account of the lower impedance of the generator compared with mains electricity, harmonic currents can also affect the voltage and lead to interference. The deviations mentioned can be compensated by suitable planning measures [4.2].

4.8 Power Sources for Safety Purposes with Accumulators

In accordance with DIN VDE 0100-710, supply from a BPS with a maximum permissible interruption time of 0.5 s and a minimum supply period of 1 or 3 h is required for surgical lights. A minimum supply period of 3 h is required when only one power generation unit is present.

Central BPS units for the supply of ME equipment are unfortunately not covered by DIN VDE 0100-710. DIN EN 60601-1 requires that ME equipment be designed such that an interruption in the power supply does not present a hazard before it is restored. On this basis, the function of the BPS is in many cases adopted

by what are known as internal power sources built into the ME equipment. There is still demand for central BPS units, however, as is evidenced by many examples. Some reasons for this are

- a central BPS generates lower costs, in particular in large medical institutions, when the high testing and maintenance costs for the internal power sources (small accumulators) are taken into consideration in addition to the investment costs,
- other indispensable lighting for the operating theater lighting (e.g., OT microscopes, endoscopes) are operated with a 230 V alternating current,
- the internal power sources of ME equipment are not sufficiently reliable,

- the internal power sources of ME equipment have no standby system,
- there is ME equipment without internal power sources in circulation,
- the central BPS units are required under building law.

For battery-supported central power supply systems (BPS) for safety purposes for supplying areas used for medical purposes, the German national standard DIN VDE 0558-507 has been applicable since October 2008.

A uninterruptible power supply (UPS) must not be used to supply ME equipment because it does not meet the necessary requirements.

4.9 Final Circuits and Plug Sockets

Important requirements for the circuits of plug sockets are mentioned in DIN VDE 0100-710. The plug sockets in the patient space must therefore be split between at least two circuits. The note includes the requirement that two medical IT systems must be set up where there are more than two electrical circuits per patient space. It is therefore virtually recommended by the standards to set up *two medical IT systems per patient space*.

When using *portable multiple sockets*, individually protected electrical circuits are prescribed. For

safety reasons, multiple sockets must not be used, with the exception of wheeled equipment trolleys (Sect. 4.3).

DIN VDE 0100-710 furthermore stipulates that all power sockets which supply ME equipment must be equipped with an optical voltage indicator. As a result, the medical personnel will immediately be able to recognize which power sockets are still carrying voltage following a fault.

4.10 Static Electricity

Static charges are dependent on the conductivity and separation speed of the materials involved. Conductive substances are those solid or liquid substances whose specific resistance is up to $10^4 \Omega/\text{m}$. Nonconductive substances on the other hand have specific resistance of more than $10^4 \Omega/\text{m}$. Particularly in the field of surgery, where there is a large amount of medical technology equipment, and anesthetic gases as well as combustible liquids such as disinfectants are used, an electrostatic discharge could ignite the *explosive OT atmosphere*, with devastating consequences. The following protective measures are therefore necessary in rooms used for medical purposes which have areas with potentially explosive atmospheres [4.5].

- Work clothes and also sheets and blankets must be made of a blended fabric consisting of at least 30%

natural cotton or viscose (without a resin finish). Rubber blankets, mattresses, and pillows must be made or covered with conductive rubber.

- The leakage resistance of the flooring may be $10^7 - 10^8 \Omega$. To achieve a certain standard insulation, the flooring leakage resistance should not fall below $5 \times 10^4 \Omega$.
- Equipment and furnishings which are exposed and are conductive must be conductively connected both to one another and to the floor. The flooring should be electrostatically conductive and at the same time connected to the potential equalization. Because explosive, volatile anesthetics such as halothane or enflurane are no longer available, a controversial discussion has arisen about the need to equip operating theaters with expensive static-dissipative flooring. Nevertheless, according

to experts, the problem of static charge remains and can negatively influence or even damage medical technology equipment (e.g., monitoring), which means that it is still sensible to keep the floor dissipative.

- Operating table systems must be connected to the potential equalization conductor or protective earth. The tabletop pad must be electrically conductive so that any electricity generated as a result of fric-

tion can be discharged via the earthed table without sparking.

- Conductive footwear (including overshoes) must have a leakage resistance of at least $5 \times 10^4 \Omega$.
- Breathing bags of inhalational anesthetic equipment and oxygen ventilation equipment must only be manufactured from conductive material. Electrically conductive latex mixtures or polypropylene are particularly suitable for this purpose.

4.11 Electromagnetic Compatibility

A very high level of electromagnetic compatibility (EMC) is required in ME equipment and ME systems to ensure the proper functioning of other electrical devices. IEC 50-161 gives the definition for EMC [4.7].

Magnetic and electrical interference fields can impair or prevent the safe operation of medical technology equipment and systems. Interference radiated or conducted from the environment can on the one hand affect medical technology electrical devices, but can also originate from such devices. One example of a radiated interference variable is electrosurgery or radiofrequency (RF) surgery. The construction of an RF generator (frequency spectrum 0.4–5 MHz) is in principle comparable to a transmitter; all that is missing are electronic components for the transmission of information and an antenna. A high proportion of the radiofrequency energy of the RF generator is radiated wirelessly from the cables into the environment, especially in the case of relatively old equipment. Further interference occurs when electrical cables are conducted parallel to the cables of the RF generator, because stray currents arise in the electrical supply cables of neighboring equipment as a result of capacitive and inductive coupling. To ensure the smooth operation of electromedical equipment and systems it is also necessary for the required mains voltage to be electromagnetically compatible, i. e., for the effective value to be stable within prescribed limits and the level of interference in the voltage to be less than the level of compatibility of the equipment being operated (EMC environment class 1 and/or 2). Major conduction-related parasitic inductions are caused by what are known as interference phenomena, such as

- fluctuations in the voltage and periodic voltage fluctuations as a result of quick load changes in the supply network (flicker),
- harmonics and interharmonics,

- voltage drops and short interruptions,
- transient overvoltages,
- imbalances,
- fluctuations in the mains frequency.

As the number and use of pieces of ME equipment increase, there is also a proportional increase in the problems with electromagnetic compatibility, which is ultimately a synonym for concepts including overvoltage, RF noise, 50 Hz mains hum, earth loops, and circuit feedback (Table 4.4).

The following EMC features are of particular interest for electromedical equipment [4.8].

- In the case of life-sustaining and life-supporting medical technology equipment and systems, correct operation without any impairment must be ensured.
- In the case of medical technology equipment and systems which are not for life-sustaining purposes, impairment may occur which is not relevant to safety and can be recognized by the operator.

Table 4.4 Reference values for interference parameters (after [4.6])

Interference variable	Unit	Reference value
Frequency range	[Hz]	$0-10^{10}$
Voltage	[V]	$10^{-6}-10^6$
Voltage variation	[V/s]	up to 10^{11}
Current	[A]	$10^{-9}-10^5$
Current variation	[A/s]	up to 10^{11}
Field strength, electrical	[V/m]	up to 10^5
Field strength, magnetic	[A/m]	$10^{-6}-10^8$
Power	[W]	$10^{-9}-10^9$
Pulse energy	[J]	$10^{-9}-10^7$
Pulses	Rise time	$10^{-10}-10^{-2}$
	Duration	$10^{-8}-10$

- Equipment with various functions which are directly connected to the patient must operate reliably, without any mutual interference.
- Specific requirements apply for the operating theater area.
- There are special interference-suppression concepts regarding leakage currents (e.g., housing leakage current).

To guarantee electromagnetic compatibility in medical technology, the following technical and organizational measures are available, among others [4.9].

1. For *direct safety*, grounding, potential equalization, shielding, filtering, protection against overvoltage, selection of cables, and circuit layouts suitable for EMC are all possibilities.
2. *Indirect safety* is achieved by spatial measures, signal conversion of the usage variables, use of interference-free software, and installation of alert technologies.
3. *Administrative safety* is achieved by measures such as a code of conduct, EMC planning, repair, maintenance, and servicing, among others.

4.12 Conclusions

The primary requirements for ME equipment and the electrical system in areas used for medical purposes are based on a safe power supply, protection against shock currents and magnetic or electrical interference, and protection against the risk of explosion and fire.

When dealing with ME equipment in the clinical environment, it is inevitable that each operator will

become familiar with the functioning and intended purpose of the electromedical equipment and with the possible combinations with ME systems. In addition, monitoring of the condition of the equipment, the accessories, and the cable lines and function checking of the ME equipment and ME systems are also crucial for safe operation.

5. Quality Management in Medical Technology

Albrecht Malkmus

This chapter aims to provide a basic understanding about the objectives, elements, and structure of a quality management system in the field of medical technology. It will show the elements and the organization of a quality management system. Practical guidance is given for setting up a quality management system.

5.1	Objectives of a Quality Management System	49	5.2	Elements of a Quality Management System	54

5.1 Objectives of a Quality Management System

5.1.1 Concepts

What exactly is a quality management system, and what does it achieve?

The standard EN ISO 9000:2008 gives the following answers to this question:

- A quality management system is a management system to direct and control an organization with regard to quality.
- Quality is the degree to which a set of inherent characteristics fulfils requirements.

Expressed in rather more everyday language, this means that, with the help of a quality management system (QMS), the relevant processes in an organization are designed and controlled such that the finished products or services rendered satisfy the requirements of the customers to the highest possible degree.

According to this understanding, other management activities such as finance management or environmental management are *not* part of quality management (QM) – unless the quality of the products and services would

be directly affected by these management systems. All of a company's customer-based and value-adding processes are accordingly the subject of QM:

- Marketing and sales
- Development, procurement, and production
- Delivery, installation, and maintenance.

A particular feature of medical technology is the comprehensive regulatory guidelines, that is to say the legal requirements which are attached to the marketing and operation of medical devices. Since these requirements have an impact on virtually all product realization processes, it makes sense in the field of medical technology to regard the systematic fulfilment of the regulatory requirements (regulatory affairs) as part of QM.

Another feature is the critical nature of medical devices: The consequent minimization of risks for the patient, user, and third parties during development, production, installation, and use of a medical device must be pursued with a dedicated risk management process.

Because the requirement for safe medical devices is part of the essential customer requirements, the techni-

cal risk management must also be an integral part of QM.

Quality Costs

Another concept which is important in understanding QM is the idea of quality costs. Quality costs are understood as being the sum of the following cost groups:

- *Prevention costs*
All endeavors which are undertaken to prevent faults from emerging: implementation of a QMS, internal audits, staff training, identifying customer requirements, designing the infrastructure and working environment, etc.
- *Appraisal costs*
All endeavors which are undertaken to detect faults: verification and validation of products and processes.
- *Nonconformity costs*
All endeavors which are undertaken to remedy faults and their consequences: reworking, warranty costs, etc.
- *External quality assurance costs*
All endeavors which are undertaken to demonstrate to third parties the existence of an effective QMS: certifications and product approvals, demonstration of the QMS to customers, etc.

5.1.2 Objectives and Clientele of a QMS

Why do businesses with high costs implement a QMS? The increase in the competitiveness of the company is the *intrinsic motivation* for implementing a QMS. This means:

- Realizing the products and services such that they fulfil the requirements of the customers as best possible
- Introducing new products onto the desired markets in as short a time as possible, while fulfilling all applicable regulatory requirements
- Minimizing the quality costs while maintaining a given level of quality.

The numerous regulatory requirements and the requirements of the market are the *extrinsic motivation*:

- An effective QMS is required by law as a prerequisite for marketing medical devices. The existence of an effective QMS is checked by independent certification authorities (*notified bodies*).

- The customers in the business-to-business sector (B2B) and also large end customers will only accept suppliers which have a certified QMS.
- The liability risk of the manufacturer within the scope of product liability can be reduced by an appropriate design of the QMS. A checklist covering these points can be found in a handbook provided by the DIHK (Deutscher Industrie- und Handelskammertag, German Association of Chambers of Industry and Commerce) [5.1].

As a result of these different objectives for a QMS, a QMS must also serve different customer groups.

The diagram in Fig. 5.1 shows the most important customer groups for a QMS in medical technology.

5.1.3 Regulatory Requirements

The numerous regulatory requirements in the field of medical technology relate to:

- The product realization processes and the manufacturer itself
- The products manufactured and the services rendered, as well as
- The marketing, installation, operation, and maintenance of medical devices.

These regulatory requirements therefore have a direct impact on the processes of the company which fall within the domain of QM and must therefore be taken into consideration when setting up a QMS. Table 5.1 gives an overview of the applicable requirements in the most important medical technology markets.

In addition to the directives, numerous guidelines have also been created for the European Union (EU) in a consensus between authorities and manufacturers of medical devices, so-called MEDDEVs, which represent a general interpretation of legal requirements. These guidelines deal with different issues, from definitions of concepts, through general and specific production requirements, to market observation. A complete list of the MEDDEVs can be found on the Internet pages of the European Commission [5.2].

In the case of the European Union, the national laws must also be taken into account, which arise as a result of the translation of European law into national law.

Those which are applicable for Germany are those shown in Table 5.2.

In addition to the European directives and guidelines and the national laws, the approval of medical

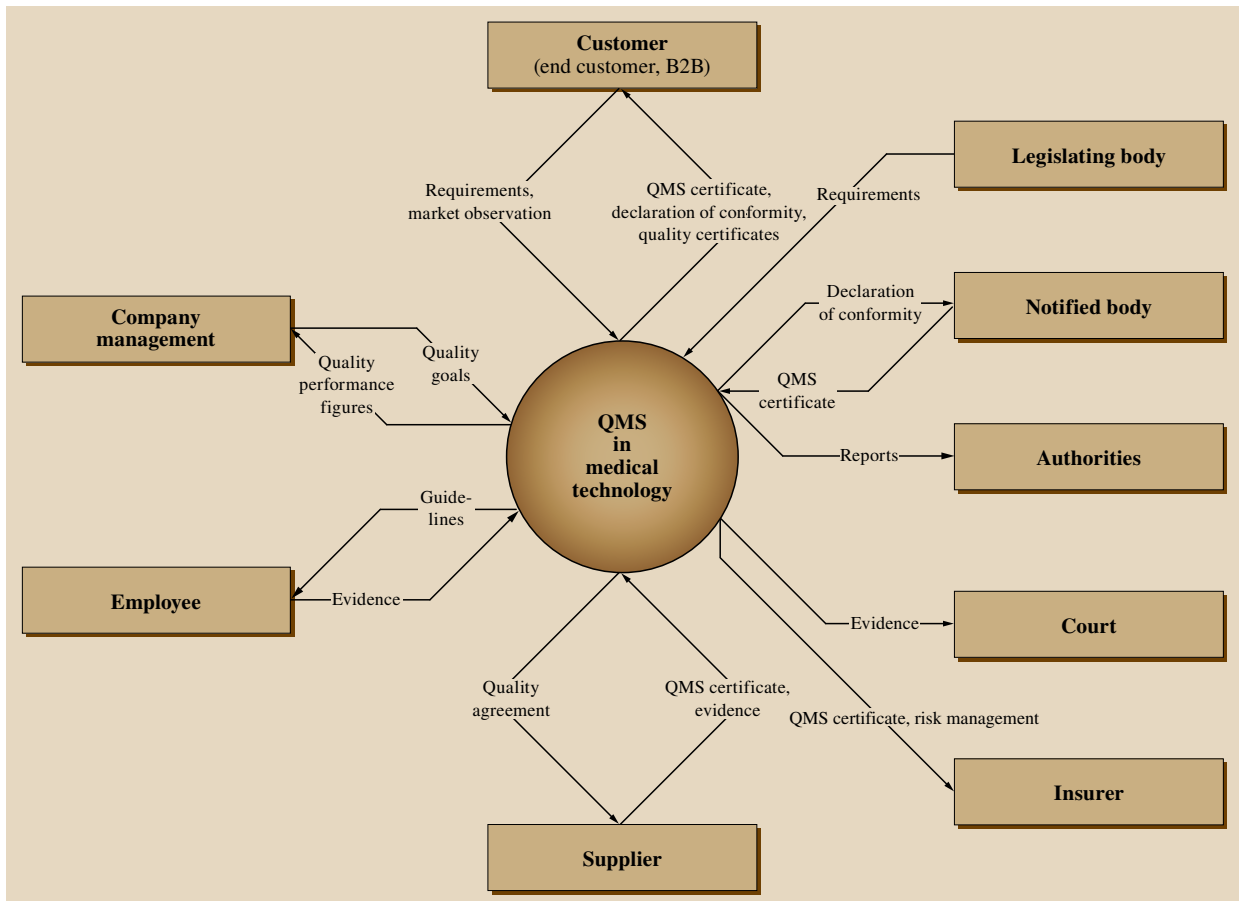

Fig. 5.1 Customer groups for a QMS in medical technology

devices in the European economic zone is predominantly based on harmonized standards:

- Harmonized standards are developed by the European standardization bodies CEN (Comite Europeen de Normalisation, European Committee for Standardization), CENELEC (European Committee for Electrotechnical Standardization), and ETSI (European Telecommunications Standards Institute) with the aim of specifying the requirements of the CE directives.
- Harmonized standards adapt the requirements to the EU member states. When a harmonized standard is satisfied, it is assumed that the requirements of the corresponding CE directive on which it is based will be satisfied.
- The implementation of (harmonized) standards is not compulsory. However, the manufacturer must

then demonstrate in some other way that the underlying requirements are satisfied.

- The harmonized standards include standards for quality management models such as EN ISO 13485, standards regarding general safety, and standards regarding the safety and effectiveness of specific product groups or products.

A complete list of the harmonized standards in the field of medical devices is provided by the European Commission on the Internet (<http://www.newapproach.org/Directives/DirectiveList.asp>). The European Directives for medical devices distinguish between different development stages of a quality management system:

- Complete quality management system. The QMS includes the areas of design, manufacture, and final checking of the products in question.

MPBetreibV	Medical Devices Operator Ordinance; 2003 (<i>Medizinprodukte-Betreiberverordnung</i>)	Manufacturer, operator
MPVertrV	Ordinance on Medical Devices Marketing Channels; 1997/2001/2003 (<i>Medizinprodukte-Vertriebswegeverordnung</i>)	Manufacturer
MPVerschrV	Ordinance on the Prescription Requirement for Medical Devices; 2002 (<i>Verschreibungspflicht von Medizinprodukten</i>)	Manufacturer, operator
DIMDIV	Ordinance on Database-Assisted Information Systems Concerning Medical Devices (<i>Verordnung Datenbankgestütztes Informationssystem über Medizinprodukte</i>)	Manufacturer, operator

- Quality management system production.
The QMS only includes the areas of manufacture and final checking of the products in question.
- Quality management system product.
The QMS only includes the final checking of the products in question.

With the lower development stages of the QMS, depending on the critical nature of the product, product-related tests must be carried out by a notified body – process steps which under certain circumstances can lead to sensitive delays in market introduction. Because the international requirements moreover do not make these distinctions, it can only be recommended that a complete QMS be implemented.

The requirements for a QMS in the field of medical technology are specified in the following standards.

- EN ISO 13485:2009. Medical devices – Quality management systems – Requirements for regulatory purposes.
- EN ISO 14971:2008. Medical devices – Application of risk management to medical devices.

Whoever is certified according to ISO 13485:2009 satisfies the European legal requirements for a QMS. In addition, compliance with ISO 13485 and ISO 14971 also for the most part means satisfaction of the international requirements (USA, Japan, Canada, etc.) for a QMS.

Table 5.3 The most important QM elements according to ISO 13485

Responsibility of the management and quality management officer	<p>Quality management is the responsibility of the company management.</p> <p>It is the responsibility of the company management to ensure the implementation and maintenance of a QMS and to regularly check its effectiveness.</p> <p>A member of the company management (<i>management representative</i>) must be nominated who has responsibility and authorization for the implementation and maintenance of the QMS and who informs the management about quality matters in the company.</p>
Quality policy and quality goals	<p>The responsibilities of the company management also include the obligation of the company to document quality in a quality policy and to form concrete quality goals from this policy.</p>
Document management	<p>Document management, which is to say the creation, release, distribution, and updating of specifications and quality certificates, must be provided in written form. The standard also stipulates what content must be documented.</p>
Human resources	<p>The employees whose work can influence the product quality must be adequately qualified for their jobs.</p>
Infrastructure and working environment	<p>The company must design the infrastructure and the working environment such that the required product properties are achieved. Examples of this include suitable premises, machines, and tools or environmental conditions, such as the atmospheric humidity, temperature, etc.</p>
<p>Product realization</p> <p>Planning of all the necessary processes within the scope of product realization (including risk management)</p> <p>Ascertainment of customer requirements</p> <p>Define product development processes</p> <p>Define procurement processes</p> <p>Define production processes</p> <p>Define processes for delivery, installation, and maintenance</p>	<p>All product realization processes must be planned and documented.</p> <p>The process chain under consideration ranges from marketing and sales (ascertaining customer requirements) to service in the field (maintenance and market observation).</p> <p>The standard stipulates at what points in the process chain checks must be performed.</p> <p>The (technical) risk management must be integrated in this process chain in the same way as the verifiable fulfilment of all regulatory requirements (conformity to standards, product approvals).</p>
Measurement, analysis, and improvement	<p>Setting up meaningful and valid performance measurement systems which provide information about the conformity of the product and the conformity and effectiveness of the QMS.</p> <p>The spectrum of the performance figures covers both technical process parameters and performance figures concerning customer satisfaction.</p> <p>Setting up effective improvement processes which make the necessary corrective and preventive measures possible.</p>

Note: ISO 13485:2009 is based on ISO 9001:2008, which is not industry specific. Allowance must be made for the fact that ISO 13485 has *not* adopted all of the

requirements of ISO 9001. Organizations which are certified according to ISO 13485 therefore do not automatically meet the requirements of ISO 9001.

5.2 Elements of a Quality Management System

The requirements for a QMS in the field of medical technology are defined in detail in ISO 13845. In case of any questions, the following standards can be used:

- DIN EN ISO 9000:2005 (Concepts)
- DIN EN ISO 9004:2000
- ISO/TR 14969 (Guidelines).

Table 5.3 aims to give a brief overview of the essential elements of a QMS according to ISO 13485: The last element “Measurement, analysis, and improvement” in particular represents a principle which forms the basis of all QM models, the plan–do–check–act (PDCA) cycle by *Deming* [5.3], a cycle for continuous improvements (Fig. 5.2):

- Plan:** Analysis of the current situation, determination of the new quality goals, specification of the new processes
- Do:** Implementation of the new processes
- Check:** Checking to ascertain whether the planned goals are being achieved

Fig. 5.2 The PDCA cycle by *Deming* [5.3], a cycle for continuous improvements

Act: Transfer the new processes into the routine and implement countermeasures in the event of deviations.

This cycle is followed continuously for the purpose of constant improvement and is a closed control loop.

The challenge when setting up a QMS is to integrate the principle of the PDCA cycle into all elements of the QMS and thus to create an active and self-adapting QMS.

5.3 Organization of a Quality Management System

If the field of application and the elements of the QMS have already been prescribed in detail by means of the European directives and ISO 13485, then there is a great deal of room for maneuver in the organization of the QMS. The spectrum of the possible forms of organization ranges from a large, central QM department, which is responsible for all QM duties, to delegation of the QM duties to all management staff and employees and to complete abandonment of a separate QM organization.

Three principles have proved to be of value in practice and are consistent with the applicable requirements:

1. Direct feeding or integration of QM into company management
2. Preferably process-oriented responsibility for the individual elements of the QMS
3. Guarantee the independence of all testing authorities.

These principles can lead to the following organizational model:

- A separate organizational unit is formed which is responsible and authorized for all superior (company-wide) QM issues.
- This central QM position is a member of the corporate management or is directly below the corporate management.
- In all functional areas of the company which are the subject of QM, one or more employees are assigned QM tasks. Depending on the size of the functional area, they take on the QM tasks either in addition to other assignments or on a full-time basis. Within the scope of their QM tasks, they report professionally to the superior QM position.
- All employees who perform checks do not belong to the organizational unit whose processes or products they check.

Table 5.4 Organization of quality management

Superior QM	QM representative of a functional area
Formulation of the company-wide quality goals in coordination with the company management	Formulation of the area-specific quality goals in coordination with the area management and the superior QM position
Implementation and adjustment of a company-wide performance measurement system	Determination of the performance figures for the functional area
Preparation of the annual management appraisal	Provision of the necessary information
Identification of the applicable legal and normative requirements and communication of these requirements in the company	Adaptation of the processes in the functional area to the applicable requirements
Coordination/performance of QM training programmes	Performance of QM training in the functional area
Implementation and maintenance of the company-wide QM handbook	Implementation and maintenance of all sections of the QM handbook which concern the functional area
Implementation and maintenance of a superior procedure model for product realization	Implementation and maintenance of all steps of the procedure model which concern the functional area
Coordination of external quality audits and certifications	Preparation and provision of the necessary documents and points of contact
Coordination/performance of internal quality audits	Preparation and provision of the necessary documents and points of contact; if necessary, involvement in the audit
Monitoring of superior corrective and preventive measures	Monitoring of area-specific corrective and preventive measures
Performance of product approvals	Provision of the necessary documents
Contact with authorities as part of the notification obligation	Provision of the necessary information

In the model above, the tasks would be distributed as shown in Table 5.4. The representation of Table 5.4 does not show the processing of customer complaints, investigation into customer satisfaction or product observation in the field. These activities can be sensibly integrated into the superior QM position and into service or sales. Demonstration of conformity of the products with technical standards is likewise not included. According to the principle of process-oriented responsibility, it is recommended that these

tasks be integrated into product development. The number of employees who are assigned QM tasks is of course dependent on the size of the company and the complexity of the products. In very small companies, all of the activities described above could also be undertaken by one employee in simultaneously held positions.

Last but not least, the principles of effective management should of course also be observed in the structuring of a QMS [5.4].

5.4 Implementation of a QMS

As in the organizational implementation, there is also a large degree of freedom in the technical implementation of a QMS. When implementing a QMS, the various customer groups of the QMS should be considered again (Sect. 5.1.2).

5.4.1 The QMS and the (End) Customers

The (end) customer is the reason for the existence of the company and the QMS. It is important that the customer is actually also integrated into the processes of the QMS as a real person. This should be done not merely reactively as part of the processing of complaints but also proactively, for example, through cooperation in the development of new products and services.

5.4.2 The QMS and the Management

The management of the company is the key customer group of the QMS. For the management, the QMS must represent a reliable instrument for managing the company. As mentioned in *Concept of a QMS* (Sect. 5.1.1) to the management the QMS is just one of many management systems. To create an easily understandable and manageable basis for decision-making for the company management, the most important performance figures from the QMS should be integrated with the most important performance figures from the other management systems to form a common instrument.

One suitable approach to this is the balanced scorecard performance and management system [5.5].

A balanced scorecard combines at least the following four perspectives of a company:

1. The financial perspective
2. The customer perspective
3. The internal processes perspective
4. The learning and development perspective.

With the help of these four perspectives, both retrospective and prospective performance figures are used to manage the company. The performance figures for the QMS fall under the customer perspective in particular, but also the internal processes perspective and the learning and development perspective.

5.4.3 The QMS and the Employees

The employees are numerically the largest customer group of a QMS. If their requirements are not met, the

guidelines of a QMS do not become a valued resource but rather an unpopular burden. The regulations of the QMS should not only satisfy the regulatory requirements but should also represent valuable tools for the employee.

This results in the following requirements for the QMS.

- The structure of the quality management manual should be orientated towards the processes in the company, and not towards the structure of a standard.
- Specifications (process descriptions, work instructions, etc.) should be written for the respective target group in an easily comprehensible form and should contain implementable instructions. For each process step, the required results should be defined in content and structure.
- All specifications should be integrated into the respective working environment, and it should be possible to find them quickly and intuitively.
- It is recommended that a structured procedure model be defined for product realization and that the necessary results be reported for each process step.

This structured procedure model is ideally implemented as an electronic workflow. This workflow is used for implementation of the QMS as well as for project management. *Note:* In the case of a paperless workflow, the international regulatory requirements for electronic signatures must be observed (see, for example, [5.6]):

- All process steps of the QMS should regularly be checked for their effectiveness, their efficiency, and the reason for their existence.
- Checking of the acceptance of the QMS by the employees should be incorporated in the QMS as a fixed component.

5.4.4 The QMS and Satisfaction of the Regulatory Requirements

The implementation of a QMS should take into consideration the regulatory requirements of all countries in which the products will be marketed. A decision must also be made regarding the language in which the documents of the QMS and the product-related documents, such as specifications, design documents or test certificates, will be written. To be able to present the QMS

externally with little effort or cost, it is a good idea to create associations between the QMS documents and the product-related documents on the one hand and the various national and international requirements on the other hand.

Ideally, these associations are managed in a database and are integrated directly into the electronic document management system and into the electronic workflow

of product realization. All necessary regulatory perspectives can then be generated from the database on demand, and the proof of conformity for the QMS and for the products can thus be provided with little effort or cost. Conversely, the electronic workflow can automatically compile the respective process steps necessary and product-related documents on the basis of the information for the planned markets.

5.5 Product Quality

Table 5.5 Product requirements of various parties in different lifecycle phases

Lifecycle phase	Distributor	Buyer/ operator	User	Patient	Technical service	Health insurance	Notified body	Legislating body/ authority
Product realization		×			×		×	×
Marketing	×	×					×	×
Commissioning	×	×	×		×			×
Operation		×	×	×	×	×		×
Maintenance		×	×		×			×
Reprocessing		×			×			×
Decommissioning		×						
Scrapping		×						×

Following the discussion of the objectives and the implementation of quality management systems, the actual subject of a QMS should still be taken into consideration: the quality of the products manufactured. What is important here is that consideration should not only be given to the requirements of patient and user during operation of the product, but also that the manufacturer takes into account the requirements of all relevant parties over the entire lifecycle of the product. Table 5.5 illustrates which parties place requirements on the product in which phase of its lifecycle.

The scope of the requirements and the significance of the individual lifecycle phases are dependent

on the nature and complexity of the medical device: nonactive or active medical device, instrument or computer-assisted device, individual product or system component, disposable product or reusable equipment, etc.

The QMS of the manufacturer of the medical device must therefore be designed such that the requirements of *all* parties for a product in the various lifecycle phases are determined at the beginning of the product realization phase and are adequately satisfied. Only in this way is it possible to guarantee that the customer receives a product which complies with their requirements over its entire lifecycle.

5.6 Concluding Remarks

The principle of QM – to systematically ensure that the requirements of the customers are met – must always also be adapted to the QMS itself. In a continuous process of reflection, or rather in a continuous plan–do–check–act cycle, checks must continuously be carried out to determine:

- Whether the QMS effectively establishes the relevant requirements for the product and ensures these requirements are met
- Whether the balance is maintained between (a) helpful guidelines and unnecessary regulation, (b) important evidence and superflu-

ous paper, and (c) customer-orientated optimization of products and mere conformity with the QMS.

The instrument of management appraisal, as required in Sect. 5.6 of ISO 13485, can perform this reflection process and maintain the balance by carefully testing and evaluating to what degree the QMS satisfies the requirements of its many customers.

In the face of strong regulatory pressure, many companies tend to forget the intrinsic motivation for the QMS and neglect the employees and the company management as customers of the QMS. This would mean throwing away valuable potential, however a QMS should never be pursued solely to meet external requirements but should always be used to increase the competitiveness of a company.

Usability of Medical Devices

6. Usability of Medical Devices

Ulrich Matern, Dirk Büchel

This chapter gives an overview on how to design medical equipment according to international standards (IEC EN DIN 62366 and IEC EN DIN 60601-1-6) with the user in mind, no matter if physician, nurse or patient. After the definition of the term usability (Sect. 6.1) and widening it to include questions of safety and user satisfaction. In Sects. 6.2 and 6.3 the general questions of usability in medical technology are positively discussed to lead to Sects. 6.4–6.6 outlining in detail the development, testing and assessment of usable devices. The chapter ends with an illustrative example (Sect. 6.7).

6.1	What Is Usability?	59
6.2	Usability in Medical Technology – Obligation or Opportunity?	60
6.3	Usability in Medical Technology – Why?..	61
6.4	Development of Usable Devices – How Is this Done?	62
6.5	Testing of Usable Devices – How Is this Done?	64
6.6	Assessment of Usability	67
6.7	Usability Development, Testing, and Assessment – An Example	67
	References	70

Usability engineering (also called human factors engineering), which is the development of devices which are fit for use, is a subarea of ergonomics. Ergonomics is an interdisciplinary science which concerns itself with adapting work to people. Until the middle of the

last century, it was the primary aim of engineers, medical scientists, ergonomists, anthropologists, physiologists, psychologists, and others to reduce the physical exertion of the worker and simultaneously increase production.

6.1 What Is Usability?

As a result also of the increasing digitalization of the working world and of leisure and consumer goods, in recent years the focus has shifted from the reduction of physical exertion to the reduction of mental exertion of the user when using devices, and it could also be said that the devices should not distract the operator's attention away from the actual task as a result of inexplicable operating concepts. Devices which are particularly simple and intuitive to operate are today described as *usable*.

Usability is a qualitative attribute which indicates how easy devices are to use. The term *usability* includes the following properties of a device:

- Effectiveness: Can the goal of the user be fully achieved with the device?
- Efficiency: What is the cost of achieving this goal?

- Satisfaction: What reaction does the device prompt in the operator: does it disturb, or provide assistance?

Another aspect is increasingly gaining in importance in connection with usability in the field of medicine itself, i.e., the aspect of safety. This is important because it has been recognized that risks to the operator or to other people and objects are possible both as a result of potential faulty operation and also as a result of correct use of a device. This recognition gained acceptance early on in the field of aviation and the power plant industry, and in these sectors there is a lot of investment in the development and testing of ergonomic and usable properties.

In other consumer sectors, however, it often becomes apparent that the terms *ergonomic* and *usable*

are used as marketing instruments, rather than the corresponding product properties being based on verifiable criteria with a scientific basis.

In contrast, products which are truly intuitive and therefore simple to use have an indisputable competi-

tive advantage. They are accepted by the customer as being *top of the line* and so become bestsellers. The iPod and iPhone have already become almost proverbial examples of these kinds of products which are extremely successful in the market.

6.2 Usability in Medical Technology – Obligation or Opportunity?

To provide all groups involved in health care with a guideline about how usability can be achieved and tested, an internationally valid standard was published in 2006 as a collateral standard for the general provisions for the safety of medical devices. This safety standard for *electrical* medical devices was authoritatively written by manufacturers of medical devices, scientists, testing institutes, and experts in usability, and has been validated in Germany as a harmonized standard since 1 February 2008 [6.1].

Another international standard for the application of usability for *all* medical devices gained validity on 1 September 2008 [6.2]: IEC 62366 is increasingly replacing the older IEC 60601-1-6, and for this reason reference will primarily be made below to the content of IEC 62366.

It is first necessary to establish how international standardization defines usability. According to international standardization, usability is the [6.2]:

character of the user–product interface, which includes the effectiveness, efficiency and learnability and the satisfaction of the user.

Through this definition alone, the device is accredited with essential features, and the user, in contrast to the manufacturer, is to a certain extent relieved of his responsibility; the device must support the user in operating the device correctly and learning how to do so.

The introduction to this process standard already includes clarification that safe usability is not an unambiguous definition, such as, the paper size according to DIN A, but rather is a challenging task, a method, a process, which demands *entirely different capabilities than the (purely) technical realization of this interface*. Ergonomics and considerations of usability constitute an interdisciplinary science which primarily involves designing, evaluating, and finally testing the configuration of the operating elements and the man–machine interface, with an external but expert eye, both with impartiality and without blinkers. The usability-orientated

developing process should therefore minimize operational errors and risks associated with use. It is closely associated with the established risk management process of ISO 14971 [6.3].

The manufacturer must establish how it specifies the usability of its medical device [6.2] and therefore minimizes risks associated with use. Which risks it accepts is left to the manufacturer according to ISO 14971 [6.3] and is thus the *policy of the manufacturer*. This provides the manufacturer with the opportunity to position itself in the market according to its concepts, goals, and possibilities. It can determine for itself how it minimizes hazards which it will not accept for its product. It can invest, for example, in an intuitive man–machine interface [6.2]:

If training is necessary for the medical device in question in order to ensure safe and effective use of the main operating functions by the designated user, the manufacturer must take at least one of the measures

- provide the necessary training material itself;
- ensure that this material is available; or
- provide the training itself.

If training of this nature is necessary, the accompanying documentation must describe the available training possibilities and give details of the approximate duration and frequency of training.

It remains to be seen whether usability will in the future be seen by manufacturers as an inconvenient obligation which must be fulfilled, or as an opportunity to set themselves apart from competitors as a premium manufacturer.

Another advantage for the manufacturers is the result of usability tests which are to be carried out in accordance with IEC EN DIN 62366 and 60601-1-6 during the design and development process and documented in what is known as the usability engineering file. Doing so, the manufacturer can increase the ease of use of his product and can avoid usability issues and risks associated with usability. This reduces the

cost and the legal risks for the manufacturers and the participating clinics in the subsequent phase of clinical testing according to MEDDEV 2.7.1 [6.4] and DIN 14155 [6.5]. Application and insurance regarding these clinical studies will become easier, because reference can then be made to the results of the usability tests which are documented in the ergonomics record. The staffing costs associated with safeguarding correct operation of the testing equipment in the clinic will be

reduced if it is possible to ensure in advance that the product can be operated easily and safely even in difficult situations.

The new standards for usability also provide the operators and users of medical devices with obligations and opportunities. There is therefore a sufficient basis for a comparative cost–benefit analysis of medical devices which, if used correctly, can furthermore make an economical and medical contribution to patient safety.

6.3 Usability in Medical Technology – Why?

The possible importance of this contribution to patient safety is just as well known as the economic benefits which it will bring to health care worldwide.

National surveys of German surgeons and operating theater (OT) nursing staff have confirmed that 70% of surgeons and 50% of OT nursing staff have difficulties in correctly operating the medical devices found in the operating theater. They do not consider themselves to be sufficiently well trained in dealing with the devices, do not attend briefings, and do not read the operating instructions. The users themselves estimate the resulting risk to the patients and employees to be considerable [6.6].

An assessment of the reports of these incidents involving medical devices, which are required by law and presented to the Bundesinstitut für Arzneimittel und Medizinprodukte (BfArM, the German Federal Institute for Drugs and Medical Devices), demonstrates that this observation is correct. Approximately half of all incidents are based on a *misunderstanding between the user and the device*, which is to say they are based on a usability problem. The dangers posed by these incidents are greater and the consequences for the patients more serious than those resulting from purely technical causes [6.7].

The Institute of Medicine (IOM) proceeds from the assumption that more people are killed every year in the USA as a result of usability incidents than are killed by acquired immune-deficiency syndrome (AIDS) or traffic accidents, and that figure is between 44 000 and 98 000 patients per year [6.8].

During a Dutch study, problems were found with the technical equipment in 87% of the operations observed [6.9].

Of the working time of medical technology service centers in hospitals, 50–70% is spent ensuring that equipment which has been *adjusted* by doctors and

nursing staff but which is reported as faulty is returned to full working order [6.10].

The economic impact is colossal. In German intensive care units alone, usability problems are the cause of additional costs of approximately €396 million per year for the health insurance funds [6.11]. In England, the number of incidents per year as a result of *user errors* with medical devices is taken to be 850 000, with costs of £400 million. Between 1984 and 1991, approximately 130 000 incidents were reported in the USA, and in 60% of these incidents incorrect operation was at least partly responsible [6.12]. The same conclusions were reached by *Bleyer* [6.13] and *von der Mosel* [6.14].

Manufacturers know these data and confirm the situation from their own experience. Although their medical devices have ever more functionality because of the increasing requests from doctors and nursing staff, it is the users who then complain about the complexity and demand repeated briefings and retraining from the manufacturers – at the expense of the manufacturers, of course, leading to hugely increasing costs.

It is of course right, as a manufacturer, operator, and solicitor, to refer to the duty of care of the user, and the user should read the manuals and participate in the equipment briefings. However, the clinics and those running practices must then provide their employees with the time necessary for this. At a time when we have a worldwide shortage of nurses and doctors and ever shorter hospital stays, this is an unrealistic requirement.

The approach of DIN EN IEC 62366 can be helpful here in specifying the expenditure on training for the medical device in question. All those involved can therefore calculate the value of the investment in a usable medical device.

6.4 Development of Usable Devices – How Is this Done?

An interdisciplinary approach is not all that is necessary for the development of usable medical devices. As soon as the decision has been made to develop a new device, consideration must also be given to how the device is to be operated. This means that the man-machine interface must be developed in parallel with the development of the technology, with the focus on the future users. Every operating element which has to be changed at a later date because it has not proved to be a success causes unnecessary costs. The fundamental requirements of usability thus belong just as much

in the functional specifications as do the fundamental technical requirements.

When designing a usable device, it is essential to understand the context of use, the user requirements, and the organizational requirements. This involves taking into consideration not only the medical application but also the cleaning – and, if appropriate, recycling – as well as the necessary maintenance work. An essential principle here is that the users should not only be questioned regarding what they expect from a new device, but rather they should be observed in their daily work

Fig. 6.1 User-oriented development process from DIN EN ISO 13407 (after [6.15])

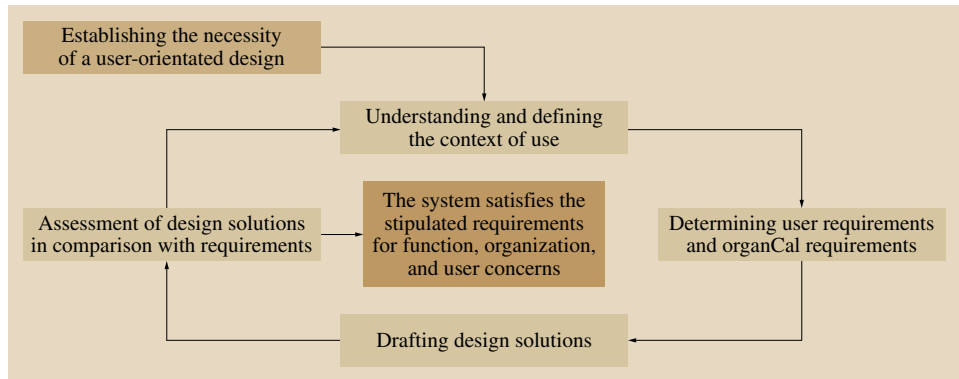

Fig. 6.2 Practical exercises as part of the training on the subject of ergonomics and usability at wvH-c GmbH

Fig. 6.3 Different stages of development in the course of the usability engineering process (after [6.16])

in a targeted and structured manner in order to identify which functions they really need. The reason for this is that users generally find it difficult to articulate their true requirements. It is only through doing this that the excessive functionality, and therefore the complexity, of the equipment can be avoided. The many unused functions of a device make it not only complex to operate but also susceptible to faults and, above all, expensive. With fewer functions, less can be significantly more in the sense of effectiveness, efficiency, and safety.

To successfully turn *less* into *more*, usability engineering uses various proven methods and fundamental technologies which are used in an iterative development process (Fig. 6.1).

The developers must have a distinct understanding of the users and the culture of usability. If this is not yet the case, training on the topic of usability should be contemplated, where possible with practical exercises in the field of the respective context of use (Fig. 6.2). At the beginning of the work, it is crucial that the developers are familiar with the concerns, needs, and working environment of their users and regard them as the focal point of the development process.

First and foremost, the context of use, including the requirements of the user and organizational requirements, must be understood and defined by the engineers: Who uses the device, in what situations and what environment, for what purpose, and on whom? Focus groups, field observations, and cognitive walkthroughs are used to answer these and other questions:

- *Focus groups*: Moderated group meetings with users and developers to ascertain the requirements and goals of the users.
- *Field observations*: Participatory observation of users in their working environment.

Table 6.1 Typical development errors

- No primary analysis of the needs and expectations of users
- No or too little understanding of the needs of the users
- Focus on using design features which are esthetic and showy
- No interdisciplinary usability engineering team
- Poor communication between the members of the development team
- No iterative development
- No or only little use of design prototypes
- No usability evaluation

- *Cognitive walkthroughs*: Usability experts run through tasks within a user interface. Here the focus is less on the device and more on the thought processes of the user during operation.

Equipped with this knowledge, the functional specifications are checked once more and refined again, in particular in terms of ergonomics and usability. What is particularly important here is that checks are continually carried out to ascertain (Fig. 6.3):

- What is really needed in the medical application; this provides a list of the main or primary functions of the devices, and
- Which supporting functions are necessary for this; the list of secondary functions should be as short as possible.

The development of the man–machine interface then begins in parallel with the development of the technical functions. To this end, the first design proposals are then drafted and checked using the simplest possible means:

- *Paper prototyping*: Operating elements, interaction concepts, and information displays are checked with users with the aid of drawings of an early operating concept.
- *Card sorting*: Interactive cards test the operational logic of menu structures and interaction concepts.

These design proposals are compared with the established requirements and tested in stages:

- *Heuristic evaluation*: Neutral experts evaluate an interface with the aid of recognized principles in software ergonomics and give suggestions for improvement.
- *User test (also usability test)*: Users tackle tasks under observation using a user interface. Experts analyze the man–machine interaction and find usability problems.

These tests usually feed into an iterative process with recurrent design and evaluation phases, as no-one succeeds in producing a perfect design at the first attempt. The planning must include the time and means to avoid the typical stumbling blocks listed in Table 6.1, which are encountered in particular when the development team is a closed group in which results are no longer sufficiently discussed. Careless mistakes of this kind mean that development quickly becomes an extremely expensive and lengthy procedure, which can be avoided

if the development team obtains suggestions from external experts at an early stage which help to overcome the typical *tunnel vision* (Table 6.1).

The design phase may extend over many cycles in which functions must be repeatedly tested, optimized, and checked. At the end of this process, there should be a usable and safe device.

The technical solution has proved its functionality and reliability in the animal model. For this purpose, long-term tests and survival tests have been performed,

where applicable using histological and biochemical methods:

- The recycling and/or disposal of the device have been tested.
- The experiences with the device have been incorporated in the manual and any possible training material.
- The design prototype has passed the normatively prescribed usability tests.

6.5 Testing of Usable Devices – How Is this Done?

When testing usability, IEC EN DIN 60601-1-6 and 62366 distinguish between the concepts of verification and validation.

Verification is understood as meaning the evaluation of the individual parts of a device during development. Various methods can be used to verify the individual functions of the man–machine interface, and these methods include heuristic evaluation, cognitive walkthrough, pluralistic walkthrough, feature inspection, and user test. Usability experts and typical users examine and test the individual functions, according to typical usability criteria in accordance with structured study protocols and guidelines, in the development stages which are available at the particular point in time (Fig. 6.4).

The validation of usability, in contrast, concludes the usability-orientated development process. During validation, all functions are scrutinized and not just

individual functions, as in the previous verification processes. Finally, it ensures that a suitable, operable device is built in which there should be no unexpected and hazardous interactions between the user and the device.

A user test (also called a usability test or laboratory experiment) is performed for validation. In this method, the strengths and weaknesses of a device are systematically evaluated with the involvement of representatives of the user group, in an environment which is as representative as possible, with representative tasks. For this purpose, the context of use is represented as realistically as possible in a laboratory.

Usability laboratories are very expensive and are fundamentally divided into two areas. The actual use situation is simulated in the test area. This area ideally corresponds 1 : 1 to the real usage environment, to give the test person the feeling of being in his or her

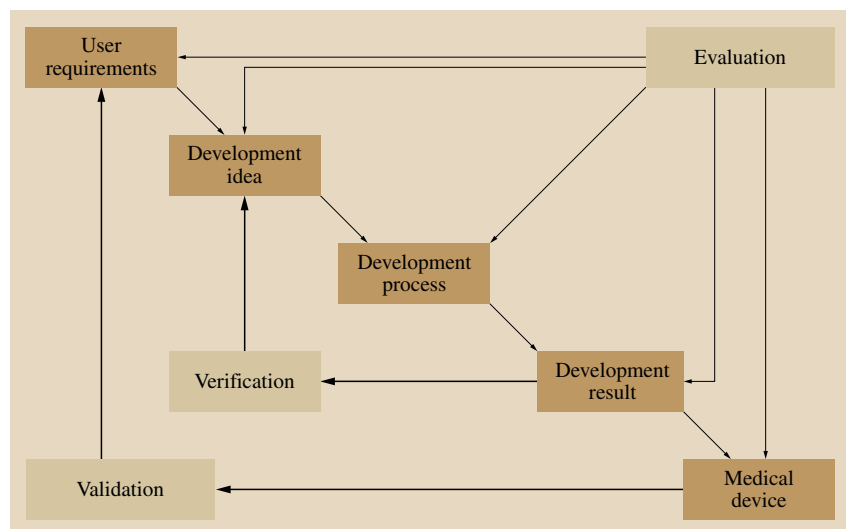

Fig. 6.4 Verification and validation in the usability-orientated development process

Fig. 6.5 Typical user test in the laboratory (wwH-c GmbH, Tübingen)

usual workplace. Recording equipment such as video cameras and microphones should be positioned as inconspicuously as possible here, so that the test person can work undisturbed with the equipment which is to be examined. In the monitoring area there is recording equipment and an intercom system. From here, test supervisors, minute-takers, and any other interested parties can observe the test participant, usually behind a semitransparent mirror or a window (Fig. 6.5). In this way, the test person is disturbed as little as possible, but assistance and instructions can nevertheless be given.

User tests are among the most widely used and most reliable methods in the world for determining the usability of a device. It takes only a few test people to find a relatively large number of problems. In the consumer sector, just six test users are generally sufficient to find 80% of usability problems (Fig. 6.6). In the safety-critical context of medicine, 10 test people from one occupational group are usually recommended to test the safety-critical functions. To ensure this, the test people must be selected with a great deal of care.

The particular advantage of this method is that, in the simulation environment, critical situations in which the device to be tested must be operated safely under nerve-racking tension can be repeated with various test people in a standardized manner, without any risks to patients. Precise tasks which correspond to the evaluation goal are set for this purpose. Problems which were not noticed in the actual situation can be subsequently

detected using the video and audio documentation and demonstrated to the development team. Quality factors such as objectivity, reliability, and validity can be maintained in the simulation environment in contrast to clinical testing on a patient.

It is a disadvantage that a completely real context of use can never be simulated under laboratory conditions, and these results are thus not 100% transferable to the real context of use. However, in a laboratory, those interferences and stress situations can be created which, for ethical and actuarial reasons, cannot be simulated in routine clinical operation and even in an animal labora-

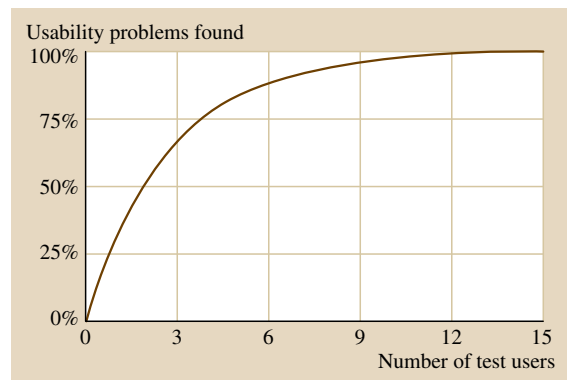

Fig. 6.6 Dependence of the usability problems found on the number of test users in a user test in the consumer sector (after [6.17])

Fig. 6.7 Three-dimensional matrix for the assessment of the usability of medical devices (after [6.18])

tory, but which are the situations which are relevant to patient safety.

It is therefore sensible in terms of patient safety for a medical device to undergo such tests for the verification and validation of usability before it is used clinically. As already mentioned, this procedure reduces the cost and

the legal risks for the manufacturer and the participating clinics in the subsequent phase of clinical testing according to MEDDEV 2.7.1 [6.4] and DIN 14155 [6.5].

During the user test, the test people are also urged to perform these typical work tasks using the equipment. Conclusions regarding the usability of the equipment

can be drawn from the observations and testimonies during the performance of the tasks. For this purpose, the criteria of effectiveness, efficiency, and satisfaction

are operationalized such that qualitative statements are possible. The results are listed and displayed, sorted according to functions and problems.

6.6 Assessment of Usability

The results of usability studies are typically documented in long accounts. However, no priorities generally emerge from these accounts for the development team. The assessment matrix developed for the field of medical technology *UseProb* provides transparency here for the manufacturer and user.

The degree of severity of the problem, the probability of occurrence, and the extent of damage are taken into consideration. Each criterion is given a grade. For the computing-based correlation of the three influencing variables, a three-dimensional matrix was selected which brings together the individual combinations to form a 10-level assessment (Fig. 6.7), which are divided into four color-coded areas. The red area (grading scale 1–3) represents safety-critical functions, that is to say

those which should have been avoided by the usability engineering process prompted by the two standards. Functions whose assessment is in the orange, yellow or green areas conform to the standards, with the green area representing very simple and safe operation.

In this way, the party commissioning the usability study receives an *overview of grades* for the product which enables them to recognize immediately which functions are problematic and also which have been excellently solved (Fig. 6.8). Thus, there is an objective instrument available which the manufacturer can use not only to further develop his product but which they can also use for marketing purposes. Those buying medical devices can likewise base their purchase on these assessments.

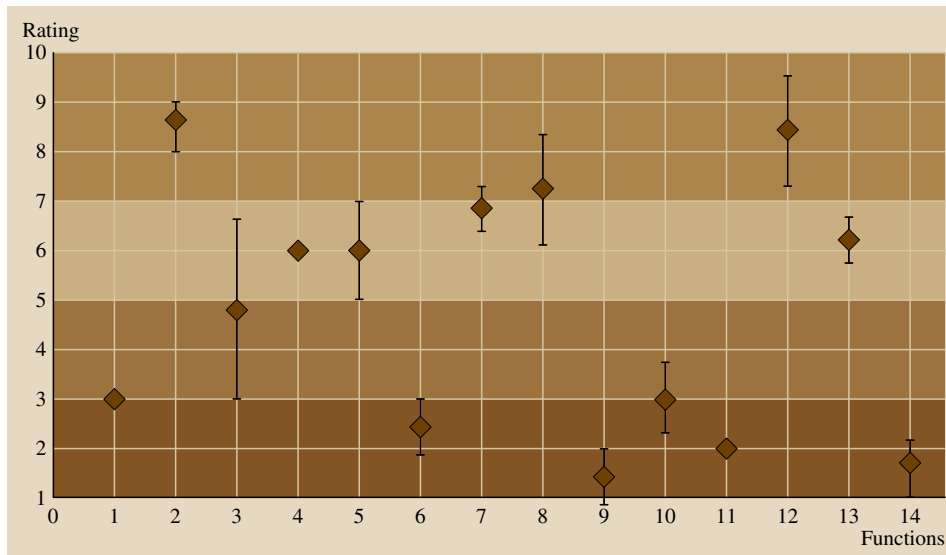

Fig. 6.8 Example of an overview of grades for a medical device which must be classified as safety-critical and therefore one which does not conform to standards. The operation of the functions 1, 6, 9, 10, 11, and 14 should be revised before the device can come onto the market (after [6.18])

6.7 Usability Development, Testing, and Assessment – An Example

In their laboratory, the *experimental OT*, wwH-c GmbH developed and tested the operator interface of a car-

diac catheter pump in accordance with the normatively prescribed design process described.

Fig. 6.9 From design drafts to the flash simulation in which the operation of all functions could be checked (after [6.18])

Fig. 6.10 The flash simulation was integrated into the hardware such that the test users did not notice the simulation

To determine the usability requirements for the equipment, a user profile was first created, and a task and environment analysis was performed. This process involved users in the development. In interviews they provided initial information about the require-

ments in practice and about problems with comparable devices to be found on the market. In accordance with the principle of *look at what your users do, but never ask them what they want* [6.19], field observations then provided the essential information about the

requirements, which were recorded in the functional specifications.

The iterative design process, consisting of repeating design and evaluation phases, could then begin. Outlines of hardware and operating concepts were drawn up, discussed with users, and tested in a first expert evaluation.

The interaction concept and the operating logic were put into concrete terms and presented in detailed design drafts (Fig. 6.9). Various experts in ergonomics tested the logic of the preset interaction steps with the aid

of the verification method of cognitive walkthrough, and revealed potential usability problems. The results of this evaluation were simulated in a flash simulation fully functioning in all menu structures. This simulation depicted the interaction steps to be carried out, and was integrated into the hardware of the catheter pump (Fig. 6.10). Using this animation, a realistic operator interface could be simulated for test users before any software code was written. Users were unable to detect that they were in reality not controlling the device.

Fig. 6.11 With the aid of a rigid foam prototype, the ergonomically expedient installation on the patient bed is tested (after [6.20])

Fig. 6.12 Results from the first user test; assessment by means of *UseProb* before the second development iteration

The hardware models were also subjected to various function checks. Figure 6.11 shows a test which verifies the installation of the equipment on a patient bed.

To prepare the final user test, ergonomics experts conducted a heuristic evaluation. The evaluation method provides initial results about potential problems, which are verified in the following user test. The tasks involved in this user test consisted of the primary tasks identified in the task analysis and some secondary tasks, as well as the potentially problematic tasks. Nine doctors and nurses were used as test people. The test tasks were completed in the form of a role play in which an employee from wwH-c GmbH gave instructions to the test people in the role of the operator. Additional recorded OT noises increased the level of realism for the test people. The test was recorded and documented using four cameras and a microphone.

Even in this first usability evaluation with real users, the positive effects of the user-orientated design process were evident. The users were able to complete the tasks set relatively quickly and were satisfied with the operation of the equipment (Table 6.2).

Nevertheless, several problems were identified in this usability evaluation. These problems were assessed with the aid of the *UseProb* problem evaluation method developed by wwH-c GmbH. This method also looks at usability problems from the point of view of safety. The results of the evaluation are shown in Fig. 6.12. They show the relevance of the problems found.

Table 6.2 Statements from the test people, typical of the result for a usability engineering process performed with such consistency

When I saw the equipment, I realized for the first time how complicated our pump is. (specialist nurse)

It was easy to operate. Considering that I was doing it for the first time, it was fantastic. (trainee assistant surgical technician)

The equipment is self-explanatory. (specialist nurse)

It makes a good impression and is simple and intuitive. (perfusionist)

Compared with other equipment, the menu sequence is positive and very simple. (cardiologist)

Following the evaluation, the problems found were analyzed and the animation optimized on the basis of the proposals for improvement acquired.

Another user test was conducted with the improved use concept. It became apparent that the usability had further improved in respect of the factors of effectiveness, efficiency, satisfaction, and safety. Until this point, all development steps of the man-machine interface were simulated. Only now, once safe and efficient operation has been ensured by the users, does the programming of the software begin.

Basic Diagnostics in Cardiology

Rüdiger Kramme

The term basic cardiology diagnostics refers to the noninvasive measurement of the cardiac electrical action potential at rest and under stress, in order to assess heart function. Due to technical developments in ECG systems, the informative value of (basic) diagnostic assessments of the cardiovascular system has improved enormously with ever-increasing accuracy. This chapter introduces equipment-based diagnostic methods: Sect. 7.1 ECG, Sect. 7.9 Holter Monitoring and Sect. 7.19 Exercise ECG.

7.1 Electrocardiography

Electrocardiography (ECG) is a method of recording electrocardiograms – which record the temporal and

spatial profiles of the electrical excitation processes in the myocardium in the form of waves, peaks and lines

Fig. 7.1 Nomenclature of the electrocardiogram (ECG)

(Fig. 7.1) – and performing diagnostic analyses of these electrocardiograms.

Every instance of depolarization through cardiac fibres is the source of an electric potential. These noninvasive measurements generally measure potential differences that occur across an electric field on the sur-

face of the body, which make up only a fraction of the potential generated by the heart. The heart is thus interpreted as a source of potential, so the ECG ultimately provides an image of the generation of electricity (potential shift) and reflects the excitation processes in the measurements selected.

7.2 Electrocardiograph Equipment Technology and PC ECG

Electrocardiographs (ECG devices for short) and PC ECG modules are diagnostic devices for recording, amplifying, storing, processing, analysing and documenting (registering) an electrocardiogram. Noninvasive electrocardiography has been a standard procedure for a number of decades, and ECG equipment is therefore as good as mandatory in both hospitals and small private practices.

7.2.1 Physical and Technological Principles

ECG systems are low-noise differential amplifiers; in other words, they consist of a strongly coupled DC amplifier with a high amplification factor and inverting (reversed) and noninverting inputs. The output voltage is a multiple of the voltage present at the input terminals. It is the differential voltage of the two voltages present at the same pole. Particularly high requirements

are set for an ECG preamplifier when compared to usual amplifier technology: interfering high-frequency AC voltages are attenuated by means of a high-frequency filter upstream of the preamplifier input, so that no overamplification or self-excitation can occur. Extreme interference voltages are likewise blocked by means of discharge sections and antiparallel diodes. A relatively high input resistance (generally $10\text{ M}\Omega$ and above) keeps the input currents very low. Capacitively coupled mains-frequency AC voltages are eliminated through high common mode rejection. Following a 20- to 30-fold preamplification, the ECG signal is separated from the direct current via a high-pass filter. The time constant of this filter is 1.5 or 3.2 s. Whereas the processed ECG signal is fed to the respective channel amplifiers (1... > 12) via an lead selector in analogue ECG equipment, this step is omitted in digital ECG equipment. The recorded signals are instead connected to 12

leads, amplified and fed to a processor system (control computer – CPU) via multiplexers and A/D converters. The system software processes all of the digitized input signals, interpolates the individual measurement readings to give continuous curves, controls equipment processes, and communicates with the operator via the keypad, display and printout; it prepares text outputs, displays the time, produces a QRS trigger signal, and evaluates the remote start ergometer input. Output occurs via a digital recording system, the thermal comb.

In analogue ECG equipment, following further amplification to $\approx 1-2\text{ V}$ using the respective channel amplifier, the ECG signal is output via a power amplifier stage (final amplifier) and finally through a mechanical recording system (e.g. lever recorder, inkjet recorder, etc.).

ECG measurement, the signal path and signal processing resemble a measurement chain, from the test object (patient) via transducers or sensors (electrodes) and the transfer of measurement readings (electrode leads and patient cables) to signal processing, signal evaluation and documentation (ECG equipment). The recording electrodes or the intracardiac electrode (signal source) on the surface of the body receive the ECG signal (useful signal) and transmit it via a cable to the input amplifier of the cardiograph. There is a galvanic potential between the skin and the metal section of the electrode, which is substantially influenced by the electrode material, the composition of the electrolytes, and by the condition of the electrode/electrolyte interface. This electrochemical contact potential can be up to 300 mV. The transmitted input signal from the amplifier consists of four different fractions:

1. The useful signal (ECG), with an amplitude of $50\ \mu\text{V}$ to approximately 1 mV, and
2. A DC voltage component of up to 300 mV that is superimposed on the useful signal; however
3. Interfering signals of up to 100 mV (50 Hz *ripple voltage*) and
4. Extreme interference voltages (resulting from defibrillators and RF surgery equipment, among other sources) of up to 3000 V can also occur.

In order to ensure that the patient is galvanically isolated from the mains voltage, the power supply and the output signal are galvanically decoupled.

In order to promote reproducibility, the ECG signal processing, recording and measuring process is standardized:

- Frequency response:
 - Lower frequency limit $f_{\text{limit}} = 0.05\text{ Hz}$
 - Upper frequency limit $f_{\text{limit}} = >100\text{ Hz}$
- ECG amplitudes: 2.5, 5, 10 and 20 mm/mV
- Times: 10, 25, 50 and 100 mm/s

7.2.2 Equipment Classification

ECG recorders are mainly classified according to the number of channels of the device and the equipment technology used (Figs. 7.2, 7.3).

From analogue to digital ECG systems with integrated recording components, a new ECG generation has developed: the PC ECG. The recorded analogue signals are amplified, digitized and supplied to data transmission equipment in an external module. The data can be transmitted to a connected computer (PC or laptop) using either a USB microcontroller or wireless data transmission technology (bluetooth technology)

Fig. 7.2 Overview and differentiation of ECG recording equipment and PC ECG modules

Fig. 7.3 PC ECG module

(Fig. 7.3). Whereas the USB port is also used to supply power to the module, the Bluetooth method makes mains-independent operation (10–12 h) possible with an accumulator battery. The transmitted data is processed and prepared on the computer using installed ECG application programs. In addition to the visual image on the computer display or external monitor, ECG graphs and interpretations can be printed out on a connected printer and plain paper for documentation purposes.

The PC ECG has practical advantages over conventional ECG equipment: the ability to save any desired ECG sequences at any time, the comprehensive availability of the data, the considerable reduction in the consumption of expensive ECG paper and therefore financial savings, the lack of mechanical equipment components, the ability to back up data on common storage media, the capacity for mobile use with mains-independent operation, as well as the possibility of interactive data exchange via the Internet. A particular disadvantage is the restricted data exchange possible via data carriers or over the Internet, as data can only be

exchanged with an application program which is compatible with the PC ECG software. An artefact that is characteristic of PC ECG equipment, and is probably a result of computer electronics, leads to interference in the sensitive ECG analysis.

7.2.3 Recording Systems

Recording systems can be considered the various technical possibilities of the recording components (Fig. 7.3). The digital thermal array recording method is the current state of the art. Thermal comb recordings have high resolution and a low susceptibility to interference from the recording system, and allow optimum reproduction of the recorded and processed ECG signal.

7.2.4 Electrode Technology

The recording and transmission of the ECG signal from the surface of the body and the quality of this signal are fundamentally influenced by the electrodes. They repre-

Table 7.1 Overview of electrode types

Type of electrode	Electrode material	Recording region	Short application time	Long application time	Observation	Emergency application	Comments
Plate	V ₂	Limbs	×				Without electrode gel
Suction	Silver/silver chloride	Chest	×				Low polarization voltage
Button	Silver/silver chloride	Limbs	×	×	×	×	Use foam plaster
Self-adhesive	Silver/silver chloride	Limbs					Comparatively low artefacts in restless patients
Single-use	Silver/silver chloride	Limbs, chest	×		×	×	Higher costs
Triple	Silver/silver chloride	Chest			×	×	Fast application possible

Fig. 7.4 ECG recording methods

sent a junction between the ionic conduction in the body and the metallic electronic conduction of the electrode surface and of the transmitting cable. There is therefore an electrical potential between the body and electrode, which is dependent on three factors in particular:

1. The electrode material
 2. The composition of the electrolytes
 3. The condition of the electrode–electrolyte interface.
- Simultaneous display of the 12 standard leads in a time frame of 15 s
 - Various alphanumeric recording options
 - High operational convenience and programmable
 - Digital signal processing
 - Automated control together with programs
 - Interfaces for communication with other systems
 - A high-resolution recording system without mechanical parts.

Electrochemical contact potentials of up to 300 mV can occur at these interfaces. The electrode impedance (also known as electrode transfer impedance) – the sum of the electrode and skin impedances and also the resistance of the contact medium, which is dependent on the current density – is the result of the current state of the skin, body, contacting agent and electrode material. For this reason, electrode pastes or gels are used to reduce the transfer impedance.

Particularly in the case of polarizable electrode material (e.g. high-grade steel), unwanted polarization voltages may occur. These spontaneous voltage fluctuations are superimposed on the ECG signal and lead to signal instabilities in the recording (drifting leads). Nonpolarizable electrodes from Ag/AgCl (silver/silver chloride) have proven to be particularly advantageous (Table 7.1).

7.2.5 System Properties

The following properties represent the performance spectrum and at the same time the requirements for modern ECG systems:

An upgradable system has the advantage of being able to perform more functions than just one ECG registration. The ECG device has these so-called multifunctional system properties when it is equipped with additional functions such as spirometry, long-term ECG monitoring, arrhythmia monitoring, Doppler ultrasound, pulse oximetry, capnography and late potentials, etc. Data communication with a PC and networking with other systems is also standard. The conditions for the use of medical EDP statistics, ECG data management and ECG software libraries are therefore satisfied.

7.2.6 Operating Modes

A fundamental distinction is drawn between manual and automatic operating modes. Automatic programs, such as standard ECGs with 12 leads, ergometry and arrhythmia, are typical of modern cardiographs which can be programmed by the user. The lead mode, formatting, baseline, calibration and sensitivity are for the most part automated. Alternatively, registration can be performed manually at any time.

7.3 ECG Methods

Figure 7.5 shows an overview of noninvasive and invasive ECG methods.

Fig. 7.5 Noninvasive and invasive ECG methods

7.4 Lead Systems

7.4.1 Measurements from the Surface of the Body

The action currents produced by biopotential differences that vary with time are measured as electrical potentials (the magnitude of the useful signal is around 1 mV) between two points on the surface of the body. Theoretically, any point on the surface of the body could be used for this purpose, but specific electrode sites have developed in practice, and the respective leads are defined according to these sites. The leads differ substantially in terms of recording technique and spatial arrangement.

Leads between two points are described as bipolar leads. In unipolar leads, in contrast, the different electrodes are connected to what is known as a zero electrode (collector electrode). This collector electrode is created by connecting together limb leads via high-impedance resistors. The limb leads provide a spatial view of the frontal plane, and the chest leads provide a spatial view of the horizontal plane.

7.4.2 Standard Leads

The standard leads are the three bipolar limb leads known as Einthoven's leads (I, II, III), the three unipo-

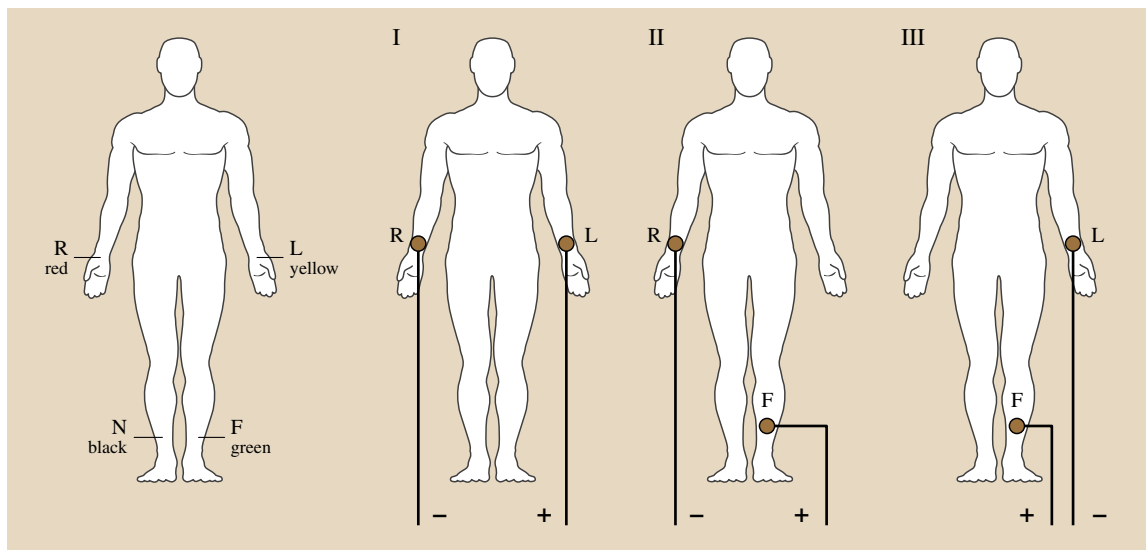

Fig. 7.6 Lead positions, connector colors and schematic diagram of the bipolar limb leads according to Einthoven

Table 7.2 Overview of the 12 standard leads of an ECG

	Limb leads		Chest leads
Description	According to Einthoven	According to Goldberger	According to Wilson
Electrodes	I, II, III	aVR, aVL, aVF	V ₁ , V ₂ , V ₃ , V ₄ , V ₅ , V ₆
Measurement technique	Bipolar	Unipolar	Unipolar
Electrode sites	Upper and lower limbs	Constructed from I, II, III	Chest wall C ₁ ...C ₆
Projection	Distal potentials of the frontal plane		Proximal potentials of the horizontal plane

lar limb leads constructed from these three bipolar limb leads (known as Goldberger's leads: aVR, aVL, aVF), and six unipolar chest leads known as Wilson's chest leads (V₁...V₆) (Table 7.2).

Einthoven's Bipolar Limb Leads (Fig. 7.6)

For these, the potential difference is measured between two electrodes:

- R: right arm = red connector
- L: left arm = yellow connector
- F: left foot = green connector
- N: right foot = black connector (earth)

The three leads lie in the frontal plane and form what is known as Einthoven's triangle (Fig. 7.7).

Goldberger's Unipolar Limb Leads

For these, the potential difference is determined between each electrode on the limb and an *electrical zero* which lies at the central potential between the two other limbs (Fig. 7.8).

aVR: $R - L + F/2$

aVL: $L - F + R/2$
 aVF: $F - L + R/2$

Wilson's Unipolar Chest Leads

The chest electrodes (V₁...V₆, V = voltage) are placed at six defined points on the thorax (C₁...C₆, C = chest). The three limb leads are combined via

Fig. 7.7 Einthoven's triangle

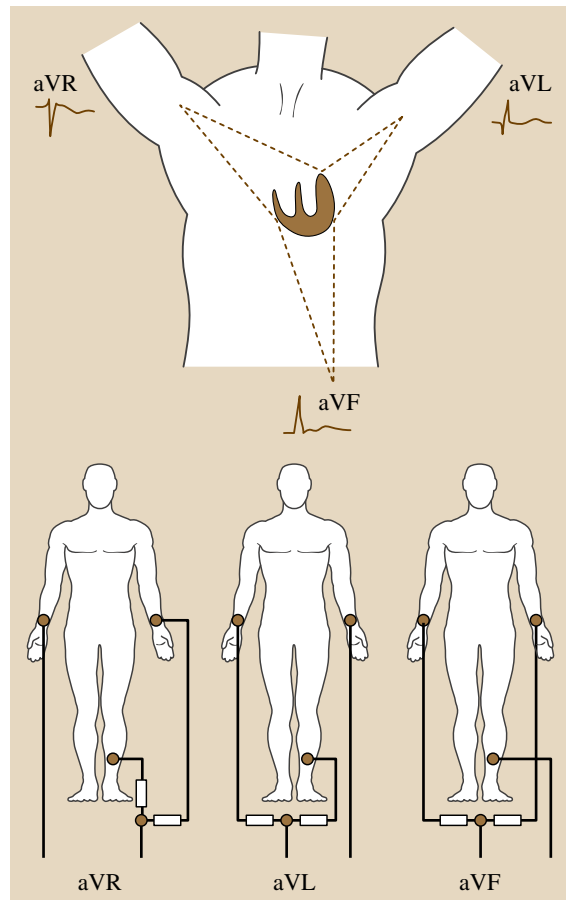

Fig. 7.8 Unipolar leads according to Goldberger, and schematic diagram

Fig. 7.9 Unipolar chest leads according to Wilson: C₁ – Fourth intercostal space at the right border of the sternum; C₂ – Fourth intercostal space at the left border of the sternum; C₃ – Fourth intercostal space at the fifth rib, midway between C₂ and C₄; C₄ – At the mid-clavicular line in the fifth intercostal space; C₅ – At the left anterior axillary line on the same horizontal level as C₄; C₆ – At the left mid-axillary line on the same horizontal level as C₄

a high-impedance resistor to form a collector electrode (indifferent electrode). Wilson’s central terminal forms the electrical zero point. As a result of the proximity to the heart, the amplitudes of the chest leads are greater than those of the limb leads (Figs. 7.9, 7.10)

Fig. 7.10 Lead positions after Wilson, and illustration in the horizontal plane

Cabrera's Lead Sequence

Cabrera’s circle is a hexaxial system that can be used, among other things, as an aid when determining the axis deviation. The circle includes leads of the frontal plane that are each rotated through 30° with respect to one another. The leads from Einthoven’s triangle are shifted parallel such that lead I assumes an angle of zero, lead II +60° and lead III +120°. The Goldberger leads are also included in this system, and have angles of: aVR –150°, aVL –30° and aVF +90° (Fig. 7.11).

By flipping the aVR lead through 180°, we get –aVR at 30°. It is possible to determine the axis deviation simply by determining the highest R amplitude from the leads. The angular space allocated to the leads determines the deviation of the axis (for example, the highest R amplitude is found in lead II; i.e. the electrical axis of the heart falls at +60°. This corresponds to the normal position of the heart in a healthy adult).

7.4.3 Augmented and Reduced Leads from the Surface of the Body

Augmented Leads

Augmented leads include the corrected orthogonal leads of Frank and the additional unipolar chest leads of Wilson.

The Frank leads are based on a theoretical model in which the heart is at the centre of a square three-dimensional coordinate system consisting of a lateral axis *x*, a longitudinal axis *y* and a sagittal axis *z*. The excitation processes can therefore be registered in the form of vector loops (vectorcardiography).

Fig. 7.11 Cabrera’s circle

In addition to Wilson's standard leads on the chest, it is also possible to include other electrode sites. These can be extended precordially to the right (V_{r3} , V_{r4} , V_{r5} , V_{r6}) or to the left (V_7 , V_8 , V_9 or V_8 two ICS lower).

Reduced Leads

Reduced leads include leads for ECG monitoring, leads for long-term ECG and ergometry leads (see the individual chapter on this topic).

7.4.4 Invasive Leads

Unipolar Oesophageal Leads

When using oesophageal leads, an electrode catheter is inserted via the oesophagus to just above the cardia. The aim is to obtain a precise assessment of proximal potentials of the posterior myocardial wall and the left atrium.

HIS Bundle Electrocardiography

Here an intracardiac electrogram (EG) is obtained using a three-pole electrode catheter. This investigation is performed with radiological and electrocardiographic monitoring (this procedure is part of routine diagnostics in cardiac centres). The particular advantage of this lead is that it is possible to precisely in-

Fig. 7.12 Surface ECG compared with the intracardiac HIS bundle EG. *HBE* HIS bundle electrogram, *A* depolarization in the atria, *V* depolarization in the ventricles, *H* depolarization in the HIS bundle

investigate the proximal potentials of the right atrium, the right ventricle and the conductive system, and in this case the HIS-Purkinje system in particular (Fig. 7.12).

7.5 Methodological Notes

Faults that occur during ECG registration can generally be differentiated into patient-, environment-, user- or equipment-related faults. Most faults (baseline shifts,

irregular and regular superpositions of AC voltage) that occur during ECG registration can be traced back to external influences.

7.6 The Diagnostic Value of the ECG

As it illustrates the electrical excitation processes occurring in the heart, the ECG provides information about the origin and rhythm of excitation, the heart position and rate, pulse propagation, as well as repolarization and repolarization arrhythmias, which in turn can be caused by anatomical, mechanical, metabolic or circulatory problems. However, the ECG has no direct informative value regarding the contraction and pumping capacity of the heart (mechanical cardiac function). The medical significance of the ECG is undisputed, although its capabilities should not be overestimated. Within the field of cardiological investigation, the ECG

is essential, and in routine internal investigations it is a valuable, possibly even crucial, investigation tool. Caution is advised regarding the informative power of the ECG in relation to the aetiology and pathogenesis of a cardiac disease, as well as in relation to the indications for and success of therapeutic measures. Anatomical damage and functional faults of the myocardium are not necessarily reflected in the ECG. It must be observed that the informative value of the ECG is dependent on the knowledge and experience of the individual providing the assessment. Whereas inexperienced users will be inclined to inter-

pret the ECG too broadly, the experienced user will give a more reserved assessment and where possible avoid schematization and generalizations. It must be

noted that, particularly with computerized evaluation programs (e.g. diagnostic hints), an individual's own assessment is essential.

7.7 Complications

Whereas incidents during noninvasive ECG recording are a complete novelty, serious arrhythmias (e.g. flut-

ter, fibrillation, etc.) can occur during intracardiac ECG registration.

7.8 Technical Safety Aspects of ECG Systems

Electrocardiographs are power-operated technical medical devices, with associated provisions, regulations and standards that are applied to protect patients and operating personnel.

ECG devices that measure intracardially, or are provided for that purpose, are subject to Annex 1 of the German Medical Devices Operator Ordinance (Medizinproduktebetriebsverordnung – MPBetreibV). The

protection classes that apply to ECG equipment are primarily protection class 1 (with a protective earth) and protection class 2 (without a protective earth). VDE 0750 allows devices to be equipped with a protection class switch so that operation in either protection class is possible. In order to maintain functional and operational safety, the equipment must be subjected to technical safety checks and tests at regular intervals.

7.9 Long-Term ECG

Long-term electrocardiography – long-term ECG for short, and also known as Holter monitoring, *ambulant* ECG or ambulatory monitoring – is a noninvasive routine ECG procedure that is central to primary diagnosis and the therapeutic monitoring of cardiac arrhythmias. As its name suggests, in this procedure, the ECG is recorded and analysed over a relatively long period of time (generally 24 h), under everyday stress.

Whereas other electrocardiographic investigation procedures, such as resting or exercise ECGs, only allow a diagnostic statement to be made over a limited period of time under specific conditions (*laboratory conditions*), the long-term ECG follows the various physical and emotional stresses that occur over the course of at least one day/night period.

7.9.1 Leads

To date there is no uniform agreement on the best electrode positions for long-term electrocardiography. Efforts are being made towards standardization, however, in order to ensure better comparability of the results obtained. The electrode sites must be selected

such that they satisfy the following criteria:

1. The electrodes must be placed on the thorax at sites where there is little muscle, since movements of the skeletal muscles during long-term monitoring can lead to undesirable fluctuations and tremors in the ECG (artefacts).
2. The patient's freedom of movement must not be restricted.
3. The amplitude of the R wave in relation to the P and T waves must be sufficient for computer-based ECG analysis of the recordings.

As a general rule, right and left precordial leads are chosen. Preference is given to the following bipolar chest leads:

MC5: This lead is applied parallel to the electrical axis of the heart; the different electrode level with the fifth ICS, and the indifferent electrode above the sternum (manubrium sterni). The position of the electrode is varied depending on the deviation of the axis.

- MX: The indifferent electrode lies above the sternum, whereas the different electrode is applied above the xiphoid process (xiphoides) of the sternum. This lead has the advantage of having the greatest freedom from interference from muscle tremors.
- CC5: The electrodes are applied to both sides of the anterior axillary line, level with the

fifth ICS, with the different electrode to the right and the indifferent electrode to the left.

In addition to the leads mentioned here, modified leads are recommended by various authors in order to optimize the sensitivity of detection.

7.10 Long-Term ECG Systems

The fundamental work of Norman J. Holter (physiologist) on the development of wireless telemetry – in 1947 he transmitted an ECG signal by radio, and then in 1949 he transmitted ECG signals from ambulant patients performing physical work – had a great influence on modern long-term ECG registration, and indeed made it possible in the first place.

Long-term ECG systems consist of a portable recording device (recorder) with 2–3 channels that registers and stores the ECG signals, a computerized playback device, and a high-performance analysis unit. By means of fast Fourier transformation, application programs enable frequency analysis for artefact recognition, automatic evaluation according to various criteria, accelerated analysis, or batch processing. If we consider the recording technology, a distinction can be drawn between continuously and discontinuously recording long-term electrocardiographic systems in which the data carrier of the recording device is either a tape cartridge or solid-state memory. The tape cassette, which records in analogue, has today been virtually completely superseded by digital solid-state memory. In continuous recording, the ECG potentials are stored in their entirety over a period of between 24 and 72 h. In addition to real-time analysis, high-quality devices also make it possible to evaluate a highly amplified ECG, long-term blood pressure, heart rate variability, and other functions on the unit in parallel.

Discontinuous system-based ECGs are plotted according to the limited storage capacity on the recording device. Following a continuous recording analysis, only time-limited ECG information and results are stored and documented. With these so-called event recorders, the

patient has the option of activating the recording via an activator or remote control unit if symptoms occur. Loop recorders have memory on a loop; in this case, ECG information remains stored for a limited period of time. Only ECG sequences that have been marked by the patient using the activator remain stored. A further development of the event recorder is the subcutaneous implantable loop recorder (ILR), which is used particularly in the case of symptomatic cardiac arrhythmias that occur infrequently. The device, which generally has an operating time of up to two years, is implanted subcutaneously in the region of the left sternum using local anaesthetic. The continuously recording bipolar electrogram is evaluated in the implant. ECG episodes that deviate from programmed ECG criteria are recorded. Here, too, the patient has the option of marking and storing symptoms or events that occur using a remote control.

With so-called simple sampling recorders, ECG sections are recorded only in certain time segments, without the recording being triggered by cardiac arrhythmias and without being influenced by the patient. This intermittently recording system, which stores information only randomly and nonspecifically, leads to recordings with only very limited informative value regarding the complete day/night rhythm.

The transmission of stored ECGs and complete long-term ECG data records via telephone to a computer in the hospital or in a private practice is increasingly gaining in significance. Developments in telecommunications are enabling ECGs to be transmitted using mobile phones, thus permitting *online diagnosis*.

7.11 Computer-Based Assessment

The nature and number of events (e.g. SVES, VES, bigeminy, couplets, salvos, R-on-T phenomena, etc.) within

a certain time interval provide insight into cardiac arrhythmia. At the beginning of the analysis, there is

Fig. 7.13 Flow diagram of a computer-based assessment of the long-term ECG

a learning phase for the program: the QRS complex that is typical of this particular patient is calculated, and the QRS morphology is *learnt* and considered the normal curve shape, in order to be able to distinguish the QRS morphology from deviating QRS complexes and from artefacts. The arrhythmia program uses detection criteria (Fig. 7.13) for the QRS complex (a parameter comparison, also known as feature extraction or characteristics recognition) to draw a rhythmological distinction between physiological and pathological cardiac actions. The polarity of the R wave, the amplitude, the QRS area and position, the offset of the QRS from the baseline, and the slope of the R wave are calculated and determined as particular features for each QRS complex. The individual parameters are used at various points in the analysis for decision-making purposes. Thus, for example, the height of the complex provides an additional criterion when validating a QRS complex. A morpholog-

ical (normal case or not) and rhythmological correlation (premature, delayed, later, etc.), as well as an individual complex assessment and ultimately a conclusion of arrhythmia, are possible using this feature determination. Continuous comparison between the current QRS complex and the learnt QRS is termed the cross-correlation method (or the template-matching method). The classification of each QRS complex forms the basis of the arrhythmia monitoring. The shape and time of occurrence of the complex are taken into account for this purpose. If the QRS shape that is typical of this particular patient is found after a learning phase, the next complex will be compared with the stored reference complex by *superimposing* the two complex shapes and checking point-for-point for a match. Where there is a low percentage of deviation, the complexes are defined as being identical in shape and are used as the reference complex for the next shape comparison. If there is no match (if the

complexes have different shapes), this is stored in what is known as a QRS class memory.

In order to qualitatively assess diagnostic effectiveness and analytical accuracy, it is necessary to test analytical programs that have equipment-specific algorithms against recognized and evaluated ECG databases, and to compare the results (validation). The quality of the analysis, and in particular the reliability of the system, can be described statistically by the sensitivity, positive correctness and specificity:

- True positive = an event is correctly recognized and evaluated
- True negative = a normal complex is correctly recognized and evaluated
- False positive = an event is incorrectly recognized and evaluated

- False negative = an event is overlooked
- True positive and true negative = number of complexes
- False positive and false negative = number of errors

$$\text{Sensitivity} = \frac{\text{true positive}}{\text{true positive} + \text{false negative}} \times 100(\%) ,$$

$$\text{Positive correctness} = \frac{\text{true positive}}{\text{true positive} + \text{false positive}} \times 100(\%) ,$$

$$\text{Specificity} = \frac{\text{true negative}}{\text{true negative} + \text{false positive}} \times 100(\%) .$$

7.12 Heart Rate Variability and Heart Rate Turbulence

Prognostic indicators such as heart rate variability (HRV) and heart rate turbulence can be calculated from the recording of a long-term ECG. Whereas heart rate variability provides information on the variations in heart rate over a relatively long period of time, heart rate turbulence refers to the variations in the interval between two heart beats (RR interval, where R denotes the peak in the QRS complex) following the occurrence of a ventricular extrasystole. In order to assess the heart rate variability, the standard deviation of the RR intervals recorded over

a period of 24 h is ascertained (SDNN). A spectral analysis of heart rate variability can be performed by most analytical devices from approximately 300 recorded sinus beats. Various frequency ranges can be discerned by means of fast Fourier transformation:

- ULF (ultra low frequency power): <0.0034 Hz
- VLF (very low frequency power): 0.0034–0.04 Hz
- LF (low frequency power): 0.04–0.15 Hz
- HF (high frequency power): 0.15–0.4 Hz.

7.13 Indications for Long-Term Electrocardiography

The range of indications for performing a long-term ECG has changed over the years. The most important indication is an investigation where there is suspicion of underlying cardiac arrhythmias (Class I indication). Other indications are risk stratification achieved by

recording ventricular arrhythmias, and the monitoring of an anti-arrhythmic therapy. The guidelines of the American College of Cardiology (ACC), the American Heart Association (AHA) and the European Society of Cardiology (ESC) provide further possible applications.

7.14 The Significance of the Long-Term ECG

The long-term ECG is of great significance for primary cardiological diagnosis and the monitoring of therapy for arrhythmias, as well as for the diagnosis of ischaemia. The resting and exercise ECG usually do not

allow a reliable judgement to be made on the frequency and nature of cardiac arrhythmias, since they record only a small period of time. A significant advantage of the long-term ECG is the continuous recording of the

ECG over a relatively long period of time (at least 24 h). In addition, the results of the analysis can be quantita-

tively measured, documented, or passed on for further data processing.

7.15 The Exercise ECG

Ergometry, the most commonly used exercise tolerance test in clinical and outpatient cardiology, is a noninvasive routine procedure in cardiovascular diagnostics.

By providing additional information to the resting ECG, ergometry yields essential insights into current cardiopulmonary performance and into limitations on performance which may result from coronary heart conditions.

The Difference Between Ergometry and Exercise ECG

Ergometry (from the Greek *ergon*, meaning work or performance) refers to the generation of a defined

and reproducible stress with an ergometer per unit time, and the subsequent monitoring of the ECG, heart rate, blood pressure and oxygen consumption. On the other hand, in an exercise ECG, the focus is less on the blood pressure, heart rate and oxygen consumption and more on recording electrocardiographic changes during and after the period of exertion. Conventional ergometry generally does not include measurements of the oxygen consumption and saturation, whereas such measurements are absolutely essential in ergospirometry (see more Chap. 8, Sect. 8.2.5).

7.16 Equipment Technology

7.16.1 Physical and Technological Principles

The work performed by the test subjects during the exercise period at various stress stages is the product of the force (in newtons, N) and the distance (in metres, m). Including the time component, the output generated can then be measured in newton metres per second = watts = joules per second ($\text{Nm/s} = \text{W} = \text{J/s}$).

If we now consider a bicycle ergometer, when the bicycle peddle is rotated, a force must be expended over a distance. The speed at which the bicycle peddle is rotated is equal to the time in which this output is generated. As the bicycle pedal rotates, the output is thus calculated from $2\pi \times \text{rotational speed} \times \text{torque}$. The torque is calculated from the force with which the pedals are rotated multiplied by the length of the pedal cranks. In the process, it becomes clear that the performance changes depending on the force or rotational speed applied.

7.16.2 Ergometry Measuring Station

In order to avoid standalone systems and restrictions on the range of equipment that can be used, complete systems known as fully automatic ergometry measuring stations are currently available. These measuring stations consist of a 3-, 6- or 12-channel ECG device, an ergome-

ter or treadmill, a 1-, 3-, 6- or 12-channel cardioscope, a defibrillator, a noninvasive blood pressure meter, an electrode application system and a portable equipment trolley that carries this equipment and thus enables flexible transportation of it (Fig. 7.14). When new equipment is acquired, conventional ECG devices are usually replaced with PC ECGs. The advantage of these systems is that they allow data storage and data transfer.

7.16.3 Types of Ergometers

In terms of technology and apparatus, there are three main types of ergometer: bicycle ergometers that are used in the sitting position, recumbent bicycle ergometers, and *treadmill ergometers* (primarily in Anglo-Saxon countries).

Essential requirements for an ergometer – primarily bicycle ergometers – are:

- Ability to adjust the stress accuracy (max. $\pm 5\%$)
- Accurate monitoring as a result of standardization and comparability
- 5 W should be the smallest stress that can be set
- Ability to display the stress and rotational speed
- Optimized adjustment options for different body sizes

Fig. 7.14 Ergometry measuring station with bicycle ergometer (courtesy of ergoline Inc., Germany)

- Low requirements in terms of space, and high stability at the same time.

Rotational Speed Dependence of Bicycle Ergometers

In bicycle ergometers that are dependent on rotational speed, the output can be increased by both increasing the braking resistance and increasing the pedalling frequency. If a particular braking action (belts, brake shoes, weights or an electromechanical eddy-current brake) that predefines the force is set, a specific rotational speed must be maintained in order to be able to precisely determine the output. In practice, this situation is rather difficult to implement. It is for this reason (as well as the inaccuracies in the coefficients of friction for different braking systems) that bicycle ergometers which depend on rotational speed are unsuitable for

ergometry. The use of these devices for medical investigations has therefore been banned. Bicycle ergometers that do not depend on rotational speed are predominantly used today. These are usually equipped with a computer-controlled eddy-current brake, and only the output to be attained is predefined; if the pedalling frequency is increased, the resistance decreases proportionally. The braking action is constantly compared with the rotational speed, the force expended and the predefined stress. Deviations are corrected electronically by increasing or decreasing the braking force. The accuracy is specific to the measuring system, and dependent on the consistency and the control rate. In good systems, deviations of between 1 and 3% in the stress set are observed; the standard allows deviations of up to 5%.

Characteristics and Criteria for Bicycle and Recumbent Ergometers

The following characteristics are important when assessing a bicycle or recumbent ergometer:

1. *Braking principle.* Computer-controlled eddy-current brake, independent of rotational speed, torque measurement.
2. *Stress range.* Dependent on the test subject clientele:
 - a) Standard ergometer 20–450 W
 - b) High-performance ergometer 20–1000 W
3. *Rotational speed range:*
 - a) 30–100 /min
 - b) 30–130 /min
4. *Stress accuracy.* No less than ± 3 W or 3% (standard 5%).
5. *Stress stages.* Smallest stress which can be manually set of 5 W.
6. *Time interval.* Smallest time interval of 1 min.
7. *Exercise tolerance testing programs.* Can be programmed freely.
8. *Seat height adjustment.* Infinitely variable.
9. *Handlebar adjustment.* Infinitely variable.

7.17 Reduced Exercise ECG Leads

As with the other ECG leads, there are currently a vast number of ergometry lead programs. There are two main requirements for the reduced ECG leads during the exercise ECG:

- Minimal susceptibility to faults due to superposition of muscle potentials and movement artefacts
- Qualitative and quantitative registration of ST segment deviations.

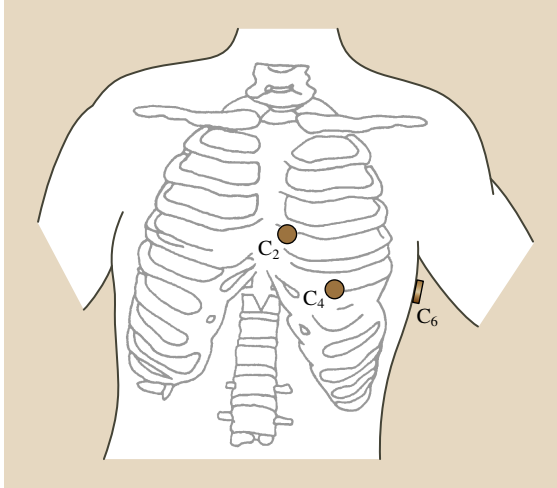

Fig. 7.15 Exercise ECG with reduced chest leads (C₂, C₄ and C₆) ◀

Six leads are generally sufficient. The measurements can be taken using multiple-use electrodes on tensioning straps and electrode belts. Appropriate use of single-use adhesive electrodes or electrode suction units is more hygienic, simpler and faster. The limb leads can be applied respectively to the right and left sides of the shoulder blade (head of the humerus) and in the lateral regions of the right and left iliac wings. These show the least superposition from muscle potentials. The chest leads are of particular interest, because ischaemic ST depressions and repolarization arrhythmias of the anterior wall appear to be most pronounced and occur most frequently in these leads. The most popular electrode sites for chest leads are C₂, C₄ and C₅ or C₆ (Fig. 7.15).

7.18 Automatic ST Measuring Programs

Elevation or depression of the ST segment in the ECG under stress allows diagnostic conclusions to be drawn regarding coronary heart conditions, so this is a major focus of measurements. Modern electrocardiographs, which usually provide an ergometry program, automatically measure and document the ST segment and amplitude. A distinction must be drawn between continuous and discontinuous ST measurement programs: in the case of continuous measurement, each QRS complex recorded is measured and analysed directly. An average beat is generated continuously for each channel from a number of beats that exhibit good correlation (usually 16). In contrast, in the case of discontinuous ST measurement, the average beat is generated from either

values taken at timed intervals (e.g. per minute) or just from a start and end complex.

To obtain the average beat, the start and end point of the QRS complex are first determined. The ST amplitude and slope are measured at point $J + x$ (J point = junction point, which marks the end of the QRS complex and the transition to the full excitation phase: the ST segment). The $J + x$ interval is determined as a function of the heart rate. The isoelectric line is established between the P wave and the start of the QRS complex. The amplitude at point x is the interval from the calculated and displayed baseline. The slope at point x is given by the angle α , and is obtained by passing a regression line through the ST segment and point x .

7.19 Exercise Test

Since the diagnostic issues and the composition of the patient clientele are assessed in very different ways, a uniform, standardized exercise tolerance test is not always possible. The guidelines compiled by the International Commission for the Standardization of Ergometry Application (ICSPE) have led to a largely standardized procedure in routine investigation and in sports medicine.

7.19.1 Stress Intensity

In ergometry, there are two different types of stress intensity in principle: maximal stress and submaximal stress. In the case of maximal stress, the exertion increases until the physical output limit of the test subject is reached (e.g. in sports medicine investigations, performance diagnosis, etc.). In the case of submaximal

stress, exertion is continued until medically relevant problems occur or their correlation with the exertion can be ascertained (e.g. arrhythmias, ST elevation or depression, etc.). The level of submaximal stress is dependent on the medical problem, and may be arrived at long before maximal stress is reached.

Stress Steps

The Standardization Commission for Ergometry (IC-SPE) has stipulated the following stress steps:

- 5 W for 1 min
- 10 W for 1 min
- 25 W for 2 min
- 50 W for 3 min.

Ergometry – according to standardized regulations – consists of a warm-up phase with a basic stress and at least three of these predefined stress steps as well as a recovery phase. The warm-up phase should stimulate circulation and prepare for the stress to come. It is generally of the same duration as the subsequent stress step. The wattage and the duration of the stress step are selected according to the physical capability of the test subject. A further criterion is that a so-called *steady state* is reached at the end of the stress stage. *Steady state* in this case means that at the end of the stress stage both the pulse and the blood pressure no longer deviate upwards – these values remain constant (equilibrium). (For more on the selection of the stress stage, see the section on PWC later.)

Stress Limits

The following is a rule of thumb for maximal stress with bicycle ergometry: a maximum heart rate of 220/min minus the age of the test subject. To ensure the safety of the test subject, the following so-called submaximal stress limit is recommended as a guide for routine investigations: a maximum heart rate 200/min minus the age of the test subject.

Assessment of Performance

To make sure that the ergometry procedure is suitable for diagnosis, it is very important to roughly estimate the performance of the test subject prior to the beginning of ergometry. The following rule applies to this:

The maximum nominal output for a man is 3 W/kg of body weight minus 10% for every decade over the age of 30. The maximum nominal output for a woman is 2.5 W/kg of body weight minus 8% for every decade over the age of 30.

As an example, let us consider the output settings for a 65 year old woman weighing 55 kg.

Nominal output: $(2.5 \text{ W} \times 55 \text{ kg}) - (8\% \times 3.5 \text{ decades}) = 137.5 \text{ W} - 28\% = 99 \text{ W}$; the maximum stress for this woman is therefore approximately 90 W. A basic stress and a stress interval must now be selected that will definitely enable the test subject to cope with three stress stages. In this case, the recommended approach would be to begin with a basic stress of 50 W and then carry out ergometer exercise with stress stages of 10 W and a stress duration of 1 min up to the maximum stress, which is expected to lie between 80 and 90 W. Another advantage of this method is that the output limit can be defined more precisely for test subjects that have comparatively low outputs with relatively low stress increase segments.

Pulse Working Capacity (PWC)

Derived from the rules for assessing performance and the rules for stress limits, the PWC method allows the comparison of outputs standardized to the pulse rate. The PWC value assesses the performance (i. e. the output achieved at specific pulse rates) in the submaximal range when the maximum rate has not been reached. The selected rate is added as an index (e.g. PWC₁₅₀). The nominal values for the PWC are not dependent on age; they are calculated based on weight and gender (for example, the nominal PWC₁₅₀ value for men is 2.1 W/kg and for women 1.8 W/kg). These values can be found in PWC tables, which generally list PWC₁₃₀, PWC₁₅₀ and PWC₁₇₀ values.

Exercise Tolerance Test Procedure

A room temperature of 18–23 °C with a relative atmospheric humidity of 40–60% is recommended when performing an ergometry test. Aberrations should be logged. A resting ECG is recorded prior to the actual exercise tolerance test. It serves as a starting point when summarising the exercise tolerance test later. Following the application of the reduced ECG leads and the blood pressure cuff, the exercise tolerance test is initiated using a calibrated ergometer according to the exercise tolerance test method described. In modern ergometry measuring stations, the customary stress programs are stored in either the ergometer or the ECG device. In a timed ergometry investigation, one of these two devices serves as the command unit for the course of the investigation. In order to provide complete documentation, an intermediate ECG printout giving details of the heart rate, the blood pressure as well as the ST segment and the amplitude is automatically printed after

each stress stage. However, it is also possible to initiate a manual ECG recording at any desired stage or to record an ECG trend over the entire duration of the test. The following actions must be performed during the exercise tolerance test:

- Constant observations of the test subject and the ECG graphs on the monitor
- The ECG strip as well as the blood pressure, the heart rate and the ST properties after each stress stage must be monitored.

Following the completion of the exercise tolerance test and a recovery phase, a resting ECG is recorded once more (and if necessary more than once), and the blood pressure is repeatedly monitored.

Types of Exercise Tolerance Testing

The general requirements for an evaluable exercise tolerance test can be summarised as follows: it should be capable of precise metering, physically measurable, and reproducible at any time. There are many types of exercise that do not satisfy these requirements, but they are mentioned below for the sake of completeness:

- *Forward bends and squats.* Insufficient for the exercise ECG because even the general requirements (*capable of metering and physically measurable*) cannot be satisfied.
- *Climbing stairs.* Unsuitable for the exercise ECG since the *reproducibility* must be questioned, there is no possibility of ECG monitoring, and the test subject cannot be subjected to maximum stress.
- *Hand crank ergometer.* Interference with the ECG recording as a result of the arm and thorax movements of the test subject and the lack of maximum stress (small muscle mass) are disadvantages of this method. However, this type of exercise tolerance test is often the only option for patients with impaired walking abilities.
- *Isometric stress (hand-grip).* Similar disadvantages to those for the hand crank ergometer.
- *Master's step test.* The one-step or two-step test offers the following advantages: it is a relatively physiological form of exercise tolerance testing, involves a simple sequence of movements, is standardized and therefore reproducible, is simple to carry out, stresses a relatively large proportion of the total musculature, and requires a comparatively low financial outlay. Disadvantages: the timescale for maximum stress, it is virtually impossible to record the ECG and blood pressure during the exercise intolerance test, and its diagnostic informative value is very low when compared to those of bicycle and treadmill ergometry.
- *Kaltenbach and Klepzig's step-climbing test.* This test is a modification of Master's test, and the advantages and disadvantages are therefore similar.
- *Treadmill ergometer.* The treadmill is predominantly used for exercise tolerance testing of competitive athletes. The fundamental advantages of the treadmill ergometer are that it physiologically stresses the entire musculature (and this can be reproduced at any time), and it allows the stress intensity to be changed (by varying the speed at which the belt runs). Disadvantages are its relatively high investment costs, its structural requirements (in particular soundproofing), and a limited clientele for exercise tolerance testing.
- *Bicycle ergometer.* The most popular and widely used type of exercise tolerance test is bicycle ergometry, which can be performed in a sitting position or in a recumbent position. Fundamental advantages of bicycle ergometry in the sitting position are the physiological stress and the use of the body weight; the procedure is also usually found to be pleasant by the test subject. Disadvantages are the recording of ECG and blood pressure during the exercise tolerance test and orthostatic complaints following the exercise intolerance test. The fundamental advantages of the recumbent ergometer are the unimpeded recording of the ECG and blood pressure and the quality of these recordings, the relatively high level of safety (predominantly for elderly or frail people), and the absence of orthostatic complaints following the exercise tolerance test.

Standardized Investigation Programmes

A number of individual and standardized exercise tolerance testing programmes from the early days of ergometry investigation are still employed. These are listed below, along with some examples:

- Hollman's standard test method (begins with 30 W and is increased every 3 min by 40 W up to the stress limit)
- The WHO's standard programme (begins with 25 W and is increased every 2 min by 25 W up to the stress limit)
- Knipping's *vita maxima* (begins with 10 W and is increased every minute by 10 W up to the stress limit)

- Kirchoff's square wave test (stress duration of 10 min with 100 W in a sitting or recumbent position; blood pressure, heart rate and ECG are monitored every 2 min).

However, ergometry has increasingly evolved into a standardized method based on the internationally

recognized regulations of the ICSPE. This has the advantage that results of investigations from different institutes and those obtained by different testing personnel can be compared and assessed according to the same standards. It is therefore the duty of all testing personnel to adhere to these regulations.

7.20 Methodological Notes

Most faults that occur during ergometry can be attributed to the patient. A large proportion of these faults are compensated for by modern equipment technology. Nevertheless, the test subject can be made aware of the fact that the necessary pedalling work can be carried out without excessive movements of the upper body. Incidents are extremely rare in the case of ergometry when performed correctly, and routine investigations are today therefore predominantly carried out by well-briefed medical assistants. The only ergometric investigations

that must be supervised by the doctor over the entire duration of the exercise tolerance test are those in which – due to the general condition of the test subject – complications cannot be ruled out. A nurse or medical assistant must be present at the same time in order to assist or to provide immediate assistance if necessary.

An emergency supply of equipment and medication as well as a functioning defibrillator must be available to hand at all times.

7.21 The Diagnostic Value of Ergometry

ST segment variation during the exercise ECG is of the utmost importance for the detection of temporary myocardial ischaemias. In addition, coronary heart conditions can be established unambiguously. Coronary angiography has made an essential contribution to im-

proving the interpretation of the exercise ECG, although there is a fundamental difference between the two: coronary angiography detects the morphological changes in the coronary arteries, whereas the exercise ECG detects the functional effects.

7.22 Indications

An indication for an exercise ECG can be given for diagnostic, therapeutic or prognostic reasons:

- Investigation of a coronary heart condition (e.g. chest pain during physical exertion)
- Investigation of the blood pressure where there is suspicion of exercise-induced hypertension
- Investigation of the stress tolerance (e.g. following a myocardial infarction, etc.)
- Assessment of cardiac arrhythmias
- Assessment of the progress and therapeutic success of medication and exercise therapy and following heart surgery
- Assessment and classification of the degree of severity of stress-induced coronary insufficiency.

7.23 Abort Criteria and Safety Measures

Exercise tolerance tests cannot be performed without risks (e.g. myocardial infarction, life-threatening arrhythmias, etc.). In order to minimize the risks, safety

measures should be taken before and after the exercise tolerance test. Before the exercise tolerance test, information from the resting ECG should be analysed,

including anamnesis, and the patient should be examined and informed. It is important to tell the patient to report any subjective complaints during the exercise tolerance test, and to continue to monitor the test subject following the exercise tolerance test (generally for 5–10 min); a monitoring ECG should be recorded again and the blood pressure should be measured.

Criteria for aborting ergometry are:

- Increasing retrosternal severe pain (angina pectoris)
- Horizontal or descending ST depression of >0.2 mV
- Cumulative monomorphic or polytopic ventricular extrasystoles
- Ventricular salvos
- Isolated extrasystoles that fall in the T wave of the previous cardiac action (R-on-T phenomenon)
- Atrial fibrillation or flutter
- Serious conduction defects (e.g. total AV block)
- Depolarization defects (e.g. bundle branch block)
- Systolic blood pressure >250 mmHg, diastolic blood pressure >130 mmHg, and drop in blood pressure
- Noticeable breathing difficulty (dyspnea)
- Signs of the beginning of left ventricular insufficiency
- ECG signs of a fresh myocardial infarction.

7.24 Technical Safety Aspects

Bicycle ergometers are subject to the provisions of the German Medical Devices Act (IIa) and DIN VDE 0750-238. They must be serviced regularly, as must the

noninvasive blood pressure meters that may be installed on them.

7.25 Notes on Planning

A room temperature of 18–23 °C with a relative atmospheric humidity of 40–60% is recommended. As a guide, a floor space of area 16 m² would be suitable. There should be the option to get changed (changing cubicle ≈ 3 m²), and bathroom facilities with WC/shower (approx. ≈ 5 m²) should also be provided.

Pulmonary F

8. Pulmonary Function Testing

Rolf M. Schlegelmilch, Rüdiger Kramme

Pulmonary function tests (PFT) examine the functionality of the lungs. This chapter describes the working principles of major test techniques and instruments including spirometry, peak flowmetry, body plethysmography, nitrogen washout, and ergospirometry. Spirometry (Sect. 8.1), specifically the measurement of the amount (volume) and speed (flow) of air that can be inhaled or exhaled, is the most basic of the pulmonary function tests. Body plethysmography (Sect. 8.2.2) offers determination of absolute lung volume and airway resistance and is particularly sensitive in the detection of obstructive pulmonary disease requiring little patient cooperation. Nitrogen washout (Sect. 8.2.4) is a common test for measuring functional residual lung capacity. Ergospirometry evaluates the complex interaction between lung, heart, and muscle by analysing the gas exchange under exercise (Sect. 8.2.5). The chapter closes with considerations of planning and laboratory space (Sect. 8.2.8).

8.1 Spirometry

Spirometers are noninvasive diagnostic instruments for screening and basic testing of pulmonary function. Offering essential diagnostic insight into the type and extent of lung function impairment, spirometry tests can be performed fast at fairly low cost. In the light of an ever-increasing prevalence of airway diseases such as asthma, bronchitis, and emphysema, pulmonary function instruments have become indispensable diagnostic tools, in clinical and office settings, in industrial and preventive medicine, as well as in epidemiology. Screening of individuals at risk, basic testing of sick patients, and treatment follow-up are key applications of spirometry.

Two essential questions of pulmonary function testing (PF testing) can be answered by spirometry:

1. What is the size of lung volume which can be inspired *or* expired?
2. What is the time it takes to exhale this volume, or what is the flow rate during exhalation?

Flow rates and resulting volumes are measured by connecting a spirometry sensor through a mouthpiece to the test subject's mouth. The most common and internationally standardized test consists of an evaluation of forced expiration after a complete inhalation, allowing the determination of forced vital capacity (FVC)

Fig. 8.1 (a) Forced spirogram and (b) flow–volume loop

and the forced expired volume during the first second (FEV_1). Recording of the test trace is taken as a forced spirogram (volume over time) or as a flow–volume loop (flow against volume). Although FVC and FEV_1 are the most common, dozens of parameters can be derived when evaluating forced expiration, all describing the shape and size of recorded traces and loops (Fig. 8.1). Besides forced spirometry, slow spirometry, i.e., the recording of slow inspiration and expiration at tidal breathing, may also be recorded, offering determination of lung-volume subdivisions such as tidal volume (VT), inspiratory and expiratory reserve volume (IRV and ERV), as well as inspiratory capacity (IC). In most cases, slow spirometry will be a part of advanced PF tests (Sect. 8.2.2).

8.1.1 Flow Recording

The basis of all PF tests consists in the recording of air flow rates against time, a procedure also called pneumotachography. Mostly, flow velocity [cm/s] is measured in a defined sensor geometry, yielding flow [l/s], also referred to as flow rate. In 1925 the Swiss physiologist Alfred Fleisch published about the clinical application of pneumotachography. While registration of spirometry traces and flow–volume loops required a recorder and manual evaluation in the past, all contemporary spirometers contain microprocessors for online data processing, displaying results on a built-in screen or transferring data to a personal computer.

Measured flow is continuously accrued to lung volume by digital integration. Independent of the size and cost of any pulmonary function device, from a handheld peak flowmeter to a body plethysmograph, the flow sensor always represents the core element (Fig. 8.2).

8.1.2 Technology

While *closed systems* such as the bell or wedge spirometer were still in use two to three decades ago, only *open systems* will be found today, offering smaller footprint and size, higher precision, and more comfortable and hygienic conditions for the patient. In an open system the patient breathes from and to the ambient air through a sensor, which in case of more advanced testing can be connected to one or more valves. The spirometer detects the flow rate from the sensor and digitally integrates flow to volume

$$V = \int \dot{V} dt \text{ (l)},$$

where V denotes the inspired or expired volume, and $\dot{V} = dV/dt$ (l/s) is the measured flow.

Figure 8.3 depicts a typical pneumotachogram (flow over time) and the resulting spirogram (flow integrated volume). The recording of breathing traces and the calculation of derived parameters are usually performed by an integrated microprocessor or a personal computer.

Measuring Range

When testing adults, the physiologically relevant flow range should reach from 25 ml/s to 101/s, optimally from 10 ml/s to 151/s, requiring a resolution of 5–10 ml/s. These conditions impose very demanding technical specifications on flow sensors. For precise detection of the first part of the forced exhalation, a linear frequency response of up to 5 Hz is required in the flow sensor characteristics.

Verification and Calibration

To verify the accuracy of a flow sensor and if needed to calibrate it, an optional verification and calibration routine should be implemented in any spirometer. Both verification and calibration are carried out by means of a manual or motorized pump of known volume of at least 2 l. When activating the calibration pump connected to the flow sensor, the spirometer will read integrated instantaneous flows. At the end of a full stroke, the spirometer should display a flow integrated volume identical to that of the pump. As digital integration can be assumed to be sufficiently precise, any deviation in volume will indicate the error in flow measurement. By moving the piston at varying speeds, flow rates between $-101/s$ and $+101/s$ can be simulated, covering most of the physiological flow range. Any deviation between a stroke volume resulting from low flow rates versus that produced at high flow rates will indicate a nonlinearity in the flow sensor or spirometer circuitry. Today, most spirometers offer a calibration program facilitating the calibration routine. Averaging over a given number of pump strokes, the deviation from the correct volume is displayed, and a correction factor will be considered in future measurements. Verification and calibration must be carried out without regard of body temperature pressure saturated (BTPS) correction (see later), as pump volume is measured at ambient not at lung conditions.

In recent years, disposable spirometer sensors have become common. Even if these sensors are precalibrated or calibration data are read into the spirometer, a verification routine should be available to allow for quality assurance. The same applies to the newer digital sensor systems which are advertised as calibration free. Nevertheless, accuracy and linearity should be verified at reasonable intervals.

The American Thoracic Society (ATS) and European Respiratory Society (ERS) have issued recommendations [8.1, 2] mandating testing of spirometers by independent laboratories prior to market release. By subjecting production models to a battery of tests,

Fig. 8.2 Pneumotachograph (nnd Medizintechnik, Zurich, Switzerland)

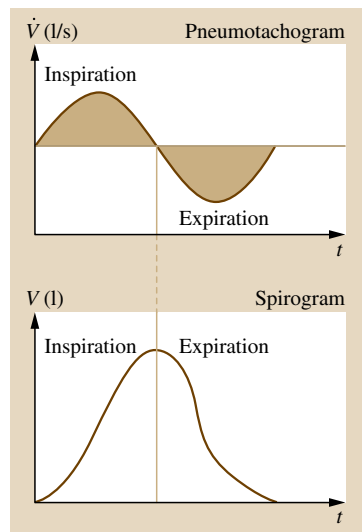

Fig. 8.3 Comparison of pneumotachogram and spirogram

manufacturers can document the overall performance of their spirometers to the user. Test laboratories employ motorized, processor-controlled calibration pumps producing standardized flow–volume loops, able to simulate a wide range of clinically relevant flows. This testing procedure is part of the obligatory premarket registration procedure in the USA [Food and Drug Administration (FDA) approval]. One can assume that spirometers which are also sold in the USA fulfill these requirements. Before purchasing a spirometry device, documented compliance with the recommendations of the ERS and ATS spirometry standards [8.1, 2] should be requested from the manufacturer or supplier.

Hygiene

Cross-contamination is an ever-present risk in spirometry. To effectively avoid the risk of infection in patients

or individuals tested with the same spirometer, suitable preventive measures should be instituted. In case the flow sensor is a fixed installation which cannot easily be exchanged, a disposable breathing filter is indispensable. Like the sensor itself, the breathing filter must have a low resistance, minimizing any hindering effect on breathing. Usually the flow sensor can be exchanged and replaced by one that has been cleaned and sanitized. In regular clinical testing, sensors do not need to be sterile; disinfection according to manufacturer's recommendations is sufficient. Many modern spirometers incorporate disposable sensors, favorably combining adequate hygiene with ease of use. As single-use sensors should not cost much more than a good breathing filter, their design is a contradiction in terms of low cost versus good performance (in accuracy and resolution, see above). In this regard a disposable item that is not part of the sensor itself may be advantageous, as it ensures hygiene while not affecting accuracy. The ERS has published recommendations concerning the resistance of spirometry sensors and breathing filters, calibration, and hygiene of spirometers [8.2].

Conversion to Body Conditions

An *open system* requires conversion of measured flow and integrated volume from ambient to lung or BTPS conditions (37°C, 760 mmHg, 100% relative humidity). The conversion needs to correct inspiratory and expiratory flows and volumes separately. While, during inspiration, 1 l of ambient air expands to about 1.1 l of lung air due to heating and humidification, 1 l of lung air will shrink during expiration to about 0.97 l

at the sensor, both corrections depending on the sensor type and the geometry of the mouthpiece. Without BTPS correction, substantial errors in the range of 10% in flow and volume parameters may occur. Conversion formulae can be found in [8.2]. In all commercially available spirometers, conversion to BTPS conditions is implemented, automatically correcting data to BTPS conditions.

In Table 8.1, the measuring principles of currently commercially available flow sensors, their pros and cons are presented.

Differential Pressure Flowmeter

The classical method to measure respiratory flow consists in the acquisition of the differential pressure ($p_1 - p_2$) in a flow tube where a resistive element is inserted. The type of the resistor characterizes the sensor principle, and usually it will lend its name to it.

As the airstream leaving the trachea and mouth is turbulent, a short tube or a breathing filter should be inserted between the flow sensor and the mouth, acting as a flow rectifier to *laminarize* the flow pattern before entering the sensor. Only laminar flow will provide a pressure drop across the resistor which is proportional to flow rate. Depending on flow direction, the differential pressure across the resistor will be positive (expiration) or negative (inspiration). The pressure is picked up by a pressure transducer and converted into an electrical and/or digital signal. All flow-measuring devices based on differential pressure transducers are sensitive to baseline instability. Even the smallest asymmetry in the transducer leads to a drift in the flow

Table 8.1 Types of flow sensors

Type	Pros	Cons
Pneumatachograph according to Fleisch	Proven measuring principle, durable	Several sensors for different flow ranges required, sensitive to contamination, difficult to clean, frequent calibration required
Pneumatachograph according to Lilly	Proven measuring principle, durable, cleaning possible	Sensitive to contamination, calibration required
Diaphragm pneumotachometer	Proven measuring principle, durable, lightweight, simple cleaning	Calibration required
Turbine flowmeter	Small, lightweight sensor	Frequent cleaning and calibration required
Hot-wire anemometer	Offers good accuracy	Simple anemometer not accurate, calibration required
Vortex flowmeter	Simple sensor construction	Not proven in routine testing, only unidirectional, difficult to calibrate
Ultrasound flowmeter	Simple sensor construction, small, lightweight, high accuracy, calibration free	

Fig. 8.4 Pneumotachograph according to Fleisch (schematic)

signal and consequently to a drift in volume. Even rather minimal flow drifts can – over time – integrate into appreciable volume offsets. To avoid this effect, a flow range around baseline needs to be defined in which no flow integration takes place (*dead zone*). As flows at the end of expirations can be rather small but are of diagnostic significance in obstructive disease, the dead zone should be kept as small as possible and may not exceed 10–15 ml/s.

The Fleisch Pneumotachometer

Until the 1980s, the pneumotachometric principle according to Fleisch was the most widely used flowmeter in PF testing, also called the Fleisch pitot tube (Fig. 8.4). The sensor consists of a bundle of capillaries, typically a roll of z-folded sheet metal acting as a fixed resistor. The bulk of flow is subdivided into small threads of flow, laminar over a certain range. The pressure difference along a capillary can be derived by applying the Hagen–Poiseuille law, which in case of laminar flow yields

$$\Delta p = c \cdot \dot{V} = \frac{8\eta l}{r^4} \dot{V},$$

where c is a constant dependent on the gas viscosity and sensor geometry, l is the length of the sensor tube, r is the radius of the sensor tube, η is a viscosity constant, and \dot{V} is the flow rate.

In the Fleisch tube, linearity between pressure difference and flow rate is attained by use of a large

number of bundled capillaries. As long as mechanical signal recorders were used, linearity in flow assessment was required to allow for direct reading of the flow rate from the trace. Today, due to fast digital online processing, also nonlinear sensor principles can be implemented for flow determination and recording. Despite the use of modern technology, sensor calibration and accuracy need to be checked regularly. Since the Fleisch tube and all other pneumotachographs employing some type of resistor are directly exposed to the exhaled air, sputum, even a small droplet, may change the resistance, leading to considerable errors in indicated flow rate. Therefore, a bend is inserted between the mouth and sensor both to retain sputum droplets and to laminarize the airstream. Alternatively, a disposable air filter can be inserted to avoid contamination and safeguard hygiene (Sect. 8.1.2).

The Lilly Pneumotachometer

Over a tube restriction, a pressure drop proportional to flow can be registered, up to a Reynolds number of ≈ 10 . This relation also holds when a combination of restrictors, such as a close-mesh screen, single or in a series, characterizes the flow sensor. An essential feature of this design is the large difference between tube and mesh diameter. In practice, a layer of several sieves improves the linearity of the flow measurement but increases the breathing resistance, which needs to be considered.

Diaphragm Pneumotachometer

In this type of flowmeter a specially slotted foil diaphragm is employed, acting as the resistor. A pressure drop across the diaphragm will occur, being either proportional to flow over a certain range or needing linearization over a larger range. Depending on design, the diaphragm will exhibit a larger differential pressure at lower flows, an overproportionally smaller pressure difference at higher flows. Certain applications, such as exercise testing or intensive care measurements, may benefit from such varying resolution. The diaphragm is less prone to humidity and contamination by sputum and may be cleaned more easily.

Turbine Flowmeter

A turbine or propeller built into the flow tube characterizes this sensor, which is also called a digital volume transducer. Excited by the passing gas flow, the rotating elements interrupt or reflect the light from a light-emitting diode (LED). Photodiodes register the rotations, returning an electrical impulse frequency proportional to flow, while the total count is proportional to volume.

To minimize inertia, the turbine bearing resistance and turbine mass have to be as small as possible. Contemporary turbine flowmeters can be dismantled easily for cleaning.

Hot-Wire Anemometer

This sensor consists of a Venturi tube in which two hot wires are installed, linked in an electric bridge circuit (Wheatstone bridge). While one wire, consisting of two types of platinum, senses gas temperature,

the other measures the heat flux into the passing gas. Temperature-corrected heat flux is proportional to gas flow.

A more modern version of this principle, the so-called mass flowmeter, is able to measure the amount of gas molecules passing the hot wire, featuring independence from gas temperature and mixture or viscosity.

Vortex Flowmeter

The phenomenon of fluid vortices was already described by Leonardo da Vinci as early as 1518. Vortices are usually caused by waves meeting a resistance in flow. In a vortex flowmeter the air flow is channeled towards a resistive element, the so-called bluff body, where vortices occur. The type and extent of vortices formed depend on the flow velocity. The number of vortices can be evaluated by different technologies: piezoelectric elements, thermistors, or optodes. The vortex flowmeter can only detect unidirectional flow and needs an independent sensor, such as a pressure sensor, for detection of flow direction. Therefore, this principle finds only limited acceptance in spirometry.

Ultrasound (Transit Time) Flowmeter

This method (Fig. 8.5) is based on the determination of transit times of acoustic waves traveling through a flowing medium. The velocity of acoustic waves across a flow tube increases at the same rate as the velocity of air in that tube. Three technical realizations exist:

1. Continuous phase shift analysis, where the phase shift of a continuously generated ultrasound signal is determined.
2. Impulse phase shift, where the phase shift between sinusoidal ultrasound waves is measured.
3. Time-of-flight impulse, where the transit time of the ultrasound traveling between a transmitter and receiver is determined.

While the principle of determining phase shifts has not been commercialized in medical technology, the time-of-flight method [8.3] has been successfully introduced in spirometry, with wide acceptance in clinical practice and epidemiology. The sensor technology employs two ultrasound elements which are built into the sensor housing and placed oblique to the airstream in a flow tube. Alternating ultrasound impulses are emitted in both directions, and their transit times across the tube are measured. While transit times are shorter downstream, they are longer upstream. The difference in transit time is proportional to the flow velocity, independent of any other variable such as gas tempera-

Fig. 8.5 Working principle of an ultrasound flowmeter (ndd Medizintechnik, Zurich, Switzerland)

ture, viscosity or humidity. In a commercially available ultrasound flowmeter a disposable breathing tube is employed, featuring sealed windows across from the ultrasound elements. While the windows are transparent to ultrasound, germs cannot pass, effectively avoiding cross-contamination. In addition to being calibration free, this sensor design also has the advantages of high accuracy and total hygiene. While the difference in transit time yields the flow, the sum of the transit times is directly related to the molar mass, the molecular or specific weight of the breathing gas, allowing instantaneous reading of the specific weight of the gas passing through the sensor. During expiration, the molar mass changes according to the composition of the exhaled gas, similar to a CO₂ waveform (Sect. 8.1.4).

Peak Flowmeter

For monitoring obstructive diseases such as asthma and for analyzing therapy response, peak flowmeters play an important role, in particular for home use. The classical mechanical peak flowmeter consists in a piston moving in a scaled flow tube. A forced expiration moves the piston up the vertically held tube, allowing a reading of maximum peak expiratory flow (PEF) in units of l/min or l/s. More modern peak flowmeters implement one of the above-mentioned measuring principles, most often turbines. Usually they offer electronic signal processing, display of results, memory and diary function, as well as data logging through a modem or the Internet. When applied over a longer period of time, verification and calibration of PEF meters should be warranted.

8.1.3 Methodology of Spirometry

Lung-Volume Subdivisions

Pulmonary gas transport depends on the filling capacity of the lungs with breathing gas and the speed and uniformity of gas distribution. Markers of lung filling are the lung-volume subdivisions, which are measured at slow breathing, while flow rates are of minor interest. When two or more volume subdivisions are combined, *lung capacities* result. The most important role in PF testing is played by vital capacity (VC), the volume of complete inspiration (IVC) or slow expiration volume (EVC), both directly accessible by spirometry. At the end of a deep expiration, residual lung volume (RV) remains in the lungs, which can be determined by gas dilution methods (Sect. 8.2.4) or body plethysmography only (Sect. 8.2.2). Consequently, the sum of VC and residual volume (RV) determines the volume at the end of a complete inspiration and is called the total lung ca-

capacity (TLC), an important measure of maximum lung volume.

Vital capacity consists of the subdivisions:

- Tidal volume (V_T), the volume ventilated during a regular breathing cycle
- Expiratory reserve volume (ERV), the volume that can be exhaled from breathing baseline, i. e., at the end of a regular breathing cycle
- Inspiratory reserve volume (IRV), the volume which can be inhaled above the inspiratory breath of a regular V_T cycle
- Inspiratory capacity (IC), i. e., the sum of VT and IRV.

As for TLC and RV, the functional residual capacity (FRC), being the sum of RV and ERV, can be determined by more elaborate methods only (Sect. 8.2). As determination of lung-volume subdivisions is time consuming and diagnostically less significant, subdivisions will be evaluated in combination with the more relevant FRC.

For standardization of lung volume testing refer to [8.4].

Forced Spirometry

Of the diagnostic arsenal of internal medicine, dynamic lung volumes, in particular forced vital capacity and forced expiratory volume in the first second (FEV₁), are considered essential parameters. Forced expiration not only delivers important information about an existing pulmonary obstruction in the sense of reduced airway diameter but may also indicate a loss in lung retraction, parallel to diminished lung elasticity and enhanced airway instability. Reduced elasticity mirrors the loss of functional tissue structure, resulting in reduced surface area for gas exchange and accompanied by a high demand in ventilation at reduced maximum oxygen uptake.

In contrast to the predominantly practiced forced expiration, forced inspiration can be used for differential diagnosis of extrathoracic obstruction, e. g., tracheal stenosis.

Being technically less demanding, the recording of a forced spirogram prevailed traditionally; today the flow-volume loop is registered together with the spirogram. The time-based spirogram offers observation of expiratory time, typically 3 s in a healthy subject but maybe as long as 10–20 s in an obstructed patient. As the forced spirogram represents the shape of an exponential function, analysis of its form requires a certain understanding of the underlying pulmonary

Table 8.2 The most important parameters of the forced spirogram and flow–volume loop

Parameter	Unit	Description
FVC	l	Forced vital capacity
FEV1	l	Forced expiratory volume in 1 s
FEV1/FVC	%	FEV1 in % of FVC or relative FEV1
FEV _t	l	e.g., FEV _{0.5} , FEV ₂ , FEV ₃
PEF	l/s	Peak expiratory flow
FEF ₂₅₋₇₅	l/s	Mean forced expiratory flow between 25% and 75% of FVC
FEF ₂₅	l/s	Forced expiratory flow when 25% of FVC has been expired
FEF ₅₀	l/s	Forced expiratory flow when 50% of FVC has been expired
FEF ₇₅	l/s	Forced expiratory flow when 75% of FVC has been expired
MTT	s	Mean transit time
FIV1	l	Forced inspiratory volume in 1 s
FIF ₅₀	l/s	Forced inspiratory flow at 25% of FVC

mechanics. In contrast, the flow–volume loop represents a linearization of the exponential expiratory decay, as an exponential and its derivative are recorded against each other. In a healthy person the rise to peak flow is steep, while the decay is (quite) straight. The very obvious deviation from a straight line towards a concave shape means a reduction in flow, which is easy to interpret.

Table 8.2 presents the most important parameters of the forced spirogram and flow–volume loop. The list of parameters derived from forced expiration could be extended (almost) endlessly. Beside the numerical evaluation of the flow–volume loop, attention should be drawn to the analysis of its shape (Fig. 8.6).

Documentation

Online recording and evaluation of the flow–volume loop has become a gold standard in basic pulmonary function testing. When testing a patient, several trials should be registered to assess cooperation and repeatability. Loop tracings should be recorded with sufficient resolution. The aspect ratio, i.e., the flow versus volume scaling, is of importance for form analysis, e.g., in pre/post broncholytic drug medication, and should be fixed to pronounce the difference between a healthy and an obstructive loop.

Practical Considerations

The quality of most pulmonary functions tests, in particular forced expiration, depends on the cooperation of the test subject and the (incentive) instructions of the operator. After preparing the spirometer, verification or calibration, and insertion of a new mouthpiece or breathing filter, the testing procedure is explained to the subject. Before and during spirometry, breathing maneuvers are further supported by the operator, and the

subject should be motivated to maximize forcing efforts and exhale completely. The subject, wearing a nose clip, should be able to breathe free and unhindered through the mouthpiece and should be encouraged to practice before recording starts. All tests should be carried out in the same body position, generally sitting. In screening and industrial testing, also a standing position is adequate. In children and seniors, use of a mouthpiece with a sealing lip is recommended. A smaller, pediatric mouthpiece should be applied in children. Unless disposable flow sensors are used, a disposable filter attached to the sensor is mandated, both as a hygienic requirement and a preventive measure to avoid intrusion of sputum into the flow sensor.

Both the ERS and ATS have issued recommendations in which at least daily volume calibration using a calibration syringe is mandated. In a calibration-free device, volume verification should be carried out at least once a month.

Slow Vital Capacity and Volume Subdivisions Instructions

The subject breathes at resting baseline. After a couple of breaths, the operator gives instructions for a slow, continuous, maximum inspiration followed by a slow, maximum expiration, followed again by a complete inspiration. The cycle should be repeated again. Parameters from repeated tests should not deviate by more than 5%.

Forced Spirometry and Flow–Volume Loops Instructions

Breathing at resting baseline, the subject is instructed to inhale completely and exhale as hard and as long as possible. This procedure should be repeated at least twice.

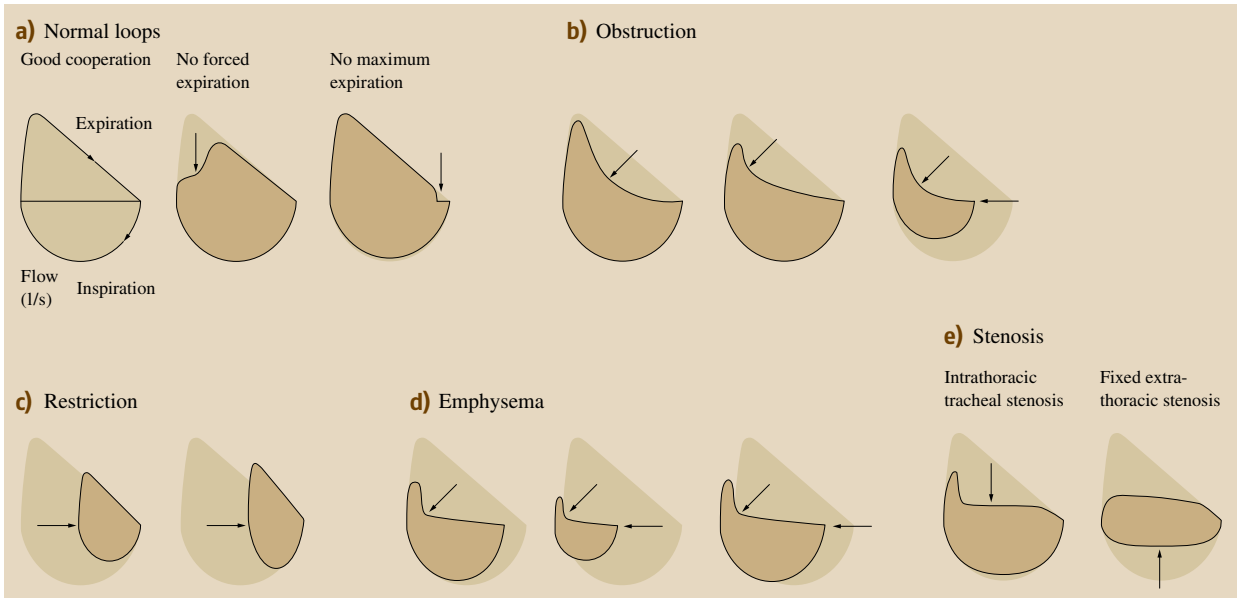

Fig. 8.6a–e Typical flow–volume loops: (a) normal, (b) obstruction, (c) restriction, (d) emphysema, and (e) stenosis

Breathing maneuvers need to be instructed clearly; especially the forced exhalation should be supported by incentive commands. For evaluation, maximum forced flow rates (FEFs) are picked from the recording. Contemporary software programs offer warnings to the operator in case quality standards (ERS, ATS) are not met. Either best values are taken from all forced traces or the trace with the highest sum of FVC and FEV₁ is considered for analysis.

Several errors may occur: Poor cooperation of the test subject may lead to a late or low PEF (Fig. 8.6a). In general, low FEFs may result in case no nose clip is worn or the lips did not entirely seal the mouthpiece. Deformation of loops and traces may result from coughing or swallowing. If no FEV₁ is given, exhalation was too short or interrupted. Varying loops indicate poor instruction and motivation. With good cooperation, all forced flow–volume loops should superimpose adequately.

After analyzing the results of forced spirometry, a first classification into normal, obstructive, or restrictive findings can take place (Fig. 8.6a–e). In frequently evidenced obstructive disturbances, even the severity can be assessed.

Predicted Values

Evaluation of spirometry testing is carried out by comparing measured data with predicted *norms* or reference

data, derived from body weight, height, age, and gender. Predictions are calculated from equations published and recommended by scientific societies. When comparing measured with predicted values, the standard deviation, an indicator of the variation of the tested parameter in a healthy population, needs to be taken into consideration. The determination of the residual R

$$R = \frac{M - S}{SD}$$

is recommended, where M is the measured value, S is the predicted value, and SD is the standard deviation, allowing comparison with a distribution in the reference population and detection of significant deviations.

The leading international societies, the ERS and ATS [8.5], have issued predicted formulae, mostly derived from Caucasian populations. These European and North American predicted values do not substantially differ from each other. When assessing pulmonary function in other ethnicities, predictions of national societies or other scientific sources should be used, or at least a percentage adaptation of Caucasian predicted values be considered.

Most processor-based test devices are equipped with different sets of prediction formulae that can be selected by the operator. The user manual should give the national background and literature references of the predicted sets.

Besides reporting measured, predicted, and percentage values, spirometry reports should contain a marker for significant deviation from certain limits, such as the standard deviation. Testing in children and adolescents requires a set of pediatric formulae.

8.1.4 Cooperation-Free Pulmonary Function Tests

For more than half a century spirometry has been a valued clinical tool and its importance has been documented in numerous publications. Forced spirometry can predict mortality better than smoking habits, existing cardiovascular morbidity, blood pressure, or gender [8.6].

As valuable as forced spirometry findings may be, it is often difficult to attain and ensure cooperation in subjects. Even well-equipped pulmonary function laboratories with well-trained staff will soon reach their limits when addressing and motivating children, geriatric or foreign-language patients. In former times, cooperation-free tests were postulated mostly for pediatric departments and epidemiological and screening studies. More recently, the cataclysmic demographic changes accompanied by a dramatic increase in the senior generation underline the urgent necessity of suitable tests. Although FEV_1 and $FEV_1/FVC\%$ are a recognized gold standard for detecting and assessing obstructive disease, more appropriate, more specific parameters might be available, correlating well with dyspnea (shortness of breath). Therefore, new, (almost) cooperation-free methods have been developed during the recent years, some of which are still pending commercial release. The next section gives an overview of proven and new developments in this area.

Ultrasound Pneumography

In Sect. 8.1.3, the ultrasound flowmeter was described and its ability mentioned to measure molar mass, the molecular or specific weight of the breathing gas, derived in real time from the sum of transit times – at no additional expenditure. While ambient air is inhaled through the sensor, the molecular weight changes during expiration as oxygen content drops and carbon dioxide increases (O_2 has much lower density than CO_2). When molar mass is registered during expiration, its waveform resembles that of CO_2 . In fact, ultrasound pneumography (UPG) makes use of the scientific expertise gathered over decades of clinical research in expiratory CO_2 waveform analysis. The former approach of complicated synchronous recording

Fig. 8.7 Ultrasound pneumography in a child (ndd Medizintechnik, Zurich, Switzerland)

of spirometry in combination with fast gas analysis, mostly by demanding mass spectrometry, can be replaced by instantaneous and genuinely synchronous measurement of flow, volume, and molar mass in UPG. Although the determination of molar mass is complicated by the dependence on temperature and humidity, recent research indicates the clinical validity of *native* molar mass derived directly from uncorrected ultrasound transit times. The subject performs regular tidal breathing into the ultrasound sensor, without the need for any special breathing maneuvers (Fig. 8.7). Molar mass waveforms are averaged and analyzed, containing information about pulmonary gas distribution. Clinical studies [8.7, 8] confirm a high correlation with FEV_1 and $FEV_1/FVC\%$ as well as the degree of obstruction.

Resistance Measurements

Forced Oscillation Technique. Applied in various forms since the 1970s, this testing principle combines a flowmeter, an inserted resistive element, a pressure transducer, and an oscillation generator (loudspeaker) [8.9, 10]. Low-amplitude (*forced*) pressure oscillations by the loudspeaker are superimposed on the patient's tidal breathing, resulting in a phase shift orig-

inating from the respiratory tract. Resulting flow and pressure signals are differentiated from the originating patient signals, independent from the patient’s breathing pattern. The analysis yields impedance Z_{rs} with its components, resistance R and reactance X , which can be plotted in a frequency diagram. Today, this technique is most often found in a variation called *impulse oscillometry*, applied in geriatric, pediatric, and industrial medicine as well as in drug studies. This method, only requiring passive patient cooperation, i. e., tidal breathing at a mouthpiece, can complement standard pulmonary testing modalities and is suited for screening of obstructive disease [8.11]. Previous concerns about its technical complexity and limited hygiene have

been cleared with the advent of modern commercial instruments. However, technical complexity and cost still exceed that of conventional spirometry equipment.

Monofrequent Oscillatory Resistance Measurement. This much simpler version of the forced modality has been proven clinically over decades [8.12]. Instead of a loudspeaker a small sinusoidal pump is used, generating small pressure swings superimposed on the patient’s tidal breathing. Analysis of measured data again results in a phase diagram of resistance and reactance. In clinical practice, however, correlation with FEV_1 is just adequate, offering lower specificity and therefore only serving as an orientation or screening tool.

8.2 Advanced Cardiopulmonary Function Testing

8.2.1 Overview

In contrast to simple spirometry, advanced cardiopulmonary function testing requires a much higher level of methodology, instrumentation, and staff. This may be the reason why advanced testing can be found predominantly in internal and pulmonary departments of hospitals and specialized practices. Nevertheless, slow and forced spirometry will always remain the foundation of any type of pulmonary function instrumentation, particularly in all more complex or advanced pulmonary devices.

Among the more demanding modalities, body plethysmography takes a prime position, efficiently combining measurement of lung-volume subdivisions and airway resistance. Diffusion testing according to the *single-breath method* and determination of functional residual capacity (FRC) by N_2 washout are sometimes

preferred in English-speaking countries. Historically, *closed systems* with gas dilution methods were widely applied for FRC studies but have been replaced by more hygienic devices. Besides the before mentioned, an array of more or less complex modalities can be found but without broad clinical acceptance. An overview of the most important methods is given in Table 8.3.

Finally, cardiopulmonary stress testing or ergospirometry, investigating gas exchange under physical exercise, has (in combination with ECG) become an important tool in assessing and differentiating ventilatory and cardiac disturbances. Especially in medical opinions and ratings, e.g., regarding compensation claims, this objective method allows global appraisal and staging of performance reductions in cardiopulmonary disease.

During recent years, the interest in continuous measurement of physical activity and metabolic monitoring

Table 8.3 Procedures and parameters in advanced pulmonary function testing

Procedure	Main parameters	Derived parameters
Body plethysmography	Intrathoracic gas volume (IGV)	FRC, RV, TLC
Body plethysmography	Airway resistance R_{AW}	G_{AW} , sR_{AW} , sG_{AW}
Compliance determination	Static compliance C_{stat}	P_{mi}
Compliance determination	Dynamic compliance C_{dyn}	Work of breathing
Airway occlusion test	$P_{0.1} \cdot P_{max}$	
Single-breath diffusion test	Transfer factor T_{LCO}	K_{CO} , V_A , TLC_{SB}
Single-breath test with O_2	Membrane factor D_M	Capillary blood volume V_c
Intrabreath diffusion test	Co-diffusion D_{LCO}	Cardiac output Q_c
N_2 washout test	FRC	RV, TLC, distribution

has seen a tremendous rise. Practically all medical disciplines, from rehabilitation of obstructive patients to dementia prophylaxis, have recognized and published the invaluable importance of physical activity for improving, rehabilitating from, and particularly preventing disease. Despite a host of technical innovations facilitating its application, ergospirometry remains a demanding procedure in regards to test equipment, duration, and evaluation. This may be the reason why much more inexpensive portable devices have been developed for activity monitoring.

Medical technology, as a part of the information technology (IT) industry, undergoes the same fast-paced cycles in innovation and cost reduction that the microelectronics mass market exhibits. In the mid 1970s a computerized body box, as a body plethysmograph is called colloquially, sold for about €100 000. Today, almost 40 years later, a more operator friendly, even more accurate device can be purchased for less than €15 000. Practically all commercial instruments incorporate microelectronics, and a PC or notebook, most often implementing software under a certain operating system, featuring networking capabilities and data exchange to a hospital information system, together simplifying operation and enhancing laboratory productivity.

8.2.2 Body Plethysmography

Physical and Methodological Principles

A body plethysmograph, also called a whole-body plethysmograph or body box, consists of an airtight chamber, similar to a sealed phone booth, in which the patient is seated (Fig. 8.8). The thoracic movements created by the patient's breathing are transferred into volume and pressure swings inside the enclosure, which are measured and evaluated.

The foundations of modern body plethysmography, originally published by *DuBois* in the USA [8.13, 14] and *Ulmer et al.* in Germany [8.12], reach back to the 1950s, historically differentiating so-called constant-volume and constant-pressure modes. Applying the latter, the test person is seated in a chamber, breathing through a tube from and to the outside air, causing total thoracic volume displacements inside the enclosure. Today, virtually all commercially available body plethysmographs implement the constant-volume measuring principle, which seems to be technologically less demanding and clinically more reliable. In constant-volume mode, the subject breathes chamber air through a flowmeter and a fast-acting shutter valve. The goal of body plethysmography lies in the determination of (mean) alveolar pressure caused by compression

Fig. 8.8 Body plethysmograph (CareFusion 234, Höchberg, Germany)

and decompression of gas volume entrapped in the thorax. Note that this method captures the (small) compressible volume which, according to Boyle's law ($p \cdot V = \text{const}$), is proportional to alveolar pressure. Simultaneously with the compression of lung volume and the corresponding decompression of chamber volume, the alveolar pressure generates a flow and consequently a volume, which is measured at the mouth by the flowmeter. Thus, the thoracic movement causes a volume and proportional pressure change inside the lung, which is reflected by an identical volume and, again according to Boyle's law, a proportional pressure swing inside the chamber (Fig. 8.9).

In a procedure colloquially called *box calibration* the proportionality factor between chamber volume change and chamber pressure change is determined. Usually a small motorized pump is built into the enclosure, generating a constant stroke displacement, e.g., 50 ml, which is registered as a pressure swing. Calibration of the chamber is typically stable and does not require frequent checks.

Determination of Intrathoracic Gas Volume

When breathing against the shutter at the mouth, a thoracic volume change takes place, causing an alveolar pressure swing, as long as pressure equilibration between mouth and alveolar space can be assumed. When registering mouth pressure against box pressure during shutter closure, the (linear) relation between mouth pressure and box pressure can be established. This ratio of alveolar pressure to thoracic volume also enables the calculation of lung volume at the time and level of shutter closure, which is called the (intra-)thoracic gas volume (ITGV or IGTV).

$$\text{ITGV} = k_{\alpha} \cdot \frac{p_K}{p_M} \quad (1),$$

where p_K is the chamber pressure, p_M is the mouth pressure, and k_{α} is a constant that depends on the chamber volume, the body volume of the subject, and the barometric pressure.

When, during tidal breathing, the shutter is triggered at the end of a normal expiration, the ITGV corresponds to the functional residual capacity (FRC).

Determination of Airway Resistance

The so-called airway resistance loop can be graphed when the box pressure is registered against flow at the mouth during tidal breathing (Fig. 8.10). According to Ohm's law,

$$U = R \cdot I \quad \text{or} \quad p_{\text{alv}} = R_{\text{AW}} \cdot \dot{V} \text{ (hPa)},$$

Fig. 8.9 The volume-constant plethysmographic principle

from which airway resistance (R_{AW}) can be derived as

$$R_{\text{AW}} = \frac{p_{\text{alv}}}{\dot{V}} = k_{\beta} \cdot \frac{p_K}{\dot{V}} \left(\frac{\text{hPa}}{\text{l/s}} \right),$$

where p_{alv} is the alveolar pressure, \dot{V} is the flow at the mouth, p_K is the chamber pressure, and k_{β} is a factor comprising mainly the ratio of mouth over chamber pressure established during the shutter manoeuvre.

Technical Characteristics of Body Plethysmography

In tidal breathing, the chamber pressure changes are fairly small, only a few hPa (or cmH_2O). Disturbances caused by a patient-related temperature increase within the chamber (body heat), by breathing-related air temperature and humidity changes, and by pressure changes related to external pressure variations, to mention just a few, can be significant and may accumulate to an error greater than the sensed measuring signal. To attain adequate pressure equilibration between mouth and alveolar space, panting during the shutter maneuver should be avoided [8.15].

The construction characteristics of the body plethysmograph chamber are essential to ensure good measuring quality. Some of these features are:

- Rigidity of the enclosure
- Heat transfer characteristics of the chamber walls
- Built-in equilibration vessel
- BTPS compensation
- Calibration unit

Fig. 8.10 Screenshot of a body plethysmographic test including airway resistance and shutter loops (Ganshorn Medizin Electronic, Niederlauer, Germany)

- Adjustment of a defined leak
- Type and speed of the shutter assembly.

The following remarks, although not exhaustive, should be made in this context. The enclosure should be constructed in a shape and from materials which ensure solid rigidity and fast heat transfer of the temperature rise caused by the patient. An equilibration vessel for common mode rejection of externally transmitted pressure artifacts should be built into the enclosure (Fig. 8.9). An automatic box calibration pump for dynamic simulation of thoracic volume compression and an adjustable defined leak (pneumatic low-pass filter for drift compensation) are indispensable for quality assurance. In a modern box, pressure- and flow-related BTPS compensation is carried out digitally. The resistance of a breathing filter must be considered when airway resistance is determined.

If the above-mentioned peculiarities are accounted for, body plethysmography can be implemented into clinical routine efficiently, offering fast and stable test results.

Technical service requirements for a body plethysmograph enclosure are relatively few. Except for mouthpieces and breathing filters, no other disposable

material is needed. Improving hygienic requirements, modern shutter assemblies can be disassembled easily. Use of breathing filters is recommended.

A complete body plethysmographic evaluation of a patient, including repeated determination of resistance and ITGV, will take about 15 min, and in combination with spirometry determining lung-volume subdivisions, less than 30 min.

Clinical Value of Body Plethysmography

As described above, body plethysmography offers determination of airway resistance and intrathoracic gas volume in a single testing procedure. Fairly independent from patient cooperation, the test can be repeated several times, representing a truly fast and efficient modality to measure the most important parameters of pulmonary function. The full spectrum of relevant pulmonary diagnostic information can be assessed by body plethysmography when combined with slow and forced spirometry and recording of flow–volume loops, which can be carried out while the enclosure door remains open, and with testing of other parameters, such as lung compliance or diffusion transfer factor, in case an additional diffusion assembly is built in.

Airway Resistance

According to *Ulmer* et al. [8.12] and *Matthys* [8.16], airway resistance can be determined as R_{tot} or R_{eff} , offering a sensitive measure of bronchial obstruction. With high sensitivity, these parameters do not only reflect reduction in cross-section but also dynamic compression of instable airways and reduced lung elasticity (loss of retraction). Shape analysis of resistance loops enables differentiation of homogeneous obstruction (e.g., bronchitis) from inhomogeneous obstruction (e.g., emphysema), therefore documentation of resistance loops is mandated.

Intrathoracic Gas Volume/FRC

Besides FRC, intrathoracic gas volume comprises all gas compartments compressed during the shutter maneuver, also trapped air in the lungs as well as abdominal gas. This method is certainly false positive in highly obstructive patients when pressure equilibration between mouth and alveolar space cannot be attained. In contrast, the dilution and foreign gas methods will be false negative, underestimating lung volume, which tends to increase in the presence of severe obstruction. Because of its accuracy and high reproducibility, body plethysmography is considered a gold standard in lung volume assessment. Combining ERV and VC obtained during spirometry with ITGV/FRC, all volume subdivisions including RV and TLC can be determined in one sequence.

8.2.3 Diffusion Capacity

Gas exchange between alveolar space and capillary blood, i.e., the transfer of gas over the alveolar-capillary membrane, is called pulmonary diffusion. The diffusion capacity of a gas is defined by the amount of gas per unit of time exchanged over the membrane and the partial pressure difference between gas and blood phase. As the oxygen capillary partial pressure is inaccessible to noninvasive testing, the diffusion capacity of oxygen cannot be assessed. Instead, the diffusion capacity for carbon monoxide (CO) is measured. Only low concentrations of CO in the ppm range are added to the inspiratory air, as CO has high affinity to hemoglobin and patient exposure to CO should be minimized.

Single-Breath Method

For decades the single-breath method, originally developed by *Cotes* [8.17], has found broad acceptance. This modality does not assess diffusion capacity itself but the so-called transfer factor for CO (TLCO). Af-

ter a deep exhalation, the patient inhales a gas mixture of air, 0.2–0.3% CO, and a low concentration of an inert gas, usually helium or methane. At full inspiration, the patient holds his breath for ≈ 10 s, allowing the gas mixture to distribute in the alveolar space. While the inert gas resides in the lung, CO will pass the alveolar-capillary membrane into the blood. After the breath-holding period, the patient exhales, and the first part of the expired air is discarded, while the center part is collected (Fig. 8.11). In more modern devices featuring fast gas analysis, the gas is analyzed continuously, and the gas concentrations of the center part are averaged. In both cases the center part is considered representative as an alveolar sample. The inert gas, not taking part in gas exchange, is diluted in the lung, characterizing the ventilatory distribution. Assuming that CO is diluted at the same rate as the inert gas, the diffusive part of the CO concentration can be estimated. The transfer factor is determined by applying an exponential decay model of alveolar CO concentration during the breath-holding period. If the initial capillary CO concentration is assumed to be zero, the transfer factor can be derived as

$$T_{\text{LCO}} = b \cdot \frac{V_A}{t_v} \cdot \ln \left(\frac{F_{\text{ACO0}}}{F_{\text{ACO}}} \right) \left(\frac{\text{mmol}}{\text{min} \cdot \text{kPa}} \right),$$

where

$$F_{\text{ACO0}} = F_{\text{ICO}} \cdot \frac{F_{\text{AX}}}{F_{\text{IX}}}.$$

F_{I} is the inspiratory gas concentration, F_{A} is the alveolar concentration of the expiratory gas sample, X is an index representing the inert gas, F_{ACO0} is the initial alveolar concentration of CO, V_{A} is the alveolar volume, t_v is the breath-holding time, and b is a constant for conversion of dimensions. Besides T_{LCO} , the alveolar volume V_{A} can be calculated from the dilution of the inert gas by using the same data as above, i.e.,

$$V_{\text{A}} = (V_{\text{IN}} - V_{\text{D}}) \left(\frac{F_{\text{IX}}}{F_{\text{AX}}} \right) (l),$$

where V_{IN} is the inspired volume prior to breath holding and V_{D} is the dead space volume consisting of anatomical and apparatus dead space. All volumes are reported in BTPS. Combining spirometry with V_{A} , RV and TLC can be derived.

Technical Characteristics of the Single-Breath Method

The technical complexity of this modality should not be underestimated, as it requires a flowmeter, analyzers for CO and the inert gas, and a valve system for switching

Fig. 8.11 Screenshot of a single-breath test (Care-Fusion 234, Höchberg, Germany)

from air to the gas mixture as well as for sampling of the alveolar gas.

Quality assurance programs could show that the quality of results depend – besides technical insufficiencies – mainly on correct operation and calibration. Avoiding frequently occurring errors, special care should be taken regarding:

- Correct and fast-acting valves
- Frequent calibration of gas analyzers with certified test gas
- Optimum patient instructions
- Performance of test according to recommendations of the European Respiratory Society [8.18].

Smokers and workers exposed to CO have higher arterial CO partial pressure, a so-called back pressure, which should be analyzed and considered in the calculation of alveolar partial pressure. If the hemoglobin content of the subject deviates from the normal range, a correction should be made when calculating the TLCO.

The test should be carried out in a sitting position.

In most cases, cleaning of the valve system is difficult, sometimes impossible, requiring the use of a breathing filter in compliance with hygiene standards. The technical service requirement for diffusion testing devices must not be underestimated, especially when complex breathing and analyzer valve systems are em-

ployed. The cost and supply logistics of testing and calibration gas should also be considered. A complete single-breath test including calibration will only need a few minutes.

Clinical Value of the Single-Breath Test

Implemented in routine clinical testing, determination of TLCO by the single-breath technique is simple and fast. When the above-mentioned errors are avoided and patients well instructed, results show acceptable accuracy and good reproducibility. The TLCO parameter does not only react to impairments of diffusion capacity in the sense of gas exchange over the alveolar-capillary membrane, but also to structural changes of lung tissue, independent from their cause, which might be either an increase or a reduction of alveolar space. A reduced TLCO cannot only be found in interstitial lung disease such as pulmonary fibrosis, sarcoidosis, alveolitis, or lung edema, but also in generalized emphysema, often characterized by loss of lung surface and increase of alveolar space. A normal or moderately reduced TLCO can also be seen in airway obstruction, while an increased TLCO may indicate obstructive hyperinflation, as attributed to asthma. Also intrapulmonary bleeding may lead to elevated TLCO levels.

TLCO is well suited for follow-up studies and therapy control and may be used as an additional parameter in the assessment of pulmonary–vascular disorders. Due

to its complexity, application of TLCO in screening may be limited to specialized studies, e.g., in workers exposed to dust. In a variation of the single-breath method using a mixture of CO, inert gas, and oxygen the diffusing capacity of the alveolar–capillary membrane, the so-called membrane component, and the capillary blood volume can be assessed, an application that might be confined to more specialized laboratories.

Additional Methods in Diffusion Assessment

During recent years, in addition to the classical modality described above, the IntraBreath method was introduced, featuring a single deep inhalation but no breath-holding before exhalation, certainly advantageous in children and dyspneic patients. Using fast infrared gas analyzers for continuous reading of low-dose CO, (inert) methane, and diffusible acetylene (soluble in blood), the capillary cardiac output can be determined in combination with the TLCO. The test can also be carried out under exercise.

Due to its high patient exposure to CO, the previously used steady-state method has been abandoned. In addition to the TLCO test mentioned, a variety of other diffusion modalities exist, in particular those using the rebreathing technique. Nevertheless, their applicability in a regular laboratory and their international recognition might be limited.

8.2.4 Nitrogen–Washout Test for Determination of FRC

Widely applied for decades in the English-speaking world, this modality requires a valve and gas delivery system to allow inspiratory switching from air to pure oxygen. With each inhaled breath of oxygen, nitrogen present in the lung, not participating in the gas exchange, will be replaced. Continuous gas sampling at the mouth by either a single N₂ or combined O₂/CO₂ analyzer allows determination of expired nitrogen volume during the N₂-washout procedure. Accumulated nitrogen volume is calculated breath by breath until the N₂ concentration falls below 1%, marking the end of the washout sequence. Before the start of the washout, the N₂ concentration (including rare inert gases) is 79.2%, which allows the functional residual capacity (FRC) to be derived as

$$\text{FRC} = \frac{V_{\text{N}_2}}{0.79}(I).$$

For standardization of lung volume determination by N₂ washout refer to [8.4].

Technical Characteristics of the N₂-Washout Method

Historically, this method required a fast N₂ analyzer or a mass spectrometer, both expensive and demanding in operation and service. Nowadays, with the advent of fast-response combi-analyzers, the complementary gases O₂ and CO₂ can be determined instead of N₂, involving less complex and expensive technology. However, this novel approach makes synchronization of digitized gas samples necessary. As most analyzers draw a side-stream gas sample from the mouth, causing a delay between gas sample and flow, the response characteristic of the analyzer needs adjustment and correction. In a dedicated calibration routine the operator should be offered verification of the response compensation. The valve systems employed in N₂ washout are similar to those used in diffusion testing, compromising hygiene unless a breathing filter is used.

The test duration of FRC determination by N₂ washout depends on the lung distribution of the subject, taking a few minutes in a healthy and more than 20 min in a severely obstructed individual.

While classical N₂-washout devices use side-stream gas sampling, the novel ultrasound molar mass spirometry offers a less complex clinical approach with instantaneous gas analysis (Sect. 8.1.2, Fig. 8.5). The ultrasound sensor is able to determine both flow and molar mass, the specific weight of the gas, with a single transducer in the main stream of the respired gas. As molar masses of O₂ and CO₂ are distinctively different, the N₂ concentration of the breathing gas can be assessed instantaneously and synchronous to flow and volume changes [8.19].

8.2.5 Ergospirometry

Ergospirometry serves as the most prominent method to determine ventilation and gas exchange under physical exercise, in the English-speaking world often referred to as cardiopulmonary stress testing. A complete instrument (Fig. 8.12) consists of:

- A device producing a defined level of physical stress (ergometer)
- A transducer for measurement of ventilation
- Gas analyzers for O₂ and CO₂
- A computer for online processing of measured data, as well as
- A multichannel electrocardiograph (ECG).

For physical exercise, usually a bicycle or treadmill ergometer (Sect. 8.2.5) will be employed. Specialized

Fig. 8.12 Ergospirometry system (Medgraphics, St. Paul, USA)

Fig. 8.13 Portable ergospirometry system (CareFusion 234, Höchberg, Germany)

ergometers such as cranking or rowing ergometers will be applied in industrial and sports medicine (Fig. 8.13).

Measurement of Ventilation

In ergospirometry, flowmeters using varying measuring principles can be applied, including pneumotachographs, turbines, thermistor mass flowmeters, and ultrasound flowmeters. Calibration or verification of flow transducers before each test seems indispensable. The relative error of flow measurement should not exceed 3% of reading; the linearity in the measuring

range should be within 2% of reading. For clinical purposes the range should cover at least 100 l/min, and for sports medical purposes up to 200 l/min. As the temperature in fully water-saturated expired air drops, humidity falls out and may cause erroneous reading in water-sensitive flow sensors. Supporting natural breathing through mouth and nose, a breathing mask should be used. The weight of the flowmeter should be as low as possible to allow direct docking of the flow transducer to the facemask.

Gas Analysis

Historically, mass spectrometry has been referred to as the gold standard in gas analysis, as all breathing gas concentrations, namely those of O_2 , CO_2 , and N_2 , can be measured quickly, synchronously, and with high accuracy. As this technology requires a large investment, continuous upkeep, voluminous space, and complex handling, its clinical application has become a rarity. Today, compact to mini-sized gas analyzers are integrated into one instrument together with other electronic components. As the response and delay of gas analyzers vary widely, a compensation algorithm is implemented in the ergospirometry software to allow for precise synchronization of all signals.

Paramagnetic or fuel cells (zirconium oxide tube) are the prevalent principles in oxygen analysis, while CO_2 is determined by means of selective infrared analyzers. The absolute error of gas analyzers should not exceed 0.1% within the measuring range; linearity should lie within 1% of reading. Before each test, the calibration of gas analyzers with certified calibration gas at two concentration levels representing inhaled and

expired air is indispensable for assurance of highly precise results. Modern ergospirometry systems contain a software-controlled module for automatic calibration and verification.

Mixing Bag Method

Reference to this method is made for didactic reasons only, as practically all presently available instruments work with the breath-by-breath method. The older mixing method separates inspiratory and expiratory air of the subject by use of a so-called Y-valve. The expiratory gas is collected in a mixing bag, from which a continuous sample is drawn and analyzed. The flowmeter is mounted on the expiratory side at the entrance port of the mixing bag, allowing determination of expiratory tidal volume and minute ventilation. Oxygen uptake \dot{V}_{O_2} can be calculated according to

$$\dot{V}_{O_2} = c \cdot V_E (F_I O_2 \cdot k_S - F_E O_2) (1/\text{min}),$$

where k_S is the so-called shrinking factor given by

$$k_S = \frac{(100 - F_E O_2 - F_E CO_2)}{(100 - F_I O_2)},$$

where V_E is the expiratory minute ventilation, and F_I the inspiratory and F_E the mean expiratory concentration of O_2 and CO_2 , respectively. Additionally a factor for the conversion from BTPS to standard temperature pressure dry (STPD) conditions has to be considered.

CO_2 output can be calculated accordingly. Response of gas analyzers or delay of the gas sample are of lesser importance as the gas mixing introduces a fairly high time constant. For decades, this modality has proven its clinical reliability. Due to its inability to follow physiological responses to changing exercise levels instantaneously, the mixing bag system has all but been replaced by the breath-by-breath method.

Breath-by-Breath Method

In the breath-by-breath (B×B) mode, flow is continuously measured at the mouthpiece or a breathing mask. A continuous gas sample is drawn as proximal as possible through thin moisture-absorbing tubing and analyzed by fast-response gas analyzers. Flow and gas concentrations need to be synchronized and precisely brought into phase. Also, the response of each analyzer needs software correction. The oxygen uptake is calculated according to

$$\dot{V}_{O_2} = \int F O_2 \cdot \dot{V} dt (1/\text{min}),$$

where \dot{V}_{O_2} is the oxygen uptake, $F O_2$ is the O_2 concentration or fraction, and \dot{V} is the flow at the mouth. Additionally factors for conversion from BTPS to STPD must be applied by the software. The CO_2 output is computed accordingly.

As elegant as it seems, the B×B method can bring about inaccuracies and errors which need to be addressed by the operator and can only be avoided by frequent calibration and consequent verification, including precise analyzer delay adjustment. Equipment operators should demand validation and documentation of implemented algorithms from the manufacturers or suppliers of ergospirometry systems. Therefore, an *open* structured software showing the delay and response adjustment of the analyzers in real time, offering step-by-step procedures for calibration and verification, facilitates quality assurance.

Clinical Value of Ergospirometry

Modern ergospirometry is based on the work of *Hollmann* and *Wasserman* [8.20].

For clinical purposes, physical exercise is increased stepwise, e.g., using a bicycle ergometer, by increments of 25 W of 2–3 min each. This form of exercise is well suited for patients, allowing the cardiovascular system sufficient time to adapt to the exercise level, while avoiding muscular fatigue, anaerobic metabolism, and lactate production.

As a valid measure of global physical performance, oxygen uptake directly relates to the interrelated organ system of heart–lung circulation, while the maximum oxygen uptake or *vita maxima* offers an objective assessment of the maximal performance capacity of the test subject. By visualizing the dynamics of ventilation, gas exchange, and heart rate, the latter derived from ECG, reduced capacity of each involved organ may be determined and differentiated from a limited degree of motoric efficiency [8.21]. Secondary parameters such as respiratory ratio and breathing equivalent (Table 8.4) as well as exercise-related blood gases assist in detecting compensation mechanisms and evaluating deficiencies even at submaximal stress levels.

The determination of the aerobic–anaerobic metabolic transition, briefly called the anaerobic threshold, plays an important role in assessing and following the effects of training in rehabilitation and fitness centers. After addition of blood gases and blood pressure data, a conclusive report of ergospirometry test results is best given in graphical format, e.g., in the nine-field graph according to *Wasserman* [8.20].

Table 8.4 Parameters in ergospirometry

Parameter	Abbreviation/definition	Unit
Load (bicycle ergometer)	P	W
Speed (treadmill ergometer)	v	km/h
Elevation (treadmill ergometer)	s	%
Tidal volume	VT	l
Respiratory rate	R_f	/min
Minute ventilation	V_E	l/min
Oxygen uptake	VO_2	l/min
Carbon dioxide output	VCO_2	l/min
Heart rate	HR	min ⁻¹
Respiratory ratio	$R_Q = VCO_2 / VO_2$	–
Breathing equivalent (for O ₂)	$E_{QO_2} = V_E / VO_2$	–
Breathing equivalent (for CO ₂)	$E_{QCO_2} = V_E / VCO_2$	–
Oxygen pulse	$VO_2 \text{Pulse} = VO_2 / \text{HR}$	ml/(min kg)
Alveolar-arterial difference	AaDO ₂	mmHg
Functional dead space	V_{Dr}	%

For assessments in compensation claims and other rating cases, in particular in industrial medicine, ergospirometry is the tool of choice when an objective measure of reduced capacity is required. Also in the assessment of athletes, an ergospirometry system represents a valuable instrument which can be found in most sports medicine centers today.

A minimum of 30 min should be considered for performing a complete stress test, including patient preparation, calibration, and evaluation of data.

8.2.6 Noninvasive Determination of Cardiac Output

While ergospirometry allows only indirect assessment of cardiac function, oxygen uptake can be instrumental in determining cardiac output through the Fick equation

$$\dot{V}O_2 = Q_t \cdot avDO_2 \text{ (l/min) .}$$

The arterio-venous O₂ content difference, which is an effort-dependent variable, requires invasive assessment by catheterization.

One of the internationally recognized noninvasive standards to determine cardiac output is the so-called CO₂-rebreathing method, an application of the Fick equation above to carbon dioxide rather than to oxygen

$$Q_t = \frac{\dot{V}CO_2}{avDCO_2} = \frac{\dot{V}CO_2}{(C_vCO_2 - C_aCO_2)} \text{ (l/min) ,}$$

where $avDCO_2$ is the arterio-venous content difference, and C_vCO_2 and C_aCO_2 are the mixed-venous

and arterial content of CO₂ in blood. Figure 8.14 depicts schematically the interaction of heart, lungs, and circulation.

Estimation of the terms in the latter equation requires a CO₂-rebreathing module as an expansion to a regular ergospirometry system. During rest or physical exercise the subject breathes through a valve box to which a bag is attached. The bag is filled with a mixture of CO₂ and oxygen gas, where the CO₂ partial pressure in the bag approximates the mixed-venous partial pressure of the subject at the current exercise level. Initially, the valve box allows the subject to breathe ambient air, just like during a regular exercise test, while CO₂ output is measured. Still under air breathing, a micro blood sample is

Fig. 8.14 The Fick principle. The diagram schematically depicts the interaction of heart, lungs, and circulation (RH right ventricle, LH left ventricle, MV minute ventilation, VCO_2 CO₂ output, Q_t cardiac output, $pvCO_2$ mixed venous partial pressure of CO₂, $paCO_2$ arterial partial pressure of CO₂). For explanation refer to text

drawn from the subject's ear lobe and analyzed, yielding the arterial partial pressure $p_a\text{CO}_2$. From a digital dissociation curve, the arterial CO_2 content C_aCO_2 is derived. If micro blood gas analysis is not available, $p_a\text{CO}_2$ can be estimated from the reading of the end-expiratory CO_2 partial pressure $p_{\text{et}}\text{CO}_2$, an acceptable approximation in healthy subjects. After switching the subject's breathing to the bag at the end of an expiration, the CO_2/O_2 gas mixture is inhaled. While rebreathing to and from the bag continues for several breaths, CO_2 partial pressure will equilibrate between the lung and the bag as long as a constant $p_v\text{CO}_2$ is delivered from the right heart and no recirculation occurs. Only a few rebreathing breath cycles are needed to reach a CO_2 equilibrium, which is monitored, and the mixed-venous partial pressure determined. Applying a digital dissociation curve, the C_vCO_2 content is derived, the last component in the noninvasive determination of cardiac output.

The CO_2 -rebreathing method is a very elegant procedure, bearing no risk for the subject while requiring little cooperation. Its accuracy compares well with that of invasive methods [8.22]. In contrast to most of the catheter procedures, the rebreathing method will only determine pulmonary cardiac output without right-to-left shunt. While the expansion module for an existing instrument may not be very complex, the software upgrade will determine the cost.

8.2.7 Metabolic Activity Monitoring

Although portable ergospirometry systems have seen a lot of progress in size and versatility (Fig. 8.13), their application in normal everyday life and at the workplace is still very limited. The biggest obstacle seems

the restriction in testing time, as a subject cannot wear a face mask or use a mouthpiece for much more than several hours. During the last decade, improved diagnostic solutions were researched, offering assessment of physical activity over a longer period of time, up to several days, without restricting the subject in conducting a normal life. In addition the devices should be small, lightweight, and inexpensive. Even if the precision of ergospirometry is not reached with such a device, physical activity or energy expenditure in total calories spent, equivalent to oxygen uptake, should become available. Several categories of instruments based on the evaluation of heart rate (training watch), steps (pedometer), or acceleration in three axes (accelerometer) have come onto the market. Depending mostly on activity itself, these principles show good correlations with energy expenditure at moderate to high activity levels, but poor agreement in sedentary conditions in which most of our everyday life takes place. A novel multisensory device worn on the upper arm (Fig. 8.15) captures several physiological parameters, such as acceleration, and skin and ambient temperature, but also heat flux from the body and skin impedance. Employing artificial intelligence for the evaluation of raw data, energy expenditure under exercise as well as at low-level activity, rest or sleep can be assessed with reasonable to good accuracy. Data are recorded continuously for up to 3 weeks, offering a complete image of the subject's lifestyle, documenting the activity-inactivity profile minute by minute. Particularly appreciated in medical research and drug studies, the device cannot be manipulated as it turns recording on when worn and turns off when not in skin contact. Due to its small size and low weight, the wearer will forget about the moni-

Fig. 8.15a,b Metabolic armband monitor for determination of physical activity (Bodymedia, Pittsburgh, USA)

tor on his arm and just pursue his daily routine. A broad literature base supports its application in different areas of pulmonary medicine, particularly severe chronic obstructive pulmonary disease (COPD) [8.23] and cystic fibrosis [8.24] where activity is an important outcome parameter.

8.2.8 Planning and Laboratory Space Considerations

The laboratory room in which a body plethysmograph will be installed does not need to be particularly spacious but should be in a quiet location, separated from

any through traffic. Big windows adjacent to the body box may lead to pressure artifacts caused by wind gusts or sun exposure. The diffusion test can be performed in the same room as the body plethysmograph or with an add-on unit within the chamber while the box door is open. N₂-washout devices or spirometers can be placed in a laboratory room or on a trolley for mobile use.

In contrast, ergospirometry requires a spacious room with good ventilation, in particular when a treadmill or ergometer, blood gas analyzer or other laboratory equipment should be placed in the same room. A changing room and a shower should be available for the test subjects.

9. Devices and Methods in Clinical Neurophysiology

Devices and

Klaus-Peter Hoffmann, Ursula Krechel

Methods in clinical neurophysiology, such as electroencephalography (EEG), electromyography/electroneurography (EMG/ENG) and the recording of evoked potentials (EP) enables the physician to evaluate the function of the central and peripheral nervous system as well as the muscular system. Thus bioelectrical potentials are recorded via measuring techniques, amplified, stored, analyzed, and evaluated. The measuring devices used for functional diagnostics are called the electroencephalograph and the electromyograph. Their respective construction and their function as well as their most widespread clinical applications are described in this chapter.

9.1 Basics

Excitable cells react to a stimulus with changing membrane characteristics. If a sensitive living cell is stimulated, the ion conductivity on its membrane is changed. The consisting resting membrane potential (50–100 mV) can grow to an action potential that is conducted via the nerve cell and leads to a muscle contraction. The motor neuron with all its related muscle fibers form a motor unit. The number of muscle fibers supplied by a motor unit differs to a great extent and contains 5 fibers in an eye muscle up to 1000 in the temporal muscle.

9.1.1 Neurophysiological Basics

The Nervous System

The central nervous system (Fig. 9.1) consists of the brain and the spinal canal. This is the central part of the total nervous system and displays a complex information processing system. The information perceived by the sense organs (9 bit/s) are decreased during

the signal processing to the central nervous system by inhibitory and excitatory circuits on the synapses to 10^1 – 10^2 bit/s. After the processing and analysis they are transformed into reactions such as motion, behavior, or organic activity. The function of the brain is not only reduced to voluntary movement, but includes emotions and abilities of the mind such as remembrance and learning.

Different levels of the central nervous system participate in the control of the vegetative nervous system.

- The limbic system for the control of the emotional drives.
- The hypothalamus for the homeostatic regulation.
- The medulla oblongata for the control of the sympathetic tone.
- The spinal cord for the spinal reflex circuit.

The peripheral nervous system (Fig. 9.1) consists of all nerves and ganglia outside of the central nervous

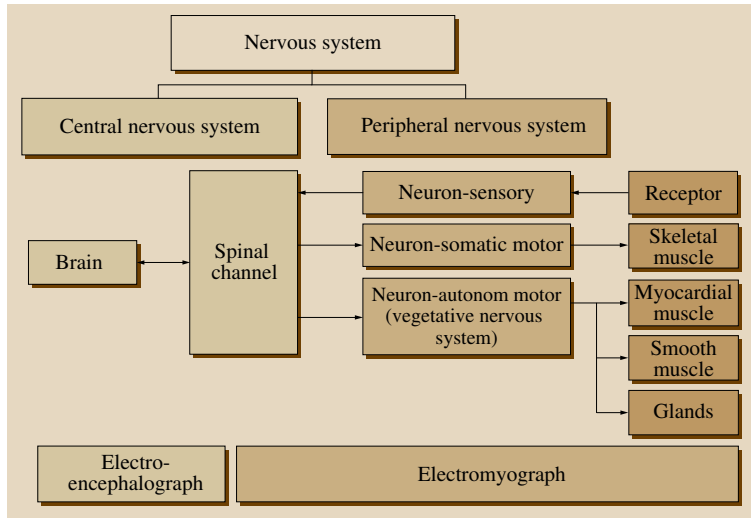

Fig. 9.1 Scheme of the central and peripheral nervous system and the application area of EEG and EMG

system. The efferent (motor) pathways innervate the skeleton muscles. The afferent (sensory) pathways conduct the stimulation from the corporal periphery to the skin receptors and the inner organs to the central nervous system.

The vegetative nervous system or the autonomous nervous system (Fig. 9.2) is a part of the peripheral nervous system. It controls the function of the organs and adapts them to their respective needs and supervises the inner milieu of the corpus. These activities function mostly unconsciously and cannot be influenced by vol-

untary control. Examples for controlled vital functions are heart beat, respiration, blood pressure, digestion, and metabolism.

The vegetative nervous system can be subdivided into three groups.

- Sympathetic: increasing performance (ergotropic)
- Parasympathetic: predominantly sustaining performance (trophotropic)
- Enteral: nervous system of the gastrointestinal tract, mostly independent from the central nervous system.

Fig. 9.2 Methods in clinical neurophysiology for the diagnostics of functional disturbances of the central and peripheral nervous system as well as the muscular system

The Muscular System

Skeletal muscles (Fig. 9.1) are able to transform chemical energy ATP directly into mechanical energy and heat. They are innervated voluntarily via motor neurons. A contraction is exclusively triggered via action potentials at the motor endplate. A significant attribute of the skeletal muscle cells are striated myofibrils with a regular succession of dark anisotropic (A-stripes) and light isotropic (I-stripes) bands.

Muscle types that are not striated are called smooth muscles (Fig. 9.2). They consist of long spindle-like cells and are loosely arranged and therefore moveable. Smooth muscles coat the inner organs such as the stomach or intestines as well as the walls of blood vessels. Smooth muscles have their own system of innervations and are involuntarily innervated by the vegetative nervous system. They carry out relatively slow movements, but have very little fatigue and are able to develop great force over quite a long time.

The heart muscle has striated and smooth musculature with its own system of innervation and is controlled involuntarily by vegetative nerves.

The Formation of Resting and Action Potentials

Different distribution of ions on the inside and outside of living cells creates a membrane potential on the cell membrane. This is continuously fed by active transport mechanisms (ion pump). The concentration of K^+ ions inside the cell is 30 times larger than outside, e.g. the inner cell in an unexcited state has a negative charge in relation to the outer fluid. The amount of this charge distortion depends on the membrane capacity.

The action potential is a voltage change on the membrane of living cells created by a cell stimulation above threshold. It performs a change in ion conductivity on the stimulated membrane and consists of three phases: brief depolarization, slow repolarization, and successive hyperpolarization. The duration of the action potential depends on temperature and the respective cell type. Motor nerves transmit the action potential along the axon, thus causing the muscle to contract.

Transmission of the Action Potential

Nerve impulse transmission differs fundamentally according to the kind of nerve fiber. Myelinated nerve fibers perform a saltatory conduction and in unmyelinated fibers they transmit impulses smoothly or continuously.

Myelinated fibers consist of axons coated by myelin, which produces an isolating effect. This myelin sheath is interrupted by nodes of Ranvier. Accordingly

nerve impulse transmission jumps from node to node over a distance of 1–2 mm, thus reaching velocities up to 120 m/s.

Neuromuscular Transition

The stimulus from one nerve cell to the next or from the nerve to the muscle is transmitted via synapses. Synapses are distinguished by electrical or chemical conduction as well as by their excitatory or inhibitory effect. The chemical conduction is carried out by transmitters. Excitatory synapses, for example, release acetylcholine, adrenaline, nor-adrenaline, and serotonin, thus creating an excitatory postsynaptic potential (EPSP). Inhibitory synapses release inhibitory transmitters like, GABA thus creating an inhibitory postsynaptic potential (IPSP). A possible transmission of nerve impulses results from a summation over time and area of the excitatory and inhibitory effects of the different singular synapses.

A neuron transmits a nerve impulse to a muscle via the motor endplate. Arriving action potentials release acetylcholine, thus producing a depolarization of the endplate. Above a certain critical threshold the muscle membrane is innervated and the muscle fiber contracts. Acetylcholine is split by cholinesterase, thus producing a repolarization of the endplate, after which the initial state is reached again and is ready for a new innervation.

9.1.2 Technical Basics

The methods in clinical neurophysiology match with the spectrum of diagnostic procedures (Fig. 9.2). They complement the diagnostic findings on the basis of the anamnesis and the clinical examination, such as other diagnostic methods like laboratory diagnostics, imaging and functional diagnostics. The total view over all the necessary evaluations and findings brings the physician to the final diagnosis and thus to the therapy. Therapy control and prognostic statements reach objectivity by additional monitoring.

In clinical neurophysiology signals of electrical potential differences are evaluated. They are recorded with needle and surface electrodes. These signals are detected via measuring techniques, which are preprocessed and amplified. The respective amplifier sensitivity and bandwidth depends on the specific recording signal. These biological signals may perform amplitudes from a few microvolt up to millivolts and frequencies from direct voltage up to 30 kHz. Differential amplifiers process and record the data using various

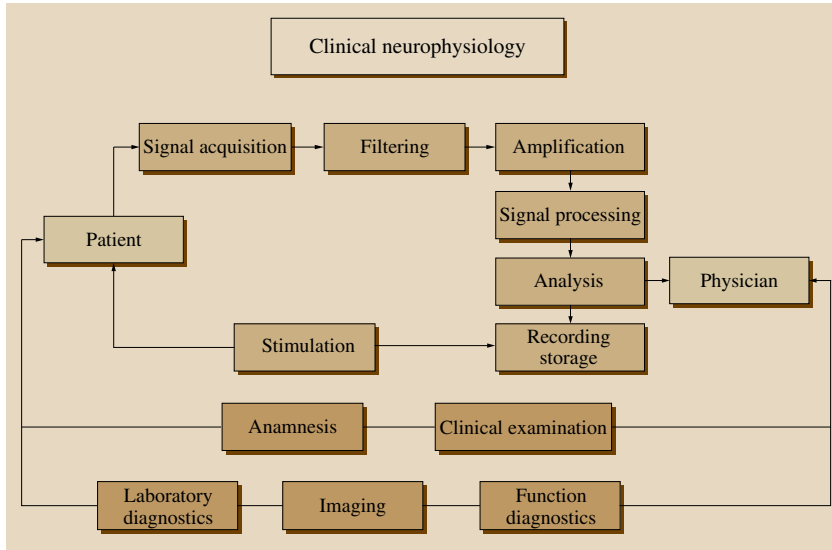

Fig. 9.3 Measuring technique for the recording of bioelectrical potentials in clinical neurophysiology in the process of diagnostic findings

different settings of sensitivities and frequency bands. The signals are evaluated visually as well as computer aided, also providing data storage facilities. The evaluation of the specific signals is supported via software adapted to the various diagnostic problems. The final diagnostic result always lies in the hands of the physician. Patient data, raw signals, analysis results, and findings are stored and printed out. In various diagnostic methods certain stimuli are applied to the patient, such as photostimulation, in the recording of evoked potentials, and in the evaluation of the nerve conduction velocity. In this case, the onset of the stimulus triggers the recording of the evoked action potentials. Different stimulators are applied for various investigations such as electrical, acoustic, optic, and magnetic stimulators (Fig. 9.3).

The purpose of signal recording, filtering, amplification, and evaluation is to record and store the data faultlessly. Reproducibility of the results is ensured by double recording e.g. in evoked potentials. The signal recording is reactionless, which means that the measurement itself does not influence the measuring values or the signal.

Electrodes

Electrodes are the interface between the biological tissue and the technical device. They make direct contact with the skin of the body via electrolytic layers (surface electrodes) or needle electrodes, which are inserted under the skin (subcutaneous) or into the muscle (intramuscular) like a cannula. Various kinds of electrode

forms and materials are available depending on the application.

From the electrical point of view electrodes may be displayed as an electromotive force and a network of capacitors and resistors. Their components depend on the electrode material, the electrolytes, the geometry, the current density, and the signal frequency. In a simplified manner the equivalent circuit diagram in Fig. 9.4 can be applied. In this case, E_p means the polarization voltage, C_{tr} the capacitor part of the transition resistance (Helmholtz capacitor), R_{tr} the Ohm resistor part of the transition resistance (Faraday resistance), and R_e the electrode resistance. The Helmholtz capacitor is directly proportional and the Faraday resistance is indirectly proportional to the recording area.

If a metal electrode is put into an electrolytic solution, positively charged metal ions are released into the solution caused by the solution pressure. The osmotic pressure and the field force of the electrical field react against it. This leads to an electrical charging of

Fig. 9.4 Equivalent circuit diagram of a recording electrode

Fig. 9.5 Characteristics of 128 Ag/AgCl electrodes over a time period of 10 days. Display of mean values of the absolute value of the impedance of all electrodes as function of the signal frequency

the electrode and to a layer of opposite charge within the molecular distance of the phase limit. This so called Helmholtz double layer acts like a capacitor within a molecular plate distance, where the plate voltage is seen as an electromotive force and is called Galvani's voltage.

Pure metal electrodes are therefore called polarizing electrodes. If these metal electrodes are coated with an antisoluble salt (e.g. Ag with AgCl), where the same anion must be found in the electrolyte (e.g. in NaCl), then nonpolarized electrodes with much less and more stable Galvani's voltage are achieved. Figure 9.5 displays the characteristics of sintered Ag/AgCl electrodes over a time period of 10 d. An excellent long-term stability and a broad bandwidth down to the low frequency range of these materials are clearly shown. Therefore, Ag/AgCl electrodes are applicable for almost all signals in clinical neurophysiology.

Bipolar Recording

The bipolar recording method is very often applied in clinical neurophysiology for the measuring of bioelectrical potential differences. Two similar electrodes are placed on bioelectrical active areas. Each electrode is connected to one input of the amplifier. A differential amplifier, which amplifies the respective difference between the two electrode potentials, is used. If sev-

eral electrodes are applied, such as e.g. in the EEG, rows of electrodes are formed. In this case, the output voltages equal the respective difference between the previous and the following electrode. If one assumes a potential distribution where the rising and falling trend is recorded via five electrodes, this results in a measuring set-up as shown in Fig. 9.6 with the center electrode being placed on the point of highest potential.

It is clearly displayed that the output voltages U_1 and U_2 point downwards and the voltages U_3 and U_4 point upwards. At the maximum of the potential distribution a phase shift takes place. Such maximum potentials are found e.g. on the fringe of a tumor, thus enabling a localization of the focus. In bipolar recordings the potential gradient is correctly measured.

Unipolar Recording

In unipolar recordings (Fig. 9.7) all channels are related to one common reference electrode. This reference electrode is preferably placed on a mostly inactive area, so that as few potentials as possible are recorded. Therefore, it is called neutral or indifferent. This point is more hypothetical because the influence of cerebral potentials cannot be excluded. The electrode that is placed on a bioelectrically active area is called the active, exploring or different electrode.

Fig. 9.6a,b Bipolar recording. **(a)** Schematic display of the electrode circuit, **(b)** Recording example. The phase shift between C3–P3 and P3–O1 is clearly demonstrated in the marked signal interval

Figure 9.7 shows a unipolar recording for the aforementioned potential distribution. The potential e_r was taken for the reference electrode. It is clearly displayed in the graph that no phase shift takes place in unipolar recordings. A possible focus is localized by the size of the correctly recorded potential difference.

Recording Against an Average Reference

In a recording against an average reference (Fig. 9.8) the reference point is the averaged value of all electrode potentials. This can be realized by software or by connecting all electrodes via resistors of the same value with a reference point. This potential relates exactly to the average value of all electrode potentials, because the sum of all currents at this point equals zero. In this recording a phase shift also takes place. The output voltage equals the difference between the respective electrode potential and the reference potential.

Source Recording

In source recordings the electrodes are also placed on electrically active areas. The recording is carried out against a reference that takes the immediate surrounding electrodes into consideration. In contrast to the recording against an average reference its potential does not influence the reference potential.

In source recordings (Fig. 9.9) the difference between the potential of the electrode of interest is formed with the weighted average value from the potentials of the surrounding electrodes. The weight factor w is calculated from the reciprocal value of the distance. In a square shaped electrode setting this factor is $w = 1$ for the single, $w = 0.5$ for the double and $w = 0.707$ for the diagonal. To obtain the weighted average value, the sum of the weighted electrode potentials are divided by the sum of the weight itself.

Source recordings are applied because they produce a better display of local events by eliminating signals

Fig. 9.7a,b Unipolar recording. **(a)** Schematic display of the electrode circuit. **(b)** Recording example. The same signal interval as in Fig. 9.6 is marked here as well. The spike shaped activity is imposed by a high amplitude in channel P3-A1

from remote areas in the actual local potential such as e.g. the influence of the EOG when opening the eyes. However, in source recordings the actual local potential itself is not recorded in a more precise manner.

Electrode Placement

For reproducible recordings and for the comparability of results in trend studies it is necessary to always place the respective electrodes in the same positions. The applied system cannot be too rigid, but must adapt to different head sizes (neonatal EEG, EEG in children and adults). Therefore, these points on the scalp must be easy to find and reliably defined. These points are the nasion (the deepest point between nose and forehead, right in between the eyes), the inion (the lower bone hunch at the middle back of the head in between the onset of the neck muscles), and both preauricular points (cavity in front of the outer auditory canal directly below the zygomatic bone and above the lower jaw joint).

The connecting lines between nasion and inion as well between the preauricular points cross at the vertex (C_z). These connecting lines are divided into 10% and 20% sections. The electrodes are placed at the crossing points of these longitudinal and lateral rows. The designations of these positions are named according to the regions of the cerebral cortex: Fp = frontopolar, F = frontal, C = central, P = parietal, O = occipital, T = temporal, A = auricular, and also cb = cerebellar as well as pg = pharyngeal. The electrode numbers are related to hemisphere (odd numbers are on the left, even numbers on the right side) and the distance to the center line, and also z = zero. The distance between the electrodes within the various rows is equal.

The line partition in 10, 20, 20, 20, 20, and 10% sections result for the lateral longitudinal row in the electrode positions Fp_z, F_z, C_z, P_z, and O_z, as well as for the center lateral row T₃, C₃, C_z, C₄, and T₄. No electrodes are placed on the positions Fp_z and O_z no electrodes. If in the same way the lines between Fp_z,

Fig. 9.8a,b Recording against an average reference. **(a)** Schematic display of the electrode circuit. **(b)** Recording example. The spike activity is shown with a very high amplitude of ca. 300 μV on channel P3-AVR.

O_z , which are led via T_3 and T_4 , are divided, on the left hemisphere this results in the positions Fp_1 , F_7 , T_3 , T_5 , and O_1 as well as Fp_2 , F_8 , T_4 , T_6 , and O_2 on the right hemisphere. Over the electrodes Fp_1 , C_3 , and O_1 as well as Fp_2 , C_4 , and O_2 two parasagittal longitudinal rows can be drawn, which cross the frontal (F_7 , F_z , and F_8) and the lateral row in the back (T_5 , P_z , and T_6). These crossing points form the electrode positions F_3 , F_4 , P_3 , and P_4 . In between these standard positions further electrode positions may be added e.g. F_1 , F_2 , F_5 , and F_7 for the frontal lateral row. The ground electrodes are fixed on the earlobes, relating to the positions A_1 and A_2 .

Amplifiers

In clinical neurophysiology differential amplifiers are used for the amplification of the recorded biosignals. These amplifiers, whose principles were developed in 1931/32 by Tönnies at the Kaiser-Wilhelm-Institute in Berlin, amplify the difference of two input sig-

nals. Practically, the amplification of common mode signals (e.g. equal phase disturbing signals, which derive from leading cables) differ from push-pull signals (e.g. a potential difference deriving from a bioelectrical generator). The relation of these two amplifications is called the common mode rejection ratio (CMRR). This CMRR should stay in the range of 80–120 dB, which means that the amplification of push-pull signals is 10 000–1 000 000 times larger than the amplification of common mode signals.

Differential amplifiers have an inverted and a non-inverted input. According to the agreement of Lyon in 1980, electrical connections are such that a negativity a different electrode is displayed with a positive polarity on the recording device. Another feature of the amplifier is the amplification factor, which is defined as the quotient between the output and the input voltage. The input impedance of the amplifier should be high (50–200 $\text{M}\Omega$). This is necessary because the potential source should by no means be loaded by current, so the

Fig. 9.9a,b Source recording. **(a)** Schematic display of the electrode circuit. **(b)** Recording example. P3-QUE shows a high amplitude here as well

measurement is carried out as reactionless. In addition, the influence of the electrode transition impedance can be minimized.

The frequency response is a measure for the dynamic transition process of electronic devices and displays the dependence of the amplification on the frequency of the signal. It can be calculated from the quotient of the complex amplitude of the output and input signal for a stationary sine wave. A high pass filter enables signals above a certain threshold frequency to pass without significant loss. The high pass filter is thus used to reduce low frequency disturbing signals, such as zero line drifting. Sometimes, a time constant value is given instead of the threshold frequency, deriving from an exponentially falling response of the high pass filter to a step function. In this case, the time constant is the time interval in which the amplitude drops to 37% of its initial value. In contrary, the low pass filter enables signals below a certain threshold frequency to pass without

major loss. The low pass filter is used to reduce high frequency disturbances such as noise.

However, the phase response is based on a phase difference that usually occurs between the input and output voltage of a recording system. Another feature of the amplifier is the noise, whose name is taken from the acoustic sound image. It is actually a small disturbing signal over a wide frequency band, which can be recorded at the output when the input is short circuited. The cause of this may be found in the thermal electrode movement in resistive components.

Recording/Storing

Apart from the raw signals other values such as the patient's name, the date, the recording program, and the respective result texts are stored in a data bank. At a single glance all recorded examinations together with their measuring results are available and in trend studies all this data may be immediately recalled.

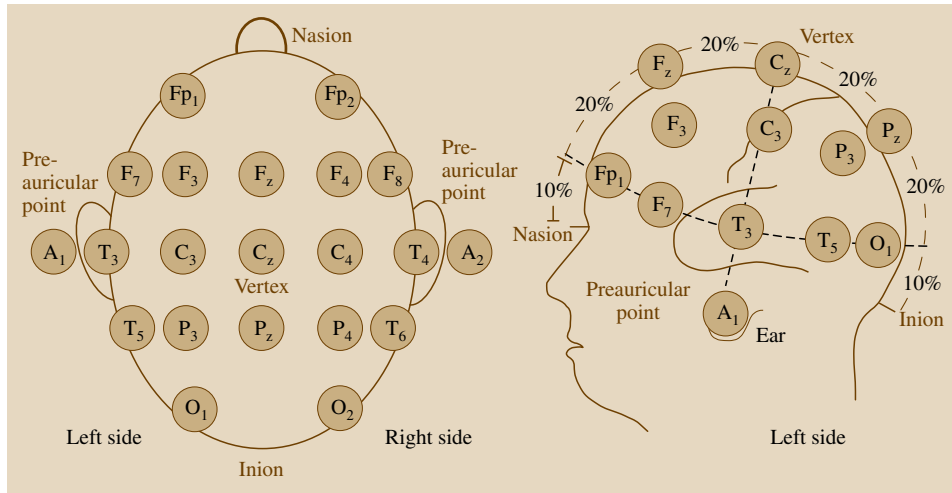

Fig. 9.10 10–20 system for electrode placement (10/20-system) Even-numbered: right scalp, odd-numbered: left scalp (F = frontal, C = central, P = parietal, O = occipital, T = temporal, A = auricular)

Network Systems

In clinical neurophysiology departments several workstations are installed for signal evaluation. In most cases, the specific recording devices are equipped for specific applications such as EEG, EMG/ENG, and evoked potentials, with the respective hardware like stimulators, examination couch, electrodes etc. There is also a difference in the workstations with respect to how the EMG examination is carried out by a specialized physician or the EEG is carried out by a medical-technical assistant in functional diagnostics. A network solution between the recording stations and establishing evaluation stations is recommended. In this case, all the data are available on each PC and for the final results the physician may recall all the information in his room.

Computer systems for neurological practice consist mostly of a recording and an evaluating station. They usually operate with a simple network function called *peer-to-peer*, where the data transfer only has to be managed between two workstations. In larger systems from four recording stations upwards and installation of a local area network (LAN) with its own server is recommended.

Signal Processing

Signal processing plays a great role in clinical neurophysiology. After preprocessing and analog/digital conversion the data are available for further evaluation. Most devices operate on a software that displays, measures, detects simple artifacts, and carries out a first analysis. The spectrum of possible analysis

programs varies greatly. Fast Fourier transformation (FFT) for frequency analysis, averaging to enhance the signal–noise ratio in evoked potentials, the application of neuronal networking for pattern recognition, the application of special filters, the analysis of sleep stages, and the localization of sources of bioelectrical activity are some examples. In most cases, the machines offer direct access to the raw data, so that through using MATLAB or LabView the user's own application software can be installed and run as well.

Artifacts

Artifacts are disturbing potentials, which superimpose the measuring signal and falsify it. Their causes may be found in technical or biological processes.

Biological artifacts are generated by the patient himself. They are physiological signals that superimpose the desired potential, e.g. the EEG in evoked potentials or the ECG and EOG in the EEG. Muscle tension, movement, or sweating of the patient cause additional potentials.

Technical artifacts are generated by the machine itself or coupled in from outside. The artifacts of the measuring device are the amplifier noise, 50/60 Hz noise caused by lacking or insufficient grounding, and the application of unsuitable electrodes. Artifacts are coupled in galvanically, capacitive or inductive.

A possible artifact rejection may consist of a 50/60 Hz band filter. Averaging selects the signal responses correlated to the stimulus out of the background activity. Special algorithms and the application of neu-

ronal networks may be used for detecting biological artifacts. Adaptive filters may serve for artifact rejection as well.

Safety Aspects

For devices used in clinical neurophysiology the general basic requirements for the application of medical technical products are validated, which means that the respective machine, the installation, and the operation must be safe. The compliance of technical parameters such as the patient's leakage current or the machine's leakage current must be checked in defined intervals.

All the above mentioned examination methods should be carried out in a separate room. Such rooms

should not be located near great current consumers such as elevators, radio stations, magnetic resonance tomographs (MRT), or computer tomographs (CT), if possible. Elevators should be at a distance of 10–15 m away. In clinics MRT and CT are usually installed at some distance from other functional units. Generally speaking for neurophysiological examinations nowadays no special room shielding in the sense of a Faraday cage is necessary, because modern amplifiers have a high common mode rejection ratio. However, one should always consider electrostatic charge from shoes and synthetic fibers, which can easily be discharged through grounding. The recording seat or the examination couch as well as the patient must be connected to ground potential.

9.2 Electroencephalograph

Electroencephalography (EEG) records electrical potential differences whose source lays in cerebral processes with the help of electrodes that are normally placed on the intact scalp. EEG-machines find their application in neurophysiological functional diagnostics in neurological private practices, in neurology departments in hospitals, in neurology clinics, as well as in epilepsy centers, neurological rehabilitation clinics, and psychiatric clinics. Furthermore, they are used in the diagnostics of neurological-psychiatric sleep disorders, in drug studies, and in clinical research. They are also applied in neurosurgery and in the monitoring of intensive care units. The diagnostic value of the EEG is found especially in the area of epilepsy (classification, therapy control), the diagnostics of diffuse cerebral functional disorders (inflammatory diseases, cerebral haemorrhage, metabolism, drugs), functional disturbances because of space occupying lesions (increase of brain pressure, haemorrhage, tumors, craniocerebral injury), sleep diagnostics, brain death detection, vigilance disturbances, and the determination of the depth of narcosis. An EEG was recorded for the first time on a human in 1924 by Hans Berger in Jena.

9.2.1 Signals

The EEG is generated through surface near nerve cells of the cerebral cortex (Fig. 9.11). The cerebral cortex is about 3 mm thick and consists of six layers, among them are stellatum cells, stellate and pyramidal cells. The apicale dendrites of the latter cells are found in five

of the six layers. An excitatory postsynaptic potential (EPSP) on the cell soma creates a dipole because of the depolarization with a positive pole near the surface. Inhibitory postsynaptic potentials (IPSP) on the cell soma create on opposite polarization due to hyperpolarization as well as the EPSP on the apicale dendrites. EPSP and IPSP could superimpose by successive potentials in time as well as potentials distributed in space, which occur synchronously in neighboring synapses. During a recording from an intact skin surface the potentials are deformed when traveling in between the cerebral cortex and the various layers of the skin with their different tissues. Resistors and capacitors of these layers act like a low pass filter, wherein frequency components below 1 kHz are mostly eliminated.

The EEG potentials form complex waves, which in their shape and size depend on neuronal factors in the cerebral cortex as well as on the gender, respiration, metabolism, homeostasis, oxygen and carbon dioxide concentration of the blood, blood sugar, drugs, and toxicants. They also depend on physiological factors: sleep or wake state, open or closed eyes in the wake state, on the general vigilance, and on age. The amplitudes of the EEG increase from a newly born to an infant and decrease from an adult to a person of old age, whereas the frequency of the waves increase from the infant up to old age.

Depending on the frequency alpha-waves (8–13 Hz), beta-waves (above 13 Hz), theta-waves (4–7 Hz), and delta-waves (below 4 Hz) are distinguished. The EEG is described by frequency, amplitude, occurrence, mod-

Fig. 9.11 Generation of an EEG

ulation, symmetry, and sensitivity. Special waveforms are spikes, sharp waves, spike and wave complexes (SW-complexes), and further waveforms such as μ -waves, vertex-waves or K-complexes (Table 9.1). The evaluation of the EEG is carried out under clinical aspects. Here, in his findings the physician evaluates the regularity, dominant frequency, predominant high or low amplitudes, physiological local distribution, and sensitivity, as distinguished from the basic activity continuous, discontinuous, generalized or localized EEG activity.

Figure 9.12 shows a normal EEG of a 21 year old with a blockage of alpha-waves after eye opening. In comparison, Fig. 9.13 displays an EEG with an epileptic pattern of a 31 year old male patient. The EEG-activities differ in relation to their amplitude and frequency.

9.2.2 Device Technology

In the last 15 years a considerable transition has taken place in EEG devices from paper based thermal recorders to computer EEG. This relates, on the one

hand, to the hardware, consisting of a PC, A/D converter, and amplifier head box, and on the other, to computerized analysis and findings based on modern software as well as digital media for signal storage and archiving. Therefore, the general appearance of an EEG device has changed drastically (Fig. 9.14).

A standard component of an EEG device is a photostimulator. It generates short bright flashes of light with a defined luminosity and frequency. In the case of double flashes the time between the two flashes is also adjustable. The main component of a photostimulator is a stroboscope or a LED array.

Electrodes

For the recording of the EEG sintered Ag/AgCl surface electrodes are applied (Fig. 9.5). They provide an optimal recording even in the low frequency range. The contact between the electrode and the scalp is produced via an electrolyte or with sodium solution soaked felt tips. The scalp is preprocessed in order to reduce the electrode transition resistance, which should be below 10 k Ω .

Table 9.1 Classification and characteristics of EEG waves and singular waves

Wave nomination	Wave frequency	Amplitude	Wave type	Occuring during
Alpha-waves	8–13 Hz	30–50 μ V	Fast, physiological	Wake, eyes closed
Beta-waves	> 13 Hz	\approx 20 μ V	Fast, physiological	Wake, eyes open, counting
Theta-waves	4–7 Hz	Up to 500 μ V	Slow, physiological	Light sleep
Delta-waves	0.5–3.5 Hz	Many 100 μ V Up to 1–5 mV	Slow, physiological	Deep sleep
Sharp waves	\geq 80 ms	Variable	Steep abnormal wave	Normal and abnormal
Spikes	\leq 80 ms	Variable	Steep abnormal	Mostly abnormal
Spike series	5–10 times with \leq 80 ms	\geq 50 μ V, often very large	Steep abnormal	For example in epileptic seizures
Spike-wave-complex	3/s	10–100 μ V	Many different kinds	Always abnormal

Fig. 9.13 EEG with epileptic patterns of a 31 year old male patient

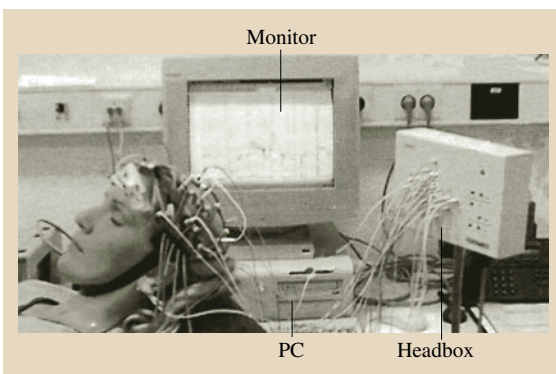

Fig. 9.14 EEG recording in a laboratory

Amplifier

A preamplifier (head box) is mounted on scaffolding near the patient's head and serves as an electrode connector and preamplifier of the EEG signals. From there they are transferred to the main device. The preamplifier has an A/D converter incorporated, therefore the digitalized signals can be faultlessly transferred via great distances without any substantial loss. The preamplifier is a differential amplifier with high demands on the signal amplification and free of distortion. Its quality criteria is a high common mode rejection ratio and a high input impedance ($> 120 \text{ dB}$ and $> 100 \text{ M}\Omega$).

For a high quality recording an active electrode, a reference electrode, and also a ground electrode must

be connected to the differential amplifier. Depending on how the electrodes are related on the respective points of the scalp and connected among each other, different EEG recordings are attained. For the interpretation of the recorded EEG the connection of these inputs per channel to the preamplifier is of vital importance; these settings are called recording programs or montages and they have to be defined and directly related to the signal. One distinguishes between: unipolar or reference recordings, bipolar recordings, and source recordings.

9.2.3 Methodology

Basic Requirements

The German Society of Clinical Neurophysiology has defined minimal demands for the recording of EEGs. An EEG device should have minimally 10 EEG amplifiers and one ECG amplifier. Electrode placement must be carried out according to the 10/20 system. Before and after a recording the device must be calibrated and the electrode transition impedance must be documented. The recording should last at least for

20 min and has to consist of reference montages as well as bipolar longitudinal and lateral row montages. The sensory sensitivity e.g. open and closed eyes (Berger effect) as well as photostimulation and hyperventilation must be included. Artifacts during the recording must be designated and possibly corrected. All important recording parameters, such as the technical settings as well as the behavior and situation of the patient, must be documented along with the recorded signals.

Recordings

During the EEG recording different montages or connections of the electrodes mounted on the scalp are applied. Principally the EEG montages displayed in Table 9.2 are available.

Usually an EEG is recorded with an amplifier sensitivity of $70 \mu\text{V}/\text{cm}$, a paper feed and a time base of $30 \text{ mm}/\text{s}$, with a time constant of 0.3 s (equalling a high pass filter with a threshold frequency of 0.53 Hz) and an upper frequency limit of 70 Hz . These values should be changed only in well considered circumstances. It is recommended to avoid a mains filter of $50/60 \text{ Hz}$.

Table 9.2 Overview and characteristics of clinically applied EEG montages

Montages or recording programs	Pin configuration of the differential amplifier	Characteristics
Unipolar or reference recordings against a reference	Different electrode with inverting input Common reference electrode on vertex or on ear Ground electrode on contralateral earlobe	Common potential parts are highlighted, Better display of generalized activity Amplitude and phases well recognisable and comparable
Reference recordings against averaged references – common average	Different electrode with inverting input Averaged reference out of summated signal of all electrodes Ground electrode on earlobe	See above, but common potential parts are not highlighted any more Recommended for signals with many artifacts
Bipolar recordings such as lateral rows, longitudinal rows, circumferences etc.	Two neighbored electrodes on bioactive area Ground electrode on earlobe	Potential differences between the electrodes are highlighted Better display of focal activity Gradient directly comparable
Source recordings – special unipolar montages with special averaged and weighted references	Singular active electrode, here called “source”, with inverting input Averaged reference from weighted summated signals of all electrodes, which are located around the active electrode (= source) Ground electrode on earlobe	Focal activities are better highlighted Amplitudes and phases remain well comparable

The concrete connection of the electrodes depends on the number of recording channels. Examples for a 16 channel recording device are given in Fig. 9.15

Methods of Provocation

In routine diagnostics photostimulation and hyperventilation are often applied as activation or provocation methods.

Hyperventilation is a provocation method that is very easy to apply. The patient is asked to activate his respiration in frequency and amplitude for 3 min, e.g. to breathe deeply and regularly at about 30 breaths per minute. During the 3 min hyperventilation the potentials

are recorded mainly from the frontal, central, occipital, and middle temporal cerebral regions.

Photostimulation is carried out in a darkened room with the help of a photostimulator. The intensity of the flash lights and their frequency should be adjustable. Photostimulation is a standardized procedure: flashes are applied for at least 10 s while the patient has closed eyes. During a duration of 2 min of photostimulation mainly the frontopolar, frontal, and occipital cerebral regions are recorded.

Further routine activation methods are sleep deprivation (awakened night) or sleep recordings (after sleep deprivation, midday sleep, rare drug induced sleep).

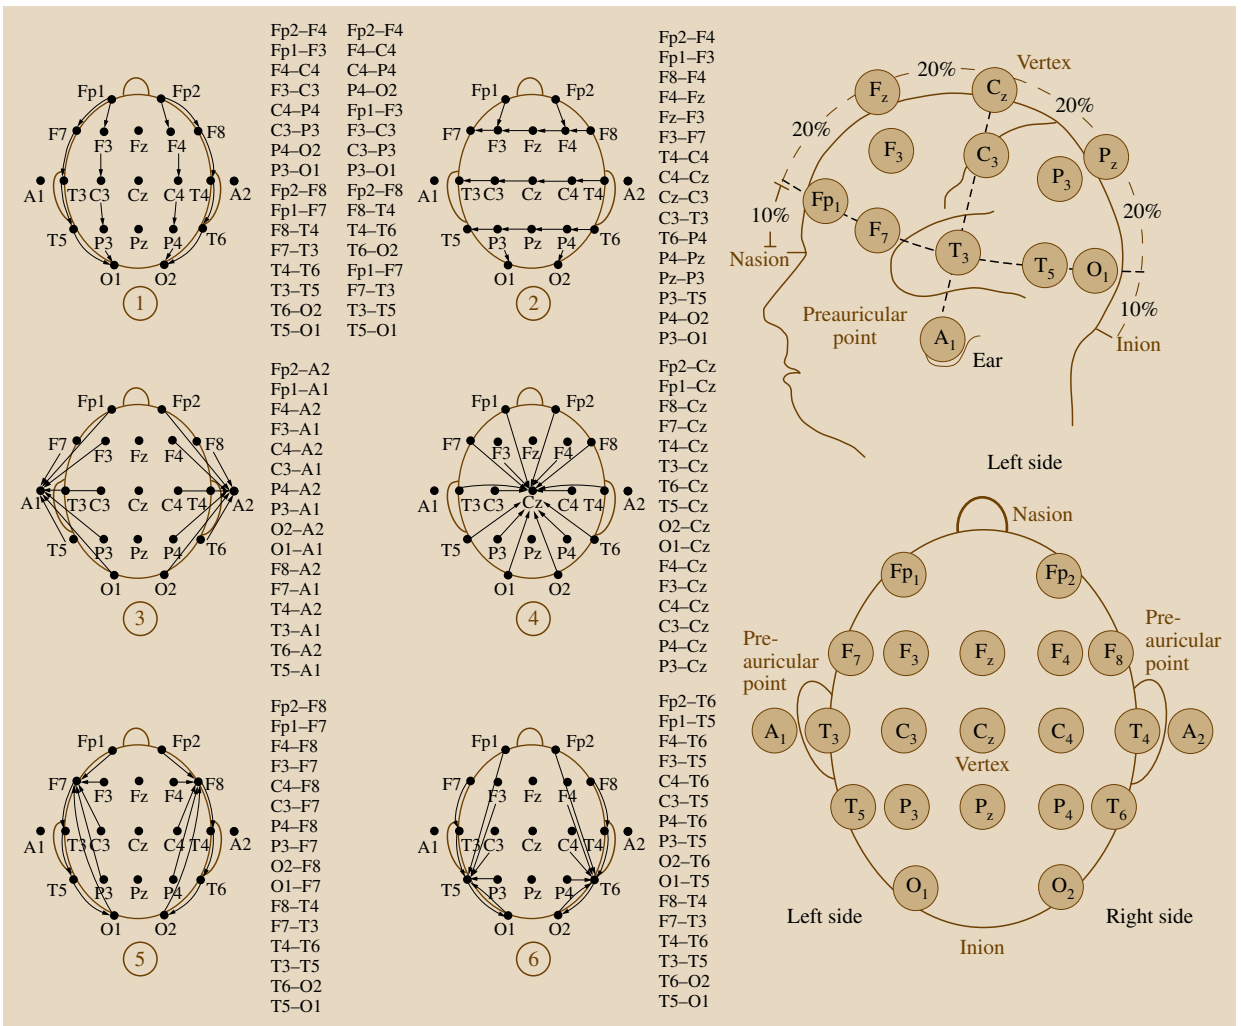

Fig. 9.15 Examples for EEG connections for a 16-channel recording device

The duration of these recordings is between about 30–60 min.

9.2.4 EEG Recording Methods

In relation to the various diagnostic applications in neurology the following methods of EEG recordings have developed been: routine EEG in neurological practice and clinics, ambulatory 24 h long-term EEG, video EEG, portable EEG, sleep EEG, and pharmaco EEG (Fig. 9.1, Table 9.3).

Routine EEG

EEG recordings should be carried out in a quiet room. The patient should position himself on an EEG couch in a half sitting, half lying position. Head and neck are to be as relaxed as possible to avoid muscle artifacts that disturb the recording. Principally, the patient's eyes are to be closed during the recording and the recording time should not fall below 20 min.

Long-term EEG

Long-term EEG recordings are carried out for 24 h in an ambulant manner with an 8-channel and 12-channel EEG amplifier. The aim is to find rarely occurring events that cannot be detected by conventional recordings. Raw EEG signals are, therefore, completely stored. The patient carries on him a small

portable battery driven data recording device or the data is transmitted via telemetry to an evaluation station. All physiological artifacts such as speaking, chewing, and eating are recorded as well, thus producing a lot of disturbed signal intervals making it more difficult to interpret the EEG.

Pharmaco EEG

A specialized area is the recording of an EEG for pharmacological purposes to evaluate the influence of drugs on the function of the central nervous system (pharmaco EEG). In particular, the reproducibility of the same or similar changes in the EEGs of different test patients is detected. Here different analysis procedures have been evaluated, for example, brain mapping. Frequency analysis calculates the respective quantified wave components in a statistic way during the recording, and the changes in the EEG are recorded and quantified over larger periods of time.

Video EEG

Parallel to the EEG routine recording a video camera records and stores the image of the patient in a time synchronized way. Also, infrared camera systems are used in order to record the video image from patients in darkened rooms. The signals of the computer EEG and the video are synchronized up to a precision of a few milliseconds. The EEG data is

Table 9.3 Application, number of channels, and recording methods in clinically standard EEG recordings

EEG method	Application	Number of channels	Recording time (average)	Evaluation
1. Routine EEG	a) Practice b) Clinic c) Epilepsy	8–12 16–24 19–32–64	ca. 10 min 20–30 min 20–40 min	Visual, computerized
2. Long-term EEG	Clinics, in addition to routine EEG, e.g. in epileptic patients	8–12	Max. 24 h	Semi-automatic computerized event recognition algorithms
3. Video EEG	Epilepsy, also more in clinics	19–24	10–60 min, event related	EEG signals directly synchronized with the video image of the patient
4. Portable EEG	Ambulant recording in intensive care, in inner medicine, and for brain death recognition	8–12	10–30 min, also 1–2 h, with display of all EEG signals	Visual, in brain death recognition additional requirements on high signal resolution
5. Sleep EEG	Sleep disorders of neurological and psychiatric origin	12–24 with polygraphy	At least 8 h at night	Semi- and automatic sleep stage recognition
6. Pharmaco EEG	Drug studies	12–24	20–30 min depending on aim of study	EEG mapping, computerized frequency analysis

Fig. 9.16 Examples of signal analysis

displayed on the screen of a PC monitor with maximum resolution and free of flickering synchronous to the video image; even different montages may be selected.

Video EEG is considered especially important for diagnostics in epilepsy. The physician can easily evaluate from the video image when and how the onset of an epileptic seizure takes place. In relation to the respective EEG, he is able to localize the focus or the starting point of an epileptic activation. The actual recording time can be assigned as a search criteria, thus displaying the EEG and the video image at the same time.

Sleep EEG

In neurological-psychiatric sleep disorders the EEG is recorded for diagnostic purposes during the night's sleep for at least 8 h. To obtain a sleep profile with its related sleep stage determination more polygraphical

channels are necessary: eye movements via the EOG, muscle tone from the chin via surface EMG, ECG, respiration and respiratory effort. Video survey of the sleeping patient is often applied.

Portable EEG

EEG recordings in the intensive care unit as well as brain death detection require a handy compact EEG unit. A notebook with a battery driven head box is used for data recording and storage. For brain death detection the German Society of Clinical neurophysiology has set special requirements for portable EEG devices: recording time should be at least 30 min, there should be double electrode distances, a 0.53–70 Hz bandwidth, a sensitivity of 2 $\mu\text{V}/\text{mm}$, and a minimum of 8 channels. The ambulant recorded EEG on the notebook may subsequently be dubbed on the central EEG archive.

Fig. 9.17 Software for the detection of paroxysm changes in long-term EEG

9.2.5 Evaluation and Signal Analysis

EEG Signal Analysis

In addition to the visual evaluation of the EEG by a specialized physician, a computerized evaluation of the EEG signals is frequently used because of the enormous amount of raw data. Here, frequency analysis and the detection of defined characteristics are helpful. Another method of EEG analysis is the dipole analysis of the EEG, which provides a dipole model related to space and time of the EEG and evoked potentials, resulting in a localization of possible sources in bioelectrical activity. The auto correlation function of the EEG leads to the dominant frequency in the signal of an EEG epoch and its drop gives a measure of the stochastic appearance of the EEG. The cross correlation function is used to detect a common frequency within two different epochs of the EEG, e.g. between two recording channels. Time variant spectral analysis is also to be mentioned, which

calculates the amplitude and frequency for each wave in the EEG and displays these in a three-dimensional frequency distribution. In Fig. 9.16 some examples for signal analysis are displayed in an overview.

Subsequent Remontage of Signal Epochs

For the evaluation of the EEG and the localization of pathological waveforms it is helpful to evaluate certain signal epochs in different montage settings. The possibility to view the same signal epoch under different *perspectives* gives the physician the chance to find the optimum montage for his findings.

Topographic Display of Amplitude and Frequency Distribution

The result of a topographic display of the EEG is a two-dimensional colored map of the cerebral activity along the surface of the scalp. Often the amplitudes, frequencies, and power spectra derived from the frequency analysis are displayed in a topographic way. The signal amplitudes of the area in between the recording electrodes are calculated via interpolation. The amplitudes gained in such a way in a two-dimensional distribution are thus quantified and given a color code, delivering a graduated picture of the potential distribution on the scalp. The display of an amplitude map in an epoch of a couple of milliseconds in a film, if e.g. a focus or a generalized activity occurs, is especially impressive.

In a frequency mapping an EEG signal epoch, whose amplitude is a function of time, is transformed via FFT into a signal, whose amplitude is a function of frequency. The result is displayed in a color code analog to the amplitude mapping, where the different colors are related to the occurring wave frequencies.

The power spectrum is calculated out of the signal transformed by the FFT. It displays the power that is

Table 9.4 Table of physiological and technical artifacts during an EEG recording

Physiological artifacts	Technical artifacts
EMG potentials from: frowning, movement of the lid, chewing, head and neck movements	Bad contact impedance of the electrodes caused by bad electrode application and slipping of electrodes
ECG-peaks or temporal pulse waves interspersing	Loose contact in the cables caused by cracks
EOG as eye movements in the frontal EEG	50/60 Hz noise from outside
Sweating – as slow fluctuations in the EEG	Large inductivities, as in neighboring elevators or radio or TV stations near-by
Respiratory movements – occipital, head movements in breathing rhythm	Electrostatically charged shoes or clothes with synthetic fibers

contained in a specific frequency or an EEG wave out of the total sum of the signal. These results are mostly displayed in the form of a histogram. The envelope of this histogram is a very obvious display of the changes of the frequency components during the different recording phases e.g. for the evaluation of drug effects or during narcosis.

Long-Term EEG Analysis

The interpretation of an ambulant long-term EEG recording is a time-consuming task because of the great amount of recorded data. An example for such a kind of analysis software is one that looks for special paroxysms by searching in the EEG raw data for the occurrence of peak values, their area, and their signal duration. The result of these calculations is a con-

densed display of the long-term EEG, which enables the physician to differentiate without any difficulty between paroxysmal events in the EEG from artifacts and normal EEG epochs (Fig. 9.17).

Final EEG Results

After the visual observation and evaluation of the EEG, the physician writes a final result text, with or without the help of computer-aided analysis. This result text is stored and archived together with the EEG signals.

Artifacts in the EEG

During the recording different artifacts may occur, which are differentiated as physiological and technical artifacts. They should be detected, classified, documented, and removed as soon as possible (Table 9.4). In

Fig. 9.18 Muscle activity in the EEG

Fig. 9.19 Blink artifacts in the EEG

order to identify physiological artifacts EC, EMG and EOG are often recorded as well.

Figures 9.18 and 9.19 give two examples of physiological artifacts. Figure 9.18 displays muscle activity especially recorded from regions F₇, T₃, and T₅. Figure 9.19 displays frontopolar eyemovements, especially recorded on Fp₁–F₃ and Fp₁–F₇, as well as Fp₂–F₄ and Fp₂–F₈.

9.2.6 Special Methods

Electrocorticography

Electrocorticography (ECoG) is used for the exact localization of lesions before a neurosurgical intervention. The electrode arrays are placed directly on the cortex. In this technique, the tissue layers between the generating location of the bioelectrical activity and the recording site are reduced considerably. The frequencies of the recorded signals have higher values.

Magneto-Encephalography

Any conductor leading electrical current is simultaneously surrounded by a magnetic field. This also applies for stimulated nerve cells. The electrical current density inside the cell is higher than outside of the cell, therefore a change in magnetic field caused by an action potential infers a stimulated cell. In contrast to electric fields, magnetic fields are not dependent on bone and tissue layers; they are only dependent on the distance between the generating area and the sensor. Therefore, this technique is able to locate the source of activity. The recorded distribution of the magnetic field along the scalp allows the location of the generated activity to be generated with sufficient accuracy, the solution of the inverse problem included.

Magneto-encephalography (MEG) in comparison to electroencephalography has the advantage of being able to determine the source of prominent activity.

9.3 Electromyograph

Electromyographs are quite universally applicable diagnostic systems. They can record, amplify, and measure the bioelectric activity of muscles and nerves under various circumstances. Their respective amplifiers perform high sensitivities, have a high input impedance, a large bandwidth, and very low noise. According to the configuration the electromyograph is equipped with an electric, acoustic, visual, and magnetic stimulator.

Fig. 9.20 Coil system of SQUIDS (superconducting quantum interference devices) for the recording of biomagnetic fields

Therefore, it is applied in e.g. the localization of a possible focus in focal epilepsy, functional disorders caused by space occupying disorders, or the influence of clearly determinable factors on the central nervous system e.g. tinnitus. Also, examinations like the localization of specific stimulation of nerve cells (acoustical, optical) or mental activities (listen to music, thinking, speaking etc.) are carried out. In connection with other methods such as MRT, PET, SPECT further functional structures of the brain may be determined.

In any case, MEG is still a very elaborate and extensive method. The applied sensors (superconductive quantal interferometer sensors (SQUIDS) are dependent on cooling by liquid helium in order to achieve the superconductive effect. Figure 9.20 shows the coil system of a SQUIDS.

The principal construction of an electromyograph is displayed in Fig. 9.21 A personal computer (PC) or microcontroller (MC) acts as the central control, signal processing, and storage unit of the EMG machine. It is equipped with a hard disk as data storage, PC monitor with color display, keyboard, and laser printer. The necessary components, like amplifier, analog-to-digital converter, and the stimulation units are integrated into

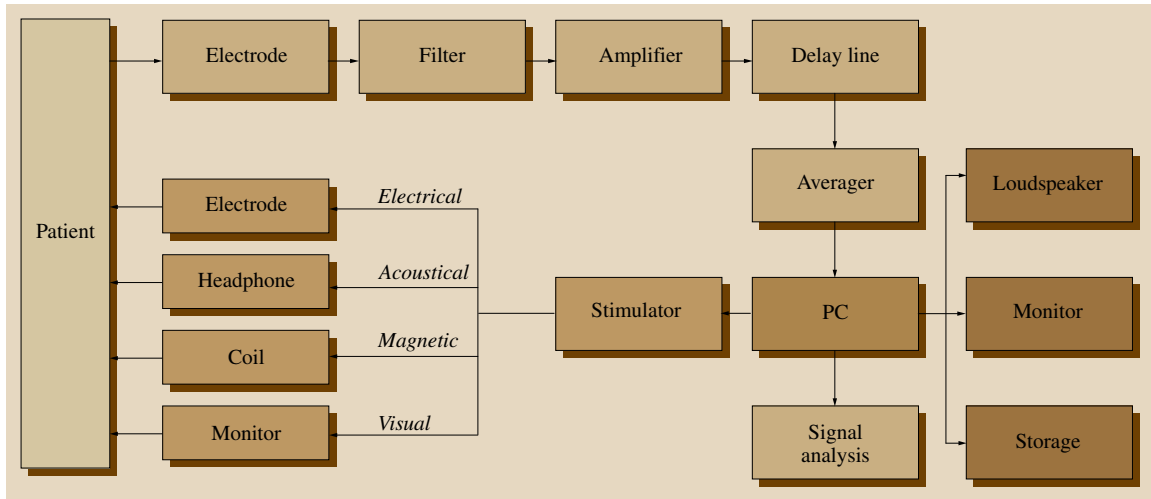

Fig. 9.21 Schematic circuit diagram of an electromyograph with four stimulators, three output devices, three hardware and software components, and the PC as the central processing unit

the PC housing. Functions like averaging, signal delay, programming of the recording programs, and evaluation of the signals are processed by software. The averaging of triggered signals serves to extract small stimulus related signals out of a surrounding signal mixture. The delay line delays signals in order to display signal components that are produced before the stimulus. A loudspeaker serves for the acoustic evaluation of the recorded signals. This is important for the immediate diagnostics, because myographic signal shapes have characteristic sound images. In addition, the loudspeaker serves as feedback for the patient, so he can judge the strength of his voluntary contraction or his relaxation.

EMG machines are applicable in:

- Neurological practices as a compact 2-channel device for EMG/EP.
- Neurological departments in hospitals as 2-channel-EMG and 4-channel EP device.
- Neurological clinics as a 4-channel-EMG and as a 4–8-channel EP device.
- Neurological rehabilitation clinics as a 2–4-channel EMG/EP device.
- Neurosurgical clinics for intra-operative EP-monitoring as a 4–8-channel EP device.
- Neurological research as an 8-channel EMG/EP device.
- Orthopedic clinics during spine operations as a 4-channel SEP/MEP device.

- Sports medicine.
- ENT as a 2-channel EMG device for larynx EMG with specialized electrodes.

To match the various requirements EMG machines are built of system components in a modular way. They especially vary in relation to the number of channels and the number and type of stimulators, software, and storage medium. Table 9.5 gives some examples.

9.3.1 Signals

Because of the great variety of an electromyograph a great number of different biosignals are recorded. Table 9.6 gives an overview of the different kinds of potentials and their measuring values that are recorded and evaluated via an EMG machine.

9.3.2 Device Technology

Electromyographs (Figs. 9.21 and 9.22) are designed in relation to the number of their channels and the kind of stimulators in a modular way. Therefore, special recording programs are available for the respective requirements. An EMG device is able to carry out a great number of neurophysiological examinations, where each examination has its own stimulation, recording, display, and evaluation characteristics. These different parameter settings are stored in the machine and may be changed or even newly designed by the user. Thus it

Table 9.5 Electrode application, stimulators, and number of channels in different EMG examinations

Examination	Recording	Stimulator	Number of channels
Needle EMG	From within the muscle with needle electrodes, only for physicians	None	1 channel
Electroneurography and reflexes	Mostly surface electrodes for stimulation and recording	Electrical stimulator for sensory and motor stimulation	2 channels
Neuromuscular transition	Surface electrodes for stimulation and recording	Electrical stimulator with pulse series stimulation	1 channel
VEP – visual evoked potentials	Surface electrodes on scalp for recording	Monitor with checkerboard reversal, stripes, bars, and colour stimulation	Practice: 1 channel Neurology: 1–3 channels Eye clinic: 1–5 channels
AEP – acoustic evoked potentials	Surface electrodes on scalp for recording	Headphones with Click, frequency specific bursts etc.	Practice: 1 channel Neurology: 1–2 channels ENT: 2–4 channels in Audiology
SEP – somatosensory evoked potentials	Surface electrodes for recording and stimulation	Electrical pulse stimulation on hands and feet	Practice: 1–2 channels Clinic: 1–4 channels also 4–8 channels
MEP – motor evoked potentials	Surface electrodes for recording on hands and feet	Magnetic stimulator with coils for cortical stimulation	1 channel

is easily possible to get to numbers of 20–40 recording programs according to the stage of extension of the particular machine. The central processing unit is often a PC, which controls the different examination programs, processes the signals, displays and evaluates them, as well as incorporating and print-out. For the signal display the international convention in neurophysiology is valid, which displays amplitudes of negative polarity on the different electrodes as positive signals.

Electrodes

The standard electrode used in electromyography is the concentric needle electrode. In a steel cannula there exists a platinum central wire coated with an isolation layer (araldite). The potential difference between the platinum wire as the active electrode and the outer steel cannula as the indifferent electrode is amplified. The electrodes are mostly 2–6 cm long and 0.3–0.6 mm in diameter. Their size and application is related to the size

of the muscle to be recorded. In some cases, also bipolar needle electrodes are used. Here two central platinum wires isolated from each other are put in one cannula.

It is necessary to use an additional ground electrode, which is applied on the examined extremity near the recording site.

In neurography and in somatosensory evoked potentials (SEP) stimulation and recording electrodes are applied. In both cases, mostly surface electrodes are used, and the ground electrode is placed in between. Only in rare cases and in specialized clinics are needle electrodes for recording and stimulation applied. These needles are applied in pairs – one proximal and one distal to the examined nerve, with this technique larger and more pronounced potentials are achieved.

In evoked potentials during clinical routine examinations surface cup electrodes are attached to the scalp; they are applied in a similar way to the EEG electrodes. Only in intra-operative monitoring are small platinum needle electrodes used.

Table 9.6 Signal amplitudes and measuring values in different EMG examinations

Examination	Signal amplitudes	Analysis time	Measuring quantity
Needle EMG:			
Spontaneous activity	20–500 μ V	100 ms	Potential duration
Slight innervation	200 μ V–2 mV	100 ms	Amplitude
Maximum innervation	500 μ V–5 mV	1 s	Discharge frequency
Electroneurography:			
Motor NCV	10 mV	20 ms	Latencies, motor and sensory nerve
Sensory NCV etc.	50–100 μ V	10 ms	Conduction velocity
VEP – visual evoked potentials	50–100 μ V	200 ms	Latencies and amplitudes
AEP – acoustic evoked potentials:			
– Early AEP (brainstem potentials)	0.1–0.5 μ V	10 ms	Latencies
– Middle AEP	20–100 μ V	100 ms	Latency differences
– Late AEP	100–500 μ V	0.5–1 s	Amplitudes
SEP – somatosensory evoked potentials:			
Arm stimulation	20–100 μ V	100 ms	Latency differences
Leg stimulation	10–100 μ V	200 ms	Amplitudes
MEP – motor evoked potentials:			
Arm recording	5–10 mV	10 ms	Latencies Amplitudes Central conduction time

Figure 9.23 shows an overview of the different types of electrodes.

Amplifier

The amplifiers used in electromyography are differential amplifiers with a broad dynamic range and a broad frequency range. Per channel there are three input con-

nectors for the inverted, the noninverted input, and the ground connector on the head box. An impedance measuring device for the contact impedances on the amplifier head box is recommended in the case of surface electrodes like in the recording of evoked potentials.

Typical technical data of an EMG/EP combined machine are listed below:

- Number of amplifier channels: 2–4–8
- Preamplifier: with optically isolated input/floating input, patient connectors on the head box
- Input impedance: > 200 M Ω
- Common mode rejection ratio: > 100 dB
- Sensitivity: 1–500 μ V, 1–10 mV in, e.g. 14 adjustable steps
- Noise: < 2 μ V_{RMS}
- High pass filter: 1–10–30–50–100–300–500 Hz with at least 12 dB/octave
- Low pass filter: 30–100–200–500 Hz, 1.5–2.5–5–10–20 kHz with at least 12 dB/octave
- Trigger level: per stimulation signal or EMG signal with continuously adjustable amplitude or window trigger
- Averager: 1–4000 averaging steps
- Artifact rejection: selectable and adjustable
- Stimulation units: electric, visual, acoustic, magnetic

Fig. 9.22 Four-channel EMG machine with integrated stimulator. Nerve conduction velocity is measured through electrical stimulation of the motor nerves and bipolar recording of the muscle action potential with surface electrodes

Fig. 9.23 Electrodes for electromyography

- Monitor: 17" or 19" monitor with a selectable waterfall display up to 32 or 64 signal traces per screen
- Time deflection: 2 ms–10 s analysis time per screen, adjustable in 10–15 steps
- Loudspeaker: two channels for listening to the raw EMG signals during the EMG needle recording with adjustable loudness control.

Stimulators

Different stimulators are mounted on the EMG machine, thus providing for various examinations such as neurography and the recording of evoked potentials. Typical values for the different stimulators are given here.

Electrical Stimulators

- Stimulation: constant current stimulator
- Intensity: 0.1–99 mA continuously adjustable
- Duration: 100–200–500 μ s in three adjustable steps
- Frequency: 0.1–99 Hz adjustable
- Programs: single, pairs, pulse trains, delayed single, pairs and pulse trains, randomized stimulation.

Acoustic Stimulators

- Stimulation: click with 50–100–200–500 ms duration, tone burst, frequency specific with a plateau time of 100 ms–1 s, rise and fall slope in 1 ms–250 ms
- Intensity: click 10–130 dB spl (*sound pressure level*) for neurology
- Burst: 10–110 db spl only in audiology
- Masking: contralateral white noise of adjustable 10–110 dB

- Polarity: suction, pressure, suction/pressure alternating
- Side: left, right, both sides simultaneously.

Visual Stimulators

- TV-Monitor: 17" with checkerboard reversal stimulation and different checkerboard sizes and steady-state-function; total field, half field and quadrant stimulation with adjustable fixation point in various positions
- LED goggles: for flash stimulation e.g. for coma patients in intensive care or in intra-operative monitoring during surgery
- LED pattern: goggles with pattern stimulation
- Ganzfeld stimulator: for electro-ophthalmological applications for the stimulation of eye movements in a determined surrounding.

Magnetic Stimulators for Motor Evoked Potentials

- Stimulation: monophasic with 100 μ s, rise time 1 ms duration
- Trigger: programmable positive and negative TTL level for input and output, released by a foot panel
- Magnetic flux density:
 - 90 mm high-power coil 2.0 T
 - 70 mm double coil/butterfly coil 2.2 T
 - 120 mm curved double coil 1.6 T
 - 40 mm small coil 4.1 T
 - 70 mm medium coil 2.6 T.

9.3.3 Electromyography

The aim of an electromyographic recording is to detect differential diagnostic findings for a muscle lesion. In particular, the question has to be answered as to whether the muscle disorder or lesion is caused by a myogenic or a neurogenic process, which means whether the supplying nerve or the muscle itself is affected. Muscle action potentials are recorded via concentric needle electrodes (needle myography), thus supplying extracellular recordings from the activated muscle. Summated muscle potentials are recorded via surface electrodes on the venter but have little relevance for EMG diagnostics.

After a profound clinical examination, the physician determines, which muscle and/or nerve he will examine via EMG. EMG is an invasive examination because of the needle electrode; the physician himself has to insert the needle and has to carry out the examination. There is no valid routine procedure available for every patient, the examination is quite individual from patient to pa-

tient. An indication for an EMG recording is generally given for:

- The differentiation of neurogenic or myogenic lesions or palsys
- Muscle weakness and movement disorders with or without muscle atrophy
- Remarkable occurrence of fatigue and neuromuscular transition disorders.

A needle EMG examination usually consists of four phases:

1. Insertion activity
2. Relaxed muscle
3. Muscle with slight voluntary contraction
4. Muscle with maximum voluntary contraction.

Examples of muscle action potentials of healthy muscles are displayed in Fig. 9.25

If the physician finds hints of a pathological change in the examined muscle in a certain needle position, this finding must be verified in other parts of the same muscle. Therefore, the needle position is changed by deeper insertion or pulling out of the muscle. In any case, at least another insertion into the same muscle must be carried out. If the second insertion cannot confirm a reproducibility of the former pathological change, an insertion must again be recorded and various needle positions observed. Only pathological potentials are stored or printed out to document the comparability.

Insertion and Spontaneous Activity

In relation to the actual insertion of the needle into the muscle a transitory muscle activity may occur, the so-called insertion activity. By listening to the insertion activity via a loudspeaker the physician can determine whether the insertion activity is within the normal range of a small lesion caused by the insertion or whether a lesion can be assumed in the muscle when an especially long insertion activity is heard.

After the insertion, a healthy muscle remains in a state of *electrical silence*. However, if in the relaxed muscle potentials such as fibrillations, fasciculation, or positive sharp waves occur, this is a first hint for a pathological state of the neuromuscular apparatus. These potentials are called spontaneous activity (Fig. 9.24). They have a distinct regular discharge frequency. If they occur, they are immediately recorded and stored on the machine without any further evaluation.

Voluntary Innervation

To evaluate the innervation pattern during slight voluntary innervation (Fig. 9.25) the patient must exert the muscle very slightly, so that singular electrical discharges are seen on the display and heard via the loudspeaker. It has to be observed that the potentials are recorded close to the needle, which is the case when the discharge produces high cracking sounds and steep potentials on the screen. Ideally the needle should pick up the area of a motor unit. In the case of pathological changes, up to 20 different motor units must be recorded, compared, and evaluated (Buchthal analysis).

Fig. 9.24 Spontaneous activity recorded with needle electrodes from *Musculus adductor pollicis* of a 57 year old patient

Fig. 9.25 Muscle potentials in slight voluntary contraction of *Musculus extensor digitorum brevis* in a 50 year old patient recorded with needle electrodes

Muscle potentials at maximum voluntary contraction of the muscle are recorded as an interference pattern. This is displayed on the screen as a dense potential pattern with high amplitudes. A healthy muscle shows a very dense pattern, whereas a muscle with pathological changes shows a cleared-out pattern with various different amplitudes. Neurogenic disturbances show few but high amplitude peaks and myogenic disturbances produce a dense pattern with a low mean amplitude.

Single Fiber Myography

With the help of a special single fiber electrode singular muscle fibers within a motor unit can be examined (single fiber EMG). The active platinum wire has a diameter of 0.25 mm. The recording area is not situated on the needle tip, but in the needle shaft, to make sure to record potentials from fibers that were not damaged by the insertion. Single fiber potentials are recorded during slight voluntary contraction and displayed with an analysis

time of only 5 ms. Here two channels are used, on the first channel the continuous recorded potentials are observed and on the second channel the detected potentials are superimposed after signal triggering, thus enabling the physician to measure the jitter. This is a measure for the variability of the discharge behavior of the muscle fiber. With single fiber EMG one can evaluate the fiber density of a motor unit.

MACRO EMG

This is another special form of a 2-channel EMG recording: on the first channel the signal of muscle fiber with slight voluntary contraction is recorded via a single fiber electrode and on the second channel triggered by the potential on the first channel the total activity of the motor unit is summated by an averager and picked up with a special macro needle. The macro needle is a unipolar needle, in which nearly the total needle shaft acts as a large active recording area. The result is an averaged macro potential, in which potential duration and

area under the averaged signal is evaluated, thus delivering a quantified value for the total amount of activity of the motor unit.

EMG Signal Analysis/Evaluation

Pathological insertion activity and spontaneous activity are not especially analyzed, because these activities are always pathological, their occurrence is simply recorded and stored.

The signals of the motor units (MUP – motor unit potential or MUAP – motor unit action potential) are evaluated in terms of signal amplitude, potential duration, occurrence of polyphasic potential, and discharge frequency and compared with normative values. These values differ in each muscle. To be able to compare these results with normative values, the EMG signals must be quantified. To record, store, and evaluate such a large amount of up to 20 MUP is a clinically very satisfying result, but also very involved and time-consuming. Therefore, a number of analysis methods have been developed. All of them agree on an overview display of the different MUPs with their evaluation values.

Online Averaging of MUPs

During the potential searching process an amplitude or window trigger level is adjusted in order to find potentials of similar size. In an automatic way the potential slope can be measured to ensure a needle position close to the motor unit, which means the optimal electrode recording position. With the help of an averager the selected potentials are averaged, automatically measured, and stored until the required number of maximum 20 MUP at different needle position is reached. Also, it is possible to quantify the discharge frequency of the examined motor unit as well as its recruitment.

Offline Pattern Recognition

Another method is the recording and storing of 1–3 s continuous MUPs. After storage, the physician marks a distinct MUP template, then this particular MUP serves as the template for an automatic pattern recognition software, searching for similar MUPs in the stored interval. Also, the measuring values are automatically calculated. This method of the subsequent analysis in an interval with MUPs also functions with pattern recognition algorithms, which are self-learning and detect reoccurring signals, averages, and measures them. This method is an offline analysis with the advantage of being able to repeat the evaluation with different parameters.

Decomposition EMG

This is a method mostly applied in the US, which takes the EMG potentials with slight voluntary innervations into an extensive mathematical algorithm, which automatically detects all repeating potential components as templates and measures them. Not reoccurring potential components remain unconsidered.

Turns/Amplitude Analysis

Muscle potentials from maximum voluntary contraction deliver an interference pattern that is quantified in a turn/amplitude graph. Here the number of reversal points are displayed over their mean amplitude. In this graph the range of normative values for the respective muscles are marked and an abnormal potential pattern is displayed as a point outside of the normative range. For a complete finding a total number of 10 EMG intervals at maximum innervations with a duration of at least 1 s in different needle positions must be recorded. This EMG evaluation is used in clinical routine examinations, because it is especially fast, simple, and concise.

Computer systems in which data banks for patient data and normative values for muscles are available and compare the results immediately with the respective normative values. This enables the physician in mostly clinical environments to examine also muscles that are not so prevalent.

9.3.4 Electroneurography

Electroneurography (ENG) is the stimulation and recording of innervations traveling along motor or sensory peripheral nerves. An important result of this examination is the nerve conduction velocity of motor and sensory nerves. Also, the examination of various reflexes, muscle fatigue testing, and the evaluation of neuromuscular transition belong to ENG.

In most cases, surface electrodes are applied for electrical stimulation and recording; needle electrodes are applied very rarely. To reduce the influence of stimulation artifacts on the recorded signal response, the ground electrode must be placed in between the stimulation and recording electrode. Machines with an automatic stimulation artifact rejection are available on the market.

The aim of a neurographic examination is the diagnosis of motor and/or sensory conduction disturbances in peripheral nerves. Often electromyographic examinations are followed by a neurographic one. Each of these various neurographic examinations work with their own

stimulation programs, recording parameters, and evaluating schemes. The user may recall them from the PC, change them and/or create new ones.

Nerve Conduction Velocity

The most frequent examination of electroneurography is the determination of the nerve conduction velocity (Fig. 9.26). The motor and sensory nerve conduction velocity (NCV) is determined. For the determination of the NCV a distance as well as a time difference is needed according to $v = \Delta s / \Delta t$. Therefore, the peripheral nerves are stimulated with electrical current on two different locations and the latencies of the two stimulation sites are between the stimulation until the onset of the response signal are measured. The stimulation site and latencies more distant from the body are called distal and the stimulation site and latency closer to the body are called proximal.

The clinical indication for a measurement of the NCV are the patient's complaints about sensory disturbances or pain in the extremities, such as nerves compression syndromes. A frequent example for this is carpal tunnel syndrome (*N. medianus*) at the joint of the hand and sulcus ulnaris syndrome (*N. ulnaris*) in the bend of the elbow. The NCV is dependent on the nerve consistency, on the age, and on the skin temperature, which changes in average per 1 K to 2 m/s. The most frequent examined motor nerves on the arm are *N. medianus* and *N. ulnaris* and on the leg *N. tibialis* and *N. peroneus*.

Stimulation and recording is carried out with surface electrodes. For the determination of the motor NCV on *N. medianus* a surface stimulation electrode on the nerve near the wrist and in the bend of the arm is stimulated supramaximal. Supramaximal means that an increase in stimulation amplitude does no more increase

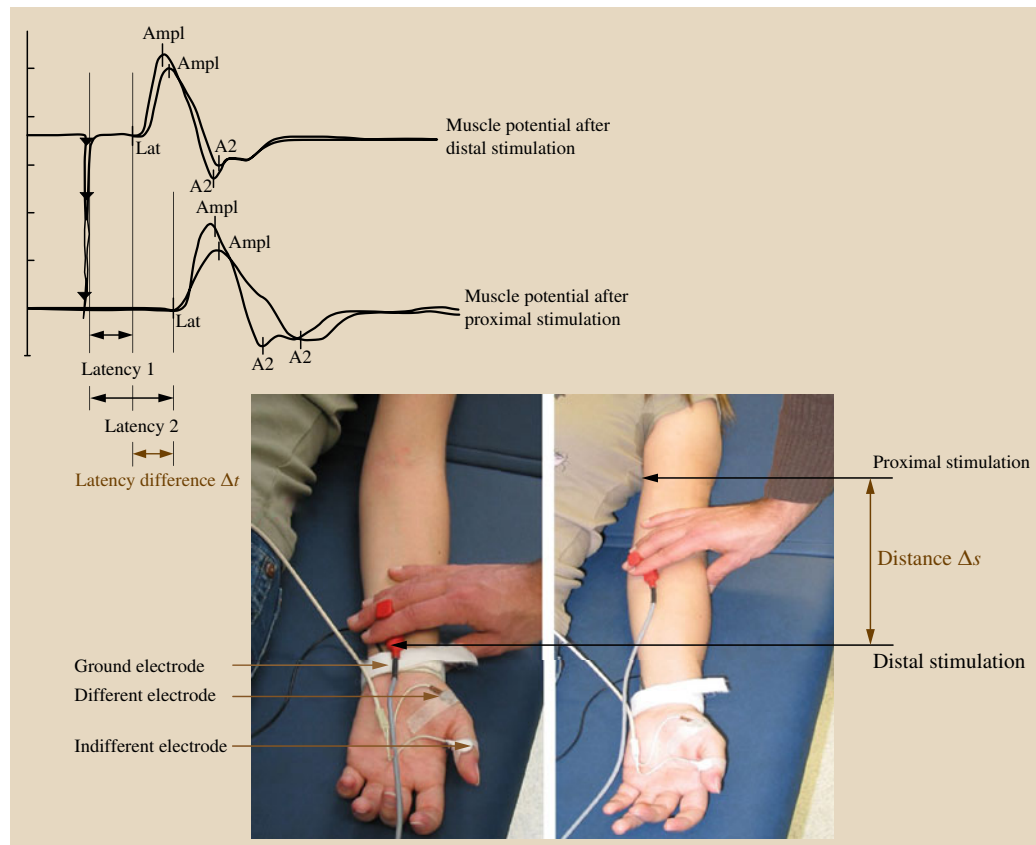

Fig. 9.26 Scheme for the determination of the motor nerve conduction velocity ($NCV = \Delta s / \Delta t$) of *N. medianus*. Stimulated in the bend of the elbow, next to the tendon of *M. biceps brachii*, and on the wrist medial to the tendon of *M. palmaris longus*. The recording is done with surface electrodes on *M. flexor pollicis brevis*

Fig. 9.27 Response potentials and determination of the motor nerve conduction velocity in the median nerve of a 27 year old patient

the response potential. The respective stimulation currents in supramaximal stimulation may reach values of 10–30 mA depending on the consistency of the top skin layer. Both response potentials are recorded on the thenar muscle with surface recording electrodes. Typical normal values for the NCV of *N. medianus* lie around 50 m/s at a skin temperature of 35 °C. Also, the absolute distal latency has a diagnostic significance; its normal value is around 4.3 ms in the median nerve.

For the determination of sensory NCV a procedure analogous to that in motor NCV is executed. The excitation continues in both directions from the stimulation site and, therefore, there is a distinction between the orthodromic (in physiological direction) and the antidromic (reverse to the physiological dispersion di-

rection) method. In the orthodromic method fingers or toes are stimulated distally, and wrist and bend of the elbows or ankle, and bend of the knee are stimulated proximally, and recorded on wrist and bend of the elbow or ankle and bend of the knee in the direction of the physiological sensory nerve conduction. The recording is simultaneous from both recording sites, e.g. a 2-channel recording is carried out. In the antidromic method the same sites are stimulated as in motor NCV, however with considerably less stimulation intensity.

Reflex Examinations

Electroneurography also includes examinations of various reflexes: T-reflex, triggered below the patella, H-reflex, and F-wave or blink reflex. In reflex exam-

Fig. 9.28 Blink reflex (*Orbicularis oculi* reflex) of a 27 year old female proband recorded with surface electrodes

Fig. 9.29 Sympathetic skin response of a 27 year old healthy female proband recorded from the upside and underside of the hands after electrical stimulation of *N. medianus*

inations mostly latencies are evaluated, which is the time period between the stimulation and the stimulation response.

The reflex bow is a neuronal conduction of the reflexory excitation process. It travels from the stimulus detecting receptors (e.g. muscle spindles, skin receptors) along the afferent branch to the spinal or central reflex centre. With the interconnection of one or several central neurones (monosynaptic or polysynaptic reflex), the excitation travels along the efferent branches to the muscle.

The recording of the blink reflex allows a statement on the function of single core regions in the brain stem. Above one eye there is a stimulation and the recording is from the two eye simultaneously. Two stimulation responses are obtained R1 and R2 – ipsilateral and early and late response is achieved; contralateral only a late response R2.

Vegetative Parameters

An objective evaluation of disturbances of the vegetative nervous system from outside can only be carried out in an indirect way. Two examples are mentioned here: the recording of the sympathetic skin response and the measurement of heart frequency variation.

The sympathetic skin response is a potential of large amplitude, which can be recorded after a surprise stimulation e.g. between the upside and underside of the hand. This response comes from a change in the skin conduction because of the activation of the perspiratory

glands and is found all over the body. The recording of the sympathetic skin response is applied in lesions of the vegetative nervous systems in the framework of the diagnosis of polyneuropathy.

Heart frequency in healthy persons varies with respiration. It increases during inhalation and decreases during exhalation. If this correlation is not found, it can lead to a respiratory arrhythmia of the heart. Heart frequency variation is recorded via the ECG, where the trigger is most practically set on the R-peak. The ECG is displayed in the time base in such a way that the variation of the following R-peaks is well displayed (Fig. 9.30).

Neuromuscular Transition

For the examination of muscle fatigue for the diagnosis of the neuromuscular transition pulse train stimulation is applied. The relation of the amplitudes and their decrement is evaluated here. In the examination of muscle fatigue and the neuromuscular transition only the amplitudes of the response potentials of supramaximum pulse stimulation are compared with another.

With double stimulation the refractory period with the absolute and relative refractory period can be evaluated. During this examination the time between the electrical double pulse is continuously decreased until the two response signals merge with each other. Then the nerve is not able to transfer the second stimulus to the muscle, because the synapses are still in their recovery phase from the first stimulus. The duration between the stimulation has to be adjustable in steps of 1 ms.

ENG – Signal Analysis/Evaluation

In the analysis of neurographic signals the response potentials to the stimulation are automatically measured. These automatic measurements are quite reliable in artifact-poor signals and increase the reproducibility of the results, because the same criteria are always applied. However, if the responses are superimposed with many artifacts or are small and hard to record due to a high degree pathology, then the physician must set the measuring cursors manually. The latency is measured as the time from the onset of the stimulation until the start of the response potential. With the help of a measuring band the nerve conduction velocity can be calculated.

9.3.5 Evoked Potentials

In the central nervous system each stimulation of receptors, afferent nerves, or brain structures in the central nervous system, the spinal channel, and in the periph-

eral nervous system leads to bioelectrical phenomena, which display a distinct time relation to the stimulation. These potentials are called evoked potentials (EP). They allow statements on the transformation, transition, and processing of particular stimulations and reflect the functional state of singular neuronal pathways. According to the kind of stimulation there is a distinction between acoustic (AEP), visual (VEP), somatosensory (SEP), and motor (MEP) evoked potentials. The aim of the recording of evoked potentials is to check whether the conduction of the sensory stimulation up to the cortical processing in the brain is normal, delayed, or recognizable at all. With SEP, AEP, and VEP the ascending sensory nerves pathways up to the brain stem are checked; with MEP the descending motor nerve pathways down to the peripheral musculature of arms and legs.

Device Techniques

The recording parameters of the amplifier, the analysis time, and the number of averages are characteristic for each EP examination. Table 9.7 shows an overview on the recommended parameter settings of the German Society of Clinical neurophysiology.

In addition, it is of vital importance to watch accurate electrode application thoroughly. Electrode placement here is also according to the 10–20 system. The skin of the scalp must be preprocessed so that the electrode transition impedance comes out below 2 kΩ. According to the kind of recorded evoked potential surface cup electrodes out of sintered Ag/AgCl or gold are applied. Unipolar platinum needle electrodes are only used in intra-operative application of evoked potentials. These do not need any preparation of the scalp, they are simply applied subcutaneously.

Before and during the recording the EEG raw signals are observed on the monitor in order that artifacts be recognized as soon as possible and eliminated. Especially muscle activity due to nonrelaxed patients occurs

Fig. 9.30 Heart frequency variation of a 32 year old male proband, displaying the change in heart frequency during respiration at rest and in deep breathing

during the recording. Therefore, the patient is placed comfortably on an examination couch during the AEP, SEP, and MEP recordings, whereas he has to sit in a chair in front of the TV monitor during the VEP.

For the recording of evoked potentials averaging is indispensable. The averager is triggered simultaneously by the onset of the stimulation signal. This way,

Table 9.7 Recording parameters for the different evoked potentials

Evoked potentials	Amplifier sensitivity	High-pass filter	Low-pass filter	Analysis time	Averaging steps
VEP	5 μV/Div	0.5 Hz	100 Hz	500 ms	64–128
SEP arm	5 μV/Div	0.5–1 Hz	2–3 kHz	50 ms	128–256, rare – 1024
SEP leg	5 μV/Div	0.5–1 Hz	2–3 kHz	100 ms	128–256, rare – 1024
AEP brainstem	1–2 μV	100–150 Hz	3 kHz	10 ms	1024–2048
ERP	5–10 μV/Div	0.1–0.5 Hz	30–70 Hz	500 ms–1 s	10–32
MEP arm	10–20 Hz	5–10 kHz	1–5 mV/Div	50 ms	
MEP leg	2–5 mV/Div			100 ms	1

the signal response components that are directly related to the stimulus grow out of the stochastic background activity, thus forming the actual signal components of the evoked potential. Other signal components such as artifacts, EEG, ECG, EMG etc. do not correlate with the stimulus and are averaged out. The increase of the signal/noise ratio correlates to the square root of the number of averaging steps.

It is also helpful for the recording of evoked potentials to use an automatic artifact rejection. However, the rejection mostly only discriminates the amplitudes: if the amplitudes transcends an adjustable threshold value, this particular signal epoch is taken out from the averaging.

Normative values and the evaluation criteria for evoked potentials consist of the latencies of characteristic peaks, their difference in the comparison of both sides, inter-peak latencies, and the lack of one or several components of the response potential.

Indications for the measurement of evoked potentials are generally in:

- The diagnostics of multiple sclerosis (MS),
- Space occupying processes
- Polyneuropathies
- Intensive medicine in coma or nonoriented patients
- Intra-operative monitoring e.g. during the operation on the spinal channel
- Intoxication and/or metabolism lapses
- Posttraumatic coma after craniocerebral injury
- Brain death determination.

Acoustic Evoked Potentials

Acoustic evoked potentials (AEP) enable the examination of the auditory nerve in connection with the auditory pathways via the brainstem to the cortex. In neurology the early components within the first 10 ms after the stimulation (brainstem AEP) are of vital importance (Fig. 9.31). These early brainstem responses are generated in the acoustic nerve and in singular nucleus regions of the brainstem. It is quite an easy examination in the case of functional malfunctions due to space occupying processes in the brainstem causing obvious

Fig. 9.31 Normal brainstem AEP of a 44 year old female

changes in the BAEP, such as in tumors and hemorrhages in the brainstem.

AEP are of distinct importance also in audiology. The AEP examination is applied in cochlear and auditory nerve lesions as well as in the objective audiometry in patients who are not able to cooperate in a normal audiometry.

The acoustic stimulator consists of electromagnetic shielded headphones, which are supplied by an electronic sound generator and therefore directly applied to the ear lobe. Electromagnetic shielding is necessary to avoid electric coupling via the recording electrodes to the amplifier, because the electrodes must be applied directly under the headphones.

If the sound generator is used for the stimulation of brainstem potentials, the stimulus consists of a short rectangular acoustic signal with a pulse width of 100 μ s, a so-called click.

- Click stimulation amplitude: 10–80 dB HL (hearing level), standardized 70 dB HL in neurology for objective audiometry, in ENT all sound intensities.
- Stimulation frequency: 1–30 Hz in 1 Hz steps; standard 10–15 Hz.
- Polarity: suction, pressure, alternating suction/pressure; white noise of 30 dB under the sound intensity contra-lateral to suppress of hearing the stimulus via bone conduction.

If the sound generator is used in ENT for further stimulation of middle and late AEP, then additional stimuli are selectable, such as frequency specific tone peps and burst pulses with adjustable times for rising and falling slopes in the normal audiometry range of 125–250–500 Hz and 1–2–4–8 kHz.

The four recording electrodes are placed on:

- Two recording electrodes on the right and left mastoid (scalp bone part behind the ear lobe) ipsilateral to the stimulated ear
- Reference electrode Cz
- Ground electrode Fz.

At first the stimulation and recording are carried out on the right ear; the left ear is simultaneously masked by white noise at 30 dB below the stimulation sound intensity. Secondly the left ear is stimulated and recorded with contralateral masking of the right ear. Finally, both stimulations and recordings are repeated in order to ensure the reproducibility of the recording.

The normative values of brainstem AEP at a stimulation loudness of 70 dB HL consists of five peak latencies and one inter-peak latency: latency I: 1.5 ms;

latency II: 2.6 ms; latency III: 3.6 ms; latency IV: 4.7 ms and latency V: 5.4 ms; inter-peak latency between the waves V and I: 4.0 ms. The potential peaks are evaluated in relation to their occurrence and their latency values. If one or several potential peaks are delayed or do not occur, the physician assumes a lesion in the respective location in the acoustic pathway.

In objective audiometry the amplitude relations between the IV-V complex and the wave I are also evaluated. In audiometry the recording of the brainstem potentials (brainstem evoked response audiometry (BERA)) is far more elaborate than in neurology because the loudness of the stimulus is successively decreased from 70 dB HL in 10 dB HL steps down to the hearing threshold. These recordings are time-consuming, taking up to at least half an hour.

The normative value of brainstem potentials are dependent on the stimulating loudness, on gender, on temperature, and pathological changes; however they are independent from the patient's cooperation. Therefore, their application is particularly suitable for monitoring during surgery on the inner ear and on the brainstem; they also are used in the detection of brain death.

Visual Evoked Potentials

Visual evoked potentials (VEP) (Fig. 9.32) enable the physician to examine the visual pathways. In neurology VEPs are applied to check the transition of the visual stimulation via the optic nerve to the visual pathways up to the visual cortex. Their clinical application is in the early recognition of multiple sclerosis (MS) and in central visual disturbances.

In ophthalmology their clinical application is e.g. in the objective visual acuity detection and in the objective recognition of disturbances in color vision. In electroophthalmology a great number of different visual stimuli are available, which are highly differentiated in color and gray scales.

The stimulator for routine VEP generally consists of a TV monitor, providing a checkerboard pattern over the total screen with maximum contrast, which produces each second a reversal checkerboard. The patient sits at a fixed distance from the checkerboard screen in the way that each checkerboard delivers a fixed gaze angle (standard 50 arcmin) in relation to the retina. The total visual field is $12^\circ \times 15^\circ$ in relation to the gaze angle of the patient. For this recording, the patient sits in a darkened room; it is of vital importance that patients with permanent glasses/contact lenses keep them on during the recording. During the recording the patient has to

Fig. 9.32 Visual evoked potential of a 57 year old female patient

fixate a small point in the checkerboard pattern (fixation point), which is located slightly above the centre of the checkerboard monitor. The patient is asked to perform great vigilance in observing the checkerboard reversal, this increases a good result of the VEP recording.

A VEP can also be recorded in coma or narcotized patients, if bright light flashes are used as stimuli. These are generated with the help of a photostimulator, which applies the flashes via LED-goggles directly to the patient's eyes.

The electrodes are placed in the following way:

- Recording electrode: 3 cm above the inion, on the centre line on the rear scalp
- Reference electrode: Fz
- Ground electrode: Fpz.

First the stimulation and recording are carried out on the right eye, the left eye is thereby covered. Then the left eye is stimulated and recorded, the right eye being covered. This is called monocular stimulation. The two response potentials are recorded once more each in order to ensure reproducibility.

The main peak in the response potential is called P100, which is the normative value of the positive peak at about 100 ms after the stimulation. Increased latencies around 10–20% are seen as pathological. The

negative peak before P100 is called N75 and is often measured as well. The latencies of the responses from the left and right sides are also compared. The normative value of the VEP is dependent on the stimulus parameters and on the age. A steady-state-potential may also be recorded at a reversal frequency of 8.3 Hz.

Somatosensory Evoked Potentials

Somatosensory evoked potentials (SEP) display an objective functional check of the somatosensory system that is the pathway from the sensory nerve endings of the upper and lower extremities via the transition along the spinal channel to the brainstem, and their cortical processing up to the cortex. They have clinical value for patients who cannot or would not give valuable data on their sensory disturbances during the clinical examination. With the help of a multi-channel recording along various points on the somatosensory pathway a possible lesion can be located and diagnosed.

SEP have clinical importance in the pathology of the peripheral nervous systems, such as in polyneuropathies and compression syndrome, during surgery of the spinal cord and the spinal column, in multiple sclerosis and brainstem lesions.

The nerve endings in the extremities are repeatedly stimulated with electrical current of rectangular short pulses of 100 or 200 μ s pulse width, which should be

adjusted to either 3–4 mA above the motor stimulation threshold or 3–4 times the sensory threshold. This causes a considerable contraction of the related muscles but is not painful. The stimulation frequency is either 1, 2, or 3 Hz for the evaluation of the early components; for the evaluation of the late components the frequency must be reduced to 0.2–0.5 Hz.

4-channel SEP of the median nerve is recorded for each stimulation site on the right or left part of the body as follows:

- Active recording electrode: per channel, channel 1: Erb's point in the cavity of the clavícula, channel 2: lower neck on the entrance of the median nerve into the spinal column, channel 3: upper neck before the entrance of the vertebral canal into the brainstem, channel 4: scalp point C3' (2 cm behind C3) for right stimulation, C4' (2 cm behind C4) for left stimulation, recording contra-lateral to stimulation, because of the crossing of the pyramid pathways in the brainstem.

- Reference electrode: scalp point Fz for all channels.
- Ground electrode: at the upper forehead, in addition a large area ground electrode on the upper arm between the stimulation and recording site (Fig. 9.33).

4-channel SEP of the tibial nerve is recorded for each stimulation site on the right or left part of the body as follows:

- Active electrode: per channel, channel 1: inner popliteal fossa above the tibial nerve, channel 2: lumbar vertebra. L5 on the entrance of the tibial nerve into the spine, channel 3: spine on lumbar point L1, channel 4: median scalp point Cz' (3 cm behind Cz) same for right and left stimulation.
- Reference electrode: scalp point Fz for all channels.
- Ground electrode: an the upper forehead, but not on a muscle, in addition a large area ground electrode on the lower leg between the stimulation and recording site (Fig. 9.35).

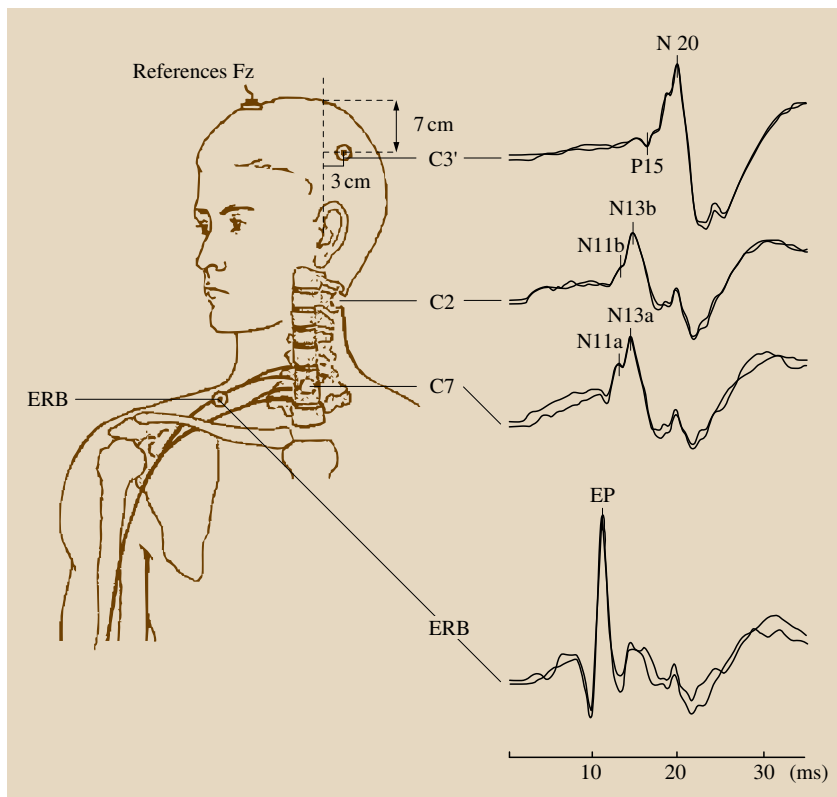

Fig. 9.33 Scheme for recording of median nerve-SEP of different recording sites with respective signals

Fig. 9.34 Normal somatosensory evoked potential of the median nerve of a 50 year old patient

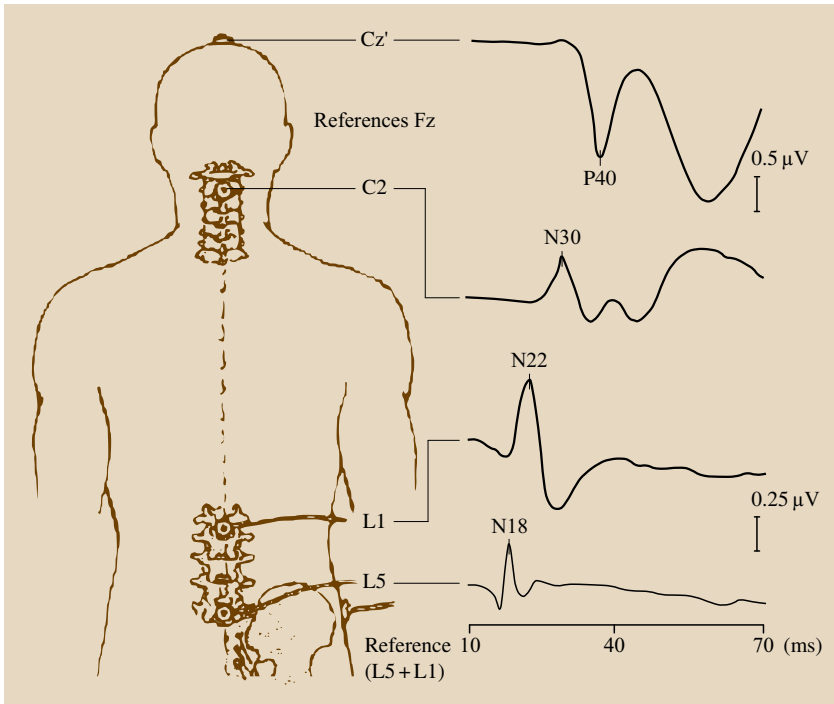

Fig. 9.35 Scheme for recording of tibial nerve-SEP of different recording sites with respective signals

SEPs are always recorded from both sides. Normative values for the cortical stimulation responses with stimulation of the median nerve are P15 and N20, which means a positive peak at 15 ms and a negative maximum at 20 ms. Normative values for early cortical stimulation responses from the tibial nerve are P30 and N33 (30 and 33 ms), for medium responses P40, N50 and P60 (40, 50 or 60 ms) and for the late responses >N75 (75 ms). Examples for responses and their measuring values for somatosensory EPs are shown after stimulation of the median nerve in Fig. 9.34 and of the tibial nerve in Fig. 9.36.

In clinics SEP is mostly recorded with four channels, so that latency differences from the singular peak latencies of the different recording sites are detected, which enables the physician to calculate the peripheral and central conduction velocity. The normative values are dependent on age, body temperature, and size of the patient. This must be considered in the conduction velocity determination.

Early cortical stimulation responses have the great advantage that they can be recorded independently from the patient's state of consciousness. They also remain mostly independent from drugs that influence the patient's consciousness, thus enabling SEP recordings in intra-operative monitoring.

Motor Evoked Potentials

Motor evoked potentials (MEP) examine the central motor pathways in an awake patient. The stimulation is carried out transcranially by a magnetic stimulator on the motor cortex in a noninvasive and pain-free way.

MEPs are often recorded in conjunction with SEP. SEP examines the ascending sensory nerve pathways together with their processing in different parts of the brain, whereas MEPs examine the descending motor pathways up to the extremities. The amplifier settings relate to the motor NCV; however longer analysis times are necessary. It is recommendable to select a waterfall display mode in order to present 10–20 MEP responses together on one screen.

The technique of a magnetic stimulator consists of a capacitor charge/discharge system with a high voltage circuit, a high power discharge switch, and a capacitor that is able to store the charged energy. The capacitor discharges via special coils; the coil construction and the geometry have great influence of the intensity, penetration depth, and the focus of the stimulation in the neuronal tissue. Therefore, coils in different shapes and forms are available for different kinds of stimulation. For the stimulation of the upper extremities a 90 mm standard coil is available. The sides of the coil are marked with the flux direction of the current. If one

Fig. 9.36 Normal somatosensory evoked potential of the tibial nerve of a 40 year old

looks at the coil from the top and the marking of the flux direction of the current is clockwise, then the left hemisphere is stimulated and the MEP response is recorded contra-lateral on the right hand. In reverse – if the flux direction is counterclockwise once the coil is turned upside down, the right hemisphere is stimulated with a contra-lateral recording on the left hand.

For the determination of the central motor conduction time (CMCT) first the motor cortex is stimulated, then the related nerve at the exit of the vertebral canal (Fig. 9.37). The MEP latencies of the cortical and cervical stimulation are measured and subtracted. The difference between them is the time, in which the stimulation pulse travels from the motor cortex to the spinal outcome of the nerve. This time is the central motor conduction time. Their normative values for the arms are between 5–9 ms, for the legs 15–19 ms. An important phenomena in cortical stimulation is facilitation. It is possible to decrease the necessary stimulation threshold to 25%, if the patient contracts the target muscle to be reached by cortical stimulation, thus carrying out a voluntary contraction. The MEP latency of the facilitated muscle then decreases to 1–3 ms.

There are some contraindications for magnetic stimulation: pace makers, metal in the scalp (e.g. aneurysma

clips), and diagnosed epilepsy. Furthermore, patient and examiner must take extra care of magnetic cards and computer disks during the examination, because the data on these devices may be changed if they are in the area around 20 cm of the stimulation coil.

9.3.6 Event Related Potentials

Event related potentials (ERP) are generated in higher layers of the cortex. They occur if the patient processes certain stimuli in a conscious way. Therefore, they can only be recorded if the patient gives importance to the occurrence of a stimulus. So the patient's cooperation is of vital importance for ERP, and he is asked to differentiate between high and low tones or count the rare tones.

In ERP only the late components are evaluated. They are called P300 or potentials after cognitive stimulation. P300 relates again to the peak value of the ERP response at about 300 ms latency after stimulation onset. An indication of the recording of ERPs is given e.g. in patients with brain dysfunctions and dementia syndromes such as M. Alzheimer's, in depression and schizophrenia, as well as in brain organic psychosyndrome.

Sleep Diagnostic Systems

Klaus-Peter Hoffmann, Robert S. Pozos

Sleep is a complex function of the brain, characterized by alternating cycles of slow waves and rapid eye movement. Sleep disorders are among the most common health problems. They have multiple causes, and different clinical disciplines collaborate to arrive at the proper diagnosis and therapy. After insomnia, sleep apnea or sleep disordered breathing is the second most common sleep disorder and is divided into two major categories: obstructive and central. This chapter discusses devices for monitoring patients at home and in sleep laboratories. Different therapeutic methods for patients with sleep apnea syndrome are discussed.

10.1 Function and Application

With a prevalence of 15–20% of the population, sleep disorders are considered to be a common disease. Of sleep disorders, 50–60% are psychogenic, whereas for an additional 30% it is not possible to distinguish be-

tween psychic and organic and 10–20% are organically caused. The last group includes patients with sleep apnea syndrome, who on the one hand suffer from an increased vital risk, but on the other hand can be quickly

and successfully treated by nasal continuous positive airway pressure (nCPAP) therapy. Overall, the international classification of sleep disorders (ICSD) published in 2001 by the American Sleep Disorders Association lists 88 different sleep disorders.

Sleep disorders have manifold causes, and their effects extend into various fields of medicine. Thus, an interdisciplinary approach is necessary for diagnostics and therapy of sleep disorders. These disciplines and

faculties include: pneumology, pediatrics, neurology, psychiatry, psychology, geriatrics, cardiology, otorhinolaryngology, internal medicine, urology, nephrology, etc. In addition, due to its complicated nature, sleep medicine has developed into a field of its own, containing medical knowledge about sleep and its disorders. In Germany, specialized knowledge in this field can today be acquired in many clinical and private sleep centers.

10.2 Sleep Diagnostics, Sleep Laboratories, and Sleep Apneas

10.2.1 Sleep Diagnostics

All procedures and methods used for evaluation of disordered and normal sleep as well as for examination of an induced therapy can be summarized under the term sleep diagnostics. For practical reasons, a multistage division has been established (Fig. 10.1).

The first stage includes questions concerning antecedents, case history, and a standardized short

questionnaire. The second stage consists of clinical examinations with laboratory tests and special sleep-wake anamneses. As an example, Table 10.1 shows a questionnaire for patients with suspected insomnia. The objective is the classification of the sleep disorder and, for sleep-related breathing disorders, a risk analysis. This analysis determines further diagnostic and therapeutic procedures.

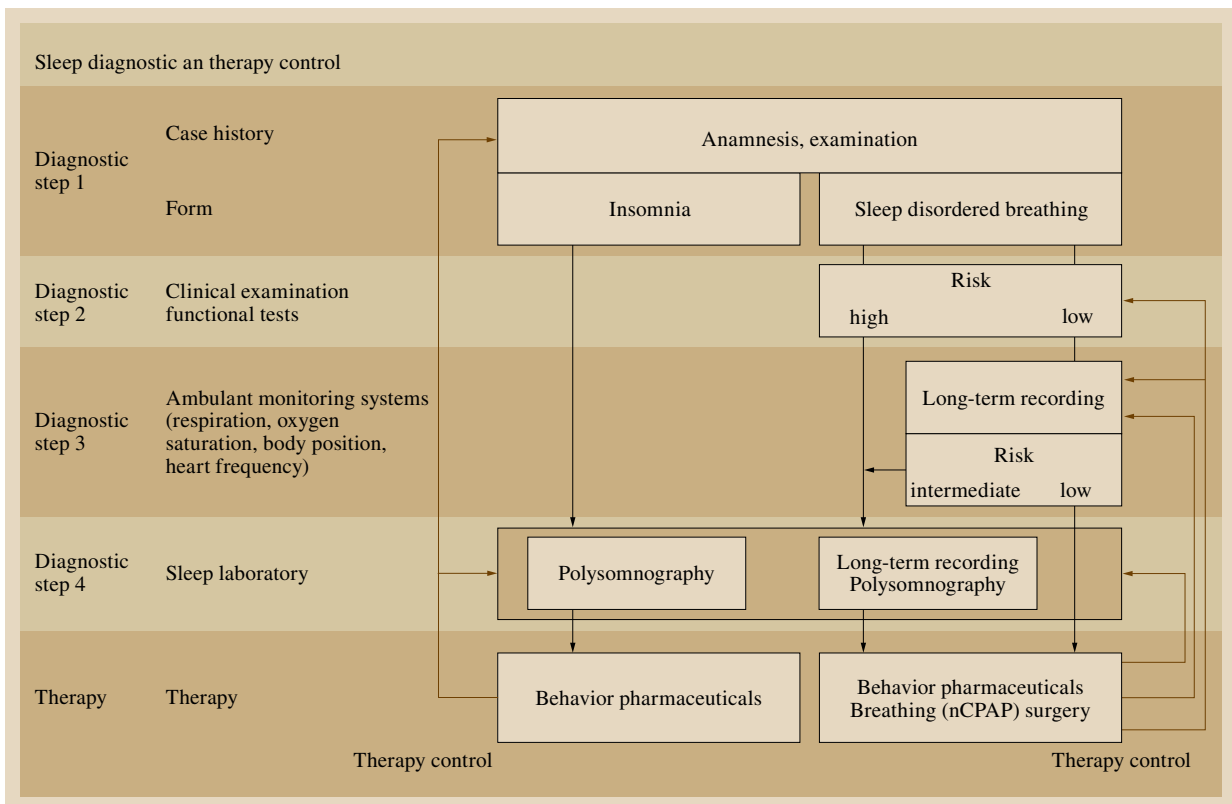

Fig. 10.1 Multistage diagnosis of sleep disorders

Table 10.1 Anamnesis, using diagnostics of insomnia patients as an example

Form of sleep disorder:	<ul style="list-style-type: none"> – Difficulty to fall asleep – Difficulty to stay asleep – Early awakening – Limited recreation
Pathology of sleep disorder:	<ul style="list-style-type: none"> – Cognitive and emotional activity in the post phase – Vegetative attendant symptoms – Special symptoms (respiratory obstructions, restless leg syndrome, nightmares, pain, anxiety)
State of health during the day:	<ul style="list-style-type: none"> – Vigilance – Activity and ability to cope with stress – Ability to concentrate and performance – Emotional state and general well-being
Sleep behavior:	<ul style="list-style-type: none"> – Time in bed and sleep duration – Sleep time – Evening habits and sleep habits
Progress and duration of the sleep disorder:	<ul style="list-style-type: none"> – Self-medication (drugs, alcohol)
Sleep prior to disease/pretreatment	<ul style="list-style-type: none"> – Nonmedicinal agents – Soporifics (form, time, and dose of intake)
Psychiatric and organic anamnesis and pathology: Influencing parameters	<ul style="list-style-type: none"> – Private and occupational life history – Living conditions and behavior affecting sleep – Physical environmental influences – General intake of pharmaceuticals – Consumption of caffeine, nicotine, alcohol, and drugs

For patients with suspected sleep-related breathing disorders, a third stage is initiated, including continuous monitoring of respiration, O₂ saturation of the blood, heart rate, and body position. For the most part, these measurements can be conducted ambulatorily.

The fourth stage includes recordings of biosignals, generally under stationary conditions in a sleep laboratory. The induced therapy is optimized and adjusted by repeated examinations to evaluate its effectiveness.

To conduct the polygraphic recordings necessary for diagnostics and therapy control, the German Sleep Society (DGSM) and the American Academy of Sleep Medicine have developed guidelines. They include respiratory mechanical measurements (respiratory gas flow, respiratory effort, nCPA pressure), cardiorespi-

ratory measurements (blood pressure, blood gases, electrocardiogram (ECG), pulse), neurophysiological measurements (electroencephalogram (EEG), electromyogram (EMG), and electrooculogram (EOG)), and patient-related measurements (motion, position, snoring sound, video recordings). Moreover, these guidelines recommend the number of channels, the parameters to set, the application of the respective sensors, the analysis including automatic processing, the evaluation of the results, and supplemental measurements.

10.2.2 Sleep Laboratory

In a sleep laboratory, sleep is examined under laboratory conditions, recording and storing various biosignals and

evaluating them with respect to manifold criteria. The cause of the disorder registered in the anamnesis is decisive for the respective diagnostic approach.

Due to the above-mentioned diversity of sleep disorders, specialized sleep laboratories have been established.

1. Psychiatric–neurological sleep laboratories are focused on psychogenic and neurological hypo- and hypersomnia, parasomnia, circadian disorders of the sleep–wake cycle, sexual disorders, and particularly epilepsy. This analysis requires additional EEG channels for seizure diagnostics including long-term EEG, EMG, body temperature, actigraphy, and registration of nocturnal erections.
2. A psychological sleep laboratory focuses on vigilance, dreams, and the causes of psychogenic sleep disorders as well as the influence of stress and noise on sleep. Neurophysiological parameters, such as skin impedance, skin and core temperature, EMG, and EEG biofeedback are additionally registered.
3. Sleep-related breathing disorders are the focus of internal–pneumological sleep laboratories. The measurement of cardiorespiratory functions including the associated change of neurophysiological parameters, such as occurrence of arousal, is typically used for diagnostics of sleep apnea syndrome. Further measured values include respiratory flow separately for nose and mouth, intrathoracic pressure, p_{CO_2} , continuous blood pressure, pH value, and long-term ECG.
4. Examinations regarding drug efficacy are conducted in a pharmacological sleep laboratory.

10.3 Technology

Depending on the stage of sleep disorder diagnostics, different methods and devices are applied. The choice strongly depends on the application, number of selectable parameters, sensor application, operability, evaluation strategies, software, etc.

10.3.1 Devices for Monitoring of Selected Parameters for Special Applications

To register, control, and document the vital functions of an infant in the first year with the risk of sudden

10.2.3 Sleep Apneas

An episode with a breath amplitude reduced by 50% for a duration of more than 10 s is denoted as hypopnea. In apnea, the amplitude is reduced by 20% for a duration of more than 10 s. A phase of apnea is accompanied by an initial decrease in heart rate and a drop in O_2 saturation after a few seconds. This phase is followed by an awakening signal of the central nervous system (CNS) and is characterized by arousal, short-term EEG activation, acceleration of the heart rate, heavy breathing, as well as an increase of blood O_2 saturation.

For obstructive apnea, the upper respiratory tracts are occluded due to the interplay of negative pressure in the pharynx and reduced activity of the pharyngeal muscles during inspiration. Here, thoracic and abdominal movements are still present and often opposed. A less frequent type of apnea is central apnea, which is due to decreased cerebral control of respiration with a decrease in respiratory flow and respiratory movements of the diaphragm. For mixed apnea, the most frequent form of apnea, the initial central apnea is followed by a phase of obstructive apnea.

10.2.4 Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) has an exceptional position among sleep disorders, as its cause(s) cannot be explained by either clinical or extensive post mortem examinations. It is the most frequent cause of death for infants in the first year. The stage of cerebral development is a possible cause. Today, the risk groups have been successfully identified, and various prevention strategies have been developed. Long-term monitoring is still the most frequently used preventive method.

infant death, special monitoring systems are provided. Monitoring may include heart rate, respiration, and movements of the infant as well as actigraphic measurements. The objective is to alarm the parents in case of loss of vital functions as well as to enable timely measures for resuscitation.

10.3.2 Ambulant Devices for Diagnostics

There are a variety of portable devices for recording and registration of polygraphic signals. The signals are

recorded in the familiar domestic environment of the patient, making habituation to laboratory conditions unnecessary. After registration of biosignals, they are either transmitted telemetrically or copied to a laboratory computer by the physician the following morning, and evaluated using automated signal analysis methods. In addition, monitoring systems are used for recording, storage, and evaluation of respiration (larynx microphone), heart rate (ECG), body position, and O₂ saturation.

Enhanced diagnostic possibilities exist due to the use of an increased number of channels and the application of nCPA pressure sensors. A sleep center can service several small hospitals with a sleep laboratory and ambulatory physicians. They transmit their recorded raw data or results based on automated analysis together with the patient data and their suspected diagnosis to the center, which assists the physicians in arriving at their diagnosis. Two-way transmission involves using modems for area networks or the web. Thus, the quality of sleep disorder diagnostics can be further improved, as referrals and inpatient confinements become more efficient.

10.3.3 Devices for Diagnostics in Sleep Laboratories

Devices for multistage sleep disorder diagnostics used in a sleep laboratory include equipment for long-term recording and polysomnography. In a network, individual devices form a closed system for signal registration, transmission, analysis, evaluation, and storage. Interfaces to other analysis systems and data processing equipment are provided. Therefore, integration into the hospital information system including patient and business management is beneficial, as, e.g., all examination findings are centrally archived and are thus available to any physician in the hospital.

As an example, Fig. 10.2 shows the setup of a sleep laboratory. It consists of four recording stations, with one of them being equipped with a laptop computer to function as a mobile station. In the awake station, all data are collected. Here, the night watch is on duty, and the signals are analyzed, stored, and archived. CPAP settings, communication with the patient, and remote data transmission via modem are possible. Simultaneously with biosignal recording, a video image of the patient is recorded and stored, and can be correlated to the signals.

In the aforementioned example, an additional evaluation station is provided for the executive physician,

who has access to all data. Wide, separate setting ranges for the recording parameters as well as sampling rates of 1–1000 Hz are required to enable an entire polygraphy. The equipment ranges from a 12-channel single-user station to linked 32-channel multibed stations with an evaluation unit and server.

For the application of recording devices in sleep medicine, it is also important that, during the recording, signals from previous periods can be examined at any time by the night watch or the doctor on call.

10.3.4 Therapy Devices

Sleep-related breathing disorders can be treated by nasal continuous positive airway pressure. The objective of such therapy is to prevent obstructions of the upper respiratory tracts in the inspiration phase by a positive pressure. Mainly, nasal continuous positive airway pressure (nCPAP) and nasal bilevel positive airway pressure (BiLEVEL) are applied. The use of a device with two separate pressures for inspiration and exhalation facilitates exhalation for high CPA pressures. The setting of the respective levels for inspiration and exhalation is controlled by the patient through breathing and has to be done precisely in a very short period of time.

If respiratory flow is plotted as a function of CPA pressure, the critical pressure p_{crit} can be determined (Fig. 10.3a). It is defined as the minimum pressure for which a respiratory flow can be detected, and it is a measure of the collapsibility of the pharynx during sleep. The critical pressure P_{crit} increases from snoring patients with obstructive hypopnea to patients with obstructive apnea respectively.

To increase patient acceptance of these devices, the pressure is slowly increased linearly during the phase of falling asleep, until the therapeutic pressure is reached. Newer devices, which are also denoted as automated CPAP, shift the pressure every 2 min by +2 mbar with respect to the current pressure level, and simultaneously measure the resulting change in respiratory flow. The objective of the analysis and potential adaptation of the current pressure is to reach the optimum pressure–respiratory flow window with no respiratory events (apnea, hypopnea, snoring) occurring.

Figure 10.3b shows a detail of an automated titration report with a plot of respiratory flow and pressure. Warming and humidification of the ventilation air as well as reduced noise emission by the integrated turbine are of great importance for patient acceptance of nCPAP therapy.

Fig. 10.2 Setup of a sleep laboratory with three stationary and one mobile recording station as well as a central wake station and an additional workstation for evaluation of the recording in the physician's room

Fig. 10.3 (a) Respiratory flow–pressure curve, (b) detail from an automated titration report

10.4 Sleep Diagnostic Procedures

10.4.1 Ambulatory Polygraphy

All recordings by nonlaboratory monitoring systems are classified under the term ambulatory polygraphy. This includes devices used in the third stage of sleep diagnostics as well as all alarm systems used for domestic monitoring of suspected sudden infant death syndrome.

10.4.2 Small Polysomnography

A small polysomnography is indicated for psychogenic/psychiatric disease patterns, for differential diagnosis of epileptic seizure disorders, and for therapy of nonrespiratory diseases. At least a four-channel EEG, the EOG, EMG and ECG are required. Continuous observation of the patient via video screen and of the polygraphic recordings is required.

10.4.3 Extensive Polysomnography

Extensive polysomnography is conducted for persistent and therapy-resistant sleep disorders which at first view are not psychogenic or psychiatrically caused, for suspected sleep-related breathing disorders, and for drowsiness. Different signals like EEG, EOG, EMG, ECG, flow, effort, blood gases, snoring, blood pressure, position, temperature, movements, erection, and

intrathoracic pressure can be recorded. Videometry is required.

10.4.4 Multiple Sleep Latency Test

With the multiple sleep latency test (MSLT), drowsiness can be examined. This test is conducted directly after a preceding nocturnal polygraphy, e.g., at 10 am, 12 pm, 2 pm, and 4 pm. Each recording session can take 20 min, and the patient should not resist going to sleep. The recordings include EEG, EOG, EMG, and ECG.

10.4.5 Maintenance of Wakefulness Test (MWT)

Like the MSLT, the MWT is conducted directly after a preceding nocturnal polygraphy, e.g., at 10 am, 12 pm, 2 pm, and 4 pm. The willingness of the patient to stay awake is measured. The patient is requested not to fall asleep during or between the recordings. The same parameters as for the MSLT (EEG, EOG, EMG, and ECG) are recorded.

10.4.6 Therapeutic Monitoring

The technological requirements are the same as those of extensive polysomnography, plus the possibility to

record the CPA pressure. Monitoring is conducted to control the nasal CPAP or the BiLEVEL setting, which is the result of a qualified adjustment. After 3, 6 and 12 months, the setting is routinely checked.

10.4.7 Intensive Monitoring (Epilepsy)

Intensive monitoring is mainly used to detect epileptic activity. Also for this technique, a multistage procedure is applied for each patient. Routine EEG recordings (from 20 min up to 1 h), prolonged recordings (1–6 h), and long-term recordings (6–24 h) can be distinguished, which together form a complex neurodiagnostic functional unit. For simultaneous double image recording, patient behavior and EEG are displayed synchronously on a monitor.

In examinations of patients with proven epilepsy, epileptic activity are detected in 75% of patients during a 48 h recording, of which 10% occurred suddenly. Thus, ictal and interictal activity can be com-

pared, and continuous analysis for classification can be made.

Sleep phases are particularly important for diagnosing epilepsy, as seizures increase in quantity at the following times: during early sleep between 10 pm and 12 am, 1–2 h before morning awakening, and after morning awakening. The proportion of specific potentials increases during sleep compared with the awake EEG by $\approx 20\%$, especially during late periods of the night and during arousals.

10.4.8 EEG After Sleep Deprivation

Previous to intensive monitoring for diagnosing epilepsy, routine EEG recordings after 24 h of sleep deprivation are conducted. During the 1–2 h period of recording, the patient is allowed to sleep. Thus, the effect of sleep deprivation and sleep itself is used to provoke and intensify epileptic activity in the EEG.

10.5 Signal Recording and Signal Processing

10.5.1 Signal Recording

The quality of signal recording is crucial for the quality of sleep disorders evaluation. Besides the choice of

the sensors and electrodes necessary for each respective case, signal quality depends on proper placement and application as well as on the recording parameters set according to the signal properties, such as amplifica-

Table 10.2 Example of recording parameters for detection of polysomnographic signals according to the recommendations of the German Sleep Society

Signal	Recording site	$\mu\text{V/cm}$	f_{\min} (Hz)	f_{\max} (Hz)	Comments
EEG	C3:A2, C4:A1 or C3:A1; C4:A2	70	0.53	70	Instead of A1, A2 also mastoid; 10:20 system
EOG	Left, right epicanthus	70	0.53	> 30	Also horizontal and vertical recording possible
EMG	<i>M. mentalis</i> or <i>M. submentalis</i> ; bipolar	20	< 1.6	> 70	
ECG	In. <i>Manubrium sterni</i> , dif. 5. intercostal area	1000			R peak as well as P and T wave readily identifiable
Respiratory flow	Mouth and both nostrils	Differentiation between hypoventilation and normal breathing			Thermistor or thermocouple
Effort	Thoracic and abdominal	Hypoventilation, normal breathing, and hyperventilation have to be identifiable			Induction, plethysmography, strain gages, piezosensors or impedance measurement
Blood gases	Saturation				Pulse oximetry, for analog output 1% per mm
EMG	<i>M. tibialis anterior</i>	20	< 1.6	> 70	Bipolar, 5 cm distance

Fig. 10.4 Polysomnography (ambulatory) of a patient with obstructive sleep apnea (channels from top to bottom: respiratory flow, respiratory effort for thorax and abdomen, snoring microphone, oxygen saturation, body position, and heart rate). Obstructions are clearly reflected by a flattening of the respiratory flow with reduced or opposed displacements of thorax and abdomen, followed by the occurrence of snoring sounds, a reduced oxygen saturation, and an increased heart rate

tion, frequency range, and sampling rate. In Table 10.2, the device settings recommended by the German Sleep Society are summarized. The sampling rate for digitization of biosignals should be at least twice the highest frequency contained in the signal. In addition, a com-

promise has to be found between recording quality and the capacity of the digital storage medium.

Figure 10.4 illustrates a printout of raw data from a polygraphic recording according to the third diagnostic stage. Quality control of recording has to be done

Table 10.3 Criteria for visual evaluation of polygraphic signals in the sleep laboratory according to the recommendations of the German Sleep Society

Signal	Analysis
Respiration	Amplitude and phase shift between thoracic and abdominal respiration – Respiratory amplitude < 10% of normal respiration > 10 s ⇒ Apnea – Respiratory amplitude < 50% of normal respiration ⇒ Hypopnea – Apnea index (AI) = apneas per hour of sleep – Hypopnea index (HI) = hypopneas per hour of sleep Respiratory disturbance index (RDI) = sum of all respiratory events per hour of sleep
Blood pressure	Systolic, diastolic, and average blood pressure – Minimum and maximum values during awake state and sleep
Blood gases	A drop of > 3–4% is clinically relevant – Oxygen desaturation index (ODI) = average saturation, desaturation per hour of sleep
EEG	Visual determination of sleep phases according to the criteria by Rechtschaffen and Kales in the phases awake, 1, 2, 3, 4, rapid eye movements (REM), and movement time (MT) (Table 10.4)
ECG	Heart rate variation, cardiac arrhythmia average heart rate awake and sleeping, moment of maximum heart rate
EMG <i>M. tibialis</i>	Quantification of periodic leg movements (PMS) – Duration between 0.5 and 5 s, > double amplitude, – Periodic for four events with an interval of 4–90 s and an average of 20–40 s – Issue of arousal, PMS arousal index = number of movements with arousal per hour of sleep, from five pathological
EMG chin	Sleep phase classification, quantification with respect to phasic and transient EMG activity
EOG	Detection of REM sleep, calculation of the average REM density slow eye movements in sleep phase 1
Erection	Diagnostics of erectile impotence; temporal association to REM episodes
Interactions	Connections between sleep phases, arousals, and other EEG elements with cardiorespiratory events and movements
Body position	Apneas and hypopneas are counted for the respective body position
Temperature	Diagnostics of chronobiological disorders of the sleep–wake behavior; examination time > 32 h

online. For polysomnographic recordings according to stage 4, a greater number of recording channels are used, and depending on the case, additional biosignals

are registered. Also, the video image of the sleeping patient can be shown, to enable direct correlation of patient movements and biosignals (Fig. 10.5).

Fig. 10.5 Polysomnographic recording of a patient in the sleep laboratory with the display of the video image in the *upper window*. The following biosignals are shown: EEG C3:A1 and C4:A2, EOG, EMG from the mouth base, respiratory flow, respiratory effort, snoring sounds, oxygen saturation, ECG, heart rate, EMG from the leg and body position

10.5.2 Visual Evaluation

The first step in evaluation is a visual review of the raw data to ascertain the recording quality and the occurrence of the artifacts. The whole recording is displayed using various time scales, to obtain a faster overview. Table 10.2 summarizes the criteria of a visual evaluation of polygraphic signals for sleep disorder diagnostics.

To assess the dynamics of sleep and sleep quality, the respective sleep phases and their changeovers are registered according to the standard classification of the sleep phases by Rechtschaffen and Kales. In Table 10.4, the essential criteria of this classification are summarized.

10.5.3 Computer-Aided Evaluation

Computer-aided methods for analysis of polysomnographic signals consider both the respiratory and the bioelectric signals. Algorithms evaluate and detect

apneas and hypopneas, and differentiate between obstructive and central breathing disorders (Fig. 10.6). Evaluating variation in heart rate and oxygen saturation will assist in further diagnosis. The concise display of changes of these parameters over the whole recording period is an indispensable aid to the physician.

Although the classification of sleep phases according to Rechtschaffen and Kales has become the standard and provides useful information for many applications, it is based on a quite arbitrary phase differentiation and depends on the experience of the physician. Other methods use Fourier analysis to separate the signal into its frequency components and calculate the power as a function of time. The sleep architecture can especially be registered through the slow activity in the range of delta-waves (less than 4 Hz). Thus, functional aspects of sleep regulation can be examined (Fig. 10.7).

Other methods include analysis in the time domain by detecting waves and patterns and the use of hybrid systems with analog filters. Newer methods use neural

Table 10.4 Classification of sleep phases according to the criteria of Rechtschaffen and Kales

State and % of total sleep		EEG	EOG	EMG
Awake (1%)	W	Dominating alpha activity (8–13 Hz), beta waves (> 13 Hz)	Eyeblinks, rapid eye movements	High tone, movement artifacts
Non-REM (5%) (49%)	S1	Theta activity, vertex waves	Slow, oscillating eye movements	Drop of the average muscle tone, small movement artifacts
	S2	Theta activity, K complexes, sleep spindles	No eye movements	Drop of the average muscle tone, small movement artifacts
(8%)	S3	Groups of high delta waves > 20%, < 50%	No eye movements	Drop of the average muscle tone, small movement artifacts
(13%)	S4	Groups of high delta waves > 50%	No eye movements	Drop of the average muscle tone, little movement artifacts
REM (24%)	REM	Theta activity, sawtooth wave	Conjugated rapid eye movements (saccades)	Low average tone, phasic activation
Movement time (MT)	> 50 % of the stage is interfered by movement artifacts, thus allocation to another phase is not possible			

Fig. 10.6 Polysomnographic display, particularly of the respiratory parameters, including their evaluation by marking detected apneas or hypopneas and desaturation

Fig. 10.7 Display of evaluation results, particularly of the neurophysiological biosignals. The classification of sleep phases according to Rechtschaffen and Kales, the frequency analysis of the EEG (two-dimensionally as a function of time), and the temporal occurrence of alpha and delta waves in the EEG are shown

networks which, after a learning stage, assess biosignals according to predetermined criteria. Currently, also algorithms based on fuzzy logic are used for classification of sleep phases.

Another parameter is the pulse transit time (PTT) which can be derived from the ECG and the pulse signal measured on the finger by photoxymetry. The

pulse transit time is the time lag between the maximum of the R peak and the moment when the pulse curve reaches 50% of its amplitude. Changes in the pulse transit time correlate with both blood pressure changes and respiratory effort. Thus, an additional parameter is obtained to differentiate between obstructive and central apnea.

10.6 Fields of Application

The fields of application for diagnostics of sleep disorders are as manifold as their causes. They range from

internal, neurological, and pneumological diseases to physiological reactions, e.g., jet lag due to crossing time

Table 10.5 Fields of indication in various medical subjects

Subject	Examples of functional disorders and diseases representing an indication for an examination of sleep-related breathing disorders
Andrology	Erectile dysfunctions
Endocrinology	Hypothyreosis, acromegaly, adipositas permagna
Hematology	Polycythemia
Otolaryngology	Detectable obstruction of the upper respiratory tracts for an awake patient
Cardiology	Nocturnal cardiac arrhythmia, hypertension, cardiac insufficiency of unclear genesis, dilatative cardiomyopathy
Neurology	Neuromuscular diseases, hypersomnia
Orthopedics	Kyphoscoliosis
Pediatrics	Disorders of respiratory regulation, SIDS survivors, children with suspected Pickwick syndrome, thriving disorders, big tonsils and adenoids
Pneumology	Hypoxia/hypercapnia with or without previously existing pulmonary disease, insufficiency of the right heart or global cardiac insufficiency of unclear genesis
Psychiatry	Hypersomnia, hyposomnia
Psychosomatics	Unclear <i>states of failure</i> , reduced performance
Oral surgery	Craniofacial malformations

zones during transmeridian flight or sleep disorders associated with pregnancy.

They also include all fields with respect to age, e.g., from sudden infant death syndrome to age-related sleep disorders in geriatrics. In Table 10.5, the in-

dividual subject areas and the respective functional disorders are mentioned. It is obvious that there is hardly any medical subject which is not directly or indirectly confronted with the problem of sleep disorders.

10.7 Methodical Instructions

The methodical instructions given in this chapter are related to polysomnographic recordings. For issues concerning maintenance and servicing, the instructions of the respective manufacturers of devices, accessories, and sensors have to be considered. As the type of sensors, their properties, and their application may vary, only a few, general instructions can be given.

10.7.1 Handling/Application

Which biosignals should be recorded depends on the clinical problem. At the beginning of recording,

in addition to technical calibration, biological calibration has to be conducted by eye movements produced by commands, body movements, arbitrary apnea, hypopnea, and hyperventilation. This is done to control the operability of the recording technique and the fit of the sensors. For recording of bioelectric signals, only electrodes of the same material should be used, either gold or silver/silver chloride.

The German Sleep Society recommends that polysomnographic examinations be conducted on at least two consecutive nights. During the first night, the

patient can acclimatize to the laboratory. Preferably, biosignals should be continuously recorded on paper with a paper speed of 10 or 15 mm/s. The German Sleep Society recommends storage of the recorded signals on optical, magnetic or digital media, so they can be analogously plotted again with a polygraph at any time.

10.7.2 Artifacts

Artifacts represent an important problem in measurement of biosignals. As a noise signal, they are superimposed onto the physiological signal, and their amplitude can be a multiple of the amplitude of the wanted signal. Biological and technical artifacts can be distinguished. The latter can be reduced by choosing the recording space, improving the sensor application (e.g., reduction of the electrode interface impedance) or changing the recording technique.

Biological artifacts can be eliminated only to some extent, e.g., by relocating the applied sensors. Those artifacts can be identified in the signal by an experienced operator. Artifacts can lead to misinterpretation if

they are analyzed by computers e.g. slow eye movements in the frontal EEG.

Fig. 10.8 Determination of the pulse transit time

10.8 Medical Significance of Sleep Diagnostics

The medical significance of sleep disorders emerges from their prevalence, and from the yearly indirect costs due to nondetection and nontreatment. Currently, about 20 million people in Germany suffer from sleep disorders not caused by external influences. About 3.3 million people are afflicted by tiredness during the day which may partially explain the high incidence of fatal motorway accidents which are due to dozing off behind the wheel (24%). In addition, 2.7 million people take soporifics on a regular base, although almost half of patients taking soporifics daily report that their disorders continue unchanged. Many people taking soporifics should be classified as addicted. It is absolutely essential that the disorder and the initiation of a causal therapy be medically clarified. This becomes even more urgent, as dangerous and widespread diseases such as obesity, arterial hypertension, heart insufficiency, cardiac arrhythmia, sudden cardiac death, and metabolic diseases can be caused by sleep disorders.

Overall, 800 000 patients suffer from sleep apnea in Germany, of which 50% have hypertension. Three

significant pathomechanisms are considered to be the major causes for hypertension:

- Blood gas changes,
- Intrathoracic pressure variations, and
- Consecutive arousal reactions.

Over time, these can lead to hypertension in the systemic and pulmonary circulation, cor pulmonale, cardiomyopathies, coronary heart diseases, cardiac arrhythmia, and stroke. Sleep research studies indicate that secondary cardiovascular and cardiopulmonary diseases do not appear or are reversible if sleep-related breathing disorders are diagnosed in time and successfully treated.

Table 10.6 summarizes the sleep disorders based on the international classification of sleep disorders published by the American Sleep Disorders Association. This international classification describes the various disorders and tries to group them with respect to their cause.

Table 10.6 International classification of sleep disorders

1. Dyssomnias	2. Parasomnias	3. Sleep disorders associated with mental, neurologic or other medical disorders	4. Proposed sleep disorders
<p>A. Intrinsic sleep disorders</p> <p>Psychophysiological insomnia, sleep state misperception, idiopathic insomnia, narcolepsy, recurrent hypersomnia, idiopathic hypersomnia, posttraumatic hypersomnia, obstructive sleep apnea syndrome, central sleep apnea syndrome, central alveolar hypoventilation syndrome, periodic limb movement disorder, restless legs syndrome, intrinsic sleep disorder not otherwise specified (NOS)</p>	<p>A. Arousal disorders</p> <p>Confusional arousals, sleepwalking, sleep terrors</p>	<p>A. 10.9 Therapy

Therapeutic methods for sleep disorders are as manifold as the sleep disorders themselves. A five-stage therapeutic scheme can be defined, distinguishing between behavioral medical psychotherapeutic, chronobiological, pharmacological, machine-aided, and surgical methods.

10.9.1 Behavioral Medical Psychotherapeutic Therapy

Besides recommendations regarding sleep hygiene and prevention of sleep-disturbing behavior, various relaxation exercises are used.

10.9.2 Chronobiological Therapy

This field includes measures that influence the periodic process of biological functions, such as light therapy, which can also be used to reduce the effect of an artificial time shift, such as jet lag or due to shift work.

10.9.3 Medicinal Therapy

For primary organic and chronic diseases, pharmacological measures are used. Depending on the disease pattern, stimulants, antidepressants, hypnotics, and neuroleptics are used. For medicinal treatment of mild

and moderate sleep-related breathing disorders, theophylline can be used. Thus, patients can be medicinally treated, if nCPAP therapy is not available.

10.9.4 Machine-Aided Therapy

For treatment of sleep-related breathing disorders, machine-aided therapy is commonly used. Predominantly, CPAP devices are used for positive-pressure ventilation. For high expiration pressures or pressure-limited ventilation devices in the treatment of both central sleep apnea and central hypoventilation, a BiLEVEL with separate control of inspiratory and expiratory pressure can be used.

Alternative solutions include the Esmarch prosthesis to advance the mandible 2–4 mm, and the Snore Ex to pull the tongue of the patient from the back of the mouth to the front. The therapeutic effect of these methods is controversial.

10.9.5 Operational Therapy

A clear indication for oral surgery resulting in positive results is rare. Uvulopalatopharyngoplasty is used to stabilize the pharyngeal lumen. Especially in infants, tonsillectomy can be applied to eliminate obstructions.

10.10 Safety Aspects

The application of all medical devices should be based on evidence that they pose no threat to the patient, the user or third persons. This is specified in standards (e.g., regulations of the German Association for Electrical, Electronic, and Information Technologies). Basic regulations are included in the medical product law, governing the fabrication, operation, and use of medical products and their accessories. Devices have to be designed in such a way that their safety, suitability, and performance are not endangered, even when affected by malfunctions or operating errors. Besides the application-related desires, a polysomnographic system has to fulfill the medical quality assurance criteria.

10.10.1 Mobile Devices

Medical devices must not endanger the health or security of patients, users, and third persons. This is particularly important for mobile devices that the patient uses at home within the scope of therapy or ambulant diagnostics of sleep disorders. Here, operabil-

ity, clarity, exclusion of potential operating errors, and long failure-free operating times have to be additionally considered. The latter is an essential precondition for use of CPAP devices in therapy of sleep-related breathing disorders, which has to be combined with a special service. Yearly maintenance should be the standard and should, besides cleaning, substitution of worn parts, and evidence of full operability, also be used to coordinate the relation between patient and machine through extensive support of and consultation with the patient.

10.10.2 Devices in the Sleep Laboratory

Devices in the sleep laboratory are used under permanent surveillance by staff. Besides device-related preconditions, training of laboratory staff is very important. The assessment procedures of the German Sleep Society for quality assurance in the sleep laboratory do not only include the control of quality and quantity of laboratory space, technical equipment, and staff, but also quality of diagnosis and therapy.

10.11 Planning Advice

10.11.1 Required Space

For the optimum design of a sleep laboratory, it should have the sleep stations and the room with the recording and processing technology (wake station) spatially separated. The sleep station area should be at least 12 m². Acoustic insulation, and possibilities to darken the room and control air conditioning should be provided. An infrared video system consisting of camera, microphone, infrared radiator, monitor, and recorder is necessary for simultaneous video recording of the patient together with the recorded biosignals, and is also used to keep the patient under surveillance. To communicate with the patient during recording, an intercommunication system is required.

10.11.2 Required Time

The time required for a sleep examination strongly depends on the case and can vary between 20 min (MSLT) and several days (diagnostics of epilepsy and chronobiological sleep disorders). Preparation of the patient and application of the sensors take 30–60 min on average.

10.11.3 Staff

A sleep laboratory is managed by a responsible director skilled in the diagnoses of sleep disorders. If he is not a physician, but, e.g., psychologist, a physician should be present to address medical issues. It is recommended to employ one physician (e.g., for outpatient clinic, clinical findings, interventional therapy, and on-call duty) and two assistants (e.g., for patient assignment, day test, evaluation, sensor application, and maintenance) per work station. A night watch should not observe more than three patients, among them a maximum of two CPAP patients and no more than one problem case. During the night, a physician on duty has to be available on call.

Nystagmography

11. Nystagmography

Klaus-Peter Hoffmann, Eduardo Fernandez

Clear vision requires both eye motion and highly accurate positioning of the fovea. Various types of oculomotor activity are distinguished (e.g., ocular reflexes, fixation, saccade, smooth pursuit). Different methods can be used to record eye movements. The most common methods for clinical application are electronystagmography, photoelectronystagmography, and videoculography. Examples for signal processing and medical significance are given.

Nystagmography is a method to record, analyze, and evaluate spontaneous eye movements in response to vestibular, visual, caloric, rotational or positional stimulation. Nystagmography provides an objective assessment of the oculomotor and vestibular systems. Figure 11.1 shows a simplified general schematic of the oculomotor system. Its primary task is to stabilize the images of the visual world on the retina and thus enable undisturbed vision and constant spatial perception.

11.1 Application

Surprisingly, even gazing at a stationary object involves smooth eye movements because the head is always in

On the one hand, the interesting image details have to be binocularly centered and fixed at the site of sharpest vision, the fovea ($\approx 0.8^\circ$) of the central visual field. On the other hand, retinal image shifts occurring with movements of one's own and of the environment have to be eliminated. For this, fast and slow eye movements are available with the oculomotor system's saccades, smooth pursuit movements, vestibular and optokinetic nystagmuses, convergence movements, and fixation. The fixation phase is characterized by microsaccades.

slight motion as the muscles of the body and neck attempt to maintain the posture. Only the accuracy of

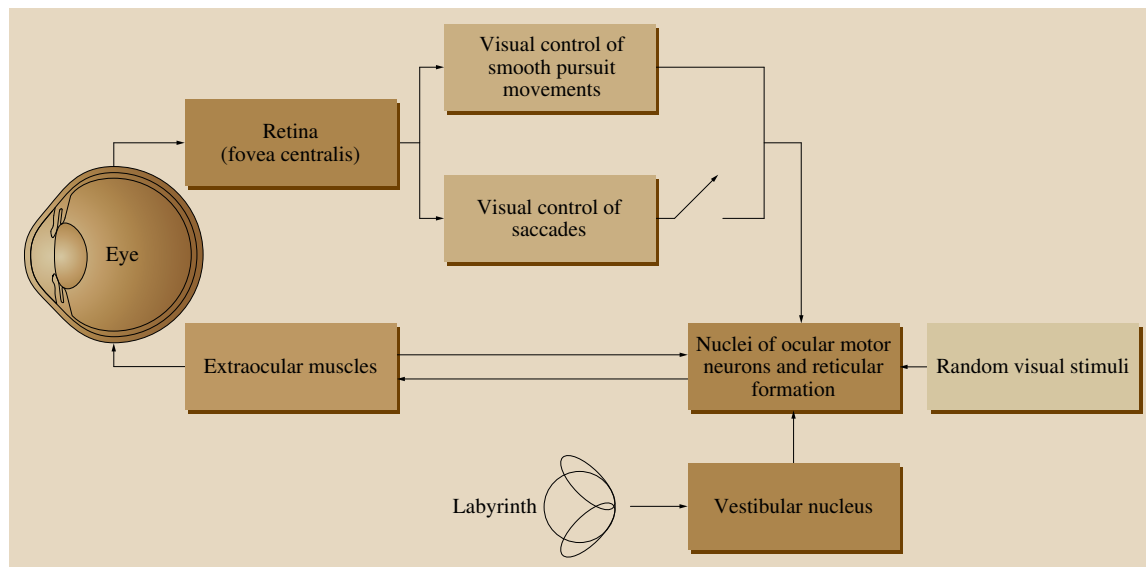

Fig. 11.1 Simplified schematic of the control of eye movements

the sensorimotor connection including the possibility to compensate for interferences secures the maintenance of binocular spatial vision. This functional performance of the oculomotor activity is enabled by the central integration of the proprioceptive, vestibular, and optic afferents.

Eye movement recording has been in use for a long time. Up to the 19th century, eye movements could only be monitored by sitting closely and watching the eyes of the subject directly. Some of the first mechanical recording methods were more precise but required a level or a small mirror system attached to the sclera, thus being uncomfortable for the subject, and were

rapidly abandoned. A breakthrough was achieved in 1922 when the potential difference between the cornea and the retina was used for recording of ocular nystagmus (Sect. 11.3.2). This procedure is still the most widely applied technique for eye movement recording in clinical routine, specially by otolaryngologists and neurologists to evaluate patients with dizziness, vertigo or balance dysfunction.

Thus, nystagmography is an interdisciplinary subject, which is particularly applied in neurology and otorhinolaryngology. Already since the middle of the last century, it has been established as a routine diagnostic method.

11.2 Eye Movements

A schematic of essential forms of eye movements is given in Fig. 11.2. This includes saccades, smooth pursuit movements, nystagmus, and convergence movement.

11.2.1 Saccades

Saccades are quick eye movements used to find a new fixation point. They are cerebrally controlled and are generated in the paramedian pontine reticular formation. Their maximum velocity increases with the amplitude of the movement and can be up to 700 deg/s. The duration

is between 30 and 120 ms. Other parameters of a saccade include latency and overshoot defined as percentage deviation from the fixation point after a saccade. If the new fixation point is not completely achieved by a saccade, a correction saccade follows after 100–300 ms.

Saccades can be divided into internally triggered volitional saccades (e.g., memory-guided saccades, antisaccades, tracking saccades), automatic reflex saccades triggered by external stimuli (e.g., visually or acoustically induced), and spontaneous, seemingly random saccades.

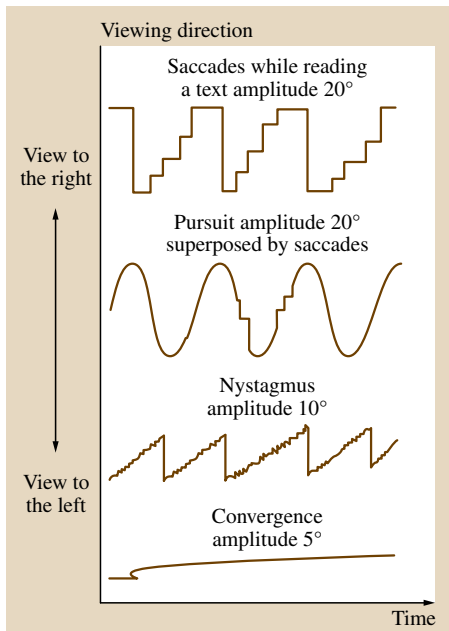

Fig. 11.2 Schematic display of eye movements

11.2.2 Smooth Pursuit Movements

Smooth pursuit movements can be described as conjugated and slow movements, by which the eye tracks a moving vision target. The outlines of the object can additionally be scanned by saccades. The average angular velocity is 30–50 deg/s. They are used to follow and stabilize a moving vision target on the retina. Care should be taken in interpretation, since these smooth movements are influenced by age and are affected by attention and patient cooperation.

11.2.3 Nystagmuses

An involuntary rhythmic ocular oscillation occurring in two phases is denoted as nystagmus. Two basic types of nystagmus can be distinguished: on the one hand the jerk nystagmus with a slow and a quick phase, with the latter determining the direction of the nystagmus, and on the other hand the pendulum nystagmus with equally quick eye movements in both directions.

11.3 Technology and Methods

The experienced clinician can conduct a differentiated examination of eye movements, especially the detec-

The optokinetic nystagmus (OKN), also called vestibulo-ocular reflex (VOR), is a jerk nystagmus caused by large-area stimuli. An example is the so-called railway nystagmus, which can be detected when watching targets out of a moving train. The slow phase corresponds to the movement of the train (pursuit movement), the quick phase to a change of the fixation point (saccade).

A vestibular stimulation can be followed by a VOR. For instance, a vestibular nystagmus occurs after caloric or mechanical stimulation of the labyrinth. The latter can be achieved by angular acceleration. During the rotation, the nystagmus is directed in the rotational direction; after termination, it is directed in the opposite direction.

Other physiological nystagmuses include the cervical nystagmus for rotation of the cervical spine, the audiokinetic nystagmus for moving acoustic sources, the arthrokinetic nystagmus for passive arm and leg movements, and the fixation or terminal nystagmus.

Pathologic nystagmuses occur due to lesions in the optomotor system. They include rebound nystagmus, vestibular spontaneous nystagmus, head-shaking nystagmus, bearing nystagmus, muscle paretic nystagmus, periodic alternating nystagmus, etc.

11.2.4 Convergence Movements

Convergence is the simultaneous inward movement of both eyes towards each other (in the vertical axis) so that the projection of the image is in the center of the retina in both eyes. The main objective is to maintain binocular vision. Interretinal image errors possibly occurring during a fixation can be compensated by convergence movements. Those are very slow (10 deg/s) and have small amplitude (maximum 15°).

11.2.5 Torsional Movements

Rotations around the visual axis with amplitude of up to 10° and velocity of up to 200 deg/s are denoted as torsional movements. They can occur spontaneously or optokinetically due to the view of an environmental roll movement or vestibularly during body or head tilting.

tion of defective eye positions, also without complex technical equipment. Quantitative registration by mea-

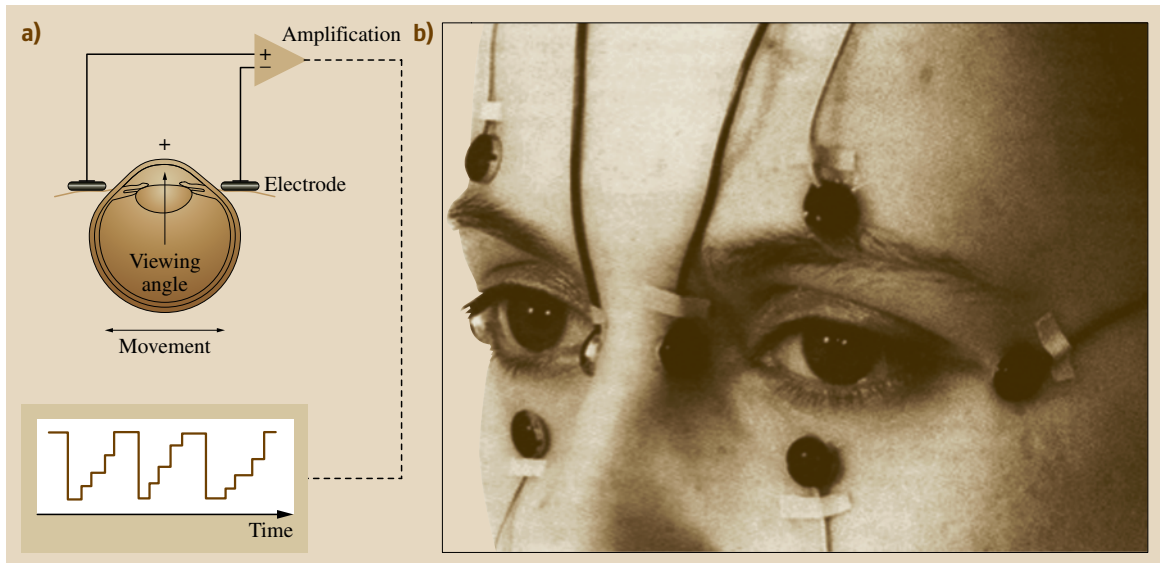

Fig. 11.3a,b Electrooculography. (a) Schematic of metrological registration. (b) Application of Ag/AgCl electrodes for bipolar recording of horizontal and vertical eye movements

asuring the latency and maximum velocity, progress observation, detecting spontaneous eye oscillations, and recording of eye movements with closed lids can only be done with appropriate technology.

11.3.1 Frenzel Glasses

Frenzel glasses comprise a pair of very thick lenses which serve to completely blur the patient's observed environment. Due to the convex lenses and the illumination of the eyes, fixation is excluded, and the evaluation of eye movements with magnification becomes possible.

The advantages of Frenzel glasses over other methods to study eye movements is their low cost. This method can only be used for qualitative statements. It is widespread owing to its easy operability and sufficient evaluability.

11.3.2 Electronystagmography (ENG) and Electrooculography (EOG)

Electronystagmography is the most widespread method for registration of eye movements in clinical practice. The signal source is the corneoretinal potential which is due to concentration differences of various ions in the retinal pigment epithelium. When the eye is moved, an electric potential can be recorded close to the eye.

The change of this potential is proportional to the cosine of the angle between the recording plane and the dipole axis. These potential changes can be bipolarly recorded using Ag/AgCl electrodes separately for both eyes (Fig. 11.3). A linear relation can be assumed for these values with sufficient accuracy up to 20° .

Electronystagmography can be performed with only little technical effort. Besides the electrodes and a registration component, amplifiers with a frequency range of 0.1–30 Hz for smooth pursuit movements and direct current (DC) up to 1000 Hz for saccades are required. Measurements in horizontal and vertical direction can be done for both open and closed eyes, for instance, during sleep. The resolution is about 1° . The signal is perturbed by a variety of artifacts, such as lid artifact, potential changes during light–dark adaptation of the eye, baseline drift due to changes in skin impedance, and muscle artifacts. Owing to its unlimited and simple operability, electronystagmography is still the state of the art for clinical routine diagnostics.

11.3.3 Photoelectronystagmography (PENG) and Infrared Oculography (IROG)

These methods rely on the fact that the white sclera reflects more light than the pupil and the iris. For the photoelectric method, infrared light-emitting diodes,

Fig. 11.4 Photoelectronystagmography: schematic of the measurement setup

which are mostly circularly arranged, are used to diffusely illuminate the eye. This light is differently reflected by the iris and the sclera. Thus, phototransistors directed towards the limbus detect potential differences during eye movement. The value of the potential difference is proportional to the movement (Fig. 11.4).

This method shows only little susceptibility to noise and is well suitable for computer-aided analysis. Also, very small eye movements down to 0.1° can be meas-

ured. Drawbacks are influences from lid movements and changes of pupil diameter. Moreover, only measurements with open eyes are possible.

11.3.4 Magnetooculography

Every current-carrying conductor is surrounded by a magnetic field. Therefore, it is possible to detect changes in the bioelectric potential by changes in the magnetic field. This is the basis of magnetooculography, which uses superconductive quantum interferometers as sensors.

Magnetooculography (MOG) is an entirely noncontact method. Currently, its resolution is still less than that of electrooculography. It demands great technical and financial effort, magnetically shielded rooms, and cooling with liquid helium to achieve superconductivity. Thus, it is only used for research purposes.

11.3.5 Electromagnetic Technology (Search-Coil System)

A contact lens with a thin wire coil is placed on the eye. The head of the patient is situated in an alternating magnetic field. Movement of the eye generates an induced potential proportional to the sine of the angle between the coil and the direction of the magnetic field. Depending on the position of the coil, both horizontal and vertical eye movements as well as torsional movements can be registered.

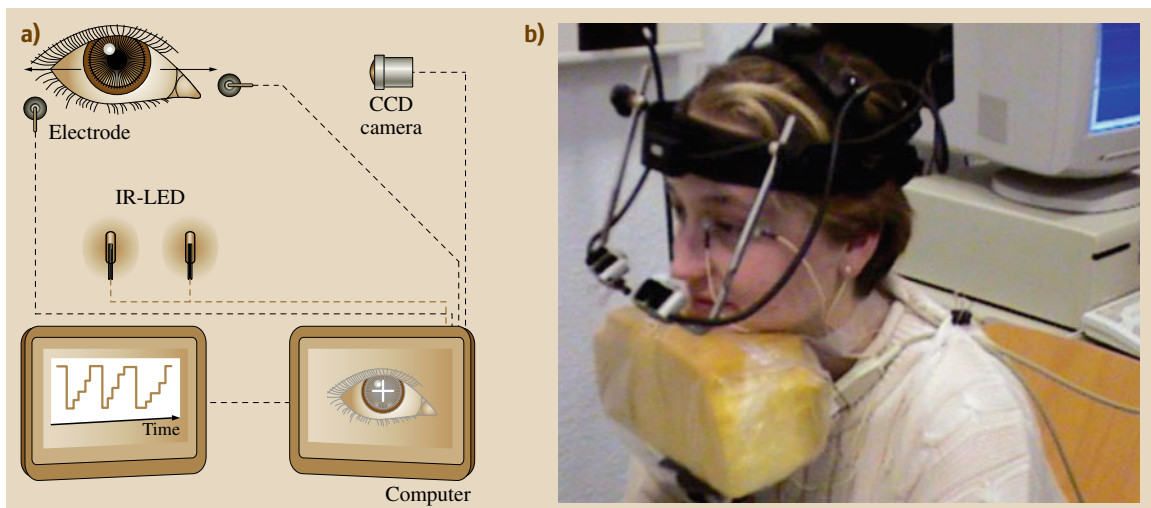

Fig. 11.5a,b Videooculography. (a) Schematic of the metrological registration. (b) Setup of a measurement station with fixation of the head. In this example, the electrooculogram was simultaneously registered by electrodes

The system provides a drift-free, low-noise signal with resolution of a few arc minutes. Owing to the application of a contact lens and the associated discomfort to the patient, electromagnetic technology has not been established in clinical practice.

11.3.6 Videoculography (VOG)

Miniaturized video cameras based on infrared-sensitive charge-coupled device (CCD) sensors enable frame rates of 250–500 Hz. This is sufficient to identify eye movements from a video image. The required illumination of the eye is achieved by at least two infrared light-emitting diodes (wavelength 850–940 nm) directed towards the eye. The pupil can be detected as the darkest point in the image, as light reflection is least

there. The center of the pupil is the intersection of the maximum line segments in the horizontal and vertical directions. Its movement represents the corresponding eye movement (Fig. 11.5).

Moreover, torsional movements can be registered. For this purpose, light marks are projected onto the eye, and the movement of defined prominent patterns of the iris is analyzed. This requires the use of image processing systems.

Due to the manifold possibilities, videoculography is a modern procedure, which has recently gained in importance. With respect to temporal resolution, it still lags behind electrooculography. New clinical potentials have emerged from the registration of torsional movements. However, measurements with closed eyes are not possible.

11.4 Methods

The examination methods depend on the clinical problem, the existing oculomotor disorders, and the respective areas of origin. Qualitative statements are

possible through simple clinical tests, e.g., movement of a finger by the physician, requesting the patient to fix the finger, or changes in the position

Fig. 11.6 Electrooculographically registered saccades with various amplitudes, showing that the maximum velocity increases with the amplitude of the eye movement

Fig. 11.7 Electrooculographically registered smooth pursuit movements of the right and left eye with various velocities of a sinusoidal moving fixation point: 10 deg/s (*top*), 20 deg/s (*middle*), and 30 deg/s (*bottom*), showing that, with increasing velocity, the smooth pursuit movements decay and the ratio of saccadic eye movements increases

of the patient. The thus provoked eye movements are observed.

In the following, some essential technical examination methods are briefly discussed.

With closed eyes, the occurrence of spontaneous nystagmus can be examined. Eye movements are mostly registered by electrooculography.

11.4.1 Saccades

Saccades are provoked by two defined fixation points, for instance, two light-emitting diodes alternately light-

ing up. The patient is requested to look at the illuminated spot, respectively. As a variation, the patient can be requested to change the fixation point at an acoustic signal, or to look at a fading light spot. Figure 11.6 shows an example for registration with various amplitudes.

11.4.2 Smooth Pursuit Movements

The patient is requested to follow a moving light spot with the eyes, e.g., a spot on a monitor moving with a velocity of 10–40 deg/s (Fig. 11.7). Gain,

Fig. 11.8 Electrooculographically registered nystagmus. The optokinetic stimulation was done with vertical stripe patterns (stripe width 3.5°) moving horizontally on a monitor with velocity of 20 deg/s. The movement direction changed. Detected nystagmus are marked for the right eye

Fig. 11.9 Measurement station for the examination of the nystagmus after optokinetic stimulation with moving patterns on a television and vestibular stimulation using different movement patterns of a swivel chair (courtesy Jaeger Tönnies GmbH, Würzburg)

coherence, phase, and velocity asymmetry are determined.

11.4.3 Optokinetic Nystagmus

An optokinetic nystagmus can be provoked by a rotary drum with, e.g., attached stripes.

If horizontally moving patterns are projected on a television, nystagmus (Fig. 11.8) can also be provoked. The velocity and size of the patterns are variable.

11.4.4 Vestibular Nystagmus

For selective stimulation of one labyrinth, the most widely used method is the caloric vestibular test. Prior to caloric testing the patient must be inspected with an otoscope to verify that there is no perforation. In the caloric vestibular test, the acoustic meatus is rinsed with warm water (44°C) or cold water (30°C). Thus, the two labyrinths can be examined separately. The patient's head is slightly raised. Thus, the lateral horizontal semicircular channel reaches a vertical position. Rinsing with warm water yields thermal convection currents, resulting in displacement of cupula and stereocilia, causing a nystagmus. It is measured whether or not the nystagmus is symmetrically triggered by both ears. This method is used for clinical examination of the vestibular system.

For rotational testing, the patient is seated on a rotating swivel chair with the head stabilized (Fig. 11.9). It is used to test the vestibulo-ocular reflex. Frequently applied methods include the rotating pendulum test, the rotation stop test, and the rotation test. During the rotating pendulum test, the chair is sinusoidally moved with defined amplitudes and velocities. For the rotation stop test, the patient is sufficiently adapted to a constant rotation, and then stopped within 1–2 s. The postrotary nystagmus can be detected. During a rotation test, the patient is first accelerated, then moved with constant velocity (plateau phase), and finally gradually decelerated. It is used to detect the perrotary nystagmus.

11.5 Signal Recording and Signal Processing

Signal recording is determined by the methodology applied. Most currently used systems provide computerized stimulus generation, response acquisition, and interpretation.

Signal processing depends particularly on the procedure used and the respective clinical problem. Besides comparison of the movement of the right and the left eye when looking to the right or left, respectively, and comparison with the default signal, direct calculation of parameters comes to the fore. For saccades and nystagmus, the calculation of velocities is significant.

However, latency, overshoot, and duration of a saccade also enable statements relevant to diagnostics. For smooth pursuit movements, the gain as an expression of the ratio of response amplitude and stimulus amplitude, the determination of the decay of smooth pursuit movements, the phase relation between stimulus and

eye movement, and correlation and coherence functions play an important role.

Calculation of the mentioned parameters is done both in the time domain and, after Fourier transformation, in the frequency domain. The results are displayed separately for the two eyes and for the respective line of sight, often as a function of the amplitude of the eye movement.

For videooculography, a variety of image processing techniques are applied to determine the position of the eyes. The requirements on signal processing are constantly increasing, enhancing the range of nystagmographic examination methods and improving the quality of diagnostic statements. Especially the description of the oculomotor system by mathematical models and different types of digital filtering facilitate new approaches.

11.6 Medical Significance

The oculomotor system is one of the most thoroughly studied human systems. Analysis of eye movement disorders in patients enables a degree of characterization and precise localization which up to now could only be achieved by modern imaging techniques. Besides localization, the principal information gained is the description of a functional limitation due to a lesion, a space-occupying lesion, a systemic disease or the effect of pharmaceuticals and other substances. In this context, it has to be considered that the attempt to compensate is simultaneously registered. This can be used to detect different lesions as well as to show the plasticity of brain.

Applications of nystagmography range from neurological diseases (such as multiple sclerosis and space-occupying lesions) and muscular diseases (such as myasthenia) to vestibular symptoms (such as vertigo). Table 11.1 shows some locations of lesions and their influence on eye movements.

Other applications for the analysis of eye movements are diagnostics of reading disorders, determination of sleep phases in sleep diagnostics, but also the control of events via the eyes, for instance, in paraplegics. Eye movements are also recorded in psychological examinations, for instance, during the observation of pictures (Fig. 11.10).

Table 11.1 Disorders of horizontal eye movements by various cerebral lesions

	Fixation	Saccades	Smooth pursuit movements	Optokinetic nystagmus
Cerebral cortex frontal lobe	Nonpermanent contraversive cortical gaze paretic nystagmus	Saccade paresis contraversive with gaze deviation ipsiversive	–	Contraversive (towards direction of the quick phase)
Cerebral cortex, occipital lobe	–	Gaze disorder due to hemianopsia	Ipsiversive	Contraversive
Pontomesencephalic brain stem	Ipsiversive	Slow down or paresis of saccades ipsiversive with contraversive gaze deviations	Ipsiversive	Ipsiversive
Cerebellum	Ipsiversive	Saccade dysmetry	Ipsiversive	Contraversive

Fig. 11.10 Analysis of saccadic eye movements. The course of the eye movement velocity is displayed. The thresholds are highlighted

11.7 Safety Aspects

Nystagmography is a noninvasive diagnostic method which is applied in a medical environment. Thus, no extra safety aspects have to be considered.

11.8 Spatial Planning

The required space depends on the method applied and varies with respect to whether a swivel chair is used or not. For routine applications of electronystagmography, the required space is comparable to other diagnostic methods, such as electrocardiography or electromyography.

Audiometry

12. Audiometry

Sebastian Hoth

The practical application of audiometric tests is determined by the needs on the one hand and the possibilities on the other hand. In clinical practice, it makes no sense to examine everything that can be tested. Only those tests are performed whose results have therapeutic consequences. This basic principle was the determinant factor for the selection of topics in the present text. The complete inventory of functional tests composed of psychoacoustic assessments and objective measures as well as the options for technical rehabilitation will be described.

12.1 Physical, Technical and Physiological Bases of Audiometry

The human auditory system has at least three properties that are responsible for the comprehensiveness of modern audiometry: it is *important*, *complex*, and *vulnerable*. The outstanding *importance* of hearing among our sensory modalities requires reliable tools for its assessment. The *complexity* of the hearing system explains why we need a large number of tests for its complete exploration, and because of its *vulnerability* there will be frequent necessity to apply these tests.

Audiometric testing is expected to answer many questions:

1. Is hearing affected significantly?
2. Which parameters are suitable to describe the affection?
3. Which component of the hearing system is affected?
4. Does the hearing impairment affect the quality of life?
5. Which therapeutic options are available to overcome the impairment?

Hearing impairment can have many reasons: debris, injuries, malformations, infections, fractures, altered pressure in middle or inner ear, intoxication, aging, undersupply, dysfunction of sensory cells, atrophy of other inner ear organs, perturbed synaptic transmission, damage or degeneration of neurons, tumors, infarcts, stroke, and loss of central auditory functions for other reasons. Manifold functional deficits may go along with hearing impairment: reduced sensitivity, altered intensity processing, restricted frequency selectivity, lowered time resolution, and loss of discrimination. Not all deficits can be compensated with the medical, surgical and tech-

nical therapeutic options that are currently available. In many cases, the functional losses caused by the hearing impairment can be compensated or substituted only partially. However, in the historical context, the possibilities of technical rehabilitation have never been as abundant as at present [12.1].

12.1.1 The Physical Description of Sound

The perception of sound is one of the fundamental dimensions of our sensory systems and nearly everyone is familiar with sound phenomena and the sensations associated with them. Nevertheless, an exact definition of sound is useful and necessary. In the context of physical acoustics, sound is defined as mechanical oscillations and waves in the frequency range between 16 Hz and 20 kHz, which elicit the sensation of tones, sound or noise to the human ear. Sound can be generated and transmitted as a local deviation from the equilibrium in solid, liquid, or gaseous media. Homogeneity, isotropy and stationarity of density, pressure, and velocity are perturbed locally by the sound source. Due to the interaction between elementary particles, the local perturbation will impact the neighboring sites, while the relaxation of forces restores the equilibrium at the origin: The perturbation leaves the place of generation. In the case of a periodic event, the origin is the source of a continuous three-dimensional wave. This physical basis of forces and interactions between molecular or atomic particles, of continuity condition, adiabatic approximation, and elastic properties is the background of the mathematical description of sound phenomena by a differential equation involving time, space coordinates, and elastic constants. Its solutions describe the propagation of local perturbation in all space directions with constant velocity [12.2].

The amount of deviation from equilibrium is described by pressure, density, and particle velocity. Their gradients proceed parallel to the direction of propagation: Sound waves are *longitudinal* waves. Time and position representations of these waves are equivalent because the differential equation depends only on $(x - c \cdot t)$ but not explicitly on position x and time t . A sound wave is described by its parameters *amplitude* or intensity, *wavelength* or wave number, *frequency* or period, and *phase*. The *amplitude* describes the actual value of pressure, density or sound particle velocity. At the sites and at the time instants of maximum pressure and density (condensation), the particles are at rest and the *sound particle velocity*, i. e. the velocity of displacement from the rest position, is zero. Accordingly, a minimum

of pressure and density (rarefaction) goes along with a zero crossing of particle velocity. On the other hand, the particle velocity is large if pressure and density are in equilibrium and their gradient and time derivative is maximum. The particle velocity is lower than the *sound velocity*, which in turn is in the order of magnitude of the thermal velocity. In the equations describing sound waves, the amplitude is denoted by the unspecific symbol a representing the deviation of either the pressure (in $\mu\text{Pa} = 10^{-6} \text{ N/m}^2$), the density (in g/m^3), or the particle velocity (in m/s) from thermal equilibrium.

The definition of frequency and wavelength is based on the phase that describes the momentary state of the elementary wave or oscillation. Among other alternatives, this state can be a maximum of pressure, a minimum of particle velocity, or a positive sloping zero crossing of density. The wavelength λ indicates the spatial distance of equivalent repetitions of these unique phases. In air and under normal conditions of pressure and temperature, the wavelength of sound waves lies between 17 mm and 20 m. The reciprocal value of λ (multiplied by 2π) is the wave number k . It corresponds to the number of waves contained in the length unit. The phase of pressure or density is shifted relative to the phase of the particle velocity by a phase angle of 90° .

The frequency f corresponds to the repetition rate of a certain phase of the wave (counts per second in $\text{Hz} = 1/\text{s}$). Its reciprocal value, the period T , lies between 63 ms (at 16 Hz) and 50 μs (at 20 kHz) for audible sound. In the case of periodic oscillations containing more than one frequency (e.g. vowels), the terms frequency and wavelength are not adequate but a period can be defined as the time elapsed between two equivalent states of the waveform. It corresponds to the lowest frequency contained in the complex waveform.

The longitudinal sound wave propagates away from its origin with the *sound velocity* c , which depends from temperature, pressure, and the elastic properties of the transporting medium. In air at room temperature and normal atmospheric pressure its value is approximately 340 m/s, in liquid and solid materials the velocity is essentially higher. Frequency and wavelength are connected to each other by the relation $f = c/\lambda$, which can easily be deduced from the above mentioned tight binding between x and $c \cdot t$. If the distance λ between the wave maxima and the velocity c of their propagation are known, the frequency of their arrival at the site of observation can be determined.

The propagation of sound is associated with an energy transport that is described by the power density and

given in W/m^2 . The intensity needed for normal hearing persons to perceive a pure tone of 2 kHz (the hearing threshold at this frequency) is 10^{-12} W/m^2 . This reference intensity I_0 corresponds to the reference sound pressure $p_0 = 20 \mu\text{Pa}$. At the upper limit of hearing the sound intensity of a 2 kHz tone amounts to 1 W/m^2 and the sound pressure to 20 Pa (level of discomfort). The largeness of the dynamic range – 12 orders of magnitude in the intensity scale – justifies the use of a logarithmic scale for the sound pressure level (SPL) L . Its dimension unit is the decibel (dB)

$$\frac{L}{\text{dB SPL}} = 20 \lg \frac{p}{p_0} = 10 \lg \frac{p^2}{p_0^2} = 10 \lg \frac{I}{I_0} . \quad (12.1)$$

The level in dB indicates by how many *tenths of orders of magnitude* the considered intensity I is separated from the corresponding reference value. For the sound pressure, this absolute measure is only half the amount because the intensity is proportional to the square of the (effective) sound pressure

$$I = \frac{p_{\text{eff}}^2}{Z} = Zv_{\text{eff}}^2 . \quad (12.2)$$

The constant Z appearing in this relation is the impedance of the sound wave, which on his part corresponds to the quotient of sound pressure p and particle velocity v . In air, the acoustic impedance amounts to 430 Ns/m^3 and in water to $1.46 \times 10^6 \text{ Ns/m}^3$. This demonstrates that the boundary between air and water is associated with a large discontinuity of impedance, which is of great importance for terrestrial vertebrates because it leads to the necessity for a middle ear apparatus as impedance transducer.

An acoustic signal that can be described by a sine wave in time and space contains only one frequency and is perceived as a pure tone. Since all time-dependent processes can be decomposed in contributions of different frequencies (*Ohm's* law of acoustics), pure tones can be regarded as the *elementary particles* of acoustics. They are the basic components of sounds in the context of music (i. e. acoustic signals consisting of a few components of discrete frequencies), noises (i. e. wideband signals whose statistic properties can be stationary or time-dependent), speech (i. e. signals with rapid changes of frequency and intensity carrying a semantic meaning), and sound pulses (i. e. short signals with steep edges). The definition of the sound pressure level of complex signals containing many frequencies require the computation of an effective pressure p_{eff} ,

which is given by the root mean square amplitude. In the case of pure tones, p_{eff} is identical with the maximum amplitude divided by $\sqrt{2}$ (correspondingly, the same is valid for the effective value v_{eff} of the particle velocity). In the case of nonstationary signals, the effective value depends on the time constant and the complete description additionally requires the peak values.

All signals mentioned so far (tones, sounds, noises, speech, and sound pulses) are used in practical audiometry for the examination of hearing capability. For some of them, the amplitude and/or frequency is modulated in special applications. Speech signals exhibit a natural amplitude modulation whose frequency amounts to about 4 Hz according to the duration of syllables. Accordingly, some stimulation paradigms in practical audiometry involve speech simulating noise signals whose frequency spectrum corresponds to the long-term average speech spectrum and whose envelope is modulated with a frequency around 4 Hz. The extreme type of modulation encountered in sound pulses requires special corrections if a hearing level that is independent of pulse duration and repetition rate is to be defined. The level of pulses is characterized by peak values since effective values are not meaningful.

The propagation of sound is affected by objects whose impedance differs from that of the carrier medium. The impact of the obstacles depends on their dimension. If the obstacle is large in relation to the wavelength, it impedes the propagation and produces a geometrical *shadow* on its back side, whereas small objects deflect the sound wave, which is therefore present at the side opposite to the source with little or no attenuation. Consequently, the distortion of a broad band signal affects its frequency spectrum. Signal components of low frequency are present at the far side of the obstacle without attenuation, whereas the intensity of high frequencies is reduced. These effects are important in the context of spatial hearing and for the quality of perception of the own voice.

If the wavelength is small in relation to the dimensions of the obstacle (i. e. at high sound frequencies), diffraction phenomena can be neglected and the interaction between the sound field and the boundaries of the medium can be described by the laws of geometric reflection. In spaces that are limited partially or totally by walls, special oscillations can occur due to the superposition of incoming and reflected waves. These *standing waves* depend on the boundary conditions. In the case of reverberant closures (vanishing particle velocity at the sonically hard ending), only waves with nodes of the particle velocity (or rather lobes of the sound pressure)

can interfere constructively with their own reflection. This condition is fulfilled only for volumes whose dimension coincides with an integer multiple of the half wavelength.

The same holds true in the case of two free closings (nodes of the sound pressure or rather lobes of the particle velocity). Some wind instruments as well as the open ear canal exhibit a free and a hard ending. Under these conditions, the wavelengths of standing waves are defined by the condition that the geometrical dimensions must coincide with an odd multiple of a quarter of the wavelength. For the ear canal with a length of approximately 2.5 cm, the lowest resonant frequency lies around 3.4 kHz. The phenomena of standing waves and resonances are important in the context of free field audiometry and they play a role in all acoustic measurements within the ear canal (impedance audiometry, recording of otoacoustic emissions, in-situ recordings) and in the provision with hearing aids (reflections within the residual ear canal volume). However, the boundary conditions (one free and one hard ending) are not fulfilled exactly since neither the walls of the ear canal nor the tympanic membrane are ideally sonically hard, and the entrance of the ear canal is not ideally sonically soft. Therefore, the real resonance frequencies do not obey the rules given here exactly.

Standing waves can arise only if the sound wave is completely reflected at the wall between two media. This presumes that the reflection coefficient

$$r = \frac{\zeta - 1}{\zeta + 1}, \quad (12.3)$$

determined by the quotient $\zeta = Z_2/Z_1$ of the impedances Z_1 and Z_2 of the media is unity. The sound wave striking the interface between two media of different impedance is partially reflected (fraction r) and partially absorbed (fraction $\alpha = 1 - r$). In the context of hearing, the most important interface is that between air (in the tympanic cavity) and water (in the inner ear). Because of the large impedance difference of these media, the reflection coefficient of the boundary is large. The middle ear has the task to overcome the impedance discontinuity. The function of the impedance transducer can be examined with impedance audiometry.

12.1.2 Anatomy and Physiology of the Auditory System

A large number of anatomic structures and very complex physiologic mechanisms are involved in processing the acoustic information within the auditory system.

The actual sense organ for the perception of sound is the organ of *Corti* in the inner ear (cochlea). Up to here, the sound energy is transported from the outer ear (concha) and across the outer ear canal (meatus acusticus externus), the eardrum (tympanic membrane), and the middle ear (tympanic cavity and ossicular chain). After mechano-electrical transduction in the inner ear, the information contained in the sound signal is transferred, processed, interpreted, and classified by the neural structures of the auditory pathway (hearing nerve, afterbrain, midbrain, thalamus, auditory cortex, and association areas). The pathways originating from both ears have projections to either sides of the brain. This provides the possibility of analyzing interaural differences of time and intensity, which play an important role in directional hearing and for the detection of signals in noisy or reverberant environments.

The peripheral parts of the auditory system are shown in Fig. 12.1. Outer ear and ear canal pick up, collect, and conduct the sound energy. They amplify the signal with a gain characteristics, which depends on direction and frequency, they protect the delicate structures of the organ against injury and they suppress the noise of flow and wind. Tympanic membrane and middle ear ossicles (malleus, incus, and stapes) feed the signal into the cochlea. They transform sound pressure and particle velocity in order to overcome the barrier between the low impedance of air and the high impedance of the inner ear liquids. The sensory cells within the inner ear are connected to ascending (afferent) and descending (efferent) fibers of the auditory nerve. The

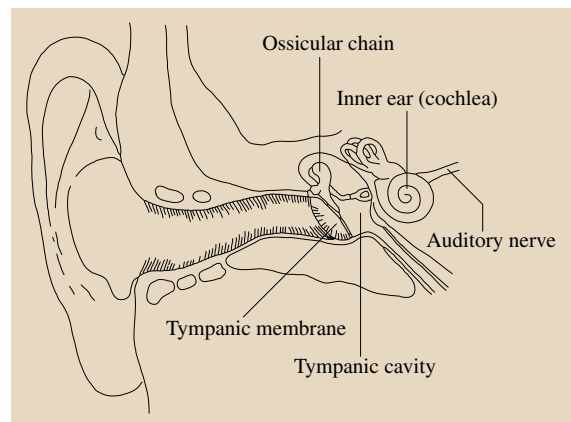

Fig. 12.1 Cross section through outer ear, ear canal, middle ear, inner ear, and hearing nerve. The tympanic cavity is connected to the nasopharynx via the *Eustachian tube* (after [12.3])

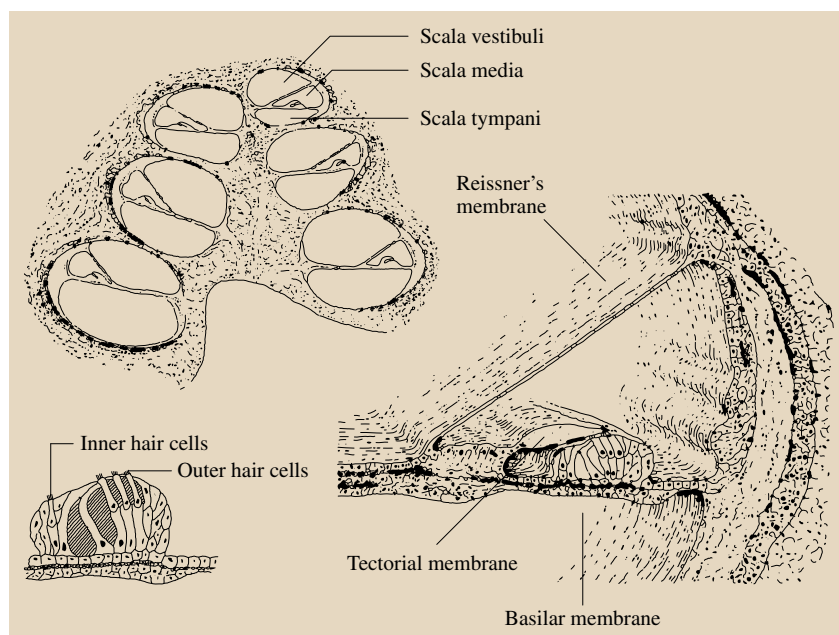

Fig. 12.2 Cross section through the inner ear and magnification of the cochlear duct with the organ of *Corti* and the hair cells (after [12.3])

movements induced by the sound wave causes them to segregate a neural transmitter, which activates the afferent fibers to produce an action potential. These elementary neural signals are the *information quanta*, which are integrated, decoded, analyzed, and exploited in the brain.

The tubular interior of the inner ear is arranged in a spiral with two and a half turns. It has a length of 32 mm in women and 37 mm in men. In longitudinal direction it is divided into three compartments by *Reissner's* membrane and the basilar membrane (Fig. 12.2): the lower scala tympani, which is filled with perilymph, the scala media (*ductus cochlearis*), which is filled with endolymph, and the upper scala vestibuli, which is again filled with perilymph. The last mentioned scala vestibuli is separated from the tympanic cavity by the membrane of the oval window that is attached to the stapes footplate. The fluid spaces of scala tympani and scala vestibuli are connected to each other at the apex by a hole, the helicotrema. In the case of static pressure differences or subsonic vibrations, this allows the incompressible inner ear fluids to escape by retracting and bulging the round window.

The organ of *Corti* located on the basilar membrane carries approximately 3400 groups of sensory hair cells, which constitute the actual receptors for sound oscillations. They can be compared to electro-acoustic transducers (microphones). There are two different

kinds of hair cells. The slim outer hair cells (OHC) are arranged in three to five rows and are connected primarily to efferent (descending) nerve fibers. The bulky inner hair cells (IHC) are located closer to the axis of the cochlea (modiolus) and are connected primarily to afferent (ascending) nerve fibers. Each hair cell carries 50–150 cilia on its upper or apical pole. The cilia of the OHC are mechanically linked to the tectorial membrane, whereas the cilia of the IHC float freely in the endolymph.

Human hair cells are highly differentiated and are not able to reproduce themselves by segmentation or regeneration. Hence, the damages and functional deficits caused by a loss of hair cells are irreversible. In recent years, some researchers succeeded in breeding hair cells out of stem cells in animal experiments, but an application in humans is not yet visible because of major methodical problems. To date and in the near future, a loss of hair cells can only be compensated by technical sound amplification with hearing aids or substituted by bypassing the sensory level of sound processing with cochlear implants.

At their lower or basal pole, the hair cells are connected via synaptic junctions to the fibers of the hearing nerve (cranial nerve VIII). This is the entrance of the central auditory system composed of neurons in serial connection to each other, which transfers the acoustic information from the inner ear to the auditory cortex.

Fig. 12.3 Oscillation of the cochlear partition at a frequency of 200 Hz. Snapshots of the traveling wave for two different instants and the envelope are shown (after [12.4])

The fibers of the first afferent neuron take course firstly as a bundle in the axis of the cochlea (ganglion spirale) and later, after leaving the inner ear canal (*meatus acusticus internus*) end up in the first relay station of the brain stem, the cochlear nucleus (nucleus cochlearis). From here, the auditory pathway branches to the superior olives of both sides. A second crossing of the neural path occurs between the inferior colliculus in the midbrain and the medial geniculate body in the thalamus. This is the origin of the acoustic radiation (radiatio acustica), which ends in the temporal lobes (gyrus temporalis), the site of the auditory cortex.

The physiological processes involved in hearing are extraordinarily complex, so that only their basic principles can be described here. From the external ear canal, the sound waves reach the eardrum, a funnel-shaped membrane with a thickness of 0.1 mm and an area of 60 mm². The sound-induced vibrations of the eardrum are carried forward to the chain of middle ear ossicles and transferred to the membrane of the oval window. Two middle ear muscles (musculus stapedius and m. tensor tympani) keep the ossicular chain in place and exert influence on its function.

The middle ear apparatus enhances the efficiency of sound transmission from the air to the inner ear. A direct excitation of the inner ear fluids by the air borne oscillation would be associated with a loss of approximately 40 dB. The impedance transducer composed of ear drum, ossicles, and middle ear cavity increases the sound pressure by virtue of the surface ratio and reduces the particle velocity by virtue of the lever action.

Theoretical considerations based on middle ear models yield variable results depending on the assumptions and boundary conditions. Experimental results show that the input impedance of the ear is reduced by a factor of 30–75, depending on frequency. The energy loss is reduced from 98% to about 40% [12.5].

The motion of the oval window membrane produces an oscillation in the perilymph, which also includes the cochlear partition composed of basilar membrane, endolymph, *Reissner's* membrane, and *Corti's* organ and propagates along the longitudinal dimension of the cochlea. Since the width and the stiffness of the basilar membrane depend on the distance from the stapes, the velocity of propagation and hence the wavelength are a function of this distance. The oscillation resulting from this dispersion is a traveling wave whose amplitude maximum is located at a unique site defined by the sound frequency (Fig. 12.3). The tonotopic organization of the inner ear, i. e. the projection of the sound frequency to a specific location, is hence a consequence of the mechanical properties of the cochlear partition. High sound frequencies are processed at a site near the oval window at the basis of the cochlea, low frequencies at its apex.

Due to the construction scheme of *Corti's* organ shown in Fig. 12.2, the transversal displacement of the basilar membrane is converted into a horizontal shearing of the hair cell stereocilia. This deflection causes the opening of selective potassium channels at the apex of the cilia, whose diameter is approximately 0.5 μm. The influx of potassium ions depolarizes the lateral cell membrane, which induces the activation of calcium channels. The influx of Ca ions leads to active contractions and elongations in the outer hair cell (OHC) and to the disbursement of a transmitter substance in the inner hair cell (IHC). After these processes, the electrical potential of the cell membranes returns to its equilibrium state (repolarization). The energy required for the actions of the hair cells is provided from the difference potential between endolymph and perilymph and is maintained by the *stria vascularis*. The transmitter molecules traverse the 20 nm synaptic gap within 0.5 ms by diffusion and activate special receptors in the nerve fiber. This initiates the generation of an action potential ascending the neural auditory pathway.

The excitation (depolarization) of the hair cell is followed by an inhibition (hyperpolarization) evoked by the reverse deflection of the cilia: the influx of K ions is blocked, the membrane potential is elevated, no mechanical activity of outer hair cells is induced, the discharge of the transmitter is inhibited, and the dis-

charge rate of the hearing nerve is reduced below the spontaneous activity. Owing to the alternation of excitatory and inhibitory deflection of the cilia, the hair cell operation is similar to that of a half wave rectifier. The movement of the single cilia is coordinated by very thin (with a diameter of approximately 50 Å) filaments between them, the tip links, and the side links. This ensures that random movements like those associated with thermal noise do not induce hearing sensations. Moreover, tip links and side links are involved in the control of the ion channels (gating spring theory).

As long as the stimulus frequency does not exceed the limit of approximately 1 kHz corresponding to the refractory period of the sensory cells, these processes take place during every depolarizing phase of the sound wave. Thus, the information about the frequency is coded both in the place of generation and in the rate of action potential in one single fiber of the hearing nerve. The limits of frequency resolution are hence determined by the sharpness of the maximum of the traveling wave and the capability of the central neural system to analyze and distinguish time patterns. The spatial separation, however, is only partially explained by the theory based on the passive traveling wave. Additional sharpness is introduced by the active and locally restricted frequency selective hair cell contractions, which at the time enhance the sensibility of hearing by orders of magnitude (Fig. 12.4). These cellular processes can be measured and exploited for diagnostic purposes in the form of otoacoustic emissions.

The inner ear is embedded safely in the hardest bone of the human skeleton, the petrous portion of the temporal bone. This favors its stimulation by solid-borne sound. Hearing by bone conduction plays some role in everyday life (e.g. perception of the own voice) and it has great importance in audiology. Stimulation of the inner ear without involvement of the normal conduction path is applied for functional testing and for provision with prosthetic devices. If the footplate of a tuning fork is placed on the skull, the osseous vibration is transferred to the perilymph, basilar membrane, and sensory cells of both ears, resulting in an auditory sensation. The sound conduction via bone is nearly free from damping [12.7]. Therefore, special care has to be taken if only one ear shall be stimulated (masking of the ear contralateral to stimulation).

The hearing nerve (nervus acusticus) consists of about 30 000 fibers, most of them being afferent and connected to the inner hair cells. Starting from their synaptic endings, the single fibers proceed to the modio-

lus where they join the fibers originating from the other cochlear turns. The nerve takes course along the inner ear canal and enters the brain stem at the cerebello pontine angle. Along their route, the action potentials propagate with high velocity due to the electric isolation of the fibers by their myelin sheath. If this coating is damaged, the velocity of neural transmission is reduced (if all fibers are affected) or the neural synchronization is disturbed (in the case of partial affection).

The tonotopic organization of the cochlea is carried forward by the hearing nerve to the cochlear nucleus and by the following neurons up to the primary auditory cortex. The information is transferred from one to the next neuron by synaptic junctions with a delay of about 0.5 ms between pre- and post-synaptic ac-

Fig. 12.4 Curves of constant basilar membrane velocity (0.04 mm/s) at one site of the basilar membrane, measured as a function of frequency with the *Möbbauser* effect of nuclear absorption of radiation. The comparison of results in a healthy ear (*full circles*) and an ear with damaged outer hair cells (*open circles*) of a guinea pig demonstrates the existence of a vulnerable frequency selective process that enhances the sensibility by about 40 dB within a restricted frequency range (after [12.6])

tion potentials. Due to the crossings to the contralateral pathways, the stimulation of one ear leads to the activation of the auditory centers in the temporal lobes of both brain hemispheres. Here, the signals are analyzed and interpreted in specialized brain regions, e.g. the speech perception field in the left hemisphere (*Wernicke's area*) and the auditory association areas. For scientific and diagnostic purposes, the electric potentials evoked by acoustic stimuli in different levels of the auditory pathway can be observed with the electric response audiometry [12.8].

The central auditory system is subject to development and maturation during childhood and adolescence up to the age of 18 [12.9]. The number of neural connections (synapses) increases immediately following birth until the age of around 4 [12.10]. After this early development, the high synaptic density of the cortex is reduced by an elimination (pruning) of neural connections to about half of its highest value. Synaptogenesis and pruning are controlled by quality and quantity of acoustic input. It is assumed that preferably those synapses are eliminated that have not been used. In the case of auditory deprivation due to a peripheral dysfunction during the sensitive periods, the system of neural connections between cochlea and cortex will atrophy. Later restitution of the peripheral function can induce processes of neural and cortical reorganization but these are far less effective than those taking place in early childhood.

12.1.3 Hearing Disorders

Due to its complexity the auditory system can exhibit manifold functional deficits. They are usually classified according to the site of lesion. External ear and outer meatus may cause conductive losses by malformations, stenoses, ear wax (*cerumen*), proliferations, debris, or foreign objects. In a wider sense, conductive hearing disorders are caused by a dysfunction of outer and middle ear as opposed to sensorineural hearing losses caused by dysfunctions of the inner ear or the components of the neural system. Sensorineural hearing disorders can have (endo)cochlear and retrocochlear origin (Table 12.1).

Conductive hearing impairments can have the following reasons:

- Irregularity in the ventilation of the *Eustachian tube*
- Reduced pressure in the middle ear cavity due to inflammatory processes
- Physical defects of the tympanic membrane
- Chronic ulceration of the middle ear bone
- Middle ear infection (otitis media) with secretion in the middle ear cavity
- Proliferation of bony tissue around the stapes footplate (otosclerosis)
- Fracture or luxation of the ossicles
- Malformations.

Conductive losses can never cause complete deafness because the inner ear is excited by bone conduction even in the case of a total disruption of the middle ear apparatus. The maximum conductive hearing loss is around 50 dB. Most middle ear disorders can be corrected by conservative treatment or middle ear surgery. If this is not possible, the restoration of hearing is possible with special hearing aids delivering vibratory stimuli (e.g. bone conduction or bone anchored hearing aids).

Inner ear or (endo)cochlear hearing impairments can have the following reasons:

- Hereditary depletion of the hair cell population, in many cases dominant in the medial cochlea.
- Slowly increasing progressive hearing loss mainly at high frequencies due to hair cell damage predominant in the basal cochlea (*presbycusis*).
- Hair cell loss mainly in the basal cochlea due to chronic noise exposition or explosion trauma.
- Deterioration of hair cells by auto immune reactions.
- Hair cell damage induced by ototoxic drugs.
- Acute degradation of hearing within minutes or hours without external reason (sudden deafness).
- Paroxysmal hypoacusis mainly at low frequencies associated with attacks of dizziness and induced by elevated endolymphatic pressure (*Morbus Menière*).
- Malformations.

Many of these inner ear diseases go along with subjective ringing of the ear (*tinnitus*) and in all of them

Table 12.1 Categories and nomenclature of hearing disorders

Outer ear	Middle ear	Inner ear	Hearing nerve	Neural pathway
	Transmission	Sensory (Endo)cochlear	Neural Retrocochlear	Central
Conductive losses		Sensorineural disorders		

the degree of hearing loss can be absolute (complete deafness). As long as some residual hearing is present, cochlear hearing impairment can be corrected with sound amplifying hearing aids. If the highest amplification yields no benefit, hearing can be restored only with cochlear implants.

A further attendant symptom of inner ear hearing loss is pathological loudness growth. Soft stimuli are not perceived while the loudness of strong stimuli is equal to that perceived by normal listeners. The uncomfortable level is less elevated than the perception threshold, the dynamic range is reduced. This loudness recruitment does not occur in conductive or retrocochlear damage. It is explained by the loss of outer hair cells, which act as active physiologic amplifiers for signals of low amplitude and as attenuators at high levels of stimulation (Fig. 12.5). Some patients with recruitment are extremely sensitive to noise (hyperacusis).

Loudness recruitment is encountered in practically all cases of hearing impairments caused by excessive noise exposition. The primary damage impacts primarily the outer hair cells particularly in the basal section of the cochlea and leads to a temporary threshold shift (TTS) at high frequencies, which is followed by a permanent threshold shift (PTS) in the case of sustained exposition. Not all persons are equally susceptible to noise-induced hearing loss (NIHL). Several current investigations focus on the question of whether the vulnerable inner ear can be identified before irreversible defects have developed.

Neural or retrocochlear hearing disorders are caused by a functional deficit of the hearing nerve or the auditory pathway. The acoustical information is not transmitted properly or not processed correctly. In many cases, the hearing loss is only an attendant symptom of diseases, which affect neither exclusively nor primarily the auditory system:

- Compression of the hearing nerve by vascular loops
- Tumors in the inner ear canal (e.g. acoustic neuroma or vestibular schwannoma)
- Multiple sclerosis (if portions of the auditory pathway are affected)
- Diffuse lesions of the brainstem without pronounced focuses
- Insufficient blood supply of brainstem regions, resulting from aneurysms or infarcts
- Atrophy or malformation of the hearing nerve.

Neural hearing disorders are frequently accompanied by functional deficits of the inner ear, since processes claiming space in the inner ear canal can also affect

Fig. 12.5 Pathological loudness growth and reduced dynamic range (loudness recruitment) can be explained by the loss of low level amplification and high level attenuation. These are the effects of outer hair cell activity (*curved line*). If these cells are destroyed, the perception threshold is elevated and the uncomfortable level is unchanged or reduced (*straight line*). After [12.11]

the arterial supply of the cochlea. Furthermore, many unspecific attendant symptoms (tinnitus, vertigo, affections of motor or sensory nerves) can occur. The treatment of neural disorders with hearing aids can be successful with respect to the hearing loss but it cannot be considered as adequate, especially in cases with normal inner ear function. Tumors of the hearing nerve or brainstem must be removed surgically since they can affect vital functions. Neurosurgery can lead to complete deafness. In such cases, therapy with cochlear implants will not restore hearing because the hearing nerve may have been corrupted. At best, some rudimentary hearing may be re-established with auditory brainstem (ABI) or midbrain implants (AMI).

A special class of hearing disorders, characterized by a normal function of the outer hair cells (as evidenced by normal otoacoustic emissions) and some alterations in the neural processing (as evidenced by altered auditory brainstem responses), is summarized under different notations as auditory neuropathy, perisynaptic audiopathy, auditory synaptopathy, dys-synchrony, or myelinopathy. According to this labeling, the function of the synaptic or neural transmission may be disturbed, but also a dysfunction of the inner hair cells or a loss of neural synchronization is discussed.

Up to now, the anatomic and physiologic correlates are not fully identified. Auditory neuropathy spectrum disorders (ANSND) according to the nomenclature proposed by the American Speech and Hearing Association (ASHA) may occur unilaterally or bilaterally and they are accompanied by hearing losses ranging from moderate up to complete deafness.

Central hearing impairment is characterized by a reduced performance of the auditory system in accomplishing higher discrimination tasks. The deficit may be caused by organic reasons as e.g. cerebral hemorrhage. If an organic origin cannot be identified, an auditory processing disorder (APD) or a central auditory processing disorder (CAPD) may be suspected. Persons with (C)APD may have difficulties in localizing the source

of sound and they do not recognize subtle acoustic differences of intensity, frequency, or time structure, even though the sounds themselves are loud and clear. These problems are more frequent in children and are more likely to occur when a person with APD is in a noisy environment. The diagnostics of APD or CAPD is based on the detection of abnormalities in complex signal analysis tasks without signs of organic defects of the peripheral hearing system or abnormalities in (nonverbal) mental health. Treatment with hearing aids is not adequate since the elevation of sound intensity is not beneficial for an intact sensory organ. The therapy is very individual; it includes training of concentration, attention, and auditory memory enhancement, as well as environmental modifications such as classroom acoustics.

12.2 Behavioral Audiometric Assessment

Behavioral or subjective examination of hearing is based on methods that constitute a subset of psychoacoustic testing. The subject is exposed to specifically defined acoustic signals, which elicit perceptions and reactions. From the observation and registration of responses, sensation thresholds, discrimination limens (*just noticeable differences*, jnds), masking phenomena, and speech perception can be studied and described in terms of the physical stimulus parameters. Since the quantity derived in these experiments is a subjective description of sensation, which involves the whole auditory system, the topodiagnostic power of subjective audiometry is rather poor.

12.2.1 Stimulus and Perception

The decibel scale defined above takes reference of the sound pressure of $20 \mu\text{Pa}$, which corresponds to the hearing threshold of young normal hearing persons at the frequency of 2 kHz, close to the place of largest sensibility (which is around 3 kHz due to the ear canal resonance). The sound pressure level 0 dB SPL is thus the lowest limit of sensation at one arbitrary frequency. Tones of most other frequencies are perceived only at higher levels. This is reflected in the dependence of the normal hearing threshold on the frequency, see Fig. 12.6.

The mean hearing threshold is the lowest of all isophones, which are defined as lines connecting the tones that elicit equal subjective loudness sensations. Generally, the volume level L_N in phon of a tone of arbitrary frequency is given by the sound pressure in dB SPL of the 1 kHz tone with equal subjective loudness. Two spe-

cial isophones are the just audible pure tones defining the threshold and corresponding to the line labeled with 3 phon, and the discomfort level at 110 phon.

The concept of volume level is adequate for the description of absolute subjective loudness across frequencies, but it fails with respect to loudness relations associated with different levels at constant frequency. At least in the region above 40 phon, the augmentation of the volume level by 10 phon corresponds approximately to a duplication of subjective loudness. To achieve a correct description of loudness relations, a scale for the relative loudness N with the unit one has been created on the basis of comparative scaling of pure tones [12.12]. N equals 1 one for a tone of 40 phon and grows by a factor of 2 with each 10 phon increment. For N less than 1 one, the simple power law is not valid and the relative loudness reaches $N = 0$ at threshold. Relative loudness plays no role in practical audiometry, where only direct scaling is applied (categorical loudness).

Besides the transformation of physical sound intensity in a subjective loudness sensation, the discrimination of intensity differences or temporal changes constitutes another field of psychoacoustic investigation. Just noticeable differences (jnd) of level can be determined with modulated stimuli or by sequential stimulation with stimuli of constant but different levels. In practical audiometry, the testing of discrimination abilities is limited to the exploration of certain hearing disorders that affect the sensibility for level differences (recruitment). In this context, also the masking of a target stimulus by a concurrent signal (e.g. narrow band noise) may be of diagnostic relevance.

12.2.2 Temporal Aspects of Hearing

The complete description of hearing requires the consideration of not only frequency and intensity but also the temporal characteristics of acoustic signals as their third dimension. For the function of hearing, as well as for its diagnostic examination, the temporal structure of acoustic stimuli is essential. Speech and many signals used in audiometry are nonstationary stimuli. Their subjective perception depends on temporal parameters such as duration: short signals appear to be softer than longer signals with the same intensity. If the duration of a stationary signal exceeds the limit of approximately 200 ms, the perceived loudness is independent of its duration; below this limit the level must be incremented by 10 dB if the duration is divided by 10 to achieve the same loudness sensation. Short pulses are thus much stronger even if they elicit the same sensation. Since the extent of hearing damage is determined by the physical intensity and not by the subjective loudness, the hazard potential of short signals is underestimated by the subjective sensation. The sound pressure of impulses may be described by the peak value (dB SPL p.e. = peak equivalent) or by the (generally much lesser) value that is relevant for subjective rating (dB HL = hearing level).

Most acoustic signals carrying information exhibit fast temporal changes of frequency and/or intensity. This holds true especially for speech, which codes a large portion of information in transients between vowels and consonants. The ability to analyze time structures is, therefore, especially important for the human ear. Physiologically, this is reflected in the existence of classes of neurons especially in the brain stem, which respond only to temporal changes. The functional integrity of these neuronal structures can be tested by psychoacoustic assessment of the time resolution capability. One of the relevant quantities is the just noticeable interval between two tone or noise pulses. It can be measured by presentation of two sequential pulses of limited duration (200 ms), one of them being interrupted by a gap of variable length. The subject has to indicate, which of the two stimuli appeared interrupted. In the case of a correct answer, the gap length is shortened, otherwise prolonged. After a defined number of reversions the mean value is determined (*gap detection threshold*). Normal hearing subjects achieve a jnd of approximately 5 ms. Similar results are obtained if the task consists in the recognition of the shorter of two or three consecutive pulses (*temporal difference limen*).

Another quantity related to temporal aspects of hearing is the processing of stationary stimuli of

Fig. 12.6 The curves of constant loudness (isophones) of the normal hearing ear define the hearing threshold (*lowest curve*) and the volume level for pure tones. The volume level L_N in phon of a tone of arbitrary frequency is given by the sound pressure in dB SPL of the 1 kHz tone with equal subjective loudness. The loudness N is defined as 1 sone for a tone of 1 kHz with 40 dB SPL and incremented by a factor of two with each 10 dB. This power law is not valid for N less than 1 sone. After [12.13]

long duration [12.14]. It is known that the perceived intensity decreases with increasing duration. The mechanisms involved in this effect are not known in detail. Empirically, adaptation is distinguished from fatigue. *Adaptation* describes the fading at low stimulus levels. It occurs within a few minutes and normal sensibility is re-established within the same time range. *Auditory fatigue* is observed at high stimulation levels and its recovery is much slower (temporary threshold shift, TTS).

As has been mentioned above, the perception threshold for tones is elevated in the presence of noise. If the noise is switched off, the *masked threshold* returns to its normal value, the *absolute threshold of hearing* (in quiet). This masking release is not simultaneous but delayed by approximately 200 ms depending on the noise level [12.14]. In the case of inner ear hearing loss, the effect of forward masking is stronger and the ability to take advantage of the gaps in a nonstationary fluctuating noise is reduced or lost. This is one of the reasons

accounting for the worse speech discrimination of persons with hearing impairment in noisy situations and reverberating environment.

12.2.3 Pure Tone Audiometry

Historically, the tuning fork was the first instrument applied to test the perception of pure tones. This crude method did not yield quantitative results, but it helped in finding out whether hearing loss was frequency-dependent and it allowed observation of its progress in time. For other purposes the stimulation of the ear with tuning forks is still integrated in practical audiometry [12.15]: if the bottom of the fork is brought in contact with the skull, the inner ear is stimulated via bone conduction. In cases of unilateral hearing loss, the lateralization of the sensation depends on the type of impairment: conductive disorders tend to emphasize the perception in the affected ear, whereas perceptive (sensorineural) disorders accentuate the perception in the better ear. In the case of mixed hearing loss with conductive and perceptive components and in cases of both-sided hearing impairment, this so-called *Weber* test is not applicable.

A second procedure based on the tuning fork – the *Rinne* test – is applied to explore the nature of impairment in one isolated ear: the comparison of the loudness elicited by the tuning fork oscillating at the entrance of the outer ear canal (air conduction) and vibrating with its foot plate brought into contact with the mastoid (bone conduction). If the air conducted stimulation is perceived stronger, a conductive disorder can be excluded. Like the *Weber* test, this test is restricted to pure forms of conductive or perceptive losses.

The hearing threshold for pure tones is defined by the lowest intensity or level of a stimulus of given frequency that leads to a perception in at least 50% of trials. In normal hearing subjects, this quantity is strongly dependent on frequency (Fig. 12.6). For clinical purposes, a curvilinear reference line is not very suitable. Therefore, the devices used for the determination of threshold (pure tone audiometers) make use of a level calibration based on the normal threshold as reference sound pressure. Thus, the normal threshold corresponding to 0 dB HL (hearing level) is a straight line in the pure tone audiogram.

Another level scale occasionally used in practical audiometry is based on the individual threshold of the ear under examination. This makes sense if the relevant quantity is given by the distance between threshold and a specific response, e.g. the acoustic reflex. Given

a hearing threshold of 20 dB HL and a response threshold of 80 dB HL, the sensation level is defined by the difference 60 dB SL.

The determination of the hearing threshold, i. e. the lowest perceivable sound level, is coupled with the problem, that the limit between silence and hearing is associated with maximum uncertainty. Even if the ambient noise in the audiometric test room does not exceed the limits specified in ISO 8253-1, the determination of the hearing threshold requires a high level of understanding, cooperation, concentration, and patience of the subject. If one of these preconditions is not fulfilled, the results of subjective testing will be very questionable.

A further problem of threshold determination results from the fact that only one of the two ears of one subject shall be examined. This is accounted for by using headphones rather than loudspeakers or tuning forks for the presentation of stimuli. Nevertheless, the stimulus can be perceived in the ear opposite to the side of stimulation. This can be prevented by masking the contralateral ear with adequate signals.

In a clinical environment, the hearing threshold cannot be determined according to the strict rules applied in experimental psychoacoustics. For diagnostic purposes an accuracy of ± 5 dB is considered sufficient. Starting at -10 dB HL, the level of the continuous or pulsed test tone is incremented until the subject indicates a sound perception, e.g. by activating the response button. At this instance, the level has already surpassed the threshold by a few dB. To correct this error, the level is now reduced and again incremented. After some repetitions of this procedure, a reliable threshold can be found. All thresholds in the frequency range from 100 Hz to 10 kHz, separated by octave steps below 500 Hz and half octave steps above 1 kHz, constitute the conventional pure tone audiogram. The extended high frequency range covers frequencies up to 16 kHz in smaller steps. Traditionally, the level axis in the audiogram runs from low values at the top to higher values at the lower border, i. e. the threshold representing normal audition lies above the threshold representing an ear with hearing loss (Fig. 12.7). The vertical distance between the reference line (0 dB HL) and the value under consideration is defined as hearing loss (dB HL).

In addition to the threshold for stimulation via air conduction (AC), the complete audiogram contains another curve representing the threshold for bone conduction (BC). The transducer is placed on the mastoidal process behind the outer ear. If contact area and force are within the normal limits, a defined quantity of sound is transferred to the inner ear via BC. Thus, the function

Fig. 12.7a–f Pure tone audiograms in case of normal hearing (a), conductive hearing loss at low frequencies (b), combined conductive and perceptive hearing loss (c), frequency independent sensorineural hearing loss (d), two stages of a noise induced inner ear hearing loss (e) and severe to complete deafness (f) with tactile perception of bone conducted low frequencies (*left corner audiogram*). All but one of the diagrams show the thresholds for air and bone conduction

of the inner ear can be tested without being affected by outer ear, external meatus, ear drum, and middle ear. The calibration of the transducers for air and bone conduction takes into account that very different quantities of energy are required for the excitation of the ear drum and of the skull; in both cases, 0 dB corresponds to the normal perception threshold.

The bone conduction threshold can be determined only for frequencies in the range above 250 Hz. For lower frequencies, the energy required for suprathreshold stimulation is very high and not only auditory but also tactile sensations are elicited (Fig. 12.7f). A second limitation at high frequencies above 6 kHz results from the fact that the bone stimulator produces air borne sound

that can reach the inner ear via the natural sound conduction chain. In addition to these limitations, the sound intensity transferred to the inner ear by BC is much less reproducible than with air conduction because of the individual variability of force and skin flap thickness. Consequently, the accuracy of BC thresholds is typically not better than ± 10 dB in a clinical environment.

The difference between the threshold for air and bone conduction is a measure for middle ear disorders. If the distance between AC and BC amounts to more than 10 dB (*air–bone gap*), the transmission of sound energy through the tympanic membrane and the ossicular chain is impacted by pathological alterations of the middle ear (Fig. 12.7b,c). From the frequency dependence of

the threshold difference, information about the type and origin of the conductive loss can be deduced. If the tympanic cavity is filled with effusion following a middle ear infection, the friction and/or the mass of the middle ear apparatus is incremented and the AC threshold is elevated, preferably at high frequencies. In the case of enlarged stiffness of the ossicular chain, the low frequencies will be damped. Fractures or luxations of the ossicles, as well as otosclerosis in the advanced state or large perforations of the ear drum affect the whole frequency range. Hearing loss caused by transmission can never exceed the limit of approximately 50 dB since every air conducted sound exceeding the corresponding intensity leads to excitation of the bone and hence of the cochlea.

The stimulation of the inner ear by bone conducted sound is not limited to one side because the whole skull oscillates independently of the site of excitation. Transcranial attenuation is negligible at low frequencies and amounts to not more than 10 dB at high frequencies. However, also the application of air conducted stimuli, acoustic *cross-talk*, leads to the involuntary stimulation of the contralateral ear if the level of stimulation exceeds a certain limit. This limit is approximately 50 dB in the case of the supra-aural headphones usually applied in audiometry. If the level L_S of the stimulus lies above this limit, bone vibrations corresponding to a hearing level of $L_S - 50$ dB are produced. Depending on the constellation of thresholds for air and bone conduction on both ears, the test tone is perceived only in the contralateral ear. To prevent this, the contralateral ear is masked by a narrow band noise via air conduction. The effective level of masking must exceed the value $L_S - 50$ dB. In the case of a conductive loss ΔL_C in the contralateral ear, the masking level L_M must be incremented accordingly

$$L_M \geq L_S - 50 \text{ dB} + \Delta L_C \quad \text{with } 0 \leq \Delta L_C \leq 50 \text{ dB} . \quad (12.4)$$

Since the loss ΔL_C due to a contralateral middle ear dysfunction cannot exceed 50 dB, the maximal masking level is given by $L_M \geq L_S$. This simple formula corresponding to the worst case does not contain any unknown quantities and can, therefore, easily be applied in practice as

$$L_M \approx L_S \quad \text{if } L_S \geq 50 \text{ dB} \quad \text{(for air conduction testing)} . \quad (12.5)$$

The validity range of this rule is limited to moderate levels of stimulation (since at high levels an overstimulation of the contralateral ear may occur) and to cases with negligible middle ear damping in the ipsilateral ear (since

otherwise the contralateral masker possibly affects the ear to be tested).

For the determination of bone conduction thresholds, somewhat different rules must be applied since the test tone is transferred without any losses to the contralateral ear (even at low stimulations levels L_S). Since the masker is presented by air conduction, a conductive loss ΔL_C in the contralateral ear must again be compensated

$$L_M \geq L_S + \Delta L_C \quad \text{with } 0 \leq \Delta L_C \leq 50 \text{ dB} . \quad (12.6)$$

While for the determination of the air conduction threshold, a total loss of middle ear transmission in the contralateral ear can be assumed for simplicity, this is not possible for bone conduction since a masking level L_M according to the formula $L_M \geq L_S + 50$ dB would mask not only the contralateral but also the ipsilateral ear. Therefore, the masking level must be lower than $L_S + 50$ dB and higher than L_S (otherwise, the test tone would be perceived in the contralateral due to the occlusion effect). Consequently, not a fixed value but only a range of admissible values can be specified for L_M ,

$$L_S + 20 \text{ dB} \leq L_M < L_S + 50 \text{ dB} \quad \text{(for bone conduction testing)} . \quad (12.7)$$

The final formulas (12.5) and (12.7) are valid in most but not all cases. The only criterion characterizing the correct masking level is that the threshold should remain stable if the masking level is incremented. In any case, special care must be taken to ensure that the masking level remains below the uncomfortable level.

12.2.4 Recruitment

Tests above the threshold are performed to identify a pathological loudness growth (recruitment), which accompanies level-dependent distortions and a reduced dynamic range. One of these tests, the alternate binaural loudness balance (ABLB) described by *Fowler* in 1937 [12.16], is applicable only in cases of unilateral hearing impairment. Both ears are stimulated alternately by tone pulses of a frequency for which the interaural threshold difference amounts to at least 30 dB. Starting at threshold intensities, the level is incremented in steps of 20 dB for the impaired ear. The stimulus level at the contralateral normal ear is adjusted to achieve equal subjective loudness perception. If the slope of the lines connecting the points of equal loudness in both audiograms decreases at high levels, the recruiting ear is identified. Parallel lines indicate that

no recruitment is present, or, equivalently, the dynamic range of the impaired ear is not reduced.

No normal contralateral ear is required for another recruitment test based on the short increment sensitivity index (SISI) described by Jerger in 1962 [12.17]. The ear under examination is stimulated by a continuous pure tone above threshold, whose amplitude is periodically incremented by 1 dB. Subjects with a recruiting ear are able to detect the increments, whereas normal subjects as well as persons with pure conductive or neural impairments are not. The increased sensibility of the impaired inner ear for amplitude modulations can be explained by the higher slope of its input/output function (Fig. 12.5). The test is performed at a frequency with a hearing loss of at least 40 dB. The continuous tone is presented with an intensity 20 dB above threshold. After conditioning of the patient, the level of this tone is incremented for 0.2 s every 5 s. If the patient detects more than 70% of the increments, a recruitment is probable (cochlear damage). Ears without recruitment (neural damage) are characterized by an index below 30%. Rates between these limits should not be interpreted, they are possibly a consequence of insufficient cooperation of the patient or of the choice of unsuitable parameters (frequency and intensity of the stimulus).

As an alternative to the SISI test, the sensibility for level increments can be examined by another procedure described by Lüscher and Zwislocki in 1949 [12.18]. In this test, the jnd is determined directly by decreasing the increments from initially 4 dB down to 0.2 dB. In accordance with the SISI test, a jnd of 1 dB is considered as the limit between recruiting and nonrecruiting ears.

Especially in the case of sloping audiograms, the perception threshold of a pure tone masked by a narrow band noise can serve as an indicator for recruitment, as described by Langenbeck in 1949 [12.19]. The masked threshold is determined for several pure tone frequencies covering the range from normal hearing at low frequencies to a hearing loss exceeding 45 dB at high frequencies. This permits the comparison of healthy and damaged regions in the same cochlea. The level of the narrow band noise, whose center frequency is equal to that of the target tone, is adjusted to a level between 45 and 75 dB. In the case of normal hearing, the masked threshold is found just above noise level. As the frequency region of impaired hearing is approached, the masked threshold can either join or deviate the threshold in quiet. In the first case, the discrimination capability is conserved in spite of the hearing loss, as is expected for a recruiting ear; in the latter case, the detection of a pure tone in noise is affected by the hearing loss and a neural

Fig. 12.8 Results of loudness scaling obtained from a normal hearing and a hearing impaired subject (schematic)

origin of impairment is probable according to the model of *busy lines* [12.20].

Some of the recruitment tests described so far are only indirect indicators of recruitment based on the sensitivity for level increments or the masked threshold. A direct assessment of the reduction of dynamic range is possible only with the ABLB test and only for single-sided hearing loss. No such limitation is imposed on the direct loudness scaling described by Heller in 1985 [12.21]. Narrow band pulses with center frequencies between 250 Hz and 4 kHz are presented in a randomized sequence by loudspeakers and assigned by the patient to one of the seven categories *not audible*, *very soft*, *soft*, *comfortable*, *loud*, *very loud*, and *too loud* (Fig. 12.8). Internally, these verbal categories are assigned to 0, 5, 15, 25, 35, 45, and 50 numerical units, respectively. For each frequency, a loudness-intensity function is constructed. Optionally, the data can be transformed to iso-response contours and transferred to the audiogram.

The intersection of the loudness-intensity-function with the horizontal axis is correlated to the perception threshold, the level judged as *too loud* corresponds to the uncomfortable level. In the case of a pathologic loudness growth, the slope of the function is larger than in normal ears and the distance between individual and normal values decreases with increasing stimulus level. This horizontal distance correlates with the need for amplification and it can be used as basis for a loudness-based fitting of hearing aids.

Recruitment tests and loudness scaling are used to identify the cochlear nature of hearing impairment. Neural dysfunctions can not be excluded with these tests. They are characterized by a pathologic auditory

fatigue, which can be detected by the threshold tone decay test (TTDT) described by Carhart in 1957 [12.22]. Tones of low intensities close to the threshold are usually perceived only within a limited time interval. In normal ears, this limit is beyond 30 s for a tone with 10 dB SL. If the intensity required for 60 s persistence lies between 15 dB and 25 dB SL, a pathological *adaptation* typical for cochlear hearing loss is probable. In the case of pathological *fatigue* typical for neural hearing loss, this level is above 30 dB SL.

12.2.5 Speech Audiometry

There is no doubt that understanding of speech is the highest level and paramount object of hearing and its preservation or restitution. The perception and discrimination of spoken speech is examined for audiometric purposes in order to assess the limitations in communication and the social handicap resulting from hearing impairment, as well as the need for amplification and the benefit of hearing aids and prostheses. Moreover, speech audiometry results may contribute to the diagnostic classification of hearing dysfunction especially in the identification of (central) auditory processing disorders (APD). For most of the other audiometric issues, speech signals turn out to be too complex, but they are indispensable in the context mentioned above, since the capabilities grouped around speech perception cannot be predicted from the threshold for pure continuous tones.

In addition to the acoustic complexity of speech, speech audiometry is associated with further difficulties arising from the large number of factors contributing to the communication by spoken speech: hearing acuity, processes of neurocognition, intellectual capabilities, level of language development, short range memory, concentration efforts, readiness to cooperate, and others. It is not possible to examine all abilities that are relevant for speech understanding in all target groups with a single test. Therefore, speech audiometry is composed of several tests differing in test material, the use of noise and, of course, the specific language. One common feature of nearly all tests is the use of diagrams showing the fraction of correct items in dependence on the stimulus level or signal to noise ratio. From the discrimination function, the speech perception threshold (SRT), defined as the level of stimulus or the signal to noise ratio associated with a correct perception of 50% of the items, is derived.

The ability for perception and discrimination of speech can be embedded in the audiological context

only if the acoustic properties of speech are considered. Therefore, the most important of these physical features shall be described here. Speech is produced by the human organs for *phonation* (production of voice) and *articulation* (modulation of voice). The simplest elements of speech are vowels characterized by a periodic oscillation composed of a *fundamental frequency* F_0 (corresponding to the voice pitch) and up to four *formants* F_1 to F_4 (higher frequency bands). The frequency ranges of the formants are unique for every vowel; they vary only to a low degree from one speaker to the other. The formant F_1 lies around 500 Hz, F_2 between 1 and 2 kHz, and the higher formants, which are less important for the identification of the vowel, lie between 2 and 4 kHz.

Consonants cannot be described by typical frequency spectra. As far as characteristic frequencies can be defined, they are located in the range of the formants F_3 and F_4 . In contrast to vowels, consonants can be voiced and unvoiced. Voiceless consonants are produced without oscillations of the vocal chords by obstructions in the vocal tract, which contribute to the acceleration of the air stream and hence generate turbulences. In voiced consonants, these mechanisms are overlaid by vocal chord oscillations. Phonetically, consonants are further divided according to the place (e.g. labial, dental, palatal, or velar) and mode (e.g. plosive or fricative) of articulation. Many consonants are merely a frequency transition between preceding and subsequent vowel (transients). Their properties depend on the vowel with which they are fused and on their placement as initial, intermediate, or final phoneme. Transients and formants are identifiable in the spectrogram (or sonogram), which is a three-dimensional diagram showing the time dependence of frequency and intensity of a speech signal (Fig. 12.9).

Frequency and intensity of language components can be roughly translated into the audiogram to assess the impact of hearing loss on speech understanding (Fig. 12.10). In the case of high frequency hearing loss the recognition of many consonants (especially sibilants) is most affected, whereas a pronounced low frequency hearing loss affects mainly the fundamental frequency, which is not very important for speech intelligibility. If the hearing loss amounts to 40–50 dB at all frequencies, vowels and strong sibilants remain audible, while the silent consonants are not properly understood. The pathological loudness perception (recruitment) found in many cases of sensorineural hearing loss has the consequence that soft language elements are too weak, whereas the stronger components are

Fig. 12.9 Oscillogram (*top*) and spectrogram (*bottom*) of the utterance *speech transformation*, spoken by a male speaker

Fig. 12.10 Projection of the frequencies and levels relevant for colloquial speech into the pure-tone audiogram

perceived clearly or even uncomfortably loudly. The problems arising from the time dependence of speech signals – especially from the rapid transitions between

loud vowels and soft consonants – cannot be illustrated in this diagram.

The selection of the test material used for speech audiometry is oriented on the objective in the special case under examination. Persons with rudimentary speech discrimination can only be examined if the test material contains sufficient redundancy, such as semantically meaningful sentences. The other extreme are virtually nonredundant monosyllabic words. The numerals used in the German *Freiburg speech intelligibility test* described below lie between these extremes. The responses of the subjects are part of a known and very limited word inventory. For a given material, the difficulty of the tests can be influenced by offering a closed set of response alternatives. To ensure that a subject can perform the same test several times without fear of distortion of results due to learning effects, the material must be divided into equivalent test lists (containing, for example, 10 or 20 everyday sentences, numerals, or monosyllabic words each). Whatever the objective, the statistical distribution of phonemes within the test material should be representative for the specific language.

The groups or lists of test items are presented through headphones or speakers, optionally with a simultaneously presented noise. The subject is asked to repeat the item (word or phrase) or to select it out of predefined answer alternatives, the examiner counts the number of correct answers. The result is the percent-

Fig. 12.11 The increase in the proportion of correctly reproduced test items with increasing stimulus level or signal-to-noise ratio is described by a sigmoid psychometric function (12.8)

age of test items reproduced correctly as a function of absolute or relative (referred to the background noise level) speech level. The relationship between stimulus level (or level difference) and the proportion of correct responses (speech intelligibility index) is called the discrimination function (performance-intensity function). It shows a step-shaped curve that can be described by two parameters: the level (or the signal-to-noise ratio) L_{50} , where the probability of a correct answer is 50% (speech perception threshold), and the slope s_{50} at this point (Fig. 12.11). For the mathematical description, the following logistic function is used:

$$p(L) = \frac{1}{1 + e^{-\frac{L-L_{50}}{u}}} \quad \text{with} \quad u = \frac{1}{4s_{50}}. \quad (12.8)$$

In German-speaking countries, the test that is most used for practical audiometry is still the Freiburg speech intelligibility test according to the German standard DIN 45621, introduced by *Hahlbrock* in 1957 [12.23]. The test material consists of two-digit numbers and monosyllabic words that have been recorded by a trained professional speaker and arranged in phonetically balanced groups (10 lists of 10 numbers and 20 lists of 20 monosyllabic words). Below a certain speech level (10 dB SPL for numerals and 15 dB SPL for monosyllabic words), none of the words is correctly understood. With growing volume, the proportion of correct answers increases and finally reaches 100% at 30 dB SPL (numerals) and 50 dB SPL (monosyllables) for normal

hearing listeners. For numerals, the normal values of L_{50} and s_{50} are 18.5 dB SPL and 5% per dB, respectively. Because of the high redundancy, the logistic function is very steep. For the same reason, hearing disorders affect only the location but not the shape of the function. Therefore, the impact of hearing loss can be described by the shift of L_{50} . This difference is called the *hearing loss for speech*. Since the correct perception of low frequency vowels is already sufficient for identifying the numerals, the hearing loss for speech correlates well with the low frequency hearing loss.

The curve describing the intelligibility of monosyllables is shifted to higher levels and is less steep than that corresponding to the numerals. This is due to the fact that the correct recognition of the test words requires not only the discrimination of vowels but also of the softer consonants. Hearing disorders not only affect the location but also the shape of the logistic function. Especially in cases of severe high frequency hearing loss the curve may be very shallow because of the difficulty of detecting the high consonants. Often, then, up to the discomfort level a score of 100% is not achieved, i. e. there is a *discrimination loss*. In rare cases, the speech discrimination decreases at high levels after having reached a maximum value (roll-off).

The standardized Freiburg speech intelligibility test is used in particular in the administration of hearing aids and the subsequent measure of control, and it forms the basis for the calculation of the earning capacity in the case of occupationally acquired hearing loss. It has some disadvantages, which have led to the development of alternative tests:

- In some patients with profound hearing loss, it provides no useful results since the numerals may be too easy and the monosyllables too difficult.
- The test lists are not phonetically balanced and not equivalent to each other regarding presentation level and degree of difficulty.
- The testing of speech intelligibility in noise is not standardized.
- The subject must be familiar with the German language.
- The test procedure is not automatable, because the response of the patient is evaluated by the investigator.
- The response of the subject is only rated as true or false, an evaluation of the confusions is not possible.
- The lack of an announcement stimulus leads to an unreasonably high rate of wrong answers.

One of the recent approaches to overcome these drawbacks is the *Oldenburg sentence test* developed by *Wagener and Kollmeier* [12.24]. It is an open set sentence test based on meaningful phrases consisting of five words (proper noun, verb, numeral, adjective and object) such as e.g. *Doris paints nine green chairs*. Each of the five words is taken from a stock of ten alternatives from which the records are assembled at random. This increases the number of usable test lists and it reduces the probability for recognition of a test item (test repeatability). At the speech perception threshold L_{50} the discrimination function of the Oldenburg sentence test has a high slope $s_{50} = 17\text{--}20\%$ per dB. Thus, the threshold can also be determined in quiet as well as in speech-simulating noise with high accuracy.

In all speech tests, the duration of the investigation can be reduced by the optimization of test materials and strategy. The time required is proportional to the number of test lists that must be tested to reach a sufficient significance. Speech tests based on redundant test material (numerals and sentences) have a steep logistic function that is shifted but not deformed in the case of hearing loss. In the ideal case of an adequate volume level, only one test list needs to be checked for a reliable determination of L_{50} . If the test material has little redundancy (monosyllables), the psychometric curve is shallower and not only shifted but also distorted intrinsically in impaired ears. For its reconstruction, at least two test lists must be checked. Regardless of the details of the curve the examiner usually aims not to carry out measurements in regions of 0 or 100% speech discrimination. Normal values and the above mentioned relations between pure tone and speech audiogram help to find reasonable starting levels in the vicinity of the inflection L_{50} . By application of adaptive procedures, the target can be achieved more accurately and faster. Here, the level of presentation is increased or reduced for each test item in accordance with the previous answers.

In addition to the speech discrimination in silence, the study of intelligibility in noise and its improvement by hearing aids is one of the subjects of speech audiometry because the combination of speech and noise constitutes one of the major challenges of many hearing impaired persons and users of hearing aids. Besides the *Oldenburg sentence test* described before, the *Göttingen sentence test* after *Wesselkamp et al.* [12.25], comprising 20 test lists of 10 sentences in combination with the voice babble noise after *Sotschek* as background noise and the *Innsbruck sentence test* after *Hochmair et al.* [12.26], composed of 30 lists of 20 sentences combined with speech simulating CCITT (Comité Con-

sultatif International Téléphonique et Télégraphique) noise (HSM test) are suitable for this purpose. The spectrum of the international standard CCITT-noise is adjusted to the average frequency distribution of several languages. It has its highest intensity at 800 Hz. The time-modulated version of the CCITT noise is called *Fastl* noise. The modulation is not achieved by a fixed frequency but with a band-pass noise whose intensity peaks at 4 Hz corresponding to the mean syllable length. The *Göttingen sentence test*, recorded with high speech velocity by an untrained speaker is suitable for use with hearing aid users, while the HSM test, due to the slow and pronounced articulation, is primarily designed for the assessment of CI users.

The speech tests presented so far are applicable only in German speaking countries. Some of the most common tests used in other language areas are described in this paragraph. At a very elementary level of speech perception, the CUNY (*The City University of New York*) closed set nonsense syllable test is devoted to the examination of the discrimination of single phonemes presented in VC (vowel–consonant) and CV (consonant–vowel) syllables [12.27]. Each test item is embedded in a carrier phrase *You will mark ... , please*, the competing noise is an equalized cafeteria noise. *Nilsson et al.* [12.28] introduced the *Hearing In Noise Test* (HINT), which consists of 25 phonemically balanced lists of 10 sentences and is suitable for the adaptive measurement of sentence SRT. Within the *European HearCom* project, the SPIN (*speech in noise*) test based on digit triplets overlaid by a rushing background noise was designed to mimic real-life circumstances. The *spondee recognition test* described by *Cramer and Erber* [12.29] is especially suitable for testing hearing impaired children. Test lists of ten spondaic words (consisting of two long syllables) are presented monaurally, the responses are indicated by pointing to labeled picture cards. Finally, the archetype of the *Oldenburg sentence test* shall be mentioned. In 1982, *Hagerman* published Swedish sentences suitable for clinical measurements of speech intelligibility in noise [12.30]. The test was developed for hearing aid evaluation in sound field as well as with earphones prior to hearing aid fitting. Ten lists of phonetically balanced five word sentences constitute the inventory for the construction of new lists by cutting and combining the single items. In the test situation, the speech stimulus is accompanied by modulated speech-simulating noise.

The accuracy and reliability of speech audiometry results are described by the variability σ , which depends on the fraction p of correct responses and the number n

of test items according to the formula

$$\sigma = \sqrt{\frac{p \cdot (1-p)}{n}}$$

The 95% confidence interval is obtained by multiplication of σ with 1.96 [12.31]. If the test is performed twice (e.g. with and without hearing aid), the difference of the results is significant if the auxiliary variable Φ given by

$$\Phi = \arcsin \sqrt{\frac{x}{n+1}} + \arcsin \sqrt{\frac{x+1}{n+1}}$$

(with $x = p \cdot n =$ number of correct responses)

of the second test lies within the interval limited by

$$\Phi_L = \Phi - 1.96\sigma_{\text{diff}} \quad \text{and} \quad \Phi_H = \Phi + 1.96\sigma_{\text{diff}}$$

calculated from the first test and using

$$\sigma_{\text{diff}} = \sqrt{2}\sigma(\Phi)$$

$$\text{with } \sigma^2(\Phi) = \frac{1}{n + \frac{1}{2}} \quad \text{for } n \geq 50$$

$$\text{and } \sigma^2(\Phi) = \frac{1}{n+1} \quad \text{for } 10 < n < 50.$$

The application of these rules, derived under the assumption that binomial statistics is valid, shows that an unexpectedly large number of test items must be used to observe significant effects [12.31].

12.2.6 Binaural Hearing

All aspects of hearing discussed so far are the result of psychoacoustic studies on the stimulation of one ear. Without doubt, however, hearing with both ears (binaural) is to be regarded as the natural listening situation. It differs from monaural listening at first by a lower threshold of perception. The difference between the monaural and the binaural hearing threshold is 3 dB (doubling of intensity). For suprathreshold stimuli, the difference between monaural and binaural hearing is approximately 10 dB, i.e. the addition of the second ear results in a doubling of loudness. This effect is called binaural loudness summation.

Many high order capabilities of the auditory system, e.g. spatial hearing, localization of sound sources, and discrimination of speech in noise and reverberation, are result of the binaural detection and processing of acoustic signals. In addition, the outer ear plays an essential role: its acoustic transfer function acts as a filter whose output depends on direction, distance, and frequency of the sound source. Spatial characteristics

of the sound field are coded into temporal features by reflection, shadowing, scattering, diffraction, interference, and resonance. The representation of these features within the central nervous system produces an impression of spaciousness that cannot be achieved by stimulation via headphones. One special aspect of spatial hearing, namely directional hearing, is based on the presence of two input signals, the crossing of the auditory pathway and the exploitation of the differences between the two signals (binaural processor). The position of the ears on both sides of the head leads to differences in level, time, and tone of the two inputs arriving from a lateral acoustic signal source. The tone differences arise from the fact that the shading effect by the head is relevant only for high frequencies. For the same reason, level differences also occur mainly at high frequencies that are not bent around the head. They contribute to the lateralization of the auditory event in so far as they amount to more than 1 dB. Furthermore, the sound waves arriving from sources that are outside the median plane reach the two ears at different times (or with different phases at the same time). The lower limit for the exploitation of these interaural time differences is less than 30 μ s. Time and level differences allow for sound localization with an accuracy of 3–5°. This location, however, is not unambiguous. All sources located on the surface of the cone shown in Fig. 12.12 (cone of confusion) have the same interaural differences; they differ only in tone. Actually, the sound event sites that are most often confused in a directional hearing test in the horizontal plane are equivalent in terms of interaural time and level differences. A special case is the confusion between front and rear. The determination of the elevation, i.e. the location of sound sources that are located in the median plane (angle of the cone equal to 180°), is done without the aid of interaural differences and is, therefore, uncertain.

Interaural time differences are only useful for the location of sound sources if the duration of the signal is limited sufficiently sharp. This condition is not satisfied with continuous tones or with the occurrence of reverberation. In these cases, the sensation of both ears merges to a single auditory event. Nevertheless, the sources of continuous stimuli or of short signals accompanied by echo can be localized because the location of such auditory events is determined primarily by the first sound pressure change that reaches the listener (law of the first wave front). This mechanism is important for hearing in closed rooms, but it fails if standing waves are generated.

Binaural hearing is critical for the detection and discrimination of signals in noise. A pure tone is easier

Fig. 12.12 In the case of lateral sound incidence from sources Q , Q' or Q'' , the signal arrives in both ears at different times t and with different intensity L . The sound event sites, which are equivalent with regard to the interaural differences Δt and ΔL , are placed on the surface of the *cone of confusion* (the tip of which is in the middle of the head and the axis of which coincides with the line joining the ears). This approximation is valid only if the head is modeled by a sphere without ears and with diametrically opposite ear canal entrances – a very crude and unrealistic approximation

to detect in noise (i. e. at a lower signal to noise ratio) when two signal sources are separated. Experimentally, the effect of binaural hearing on the masking of a signal can be replicated simply by presenting a mixture of test tone and broadband noise to one ear via headphones. The subject adjusts the test tone level such that it is no longer perceived. If the same noise is now presented to the other ear, the noise sensation is louder but the test tone is heard again and hence the binaural hearing threshold is lower than in the monaural case (binaural masking level difference, BMLD). Similarly, the binaural hearing threshold for the intelligibility of speech in noise can be determined and compared with the monaural threshold (binaural intelligibility level dif-

ference, BILD). Depending on the spatial arrangement of the sources of signal and noise, the threshold difference amounts to about 10 dB in normal hearing subjects. The enhancement of discrimination and intelligibility described by BMLD and BILD is closely related to the ability of to understand speech in babble noise (cocktail party effect), which requires a functioning binaural system. Mild single sided hearing loss is sufficient to affect its function seriously. The assessment of monaural and binaural thresholds in noise is, therefore, suitable for a quantitative description of the ability to follow a conversation in noise. It has been shown that BMLD and BILD are lower in hearing impaired patients and in older normal hearing subjects.

12.3 Objective Audiometric Assessment

In contrast to subjective audiometry, which makes use of psychoacoustic methods, the methods in which a physiological reaction or response of the auditory system is measured for audiometric purposes are referred to as objective audiometry. The responses depend to a much lesser degree on attention and active participation of the patient than in the subjective methods. Among the reactions to acoustic stimuli, the physical properties of the tympanic membrane (impedance audiometry), the sound emitted by the inner ear (otoacoustic emissions) and the electric processing in auditory nerve, pathways and cortex (auditory evoked potentials) are part of audiologic diagnostics. Since all of these signals are superimposed by physiologic and external interferences, the accuracy of the objective measures is limited. Therefore, some of the applications are of interest primarily in patients who are unable or unwilling to cooperate. Other applications provide specific diagnostic information that can not be obtained with subjective methods. In the context of identifying the cause of hearing impairment, objective measures are not merely a substitute, but a complement to the subjective procedures.

12.3.1 Impedance Audiometry

Impedance audiometry involves all audiologic examinations based on the measurement of the acoustic resistance opposed by the eardrum to the incoming sound wave. The dependence of this impedance on air pressure and probe tone frequency provides information about the physical properties of eardrum, middle ear, and ossicular chain. Moreover, the recording of impedance during acoustic stimulation with tonal pips allows the observation of physiological responses of the auditory system.

At the interface between two media of different acoustic impedances Z_0 and Z_1 , sound waves are reflected. The measurement of the impedance is based on the relationship between the reflection coefficient r and the normalized impedance difference

$$r = \frac{(Z_1 - Z_0)^2}{(Z_1 + Z_0)^2}. \quad (12.9)$$

The impedance of the middle ear depends on the mass M (tympanic membrane, ossicles, possibly secretions), the friction R (middle ear and inner ear), the elasticity k (eardrum, middle ear tendons, tympanic air), and the sound frequency f or angular frequency ω

Fig. 12.13 Vector calculation of the complex impedance Z from the real components (ωM and k/ω) and the imaginary part R (R = friction, M = mass, K = elasticity, ω = frequency)

(Fig. 12.13) [12.32]

$$Z = \sqrt{R^2 + \left(\omega M - \frac{k}{\omega}\right)^2}. \quad (12.10)$$

Apart from the frequency, all variables that enter into the calculation of the impedance characterize the condition of the middle ear. This fact accounts for the diagnostic importance of impedance. At the usual low test frequencies, the largest contribution to the impedance and its diagnostic importance arises from the elasticity term.

The relationship between impedance and sound frequency plays only a minor role in practical tympanometry because the impedance is measured almost exclusively with a test frequency around 220 Hz. The main reason is that at higher frequencies, standing waves can occur ($\lambda/4$ resonance) and the result of the measurement is governed by the geometry of the outer ear canal. Measurements with higher frequencies (e.g. 600 or 1000 Hz) yield more information about the physical processes in the middle ear, especially in children, and the improvements achieved by operational interventions can be observed, but the results obtained in different patients are less comparable.

In the context of audiometry, the use of impedance (in the appropriate unit *acoustic Ohm* = $\text{kg}/(\text{m}^2\text{s})$) is less common than the use of its reciprocal (the admittance). Since the impedance describes the resistance of the middle ear, the admittance corresponds to the willingness (compliance) of the middle ear to forward the sound to the inner ear. A large admittance is, therefore, equivalent to a low acoustic impedance and thus to a high flexibility of the eardrum. The unit of compliance is $\text{m}^2\text{s}/\text{kg}$ or mho (the reciprocal to ohm). Since

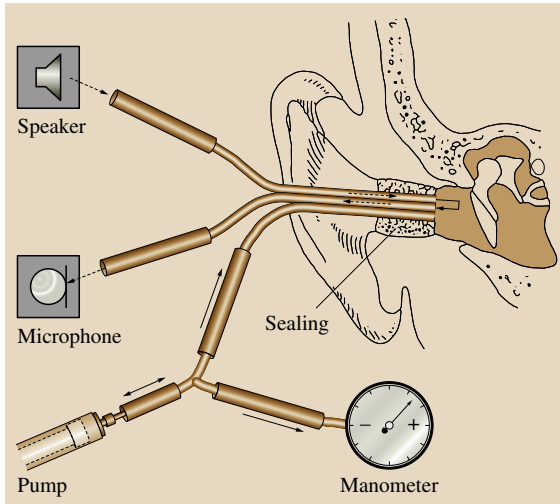

Fig. 12.14 Impedance ear canal probe with three tube lines for speaker, microphone and air pump/gauge, and an individual tip sealing the ear canal (after [12.33])

this unit is not particularly clear, the description of the compliance by an equivalent volume (whose unit is cm^3 or ml) is more usual. The ear canal and its boundary with the middle ear is understood to be a variable volume of air. If the sound is reflected, the entire system behaves like a small volume of air (with rigid walls); if the sound is absorbed, it represents a larger volume.

The measurement of the impedance is done indirectly by measuring the reflected portion of a test tone of known intensity, which is radiated into the ear canal. The key components of a device to measure the middle ear impedance are:

- A speaker for producing the test tone
- A microphone to measure the intensity of the reflected sound
- A pump and a pressure gauge for application and measuring the air pressure in the ear canal
- A device to display the results.

The probe is inserted into the ear canal and fitted with an air-tight, variable size ear tip (Fig. 12.14).

Tympanometry

The *tympanogram* reflects the compliance as a function of the pressure applied and air measured in the ear canal (Fig. 12.15). In the case of elevated pressure, the eardrum is displaced inward and it reflects a large part of the probe tone. Consequently, its elasticity decreases and thus the impedance is higher and the compliance

Fig. 12.15 In the case of normal middle ear function, the application of overpressure or underpressure in the ear canal results in very low values for the compliance of the tympanic membrane. At normal atmospheric pressure (no pressure difference between ear canal and middle ear), maximum compliance is recorded (schematic representation)

lower. At reduced pressure the eardrum is also more strained than at normal pressure because of the (unaltered) pressure in the middle ear, thus resulting also in a lower compliance. The vibrational properties are most favorable if the pressure in the outer canal equals the pressure in the middle ear, normally at atmospheric pressure. Therefore, the normal tympanogram exhibits a maximum of compliance at normal pressure ($p = 0$). The pressure differences applied for routine measurements are within ± 30 hPa.

The most important feature of a tympanogram is the maximum of compliance, which is described quantitatively by its location, its height, and a form parameter. The height of the peak has a pronounced individual variability. If the maximum compliance is significantly higher than the normal value, an atonic cicatrice in the tympanic membrane, a fracture of the stapes, or a defect of the incus may be present. Very flat compliance maxima will be observed when the middle ear is filled with secretion (otitis media with effusion, OME) or when the tympanic membrane is reinforced by a scar. The shift of the maximum to positive or negative value indicates an overpressure or underpressure in the tympanic cavity. An excess pressure can be due to dysfunction of the *Eustachian* tube, a reduced pressure indicates oxygen-consuming inflammatory middle ear diseases – e.g. the onset of otitis media without effusion. Variations of the middle ear pressure in the range of ± 10 hPa have no diagnostic significance. If a viscous middle ear effusion is present, secretions are deposited on the ear drum, which limits its mobility. The corresponding tympanogram exhibits no compliance peak, it is flat with a slight increase

at negative pressure. A similar result emerges in the case of a perforated eardrum because the admittance of the large composite volume of ear canal and middle ear is independent from pressure and not influenced by the tympanic membrane. Flat tympanograms can also indicate errors of measurement (e.g., a probe blocked by debris or pointing to the wall of the ear canal).

One of the main objectives of impedance audiometry, the diagnosis of otitis media, is better achieved by multifrequency tympanometry (MFT) using additional probe frequencies higher than 226 Hz ([12.34] and references therein). Tympanograms recorded around 660 Hz and 1000 Hz exhibit several and variable peaks and notches in the pressure dependence of conductance and susceptance. Their exploration is recommended in children having a history of otitis media, or else abnormal or notched 226 Hz tympanograms. As verified by myringotomy (a tiny incision created in the eardrum in order to relieve pressure caused by the excessive build-up of fluid), the MFT method has been proved to detect middle ear abnormality at a higher rate.

Middle Ear Reflexes

The second application of impedance audiometry is the detection of the stapedius reflex, mediated by a temporal change in impedance during the acoustic stimulation of one ear (Fig. 12.16). The impedance change is caused by contractions of the stapedius muscle affixed at the head of the stapes. The contraction is activated by strong acoustic stimuli and results in a stiffening of the ossicular chain and thus in an increase in the eardrum

Fig. 12.16 Shortly after presentation of a sufficiently strong tonal pip, the impedance of both eardrums is temporarily increased in normal hearing as a result of the acoustic reflex

impedance. Contraction and impedance change follow the stimulus onset with a slight delay of about 10 ms and they last for the duration of the stimulus.

The reactive contraction of the stapedius m. evoked by strong acoustic stimuli disables the oscillation of the stapes, thereby protecting the inner ear from excessive noise intensities. In order to fully understand the reflex process and to interpret the findings, the reflex arc has to be considered (Fig. 12.17). The acoustic reflex is an acoustic-facial reflex, i.e. the triggering (afferent) branch includes the middle ear, inner ear, and the auditory nerve; the executive (efferent) limb is the facial motor nerve that innervates the middle ear muscles. Afferent and efferent limbs of the reflex circuit are connected to each other in the brainstem nuclei of auditory and facial nerves. Since the executive branch innervates the middle ear muscles of both ears, a monaural acoustic

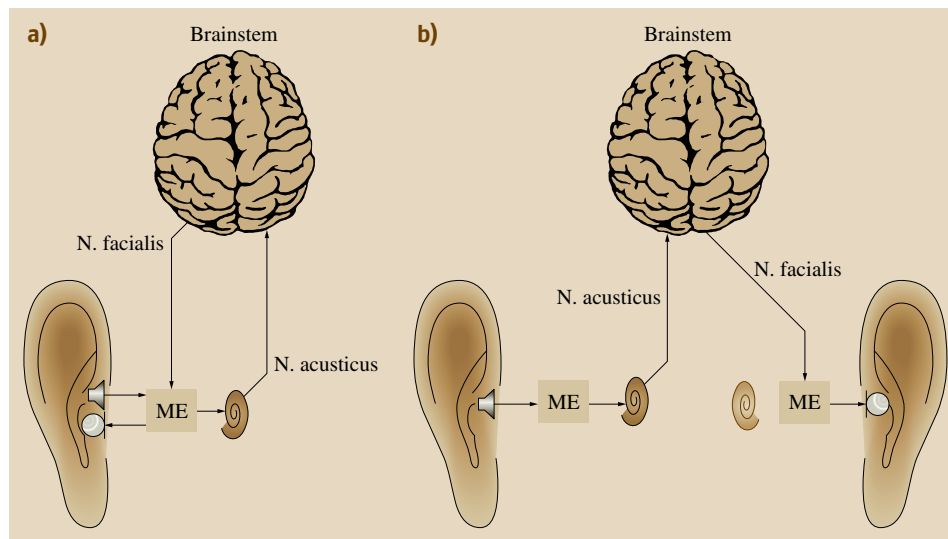

Fig. 12.17a,b Course of the ipsilateral (a) and contralateral (b) arc in the induction of the acoustic reflex (schematic representation). The acronym ME stands for middle ear

stimulation causes impedance change on both sides: the acoustic reflex can be triggered by ipsilateral and contralateral stimulation. In most practical applications, the question arises as to whether the reflex can be elicited in one ear. In others, however, the interest is not focused on the stimulus ear but on the probe ear.

For the observation of the ipsilateral acoustic reflex, the speaker integrated in the ear canal probe presents not only the continuous probe tone (e.g. 226 Hz) but also a reflex-inducing tone burst (duration e.g. 1 s) of arbitrary frequency (e.g. 500 Hz, 1 kHz, 2 kHz, or 4 kHz) and high intensity (70 to 110 dB HL) only. To measure the contralateral stapedial reflex, a headphone is placed on the stimulus side and the probe is placed in the ear canal on the probe side. In either case, the measurement is performed at the pressure corresponding to the compliance maximum. Starting at about 70 dB HL, the stimulus level is increased until the reflex threshold is exceeded. In normal hearing ears, this threshold is found typically at levels between 70 dB HL and 90 dB HL. A small percentage of normal hearing subjects exhibit no reflex.

The acoustic reflex is generally triggered only by stimuli associated with a large subjective loudness. The acoustic reflex threshold (ART) is, therefore, not primarily correlated with the level of the stimulus (dB HL), but rather with the level difference related to the individual threshold of the examined ear (dB SL). In case of conductive dysfunctions, the reflex threshold is, therefore, increased by the amount of hearing loss. If the hearing loss amounts to more than about 30 dB, no reflex will be triggered, because that would require a stimulus level of at least 110 dB HL (≥ 70 dB above threshold). In sensorineural hearing loss, the reflex threshold is elevated only when the hearing loss is more than 50 dB. Consequently, the reflex threshold is closer to the hearing threshold in many ears with sensory hearing loss. This manifests the restricted dynamic range of the hair cell-damaged ear (*Metz* recruitment [12.35]). Inner ear dysfunction impacts only the stimulus side but not the probe side.

The effect of neural hearing loss on the stapedius reflex depends on whether the lesion is located peripherally in the auditory nerve or more centrally in the brainstem, referred to the acoustic-facial reflex connection. In the first case, the reflex is absent or branded by a pathological reflex fatigue (decay); in the second case, the acoustic reflex is not impaired. Abnormal findings may be present both in the stimulus ear and in the probe ear. In many cases, the interpretation of the findings is obscured by additional cochlear pathologies.

12.3.2 Otoacoustic Emissions (OAE)

Otoacoustic emissions (OAE) are sound waves that are generated in the inner ear and radiated in the external auditory canal, mediated by the middle ear ossicles and the tympanic membrane. They were first described by *Kemp* in 1978 [12.36]. Otoacoustic emissions may be spontaneous (SOAE) and evoked (EOAE) by acoustic stimuli. The existence of OAE is attributed to the nonlinear and active cochlear processes involved in the sound preprocessing in the cochlea. These processes manifest themselves in the micromechanics of the basilar membrane and they are responsible for the high sensitivity, the wide dynamic range, and the good frequency resolution of hearing. The source of the OAEs are microscopic movements of the cochlear outer hair cells (OHC). If isolated OHCs are held alive in preparation, they can be stimulated to active contractions by chemical, electrical, and mechanical stimuli. It is supposed that OHCs at their natural site are triggered to contractions and elongations by acoustic stimuli as part of the physiological hearing process if the stimulus frequency corresponds to the targeted area of the cochlea. This enhances the displacement of the basilar membrane on the one hand and, on the other, it induces a retrograde traveling wave of small amplitude, which propagates to the oval window, through middle ear and eardrum and finally manifests itself as measurable sound pressure fluctuations in the ear canal. The evoked emissions can thus be regarded as a by-product of a nonlinear mechanical system with active feedback. Depending on the nonlinearity of the biological transduction, quadratic, cubic, and higher effects might occur, which can be detected by the corresponding distortions of the input.

Among the different types of OAEs, only EOAEs are routinely used in audiological diagnostics. They are detectable in almost 100% of normal ears. Because of their low intensity and the inevitable presence of noise, a sensitive microphone and complex signal processing are necessary for their detection. Another difficulty arises from the necessity of an acoustic stimulus, whose intensity exceeds that of the emissions by orders of magnitude and causes a passive echo response of the eardrum and ear canal walls, which is superimposed on the physiological signal.

EOAEs are divided into post-stimulatory (delayed) transient evoked otoacoustic emissions (TEOAE) and per-stimulatory (simultaneous) emissions (Table 12.2). The latter are further differentiated as stimulus frequency otoacoustic emissions (SFOAE), whose frequency matches that of the stimulus, and distortion

Table 12.2 Classification and nomenclature of otoacoustic emissions

Otoacoustic emissions (OAE)			
Spontaneous OAE (SOAE)	Evoked OAE (EOAE)		Per-stimulatory OAE
	Post-stimulatory OAE		
	Transitory evoked OAE (TEOAE)	Stimulus frequency OAE (SFOAE)	Distortion product OAE (DPOAE)

products or distortion product otoacoustic emissions (DPOAE), whose frequency is different from that of the stimulus. TEOAEs are firmly established in the audiological diagnosis because of their high reliability. In contrast, the detection of SFOAEs is difficult. Therefore, among the per-stimulatory OAEs only DPOAEs are used for diagnostic purposes. Only the two types of OAEs established in practical audiometry – TEOAE and DPOAE – are described in two sections of this chapter.

It is not yet clear whether the mechanisms underlying the generation of TEOAEs and DPOAEs are different and whether thus delayed and simultaneous emissions provide different information on the function of the inner ear. Most probably, the different emissions reflect only two different aspects of the same active and nonlinear cochlear amplifier. The difference of the techniques used for their detection impacts the practical application and the information outcome because at comparable stimulus levels, DPOAEs are detectable with greater sensitivity, i.e. even with a more pronounced hearing loss, than TEOAEs.

Transitory Evoked Otoacoustic Emissions (TEOAE)

For the measurement of TEOAEs (TEOAE), the acoustic signal is recorded in the ear canal immediately following a transitory stimulation. The active physiological echo is superposed by the stimulus, its passive

(mechanical) echo and ambient noise. The amplitude of these competing signals exceeds the target signal by several orders of magnitude. In order to detect the delayed emission, the signal to noise ratio must be improved by analog and digital signal processing. The main principles are effective acoustic screening and the selection and averaging of many signal segments.

In most TEOAEs applications, the acoustic stimulation is performed with a temporal sequence of clicks, i.e. single square-wave signals of a duration of about 100 μ s, which are presented at regular or irregular intervals of at least 20 ms. The time course and spectrum of a click stimulus are shown in Fig. 12.18. The recording of the stimulus and its frequency spectrum in the ear canal are the base for monitoring and the eventually corrective adjustment of the probe. In the ideal case, the click stimulus exhibits a white spectrum, i.e. all frequencies are represented with the same intensity. Such a constellation is the criterion for a closed ear canal volume free from resonance and, on the other hand, it is also a prerequisite for the functional testing of the entire cochlear partition with a single stimulus.

The probe introduced into the ear canal (Fig. 12.19) contains a magnetic transducer that delivers the short-term stimulus (click or tone burst) and a sensitive electret microphone for the registration of the sound pressure signal. The analog processing of the microphone signal registered after the stimulus consists of band-pass filtering in the range of about 300 Hz to 10 kHz and a linear amplification. The amplified signal sweep is digitized with a sample rate matched to the upper frequency limit and fed to the computer. The first step of the digital signal processing is the selection of appropriate signal sections in accordance with an amplitude criterion (artifact rejection). If at least one sample within a sweep exceeds a given (but variable) amplitude limit, the whole segment is excluded from further processing. This is equivalent to an interruption of the measurement in times of less favorable signal to noise ratios. The sweeps that pass the artifact suppression are added together point by point and thus provide a time-dependent mean curve. This signal averaging emphasizes all signal components that are correlated to the stimulus, while the amplitude of

Fig. 12.18a,b Temporal oscillogram (a) and frequency spectrum (b) of the click stimulus. Ideally, the spectrum registered in the ear canal is very broad and nearly flat (after [12.37])

Fig. 12.19 View of the ear canal probe used for acoustic stimulation and recording of OAE (Madsen *Capella*, GN Otometrics, Münster)

stochastic components is diminished. The resulting improvement of the signal to noise ratio is based on the validity of different laws for the addition. The amplitude of the physiologic signal responding to the stimulation increases linearly, whereas the stochastic components are superposed according to their variances. If the conditions of a stable deterministic stimulus response and a stationary noise source are met, the signal to noise ratio

improves by a factor of \sqrt{N} after N additions or averages (Fig. 12.20).

The improvement of signal to noise ratio generated by averaging is not equivalent to a selective amplification of the physiological response, since it emphasizes all stimulus related signal components such as the acoustic stimulus itself and its time-decaying echoes. In order to separate the passive (mechanical) from the active (physiological) responses, a particular stimulus sequence is applied (the nonlinear stimulus block in Fig. 12.21).

The effect of the nonlinear stimulus sequence is based on the different behavior of physiological responses and competing signals related to the stimulus. While the growth of the OAE amplitude with increasing stimulus amplitude is nonlinear and saturates at high stimulus levels, the amplitude of the mechanical response increases linearly. Therefore, the passive mechanical responses to $k = 3$ stimuli can be canceled through a stimulus of threefold amplitude (and analogously for arbitrary values of k). For the nonlinear active signal components, this cancelation is incomplete. When using a nonlinear stimulus sequence, i. e. a sequence suitable to compensate linear signal

Fig. 12.20a,b By averaging or summation, invariant (stable) signal components are amplified to a greater extent than noise. While the signal amplitude grows linearly with the number of summations, the noise increases only as a root function. If the effective amplitude of the unaveraged noise is 10 times larger than the (unaveraged) signal amplitude, the amplitudes of signal and noise are equal after 100 summations (a). If the same facts are considered in a double logarithmic representation (b), the inversion of a negative to a positive difference of signal and noise is even more pronounced. The consideration of averaging instead of summation causes only a scale correction, but no change of the amplitude relations (after [12.37])

Fig. 12.21 Utilization of the nonlinearity of the TEOAEs for their separation from the stimulus artifact (which depends linearly on the stimulus level) by application of a stimulus sequence composed of several elementary events with canceling amplitude (after [12.37])

components, the resulting signal contains only the uncompensated portion. Compared with conventional stimulation (*linear mode*), the cochlear emission loses amplitude but it appears more prominent relative to the mechanical stimulus response.

The result of a TEOAE measurement consists of one or two curves that reflect the averaged time-dependent behavior of the ear canal sound pressure in a time window starting with the stimulus presentation (Fig. 12.22). The transformation of these curves in the frequency domain provides the spectrum of the TEOAE. If two equivalent (but not identical) partial averages are available, the spectra of signal and noise can be calculated separately (cross-power spectra). Furthermore, the availability of two mean curves of $A(t)$ and $B(t)$ allows us to calculate a correlation coefficient (reproducibility) and to estimate the variance of the residual noise. From the grand mean $(A + B)/2$, the effective amplitude of the compound signal (emission and noise) can be calculated. The effective amplitude of the residual noise can be estimated from the root of the variance (root mean square, RMS) of the mean deviation $(A - B)/2$. In addition to these data, the representation of the wave form and spectrum of the stimulus recorded in the ear canal, the number of averaging steps and artifacts, the position of the amplitude limit, the stimulus intensity, and the stability of the stimulus conditions are part of the documentation of a TEOAE study.

For the diagnostic evaluation of TEOAE measurements, the presence of signals of cochlear origin must be verified. This is equivalent to the differentiation of delayed emissions as compared to averaged noise (residual noise) and passive echoes (stimulus artifact). An important criterion is the reproducibility expressed by the correlation coefficient $R(A, B)$. If the reproducibility is large, it is improbable that the measured signal is pure noise. The effect of the stimulus artifact (which is not completely abolished by the nonlinear stimulus mode) can be assessed with the aid of windowing. If a high reproducibility is found only in the first few milliseconds following the stimulus, the cochlear origin of the signal is unlikely.

The reliable and unambiguous distinction between signals of cochlear origin and interferences constitutes the most essential part of TEOAE evaluation. If delayed emissions are present, the ear under examination has a near-normal hearing threshold at some frequencies. The incidence of detectable TEOAEs decreases steplike from 100 to 0% with increasing inner ear hearing loss. The position of the step depends on the stimulus intensity. For a stimulus level of $L = 80$ dB SPL, the point of 50% incidence lies at $HL_{\min} = 32$ dB [12.38]. Here, HL_{\min} denotes the minimum hearing loss (i. e. the lowest threshold) in the frequency range from 1 to 4 kHz. As soon as a restricted area of the organ of Corti functions normally, TEOAEs will be present. No regions with substantial hearing loss contribute to the response. The frequency spectrum and the reproducibility (or signal to noise ratio) calculated in individual frequency bands allows a rough assessment of the frequency range affected by hearing loss.

The relationship between hearing threshold and TEOAEs described so far is valid for the special case of pure sensory (endocochlear) hearing loss. However, of course, also conductive disorders affect detectability and amplitude of the TEOAEs. The deterioration of sound transmission through the middle ear leads to an attenuation of both stimulus and response. If the air-bone gap exceeds the limit of 20 dB at all frequencies, TEOAEs are no longer detectable. Purely retrocochlear hearing disorders do not affect the TEOAE, they are typically characterized by the constellation of poor hearing with nearly normal emissions. However, since many causes of retrocochlear hearing disorders – e.g. space-occupying lesions in the cerebellopontine angle – are associated with cochlear damages, this constellation is rather rare. Especially in the case of large or long-term existing tumors, the TEOAE measurement provides no reference to the neural genesis of hearing impairment,

Fig. 12.22 Transient evoked otoacoustic emissions recorded in a normal hearing ear. The primary test results are the mean partial averages $A(t)$ and $B(t)$ (large box). These curves are the source for the calculation of frequency spectra, emission amplitude, reproducibility and residual noise. Moreover, the stimulus parameters and noise conditions are given

i. e. detectable emissions are limited to the frequencies of the normal threshold [12.39].

The measurement of TEOAEs does not allow for quantitative and frequency-specific determination of the hearing threshold. The spectrum of each delayed emission exhibits irregular and individual peaks and notches, facing no hearing loss in the audiogram. Only the absence of emissions in a wide frequency interval can be interpreted as an indication of a raised threshold for those frequencies. A special feature must be noted, however: if the hearing loss is limited to low frequencies, not all low frequency components are missing but only those with long latency (since the apical cochlear responses are generated later). This can be read from the OAE waveform or from the spectrogram and it can be confirmed by windowing and band-pass filtering the original response.

The spectrum of emissions evoked by broadband stimuli (click) contains all frequencies for which the

cochlea has a near normal function. Functional losses exceeding the limit of about 30 dB result in the disappearance of the corresponding TEOAE components. The complete absence of physiological echoes thus means that the hearing loss exceeds this value at all frequencies. Conversely, the presence of emissions permits the conclusion that the function of at least some of the hair cells is nearly normal and thus the minimal hearing loss is less than about 30 dB. The validity of these statements is limited to the frequency range between 1 and 4 kHz, a hearing loss outside these limits cannot be detected with TEOAEs.

Distortion Product Otoacoustic Emissions (DPOAE)

The nonlinearity of cochlear signal processing is accompanied by several consequences, one of them being the inability of the inner ear to process two frequencies independently if they are sufficiently close to each other.

If the cochlea is excited simultaneously with two (primary) pure tones, their physiological processing results in the production of secondary tones with frequencies that are not included in the stimulus. These distortions can be perceived subjectively and they can be measured as acoustic emissions from the inner ear in the ear canal. This is the basis for the detection of DPOAEs (distortion product otoacoustic emissions).

From the mathematical analysis of nonlinear distortions, using a power series expansion and the calculation rules for trigonometric functions, the formulas for the frequencies present in the output of a nonlinear system processing the input frequencies f_1 and f_2 can easily be obtained. Arranged according to their frequencies, the symmetric (quadratic) distortion leads to components with $f_2 - f_1$, $2f_1$, $f_2 + f_1$ and $2f_2$, and the anti-symmetric (cubic) distortion delivers signal components with the frequencies $2f_1 - f_2$, $2f_2 - f_1$, $3f_1$, $2f_1 + f_2$, $2f_2 + f_1$ and $3f_2$. Many of these theoretically possible combination tones were measured in the ears of experimental animals and humans. The functional testing of hearing is limited to the cubic distortion products with the frequencies $2f_1 - f_2$ and $2f_2 - f_1$ because of their good detectability, and among these, mostly the former: the tone whose frequency

lies below the two tones, separated from the lower one by the difference of the primary stimulus frequencies (Fig. 12.23a).

In contrast to the delayed TEOAEs, the pre-stimulatory DPOAEs can be disaggregated from the stimulus not in the time domain but only in the frequency domain. Since the frequency of the cochlear emissions can be predicted accurately from the stimulus frequencies, the signal detection can be automated. The release of measurable distortion product works best with a stimulus that is composed of two suprathreshold continuous pure tones of approximately equal intensity with the frequencies f_1 and $f_2 \approx 1.2f_1$. To allow the detection of distortion effects of physiological origin, technical nonlinearities must be reduced as much as possible. For this reason, the two sine tones are presented by separate transducers. Therefore, the DPOAE probe contains two speakers and a microphone.

Prior to the DPOAE measurement, the acoustic conditions in the ear canal are checked by recording the transfer function upon excitation with broadband click stimuli. Ideally, the stimulus spectrum is flat over a wide frequency range. In the case of larger fluctuations, the probe position must be controlled and corrected. If the

Fig. 12.23a,b Frequency spectrum measured in the ear canal when stimulated with two pure tones (a). With increasing number of averages, the cubic difference tones (distortion products) grow clearly out of the noise background. (b) Diagram showing the amplitude of the distortion product in dB SPL as a function of the stimulus frequency f_2 in kHz (DPgram) for stimulation of a normal hearing ear with two primary tones of equal intensity ($L_1 = L_2 = 67$ dB SPL). The shaded area in the lower part of the diagram corresponds to the residual noise, its upper limits are given by the average noise level incremented by one and two standard deviations (after [12.40] with kind permission)

transducers are fed at different times and the responses are recorded separately, not only the ear canal response, but also the function of the two loudspeakers and their feedthrough can be checked.

During the DPOAE measurement, the microphone signal is recorded and sections of this continuous signal, which are synchronized to the phase of the stimulus tones, are summed. The phase-aligned summation results in a gain of stimulus and cochlear response relative to the unsynchronized noise. In the spectrum of the running average, the lines corresponding to the frequencies of the distortion products emerge increasingly from the background noise (Fig. 12.23a). From this spectrum, the amplitude of the distortion product at the frequency $2f_1 - f_2$ is extracted, together with the amplitude of the background noise, derived from a narrow frequency band centered around $2f_1 - f_2$. In the DP-gram, these data are displayed for several stimulus frequencies (Fig. 12.23b).

The selective stimulation with two frequencies excites only two places of the basilar membrane. According to the constant frequency ratio $f_2/f_1 \approx 1.2$, the activated regions are separated by a constant distance, independent of the stimulus frequencies. The distance is about 1.3 mm and it corresponds roughly to the equivalent rectangular bandwidth (ERB) for frequencies above 500 Hz. The distortion product is generated in the overlapping zone of the two excited areas. Because of the asymmetry of the traveling wave peak, this zone is located close to the place where the higher of the two frequencies (f_2) is processed. Accordingly, the correlation between the amplitude A_{DP} of the emission with the hearing threshold $HL(f_2)$ is much larger than between A_{DP} and $HL(f_1)$. Further evidence for the generation site of the distortion product can be deduced from suppression experiments: It has been shown that the suppression of the DPOAE by application of a masker with variable frequency has the greatest impact if the masker frequency is equal to f_2 [12.41]. The width of the overlap zone increases with increasing stimulation level. This has two consequences: First, the information obtained from the measurement of DPOAEs at high stimulus levels is not solely specific for the hearing threshold at the stimulus frequency, and second, the frequency ratio and/or the level difference of the primary tones have to be modified if the DPOAE are to be measured with stimulus levels close to hearing threshold (scissors paradigm) [12.42].

The relationship between DPOAEs and hearing loss parameters is controlled by rules that are very similar to those for TEOAEs:

- The incidence of DPOAEs evoked by frequencies f_1 and $f_2 = 1.2f_1$ is close to 100% in normal hearing ears.
- The amplitude of the emission decreases with increasing hearing loss.
- If the hearing loss at frequency f_2 exceeds the limit of about 50 dB, the DPOAEs are no longer detectable.
- Incidence and amplitude of DPOAEs are not influenced by purely retrocochlear hearing disorders.
- Conductive hearing loss causes predominantly an attenuation at low frequencies; in the case of larger hearing loss, the DPOAEs disappear completely.

These rules apply to all pairs of stimuli for which f_2 lies between 1 and 4 kHz. At lower frequencies, the incidence of detectable emissions is well below 100% even in normal hearing ears. At higher frequencies, the detection of DPOAEs is often impacted by technical distortions.

The current application of OAEs in practical audiometry permits a categorization of hearing impairment in the categories of mild, moderate, and severe hearing loss; an exact determination of the hearing threshold is not possible. The categorization is achieved by the combination of TEOAE and DPOAE, since in standardized test conditions, the former are detectable only if the hearing loss does not exceed 30 dB at any frequency, whereas the latter remain observable up to a threshold elevation of about 50 dB. Particularly TEOAEs, whose susceptibility for the disturbing interferences is very low, have proved to be suitable for a reliable and objective assessment of hearing, making this method optimal for newborn hearing screening and early detection of pediatric hearing loss. To date it is not yet clear whether OAEs, beyond their dichotomy, are able to yield quantitative results in terms of a frequency specific objective determination of the hearing threshold. Some current works are focused on the question of whether the threshold can be quantitatively determined using the stimulus level dependence of the amplitude (*growth function*) or other parameters of OAEs. The results of these works are encouraging, but not yet secured for practical use.

12.3.3 Evoked Potentials of the Auditory System

Auditory evoked potentials (AEP) are electrical voltages of physiological origin that are associated with auditory sensations and can be triggered by acoustic

or electric stimuli and measured using electrodes. The techniques used for investigating properties of hearing with the help of the AEPs are summarized as electric response audiometry (ERA). They are objective performance tests that allow a quantitative determination of the hearing threshold. This feature is one of the columns accounting for the great importance of ERA in the audiometric test inventory [12.8]. An additional benefit arises from the fact that with the help of the ERA differential topodiagnostic statements, especially for the distinction between sensory and neural hearing loss, can be obtained.

The difficulty in measuring the AEPs is that a signal of very small amplitude (the AEPs) must be detected in the presence of strong noise (the spontaneous EEG). The amplitude of the interference can exceed the amplitude of the target signal by several orders of magnitude – especially if the EEG is superimposed by muscle activity and external electromagnetic interference. The first requirement for the measurement of AEPs is, therefore, a substantial reduction of avoidable contaminations. The following measures help to improve the signal to noise ratio:

- Relaxed and comfortable positioning of the patient
- Acoustic and electric shielding
- Linear EEG amplifier with high common mode rejection
- Filtering of the EEG signal
- Artifact suppression
- Signal averaging.

The measurement of AEPs is based on the recording of the EEG during acoustic stimulation. The patient should sit or lie relaxed during the measurement. As far as the potentials and their parameters are independent of the vigilance (as is the case with the peripheral components of short latency), the measurement under conditions of spontaneous sleep, sedation, or general anesthesia can improve the outcome. The acoustic stimuli are presented mainly via headphones, in special cases via free sound field (loudspeaker), bone conduction transducers, or insert ear phones. In most practical applications, the acoustic stimuli have a short duration or they are modulated in time. The EEG activity is recorded via surface electrodes fixed on the scalp. If an acoustically and electrically shielded room is available, patient, transducers, and EEG amplifier should be housed in it. Outside the shield are the investigator and the remaining parts of the apparatus, consisting essentially of a stimulus generator, an analog/digital converter, and a computer.

Transient Responses

Most of the electrical responses of the auditory system can be registered only as a delayed and temporarily limited (transient) response to a transitory stimulus. Stimulation and EEG analysis are synchronized with each other, whereby the intervals between two stimuli can be constant or randomized. The registration of the EEG sweep begins with the onset of stimulus or shortly before. The averaging of many signal segments yields a time-dependent curve composed of the AEPs and the reduced amplitude of the EEG noise (residual noise). The diagnostic conclusions arise from the evaluation of curves measured with different quality (e.g. frequency) and intensity of the stimuli and from the parameters derived from these curves.

For the emergence of measurable evoked potentials, a large number of nerve action potentials must be generated with a high degree of synchronization. This is possible only with stimuli that go along with rapid changes. In principle, these changes can affect every auditory differentiable characteristic of the stimulus. Most often, this characteristic is the intensity or the sound pressure of the stimulus, and the change is brought about by switching the stimulus on or off. The usual transient stimuli are the broadband click and frequency selective tone bursts. High frequency selectivity and short stimulus duration principally exclude each other. Therefore, responses that require a high degree of neuronal synchronization supply less frequency specific information. Conversely, frequency selective stimuli are not suitable for yielding precise information on the time dependence (latency) of the responses.

Transient AEPs are composed of many individual vertex positive and negative potential peaks, which are generated in different parts of the ascending auditory pathway and are classified into three groups according to their latency: early auditory evoked potentials (EAEP), also denoted as auditory brainstem responses (ABR) in the time range from 1 to 10 ms, middle latency AEP (MAEP) with latencies up to 50 ms, and late or slow AEP (SAEP) with latencies up to 500 ms. The methods used to measure these responses are denoted with BERA (brainstem electric response audiometry) for early, MLRA (middle latency response audiometry) for middle, and CERA (cortical electric response audiometry) for late AEPs. Some of these names make reference to the anatomical location of the response generators. The assignment is not unambiguous, but it may be regarded as certain that J1, the first among the EAEPs originates in the auditory nerve and the subsequent ABR components J3 and J5 in the brainstem,

whereas the MAEP are generated in the thalamus (diencephalon) and the primary auditory cortex, and the SAEP in the auditory cortex.

In addition to the electrical potentials mentioned so far, later components that reflect the processes involved in auditory perception, cognition, and discrimination are known. One of them is a vertex negative wave with a latency of approximately 200 ms (N200). It can be observed as specific response to deviant stimuli that are embedded randomly in a series of standard stimuli (mismatch negativity, MMN). If the subject is asked to count the rare stimuli or to react with a motor response, a positive half-cycle wave with a latency of 300 ms (P300) can be observed (event related potential, ERP). Since the detection of this potential requires active cooperation of the subject, they are not used routinely in objective audiometry. Further, very slow changes of voltage (contingent negative variation, CNV) and still later processes (N400) reflect the expectation of a stimulus announced by a preceding warning signal and the processing of semantic information in speech signals.

Due to the different paradigms used for stimulation and signal processing, it is not possible to record all AEP components with a single measurement. In principle, the approaches for measuring early, middle, and late evoked potentials are identical, so that nearly all responses can be recorded with the same equipment by changing some parameters (stimulus type, stimulus interval, EEG gain, filter limits, time window, sampling rate, and number of averages).

The EEG signal is detected by electrodes which are usually attached to vertex and mastoid, the ground electrode being located on the forehead. After amplification, filtering, and A/D conversion, the EEG signal is subjected to an artifact control to select those sweeps that do not exceed a predetermined amplitude limit. The summation of N signal sections ($N \approx 2000$ for ABRs, $N \approx 600$ for MAEPs, and $N \approx 50$ for SAEPs) enhances the signal components related to the stimulus (such as the AEPs) linearly, while stochastic components are amplified approximately proportional to \sqrt{N} in the case of stationary conditions. Thus, the signal to noise ratio improves according to the noise release gain given by $G = 10 \log N$ dB (Fig. 12.20). If the interferences are not stationary, the signal quality can be improved by weighted averaging, using the reciprocal value of the variance or of the maximum amplitude of the individual sweep as weight (artifact rejection is a special case of weighted averaging making use of the weighting factors 0 and 1).

Quality and reliability of the results can be characterized by the ratio of the variances of overall response and residual noise (response to noise ratio), by the correlation coefficient calculated out of two equivalent partial averages (reproducibility) or estimated by visual comparison of the partial averages. The evaluation and diagnostic exploitation of AEPs include the identification of the response components and the determination of their coordinates (latency and amplitude). The former is used to determine the hearing threshold, the latter contributes to the differentiation of type and site of hearing disorders.

The early responses of auditory nerve and brainstem, often referred to as auditory brainstem responses (ABRs) are studied with BERA. This method includes the post-stimulus time range from 1 to about 12 ms. Due to their small amplitude (50 nV to 0.5 μ V), ABRs can be measured with a sufficiently large amplitude only if the elementary neural events are highly synchronized. This can be achieved by stimulation with a short rectangular pulse (click). ABRs evoked by click stimuli are, therefore, not suitable for a frequency specific determination of the threshold. The early responses are very stable regarding the influences of vigilance and drugs and therefore easily recordable during sleep or under anesthesia. They are regularly present at birth, but their morphology and parameters (amplitude, latencies, latency differences) are different from the pattern observed in the adult. In the course of maturation of the neural auditory system, the modifications disappear during the first 18 months of life. The whole ABR is composed of several components generated in various stages of the ascending auditory pathway and referred to as waves J1 to J5 according to their temporal sequence (Fig. 12.24).

The complete response pattern is observed only at stimulus levels far above threshold. The amplitudes of all components increase with increasing stimulus intensity while their latencies decrease (i. e., stimuli of lower intensity are associated with a longer cochlear processing time). These relationships are represented in a diagram, which facilitates the identification of deviations from the normal values.

The lack of frequency specificity of ABRs evoked by broadband clicks limits a wide field of application, in spite of their otherwise favorable properties. This was motivation to intensify the efforts to find a frequency specific audiometric assessment based on early potentials. One of the approaches based on stimulation with brief tonal bursts and simultaneous masking with broadband noise passed by a filter with a notch

Fig. 12.24 Auditory brainstem responses (ABRs) evoked by clicks and recorded in a normal hearing 15 year-old female subject. The left panel shows the original responses recorded at various stimulus levels in right (ri) and left (le) ear. Latencies and amplitudes derived from these curves and their level dependence are shown numerically and graphically on the right-hand side (GMW means weighted average)

around the burst frequency (notch noise ABR [12.43]). The responses obtained with this method can be evoked by frequencies between 500 Hz and 4 kHz and detected down to stimulus levels close to the hearing threshold in many cases. According to the properties of the cochlear traveling wave, the latencies of the responses are longer for low than for high stimulus frequencies. The same physiological mechanisms are the reason that the neural activity is less synchronized at low than at high frequencies, and this in turn limits the accuracy of the hearing threshold determination.

The most important applications of the ABRs are the objective determination of hearing threshold in infants and children and the topodiagnostic distinction between sensory and neural hearing disorders. The

hearing threshold is extrapolated from the response threshold, which is defined as the lowest stimulus level eliciting a clear response and deduced visually from the series of curves. For the derivation of topodiagnostic statements, latencies and amplitudes are measured and plotted as functions of the stimulus level. Based on the comparison with the normal values, on the calculation of latency differences – especially the cochleo-mesencephalic latency difference (*central conduction time*) $t_5 - t_1$ – and on the evaluation of side differences, the hearing disorder can be classified and identified as conductive disorder, sensory deficit, or neural lesion. In the case of a conductive hearing loss, the latencies of all responses are prolonged and the amplitudes are reduced at all stimulus levels because of the

acoustic attenuation. In cochlear hearing impairments, the alterations of the AEP depend on the frequency range affected by the disorder. In many cases, the latencies are prolonged at low stimulus levels and nearly normal at high intensities. This holds true for t_1 , t_3 and t_5 , the central conduction time $t_5 - t_1$ is not affected. In other cases, the prolongation of latencies is independent of the stimulus level and it may be different for t_1 and t_5 , resulting in a shortened central conduction time. Hearing disorders of neural origin caused by space occupying processes or neurologic degenerations are typically labeled by a prolongation of $t_5 - t_1$, a reduction of amplitude, and significant side differences.

BERA has a high sensitivity for the detection of mass lesions in the cerebellopontine angle, in contrast to subjective tests, which are at best able to identify a cochlear involvement. In the diagnostic context, the ABRs are supplemented by the analysis of the middle ear reflex and the functional test of the vestibular system. If one or more of these studies confirm the suspicion of the existence of a retrocochlear disorder, the finding is controlled with the help of imaging techniques (computed tomography and magnetic resonance).

The middle latency auditory evoked potentials (MAEP) are only marginally used in audiological diagnostics. In terms of their properties (e.g. amplitude,

Fig. 12.25 SAEP recorded with CERA in a 51-year-old normal hearing subject at four different frequencies and various stimulus levels in both ears. Next to each curve, the level of stimulus and contralateral masking are given on the *left-hand side* and the response to noise ratio (RMS amplitude of the overall average divided by the RMS amplitude of the residual noise) on the *right-hand side*

impact of maturation, vigilance, and alertness) and their diagnostic significance (e.g. frequency specificity), they are settled between the early and the late AEP components. MAEPs possess neither the high stability typical for ABRs, nor can they compete with SAEPs in the reliability of frequency specific determination of the hearing threshold.

The late or cortical potentials measured with CERA essentially comprise the maxima and minima of voltage located at about 100, 200, and 300 ms, denoted by N1, P2, and N2 (Fig. 12.25). The amplitude of the responses increases with increasing stimulus level, their latency depends on stimulus intensity only very close to the threshold. Latency and amplitude change considerably if the subject falls asleep. Reliable results can, therefore, be expected only in awake and attentive patients. This partially explains why the application of CERA is not useful in infants and young children. Another reason is the uncompleted maturation of the cortical auditory pathways.

Auditory Steady State Responses (ASSR)

While the measurement of transient auditory evoked potentials discussed so far requires a silent break between the acoustic stimuli, the auditory steady state responses (ASSR) examine the auditory system under per-stimulatory stationary conditions. The acoustic stimulus is present without interruption while the EEG signal is recorded and analyzed. Signal processing comprises averaging and statistical analysis in the time and frequency domain with the aim to isolate a feature of the EEG signal which is closely related to the physiological stimulus processing. The adequate stimuli are continuous and stationary but not invariant in time because the neuronal activity evoked by acoustic signals without any temporal structure is not detectable in the compound EEG activity.

Among several variants of the ASSRs, the responses to amplitude modulated stimuli (amplitude modulation following response, AMFR) have recently gained particular practical importance. Acoustic stimulus and signal detection are shown schematically in Fig. 12.26. The amplitude of a continuous tone whose carrier frequency f_C lies in the range from 250 to 8000 Hz is modulated with a modulation frequency f_M between 40 and 120 Hz and a modulation depth from 80 to 100%. The amplitude modulation may be combined with a frequency modulation with the same modulation frequency but a much smaller modulation depth of typically 10%. The modulated stimulus leads to a synchronized excitation of groups of neurons in the auditory pathway,

most probably located between midbrain and thalamus. Therefore, the modulation frequency is present in the EEG signal, which is recorded either laterally (e.g. vertex versus mastoid) or – especially in the simultaneous stimulation of both ears – medially (vertex to occiput). For the detection of this frequency, the electrode signal is transformed into the frequency domain after amplification and narrow band filtering and its amplitude and phase is analyzed in the vicinity of the modulation frequency. The neural response is considered to be present if the amplitude of the frequency f_M protrudes significantly from the background and/or if its phase statistics deviates significantly from random distribution. The impact of alertness, vigilance, and age on the response amplitude is stronger for high than for low modulation frequencies. It is the aim and claim of the method to allow a frequency-specific, objective and automated determination of the hearing threshold in children. For this purpose, modulation frequencies around 90 Hz have turned out to be most suitable. Since the identification of AMFRs is based on the detection of the modulation frequency of the stimulus in the EEG spectrum, several stimuli with different carrier frequencies and different modulation frequencies may be presented simultaneously, and even on both ears at the same time, as far as mutual masking is excluded [12.44].

To date, the diagnostic potential of ASSRs cannot be appraised definitely as yet. Currently, effective stimulus paradigms and statistical methods for signal detection are being tested and compared in terms of their performance. For practical applications, some systems that detect the EEG activity evoked by the amplitude-modulated stimulus and optionally seek the response threshold automatically using adaptive algorithms are commercially available.

Objective Audiometry for Screening Purposes

If audiometric testing is carried out for screening purposes, e.g. for early detection of congenital hearing loss in newborns, objective methods are preferably applied because of their independence from the individuals ability and willingness to actively cooperate. In this context, the methods are not operated at their maximum performance level (described in the preceding chapters) but in a simplified and automated procedure, which ensures high stability and sensitivity. As was shown earlier, ABRs are detectable approximately 10 dB above hearing threshold. If a hearing loss of 30 dB is considered relevant for therapeutic intervention, a stimulus level of 40 dB is adequate for detecting the relevant cases. Application of high-intensity stimuli would im-

prove the detectability of the response, but it would also include the risk that babies with hearing loss exceeding the therapeutic limit are considered as normal (missing hits).

In the case of OAEs, the responses elicited by stimuli of high suprathreshold intensity remain detectable as long as the functional structures generating them are present and functioning. Although the response detectability decreases with lower stimulus intensity, it is still not clear whether the loss of functional elements elevates the response threshold or just reduces the response magnitude. It has been shown [12.45, 46] that TEOAEs disappear if the relevant hearing loss (which remains to be defined) exceeds the limit of 30 dB, no matter how intense the stimulus. Similarly, the loss of DPOAEs indicates a relevant hearing loss of at least 50 dB. For TEOAEs, the *relevant hearing loss* is the best value of threshold in the frequency range from 1 to 4 kHz, for DPOAEs it is the threshold at frequency f_2 (i.e. the higher among the two primary tone frequencies). In contrast to ABRs, the application of high stimulus levels does not imply the risk of missing hits since neither a low nor a high stimulus can evoke a response of hair cells that are out of order, but it improves the signal detection. For field conditions, a click level between 65 and 80 dB SPL (equals 35 to 50 dB HL) has proven suitable for the TEOAEs. DPOAEs can be recorded at $L_1 = L_2 = 65$ dB SPL with sufficient probability, but their application is less favorable for newborn hearing screening since their sensitivity limit of 50 dB hearing loss is too high if all cases of therapeutic relevance are to be identified.

If ABRs are detected, all components of the hearing system from the most peripheral site up to the auditory nuclei in the brainstem must be functioning properly. Hearing disorders of conductive, sensory, or neural nature affect the response. The elevation of the hearing threshold corresponds exactly to the elevation of the response threshold. In the case of OAEs, the presence of a response depends only on the functional state of sound conduction through the middle ear and its amplification by the outer hair cells. The relation between hearing loss and presence of a response may be somewhat obscured by the influence of conductive losses, which impede the transmission not only of the stimulus but also of the response. Because of this double impact, responses of dichotomic nature usually disappear already when the damping reaches 20 dB.

Hearing assessment within screening programs should work without intervention of qualified per-

Fig. 12.26a–c Schematic illustration of stimulus properties and signal detection in the registration of AMFR. The spectrum of the amplitude-modulated stimulus tone (a) with carrier frequency f_c consists of three lines at the frequencies $f_c - f_M$, f_c , and $f_c + f_M$ (b). The modulation frequency f_M is found in the EEG spectrum (c)

sonnel. This requires an automated signal detection yielding a dichotomic result (PASS or REFER). Different algorithms can be used to decide whether a response is present or not, the most simple among them being based on reproducibility or signal to noise ratio. In some commercial systems the classification is based on the averaging of signal polarity and its evaluation by statistical considerations. For each sample of the

microphone or electrode signal, a digital counter is incremented by one unit in the case of a positive sample and decremented by one unit in the case of a negative value. After recording enough signal epochs, the decision whether the dominance of positive or negative values is statistically significant is made according to binomial distribution. This algorithm is very powerful

in distinguishing between stochastic and nonstochastic signals and it is very stable against perturbations by artifacts. In the case of OAEs, a response is considered as present if a given probability level is exceeded by at least eight samples. In the case of ABRs, a similar procedure is applied to the averaged response after convolution with a template typical for newborn ABR.

12.4 Technical Hearing Devices

Many hearing disorders can be compensated at least partially with technical devices. These devices may be conventional amplifying hearing aids, implantable hearing systems, or cochlear implants. Since neither sound amplification nor implanted prostheses are able to reconstitute normal hearing, technical compensation is only considered if conservative and surgical treatment does not lead to satisfactory results. In any case, the benefit to be expected and the risk of unwanted side effects must be traded against each other. The amplification of sound through hearing aids is associated with a stronger and potentially hazardous sound exposure of the pathologic ear. Implantations bear the risk of anaesthesia and eventually loss of the residual hearing, especially in the case of cochlear implants. This makes clear that ENT physicians must be involved in the administration of hearing devices and the control of success and rehabilitation. Other disciplines engaged in the process of rehabilitation are audiologists and acousticians, furthermore logopedists and pedagogues, and experts for pediatric audiology where appropriate.

12.4.1 Conventional Hearing Aids

The decision to administer hearing aids is based on a complete audiometric exploration, which allows the identification of type and site of lesion and the amount of hearing loss. Sound amplification is the only therapeutic option in cases of irreversible cochlear damage, whereas conductive and neural impairments do not belong to the classical target group. The audiological criteria for the prescription of hearing aids are a hearing loss of at least 30 dB at frequencies between 500 Hz and 3000 Hz and a speech discrimination (monosyllables) below 80% at 65 dB SPL. If both ears are affected, the supply with hearing aids should be bilateral because less amplification is required, acoustic sources can be localized more easily, and speech discrimination in noise and reverberation is improved. Moreover, the auditory de-

privation in the impaired ear can promote the emergence of tinnitus.

Hearing aids are available in different mountings, which are worn behind the ear (BTE), in the ear (ITE), or even completely in the canal (CIC). The latter helps to take benefit of the natural gain and directional filtering of the outer ear. This reduces the gain requirement and it is advantageous for directional hearing and speech intelligibility in noise. In addition, the sound signal is less distorted, as no tube is necessary to feed the sound to the external meatus. In contrast, most BTE hearing aids are combined with a tube and an ear mold in order to prevent acoustic feedback. If the hearing loss is only moderate, BTE devices can be equipped with external transducers placed in the ear canal or with microtubes, which do not require an ear mold.

The conventional sound-amplifying hearing aid is an electronic device that provides the acoustic stimulus with higher intensity. Its main technical components are a sound sensor (microphone), an amplifier with control elements, an energy source (battery) for operation of the amplifier, and an output transducer (loudspeaker). Additional components may be available, as acoustic filters, an induction coil (telecoil), an external input, and a remote control.

The basic components of a hearing aid and their operation are shown in Fig. 12.27. The sound signal is converted in a time-dependent voltage by the microphone. If the acoustic information is available additionally as an electrical signal (e.g. from telephone or TV), two conversions may be bypassed if the electrical signal is fed directly into the hearing aid either through an induction coil or an input socket. The electrical signal is amplified by a factor that may depend on frequency and intensity, optionally filtered and limited, and supplied to the output transducer (loudspeaker). The output signal reaches the eardrum either directly or through a tube. If necessary, means for the elimination of acoustic feedback can be provided.

Fig. 12.27 Simplified drawing of the essential components of a hearing aid

The high requirements of a microphone suitable for hearing aids in terms of dimension, efficiency, transmission characteristics, sensitivity, energy requirements, and independence from temperature are met by an electret microphone powered by a field-effect transistor as impedance converter. Its working principle is that of an electrostatic converter whose capacitor charge is not maintained by an external power source but by a pre-polarized film. In most hearing aids, omni-directional microphones (pressure transducers) are used. A directivity is given by the head and the position of the microphone entrance behind the ear, the outer ear, and the ear canal. Directional microphones with two openings (pressure gradient transducers) or arrays of multiple microphones are used optionally to improve acoustic focus and noise reduction.

The amplification of the electrical microphone signal is described by the input/output characteristic of the amplifier, i. e. by the functional relationship between input level L_i and output level L_o . In general, the gain is dependent on frequency and level of the input signal. If this is not the case, the amplifier characteristics are straight lines with slope $\Delta L_o / \Delta L_i = 1 \text{ dB/dB}$ parallel to the angle bisector for all frequencies in the double logarithmic representation (Fig. 12.28a). The gain factors corresponding to different curves are then moved parallel to each other. From the *i/o*-characteristics of a linear amplifier, the gain in dB can be read as the difference $\Delta L_o - \Delta L_i$ at a single point.

The output of each amplifier is limited by the operating voltage. In hearing aids, a further limit is given by uncontrollable acoustic feedback at high output levels. Feedback can be prevented by a circuit composed of diodes, which cuts the voltage spikes above a predetermined limit (peak clipping, PC). In the input/output function, the PC is characterized by a horizontal branch at high input levels (Fig. 12.28b). Unlike other techniques used in hearing aid amplifiers, the PC takes effect without any delay. Additionally to the upper limit of the output level, a lower limit is given by the noise of amplifier and converters. This noise is partially ampli-

fied, so that it is equivalent to a minimum input sound level. Signals whose level is below that limit cannot be transmitted by the hearing aid because they are at least partially covered by noise.

The limitation of the output signal protects the hearing aid user against noise intensities that exceed his discomfort level but it cannot compensate the loss of natural dynamic compression occurring in many sensorineural hearing impairments. A better approach to compensate pathological loudness growth is the reduction of the gain factor continuously at levels above approximately 50 dB. Manual operation of the volume control by the hearing aid user is neither precise nor fast enough to react efficiently to changes of sound level. Therefore, many hearing aids are equipped with an automatic gain control (AGC). It causes a reduction of gain with increasing noise level and thus a compression of the acoustic dynamic range. Unlike the limiting circuits, AGC does not react simultaneously but with a certain delay.

The attack and release time of the gain control must be greater than the period of the lowest frequency to be amplified, because otherwise the amplitude within a single sound wave would be regulated and the signal would be distorted. The lower limit is thus at about 10 ms. In the steady state of the amplifier, the sine waves of all frequencies must be transmitted as sine waves. Transient effects and decay processes do not occur in the case of slow changes of sound level (stationary signal), but they arise at rapid changes, such as those occurring in speech signals (dynamic behavior). They can cause short-term noise peaks that exceed the maximum permissible output level. To prevent this, the AGC is always combined with a PC.

Systems with very long time constants (>200 ms) react only to very slow changes of sound level and are denoted by automatic volume control (AVC). Response times below 20 ms are suitable to compress individual syllables. This improves speech intelligibility, since the forward masking of speech elements with low level (e.g. fricatives) preceded immediately by elements with high level (e.g. vowels) is prevented (syllabic compressor).

The effect of gain control on the static *i/o*-function of the hearing aid is shown in Fig. 12.28c,d. Depending on whether the gain is controlled by the input or the output signal, input-controlled (AGC/*i*) and output-controlled (AGC/*o*) systems are distinguished. In both cases, the dynamic characteristic deviates from linearity above the control threshold (starting point or knee point) down on the gain line. Thus, the amplifier oper-

Fig. 12.28a–f In a double logarithmic representation, the dynamic characteristics of a linear amplifier are straight lines, which run parallel to the angle bisector and whose positions depend on the gain (a). A peak clipping (PC) circuit limits the maximum compression level to predetermined values (b). The input controlled automatic gain control (AGC/i) causes a dynamic compression in the level range above the knee point. If the basic gain is reduced, the knee point moves to a lower output level (c), in contrast to the AGC/o, whose knee point is located at a fixed output level independent of the basic gain (d). In case of a low-lying threshold, a bypass can provide a linear reproduction without amplification at high levels (e). Two AGC circuits can be combined to realize a level-dependent compression with low threshold (f)

ates linearly below the cut-off point; above this point the gain decreases with increasing level. The compression $c = \Delta L_i / \Delta L_o$ is defined as the slope of the static amplifier characteristics.

It is the purpose of the gain control to prevent the occurrence of high noise levels at the ear of the hearing aid user. From this point of view, only gain control according to the output signal (AGC/o) is useful. Since this is associated with significantly longer recovery times than an input-controlled AGC, the AGC/i is often advantageous. As shown in Fig. 12.28, the AGC/i controls the

output level in the same way at different basic gains, although the hearing aid user may not need compression at lower levels. Thus, both AGC circuits have advantages and disadvantages. Therefore, it depends on the individual case whether the independence of the basic gain or the shortest possible response times have higher priority for the hearing-impaired patient.

Specific requirements for the dynamic behavior of the hearing aid can be fulfilled with special analog circuits, or – much more flexible – with digital signal processing. For example, to achieve a low-frequency

compression, a two-channel AGC/i can be used to attenuate the predominantly low-frequency noise, including the voice of the hearing aid user. As with the conventional AGC/i, the gain increases with increasing input sound pressure level, as well as the emphasis of high frequencies. At high input levels (above 80 dB) only a slight amplification in the range of 3 kHz is effective, intended to compensate for the lost ear canal resonance. The starting point of gain control is 40 dB, the compression ratio is 2 : 1 (Fig. 12.28e). The high frequency range is amplified linearly in such two-channel devices. The improvement of speech intelligibility is based on the fact that upward masking of the high frequency signal components is avoided by the onset of compression at low levels in the low-frequency range.

An even more effective use of the residual dynamic range can be achieved with hearing aids whose compression ratio is adjustable in the entire dynamic range (wide or full dynamic range compression, WDRC or FDRC). Below the control threshold at $L_i = 45$ dB the amplifier works linearly, at higher levels up to 85 dB the compression ratio can be set individually between 1 and 3. At higher levels, a conventional AGC is effective with a fixed compression ratio (Fig. 12.28f).

In summary, the main feature of PC and AGC is the reduction of gain with increasing sound intensity. This corresponds to a nonlinear system and it is inevitably associated with signal distortions. The result of these distortions are additional tones that have a negative effect on sound quality and speech understanding.

The amplifier characteristics described so far are related primarily to the level dependence of amplifier gain. In general, however, the hearing loss and hence the need for correction, also depend on frequency. This can be effectively taken into account by a digital multichannel signal processing. For devices with dynamic compression, this is also advantageous if the gain does not depend on the frequency, because a narrow band noise of sufficient intensity would otherwise reduce the gain in the entire frequency range. In multichannel devices, the input signal is split into several components by a filter bank. The basic amplification starting point of the AGC and possibly also the compression ratio can be programmed and stored separately for each channel. The output signal is reconstructed by summation of the components processed individually.

Multichannel hearing aids were previously implemented as digitally controlled analog devices in which storage for different programs was available. In fully digital hearing aids the preamplified microphone signal is digitized and processed in a signal processor working

in real-time. The systems with multichannel nonlinear amplification with a flexible setting of parameters can include optional noise reduction systems, passive or active feedback cancelation, and they may automatically adjust the listening program to the sound environment using adaptive neural networks to identify acoustic objects. The digitally processed signal is D/A converted and fed to the final amplifier.

A special feature of signal processing in some digital hearing systems is the frequency transformation. In order to make the high frequency range accessible to hearing impaired persons, either a *transposition* algorithm is applied, which shifts signals of high frequencies to lower frequency regions, or the bandwidth is *compressed* above a defined cut-off frequency (knee point), leaving the low frequency range unchanged. For mild or moderate hearing loss, a high cut-off frequency and a low compression ratio is selected, whereas severe hearing losses require a lower knee point and more compression. Clinical and practical experience shows that the recognition of high frequency consonants improves significantly by nonlinear frequency compression [12.47].

After processing, the electrical signal must be converted to an acoustic output and supplied to the ear. The electro-acoustic transducer is supposed to meet the requirements of small size, high efficiency, constant transmission factor over a wide frequency range, and a linear dynamic behavior. These requirements are partially contradictory (such as the quality of reproduction of low frequencies and small dimensions) and are, therefore, not always fulfilled at the same time. Hearing aid speakers are based almost exclusively on the electromagnetic principle, i. e. the change of magnetic induction by moving a metal diaphragm (anchor) in the field of the coil of a permanent magnet.

Practically all types of hearing aids are faced with the problem of acoustic feedback produced by the re-entry of the amplified output into the microphone entrance. If the gain factor for this loop amplification is greater than 1, the speaker produces a whistle tone whose intensity is only limited by the clipping of the amplifier. To avoid this, either the gain must be reduced or the re-entry of the output prevented. The former is rarely possible or advisable, as the required gain is determined by the degree of hearing loss and not by the feedback risk. For the latter, several solutions are available: the use of directional microphones, acoustic isolation of the output from the input using contralateral routing of signals (CROS), or acoustic isolation through an ear mold, which seals the ear canal partially

or completely and thus interrupts the acoustic connection between output and input. In many digital hearing instruments, acoustic feedback is prevented by filtering or active sound compensation, thus making an ear mold unnecessary (open fit).

For the production of a custom-specific ear mold, an ear canal impression is taken and used for the production of the actual earpiece either from transparent hard plastic or soft silicon. In ITE devices, earpiece and equipment housing are identical. For BTE, the connection between speaker and ear mold is made by a tube attached to the support hook of the hearing aid. The sound is supplied to the residual ear canal volume through a hole in the ear mold.

Hole and hose lead to distortions of the sound signal. This mainly affects the high frequencies while low frequencies are transmitted almost without attenuation. The acoustic properties of the ear piece can be influenced by additional drilling with different diameters and shapes. Drilling with about 2.5 mm in diameter suspends the low frequency amplification, so that in the case of a pure high frequency hearing loss the low frequencies can still be processed by the natural ear.

The possibilities for influencing the acoustic properties of the coupling by additional drilling is even more limited, the larger the required sound amplification. Severe hearing disorders require an acoustically

tight closure of the residual ear canal volume in most cases and cannot be supplied with external transducer technology, which has recently been introduced. If, however, the hearing loss is lower than 80 dB, the output transducer can be placed in the ear canal and held with a mushroom-shaped seal. A major advantage of open dome fitting with external receivers is the lower loss in high frequencies, which results in a better sound quality.

The description of the properties of individual components does not allow reliable conclusions about the acoustic behavior of the whole hearing system. To assess the overall response of the hearing aid, acoustic measurements in the coupler – a cavity that emulates the geometry and acoustics of the ear canal – or *in situ* – with a probe microphone in the ear canal – must be carried out. The result of such measurements are curves and diagrams containing the reproduction characteristics of the hearing at different frequencies and levels. Among these curves, the *reference frequency response* is the most important. It is obtained by recording the output level L_o while feeding the hearing aid with pure tones of variable frequency and fixed input level $L_i = 60$ dB SPL. The parameters of the hearing aid are set so as to achieve an output level lying 15 dB below the output level achieved with an input level of 90 dB SPL and maximum gain at the reference test frequency (usually 1600 Hz, but 2500 Hz in special high

Fig. 12.29a,b Measurement of the acoustic frequency responses of a hearing aid with the 2 cm³ coupler is shown in (a). Each curve $L_o(f)$ is measured at a fixed input level L_i . The setting of the hearing aid parameters is the same for all curves. The dynamic characteristics $L_o(L_i)$ are formed out of the three-dimensional representation as cross-sectional areas of constant frequency

frequency devices). The test gain characteristics $L_o(f)$ corresponding to other input levels (50 to 100 dB SPL) are measured without changing this device setting. The complete array of frequency responses provides an overview of the frequency-dependent and level-dependent response of the hearing aid (Fig. 12.29).

In addition to the hearing aid performance curves recorded with constant parameter settings, the data sheet of a hearing aid often contains the frequency response at the largest achievable sound level. By default it is recorded at the highest amplifier position and at a constant input level of 90 dB SPL over all frequencies (OSPL90). Another common and standardized graph is the curve of maximum gain representing the gain measured as a function of frequency with an input level of 50 dB SPL in the range of linear operation of the hearing aid set to maximum amplification.

The complete graphical representation of the performance of a hearing aid is a multidimensional problem, because the output level L_o depends on the input level L_i , the sound frequency f , and the hearing aid settings (e.g. amplification gain $g = L_o - L_i$ and compression ratio $c = \Delta L_i / \Delta L_o$). From the complete array of frequency responses $L_o(f)$ shown in Fig. 12.29, the dynamic functions $L_o(L_i)$ shown in Fig. 12.28 can be constructed, each of which is valid for a fixed frequency and a particular hearing aid setting.

The array of frequency responses yields direct information on the range of input levels in which the hearing aid behaves linearly. An ideal linear signal processing

by a straight frequency response $L_o(f)$, which shifts vertically when the input level L_i is changed by ΔL_i . This is equivalent to the requirement that the dynamic functions $L_o(L_i)$ have a constant slope of 1 dB/dB at all frequencies and over the whole level range. Although (or perhaps *because*) no real hearing system fulfills this requirement, it is common to denote a hearing aid as linear if its frequency responses $L_o(f)$ measured at different input levels differ by not more than a mere vertical shift (even if this shift is different from the corresponding input level difference). In this nomenclature, a nonlinear hearing aid is characterized by frequency responses which do not run parallel to each other.

The best possible knowledge of the hearing aid properties is only one of three pillars of a rational hearing aid provision. The second column is the entity of audiometric data. As the third pillar, the individual adaptation of the hearing aid connects acoustical and audiological data, producing a particular parameter set for the perfectly fitted hearing aid. The task of this unit is to map the frequency and intensity range of normal hearing (especially the language area) to the restricted field of hearing of the ear to be supplied (Fig. 12.30).

The essential characteristics of the hearing aid are the effective acoustic gain, the compression ratio, and the maximum output level. As can be seen in Fig. 12.30, these variables can depend on frequency and level. Apart from these parameters, the temporal behavior of the hearing aid is of great importance for speech intelligibility. It plays an important role, especially if the gain

Fig. 12.30 Projection of the language area in the residual field of hearing of the hearing impaired using a hearing aid. The *interconnected circles* indicate the threshold of hearing

is controlled automatically. The audiometric data consisting of hearing threshold, discomfort level, loudness scaling, and speech audiogram determine the selection and first setting of the hearing aid.

The necessary amount of amplification and its frequency dependence can be estimated from the hearing threshold. The obvious idea that the required gain equals the degree of hearing loss (mirroring the audiogram) proves to be useless because the amplified internal noise would become audible. In general, the amplifier gain will be lower than the threshold shift. According to the simplest among the prescriptive methods, the gain g measured in the 2 cm^3 coupler is given by half the hearing loss HL: $g = \text{HL}/2$. A refinement of this rule is Berger's formula, according to which the necessary gain is also calculated solely from the hearing loss, divided by a frequency-dependent number N

$$g(f) = \frac{HV(f)}{N(f)} + C(f). \quad (12.11)$$

The denominator $N(f)$ lying between 1.5 and 2.0 depends on the frequency in such a way that the gain is slightly higher at medium frequencies than at low and high frequencies. This accentuation of the mid frequency is further emphasized by the additive correction $C(f)$ regardless of the hearing loss. The formula ((12.11)) proposed for BTE devices must be modified for ITE systems to take into account the lower need of amplification.

According to another formula (prescription of gain and output, POGO), the correction of hearing loss by division does not depend on frequency:

$$g(f) = \frac{HV(f)}{N} + C(f). \quad (12.12)$$

Finally, the National Acoustics Laboratories, Sydney (NAL) method is based on a formula that calculates the target gain $g(f)$ at given frequency f out of the hearing loss $\text{HL}(f)$ determined at this frequency and (with less weight) the hearing loss averaged over three fixed frequencies (0.5, 1 and 2 kHz). For a given threshold curve, the results obtained from the formulas according to Berger, POGO, and NAL can differ considerably. This demonstrates that the threshold is not a valid and reliable criterion for calculating individual amplification needs.

In the methods described so far, the target gain is derived from audiometric data and the setting of the hearing aid is adjusted on the basis of these presettings with the help of a coupler measurement (see below). This approach contains two systematic sources of error: the transducer used in pure tone audiometry and

the simulation of the ear canal through a standard coupler volume. Neither meet the conditions in the real ear canal. The deviation is especially large in children whose ear is small and growing. It is the goal of the DSL method (desired speech level) after Seewald et al. [12.48] to limit the influence of these sources of error. The approach is to describe the hearing threshold by the sound pressure level in the ear canal, which is measured with a probe microphone system or with insert earphones. Using the individual transfer function (real ear to coupler difference, RECD) or standard correction factors, the requirements to achieve the desired speech level can be determined. This is to ensure that the broadband speech signal is audible, sounds well, and is not distorted. The success of fitting depends essentially on regular controls of the ear-coupler transfer function and the corresponding correction of the gain.

The sole focus on hearing threshold is unsuitable for a proper setting of the hearing aid in the entire area above the threshold. The correct setting requires the involvement of at least the discomfort level or preferably the entire area of hearing, which can be assessed by subjective loudness scaling. From the loudness growth function measured at different frequencies and levels, the required gain can be deduced by comparison with the normal curve (Fig. 12.31). Loudness scaling is thus the only method that considers consistently the frequency and level dependence of subjective loudness perception and provides not only the target gain but also the compression needed.

The prescribed gain of the hearing aid can be checked with the ear simulator in the test box. These measurements of output level at defined input signals provide very accurate and reproducible results, but they are not always relevant for the conditions in the target ear canal. In order to determine the real performance of the hearing aid at the eardrum, probe microphone measurements must be performed in the ear canal (in-situ measurement). In contrast to the coupler measurements, they capture the output of the hearing aid in the residual volume under the influence of sound feeding, ear mold, ear canal geometry, and middle ear impedance.

In many in-situ systems not the microphone itself but a probe tube connected with it is placed in the ear canal. The measurement is carried out both without and with the hearing aid (Fig. 12.32a,b). The probe microphone records the sound in the ear canal signal during presentation of noise or sinusoidal stimuli of defined frequency and intensity. A real-time analyzer processes the microphone signal and constructs the fre-

Fig. 12.31 Determination of the level-dependent need of amplification for one frequency (narrow band noise) from the comparison between the individual loudness growth function of a hearing impaired subject (*data points*) with the *shaded* normal range. The length of the *horizontal arrows* shown for the categories *soft* (15 categorical units, cu), *medium* (25 cu) and *loud* (35 cu) is equivalent to the corresponding required gain (after [12.49] with kind permission)

quency transfer functions $L_o(f)$ as well as the dynamic characteristics $L_o(L_i)$.

At the beginning of the in-situ measurement, the external ear transfer function is measured by the probe tube placed in the open ear of the patient. Plotted as a function of frequency, several maxima in the range between 2 and 5 kHz are usually observed (dark area in Fig. 12.32c). If the input level is independent of frequency, this curve reflects the natural amplification of outer ear and ear canal (open ear gain, OEG). As a next step of in-situ fitting, the sound intensity is measured in the ear canal after insertion of the ear piece and activated hearing aid (bright area in Fig. 12.32c). The difference between the frequency responses obtained with and without the hearing aid is the effective acoustic gain (insertion gain, IG).

The in-situ measurement is an advantageous and convenient alternative to the coupler measurement. This holds true particularly in children, whose ear canals are approximated only poorly through a coupler and vary

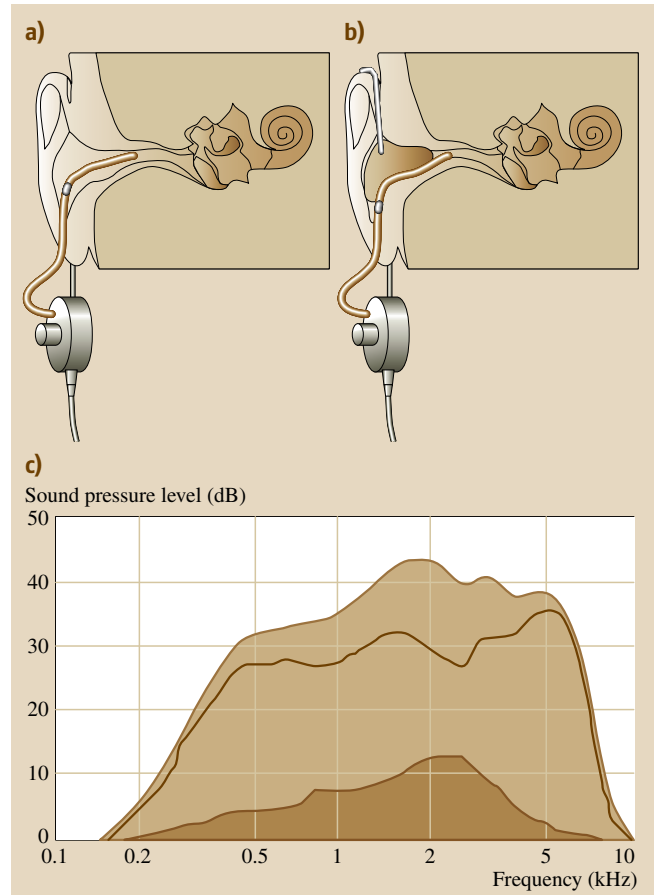

Fig. 12.32a–c In-situ measurement with probe tube in the ear canal, without (a) and with (b) hearing aid (after [12.40]). The probe measurement (c) yields the outer ear transfer function (*dark shaded*) with open ear canal (open ear gain) and the in-situ amplification (*light shaded*) with hearing aid. The difference between the two curves (*middle line*) represents the effective acoustic amplification (insertion gain)

considerably. Regarding the assessment of the ear piece and its transmission properties, the in-situ measurement is even without competition. It allows the detection of the effects of additional drilling installed by the acoustician for influencing the sound quality and is hence an indispensable tool for systematic manipulations of the ear mold.

Despite these advantages, a hearing aid can not be fitted solely on the basis of in-situ measurement, since even the precise measurement of the sound field at the eardrum does not provide information about the subjective sound perception of the patient and especially on

his speech intelligibility. To fine tune the hearing aid and for monitoring the outcomes, only scaling methods and speech tests are appropriate. The threshold determined with wobble tones in free soundfield with active hearing aid (aided threshold) is not very useful in this respect because it describes only the steady state conditions but not the dynamic behavior of the hearing aid in the processing of speech signals. Therefore, it is used in assessing the success of hearing aid provision only as orientation.

The profit achieved in understanding speech with a hearing aid is defined and checked in terms of free field speech audiograms. The fitting is considered successful if the intelligibility of Freiburg monosyllables improves by at least 20% at 65 dB or if the aided speech discrimination at 65 dB is as good as the optimum achievable without hearing aid. In addition, the speech discrimination at 80 dB in quiet and at 60 dB in noise should be checked (e.g. with the Göttingen or the Oldenburg sentence test). In the case of binaural rehabilitation, the gain of speech discrimination can be demonstrated with the improvement of speech intelligibility in noise, e.g. by measuring the BILD (*binaural intelligibility level difference*; see above).

12.4.2 Implantable Hearing Systems

The conventional sound amplifying hearing aids described so far are associated with various disadvantages, some of which may be offset by surgical implantation of the hearing aid or some of its components. To describe these disadvantages and to define the applications of implantable hearing aids, acoustic, audiological, medical and cosmetic aspects must be distinguished. The specific shortcomings of conventional hearing aids are the acoustic feedback, the poor transmission of high frequencies, the possible intolerance of ear molds and the stigma of the hearing aid worn as a visible prosthesis.

The common feature of all (fully or partially) implantable hearing systems is the direct mechanical transmission of the processed sound signal by vibrational excitation fed either to the ossicles or directly into the fluid of the cochlea. In comparison with acoustic stimulation, two conversions of the signal can be avoided and the final stimulus is less distorted. This improves the sound quality especially at high frequencies. In a partially implantable hearing system, the external parts comprise microphone, signal processor, and power source. A transcutaneous inductive link serves to transmit the information to the implanted unit, as well as its energy supply. The implanted amplifier mod-

ule controls a magnetic vibration system attached at the incus (floating mass transducer, FMT), a coupling rod which is implanted in the surgically enlarged middle ear space and connected with the incus (*Otologics Carina*), or a hydromechanical drive that transfers the vibration directly into the inner ear fluids (direct acoustic cochlear stimulation, DACS). The FMT (*MED-EL Vibrant Soundbridge*, Fig. 12.33) consists of a small cylinder, the wall of which contains a coil driving a magnetic mass moving along the cylinder axis. The oscillation of this mass is transferred to the incus whose movement is conducted by the stirrup to the inner ear as in natural hearing.

In the case of fully implantable systems, all components including microphone, signal processor, amplifier, output transducer, and power source are implanted. In one of the current systems (*Otologics Carina*, Heidelberg, Germany), the microphone is located under the skin behind the ear. Its output signal is fed to the processing unit implanted in the mastoid, the output of which drives a piezoelectric transducer. A coupling rod whose end is fixed to the joint of malleus and incus conducts the vibration to the ossicular chain. Energy is delivered from batteries that are implanted in the

Fig. 12.33 View of a partially implantable hearing system (*MED-EL Vibrant Soundbridge*, Innsbruck, with kind permission)

main module and charged transcutaneously by an induction coil worn temporarily with a headband. The system is suitable for moderate to profound sensorineural hearing loss and limited by feedback problems of the hydrophone that may arise at high amplifications.

In another fully implantable hearing system (Es-teem, ENVOY medical, Cologne, Germany), the sound signal is picked up by the natural eardrum, which acts as microphone diaphragm, and converted by a piezoelectric sensor attached to the hammer (malleus). The electronics module implanted behind the ear amplifies the signal and transmits it to a second piezoelectric transducer fixed to the stirrup (stapes). To avoid acoustic feedback, the junction between anvil (incus) and hammer has to be dissolved – an aspect that is currently discussed controversially among experts.

To assess the value of the implantable hearing aids, the aspects mentioned at the beginning of this section must be considered separately. The compelling advantage common to all of these systems is the superior sound quality due to the direct mechanical stimulation of the inner ear. The aspect of the occluded ear canal has lost some of its original weight since the acoustic feedback control based on digital technology has improved such that today an open dome fitting is possible with conventional hearing aids in many cases. Partially implantable systems are unfavorable from the audiological point of view because the extra-auricular placement of the microphone is disadvantageous at least in comparison to ITE devices. Cosmetic aspects and the stigmatizing effect of the conventional hearing aid should not be overestimated, as only fully implantable systems are really invisible.

The main target group of implantable hearing systems is constituted by patients with moderate to profound inner ear hearing loss. In contrast, the bone-anchored hearing aid BAHA (Cochlear Ltd. Europe) is suitable for cases of conductive hearing loss caused by outer and middle ear problems (e.g. atresia) that cannot be corrected by surgery. It consists of a bone conduction hearing aid, which is attached to a titanium screw implanted in the skull bone behind the ear. The sound is picked up by the integrated microphone and converted to a vibrational excitation of the bone so that outer ear, ear canal, and middle ear are not involved in the transmission chain. The skull vibration stimulates both inner ears with a relevant intra-cranial attenuation around 10 dB only at high frequencies.

12.4.3 Cochlear Implants

In cases of complete deafness, profound hearing impairment, or residual hearing, the function of the auditory system cannot be restored neither with conventional sound-amplifying hearing aids nor with the implantable hearing systems described above. The inner ear does not need to be aided but its function needs to be substituted. This functional substitution and hence the (re)habilitation of deaf patients is possible with the cochlear implant (CI). The CI stimulates the distal endings of the hearing nerve fibers or the spiral ganglion by using intracochlear electrodes (Fig. 12.34). The parameters of the electrical stimuli are calculated in a speech processor and transmitted transcutaneously to the implant as high frequency pulses.

The artificial electrical stimulation of the auditory nerve is fundamentally different from the physiological process, in which the action potentials are evoked by the segregation of neurotransmitters and mediated by elementary generator potentials. If the afferent radial fibers of the auditory nerve are exposed to an electric field, action potentials are generated and synchronized by rectangular pulses applied between two electrodes. The electric field distribution depends on the relative position of the electrodes to the auditory nerve and the intermediate fluids and tissues. Usually, the stimulation is monopolar, i. e. the reference electrode is located a large distance away from the stimulating electrode (e.g. in the temporal muscle).

It is the task of the CI system to transform the temporal structure of frequency and intensity of the acoustic signal in a sequence of action potentials, which is suitable for central processing in the auditory cortex. An exact imitation of the cochlear function fails because of its complexity and the incompleteness of our knowledge of details. With regard to the neural coding of frequency, it is plausible (and justified by the success) to simulate both the tonotopic organization of the cochlea and the ability of the auditory nerve to analyze the periodicity. Therefore, the stimulating electrodes are located in the inner ear where they are lined up along the cochlea and permit a selective stimulation of the region that is specific for the actual frequency. In most speech coding strategies, also the time structure of the signal is coded at least partially in the pulse sequence.

In all prostheses based on pulsatile stimulation, the stimuli are biphasic, charge-balanced current pulses that are submitted by the programmable current sources to each of the electrodes. In the case of bipolar stimula-

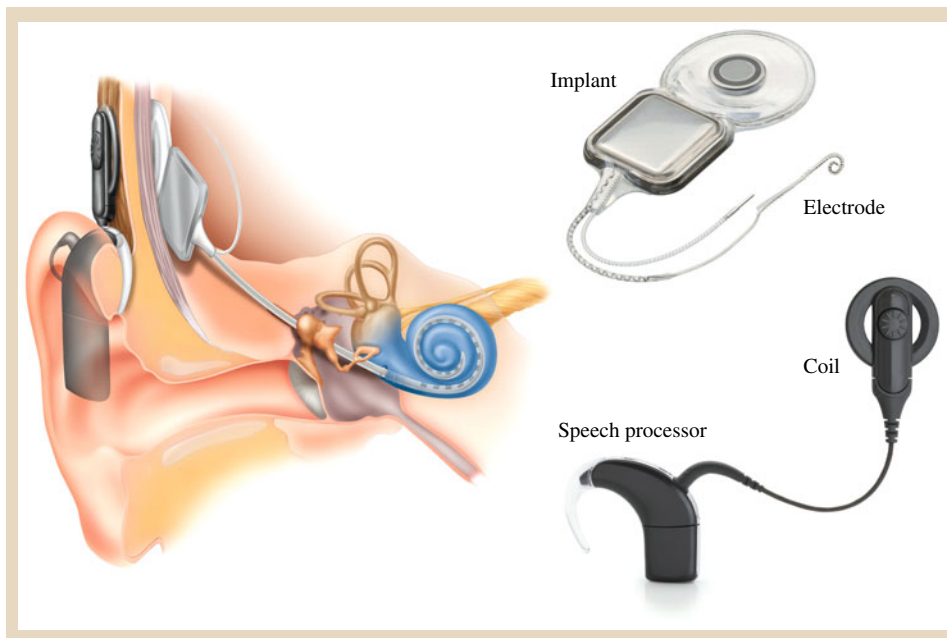

Fig. 12.34 Components of a CI system (Nucleus System N5). The actual implant consists of the encapsulated receiver and decoder circuit and the intracochlear electrode array. The external parts are the speech processor and the transmitter coil, which is magnetically held behind the patient's ear. In the *right section*, the implant CI512 and the speech processor CP810 are shown (with kind permission of Cochlear, Macquarie University, Australia)

tion, the adjacent electrode or more distant electrodes can be chosen as reference. A close bipolar mode results in a very limited local distribution of the electric field, but it will require high current to reach the distant neural structures. The lowest threshold is achieved if all nonactive electrodes are connected to a common reference point (common ground). In monopolar stimulation, the housing of the implant and/or an additional extracochlear electrode is used for as reference for the current path.

In natural hearing, the sound intensity is encoded in the discharge rate of the individual fibers and the number of active fibers. In the case of electrical stimulation, the number of action potentials grows with the current strength and duration of the electrical pulse, and the subjective loudness increases. The stimulation covers all fibers located in a region above the threshold field strength. The number of intracochlear electrodes is limited by the superposition of electric fields to about 15–20 for weak stimuli. By increasing the stimulus intensity, the spatial resolution decreases, as well as the ability to distinguish between pitches. The time resolution is limited by the duration and repetition rate of pulses. Typical values are 25 μs and 1000 pulses per second (pps) and electrode, respectively. Due to the staggered temporal sequence of electrode activation, the total pulse rate increases according to the number of electrodes, typically to 14 400 pps.

A CI system includes several components (Fig. 12.34). The actual implant is an encapsulated integrated circuit, which is located below the scalp behind the ear. Its longitudinal dimension is about 2 cm, its thickness a few millimeters. Additional parts of the implant are a receiver coil with a permanent magnet and a thin tube-shaped extension with 12–22 ring-shaped or spherical platinum electrodes located at its tip. The electrodes are inserted into the lower one and a half turns of the scala tympani. The spatial arrangement of the electrodes is adapted to the natural tonotopic organization of the inner ear. The activation of the front electrode excites apical or medial fibers of the auditory nerve and elicits the sensation of low pitch, the posterior electrodes located at the basal end of the cochlea produce high pitch sensations. In addition to this tonotopic frequency assignment (place pitch), the pitch perception is also affected by changes of the pulse rate (rate discrimination).

The external components of the CI system are the microphone, the speech processor, and the transmitter coil. Microphone, speech processor, and batteries are integrated in a housing that is worn behind the ear. The transmission coil is equipped with a permanent magnet, which fixes it opposite to the subcutaneous receiver coil.

The transformation of the acoustic signal into electrical pulses starts with the analog preprocessing of the microphone signal (amplification, high pass filter-

ing, and possibly compression) and its conversion into a digital signal. The digital processing described below yields the parameters of the electric stimuli, which are encoded in high-frequency pulses (e.g. $f = 5$ MHz). The RF pulses are transmitted transcutaneously and decoded by the implant, which is supplied with energy by additional power-up pulses. A control logic ensures that transmission errors are detected and unintended stimulation is prevented. The programmable current sources deliver rectangular biphasic pulses of variable duration (in the range from 20 to 500 μ s) and strength (up to a maximum of 1.5 μ A) to the electrode selected by a multiplexer circuit. Each electrode is assigned a frequency band whose center frequency and width increase logarithmically from apical to basal end. All current CI systems have the option to measure the voltage between two electrodes and transmit the actual value to the external components by a detuning of the RF resonant circuit (backward telemetry). In this way, the electrical impedances between electrodes and the electrically evoked action potentials of the auditory nerve can be measured (telemetry of electrically evoked compound action potentials, TECAP) [12.50].

Most of the strategies applied for signal coding are based on the pulsatile stimulation of the auditory nerve. An exception is the compressed analog stimulation strategy (CAS) in which the time course of the acoustic signal corresponds directly to the electrode current. Here, the microphone signal is split into several partial signals with a filter bank. Each band-pass filter is associated with an electrode. The individual components are digitized and transformed to the dynamic range of the associated electrode (mapping). This results in a sinusoidal time course of the electrode currents with high frequency at the basal electrodes and low frequency at the apical electrodes. The stimulation amplitude corresponds to the sound intensity in the individual frequency bands and the sound signal is transmitted without any coding loss or delay. Unlike the pulsatile strategies, several electrodes may be addressed simultaneously. However, the resulting overlap of electrical fields can affect the discrimination and lead to unpleasant side sensations.

Historically the first pulsatile coding strategies were based on the principle of feature extraction. Here, the signal was reduced drastically to very few relevant elements – the fundamental frequency F_0 (voice pitch), the first and second formants F_1 and F_2 of vowels, and the total amplitude. The frequency of the formants determined the selection of the stimulating electrode, the fundamental frequency defined the pulse rate, and the

overall sound intensity was transformed to current and width of the stimulus pulses for each electrode within the patient-specific limits. Despite the obvious limitations, especially in regard to the voiceless sounds (for which F_0 is not defined), many CI users achieved a good speech discrimination up to open speech intelligibility.

In the so-called *n of m strategy*, which is less language-specific, n stimulation electrodes are selected from the total of m available channels in accordance with the ranges of largest intensity in the sound spectrum. The preamplifier with automatic gain control is followed by a programmable filter bank with band-pass filters whose center frequencies lie between 250 Hz and 10 kHz. Each band-pass is associated with an electrode in a tonotopical order. The number n of active electrodes and the stimulus rate (between 180 and 300 pps) depends on the overall intensity of the signal, resulting in a higher density and frequency of pulses for strong vowels than for soft consonants. The electrodes are activated sequentially from basal to apical, whereby all nonselected electrodes are skipped without pause in order to achieve a high transfer rate of information.

While the coding strategies presented so far are largely based on the principle of tonotopy, the CIS strategy (continuous interleaved sampling [12.51]) emphasizes the time structure of the sound signal and thus utilizes the ability of the auditory system to analyze periodicities (Fig. 12.35). After amplification and high pass filtering, the microphone signal is split in a device-specific number of frequency bands with a gammatone filter bank. In each channel, the envelope of the time signal is calculated by rectification and low pass filtering. From the samples of the envelope, the amplitude of the stimulus pulse is obtained by a nonlinear transformation. Due to the fast continuous staggered sampling and the sequential activation of the electrodes, the time and frequency dependence of the sound intensity is reflected in the chronology and spatial distribution of the pulses. Using a typical pulse width of 80 μ s, stimulation rates of about 1 kHz per channel can be realized. Except for the very coarse grid of the frequency axis, this coding strategy is very similar to the natural model of peripheral signal processing in cochlea and auditory nerve.

Additional temporal information can be transmitted by coding the fine structure of the signal. For this purpose, the zero crossings of the signal within one frequency band are determined from the half-wave rectified signal component. The presentation of the stimulus pulses in some of the lowest frequency channels is then synchronized to the zero crossings (fine structure processing, FSP).

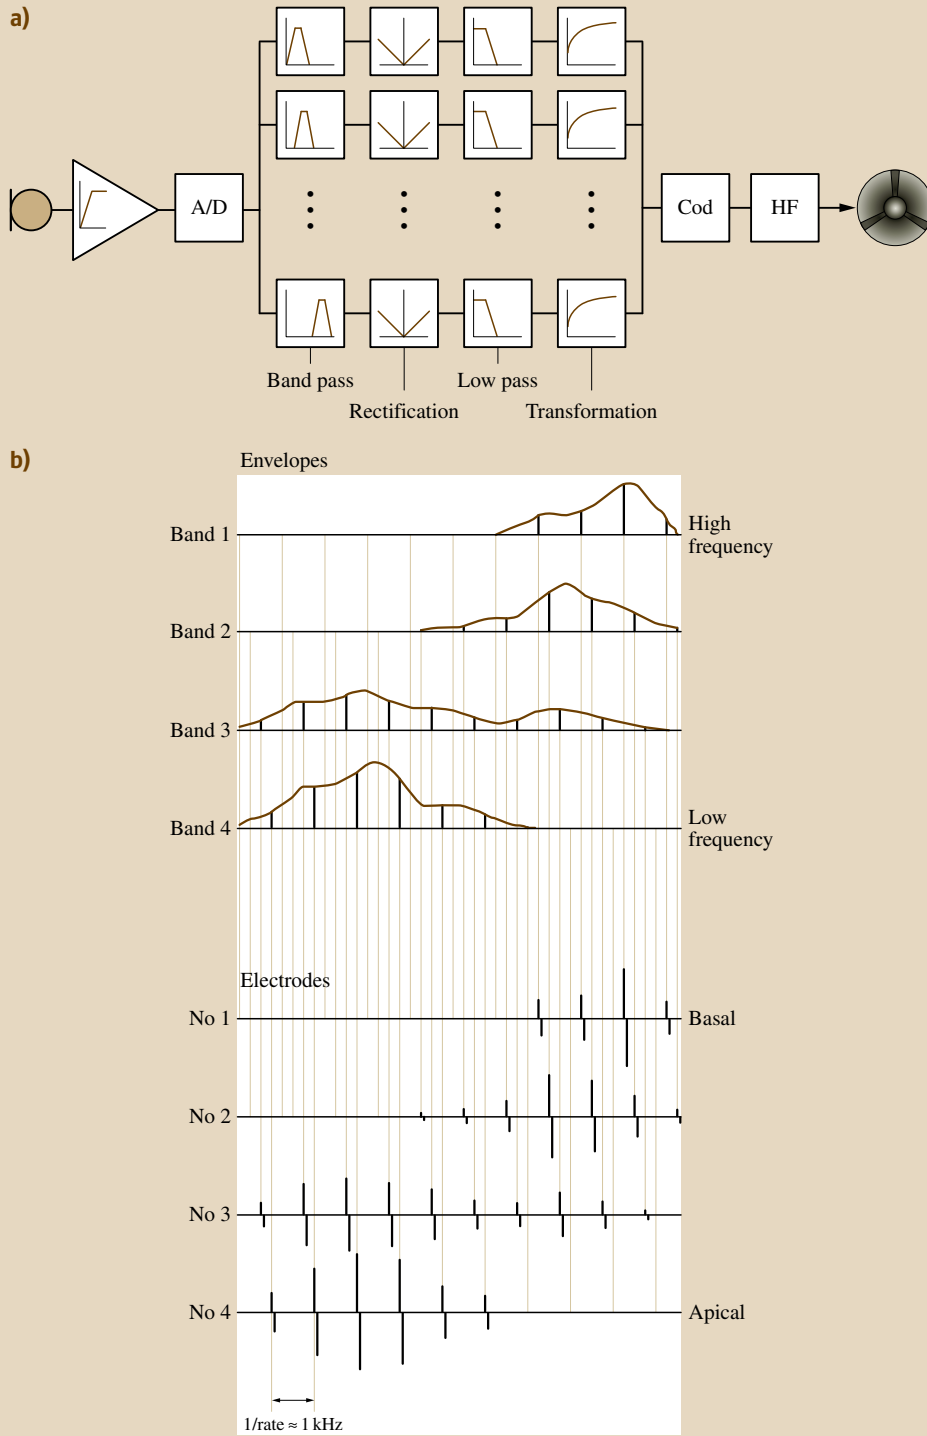

Fig. 12.35a,b Block diagram (a) and functional scheme (b) of the CIS strategy. The relationship between the amplitude of the envelope and the temporal sequence of electric pulses is shown for a sound signal developing from initially low frequencies (vowel) to high frequencies (sibilant)

Fig. 12.36a,b Perception thresholds (PT) and comfortable stimulation levels (CL) for the 16 electrodes of a (fictional) CI system. The limits reported by the patient define the dynamic range (a) and the mapping rule that associates the acoustic sound pressure to the electrical stimulus intensity (b)

In addition to *n of m* and CIS, the ACE strategy (advanced combination encoders by Lochlear Ltd.) is applied widely in one of the current CI systems. It can be regarded as a modification of the *n of m strategy* in which the maximum number *n* of active electrodes and the channel rate are varied within the limits given by the device-specific capacity (typically 20 000 pps). Unlike the competing strategies, the *n* activated electrodes are redefined out of the total inventory *m* for each stimulation pattern (frame) so that a high-resolution spectral mapping of the signal is possible even with low values of *n*.

Generally, the speech coding in CI systems is designed to mimic the natural pitch detection and time pattern analysis by mapping the frequency spectrum to the electrode locations and by transforming the time structure of the speech signal into an appropriate pulse sequence. The realization of this goal is limited by technical shortcomings. The available systems differ in their performance, but these differences are minor in relation to the discrepancy between the natural system and its technical surrogate. In spite of the further progress to be expected – particularly in speed and performance of signal processing, but also in the number and density of the electrodes – this gap will most probably remain. The replacement of about 3400 natural receptor groups by 12–22 electrodes cannot lead to a restoration of the normal signal discrimination and speech intelligibility. This is the main reason why patients supplied with a CI need intensive technical, audiological, speech therapeutic, and educational support after surgery.

The condition to be fulfilled for the supply of a CI is a deafness or hearing impairment whose severity does not justify the expectation of rehabilitative success in terms of speech intelligibility on the basis of conventional amplifying hearing aids. The success of rehabilitation depends largely on onset and duration of deafness. For congenitally deaf or prelingually deafened patients, the late supply of a CI will generally not lead to an open speech understanding. Early intervention, however, may make a nearly normal development of auditory and language skills accessible to many deaf infants and young children.

In the border area between hearing aids and cochlear implantation, patients with residual hearing at low frequencies can be subject to a successful auditory rehabilitation by the combination of electric and acoustic stimulation (EAS). In these cases, implantation techniques which guarantee hearing conservation and short electrode arrays that do not reach the apical regions are applied. The technical equipment is a sound amplifying hearing aid combined with a CI speech processor in a single device, which delivers both acoustic output and RF pulses for the implant. It has been shown that a large number of patients take benefit from this special option in terms of their speech discrimination performance [12.52].

The supply of a cochlear implant requires extensive preoperative diagnostics. Beyond the basic audiologic tests, it includes imaging techniques such as computed tomography (CT) for the representation of bone formation in the implantation area and magnetic reso-

nance imaging (MRI) for the detection of a fluid-filled cochlea. The functional integrity of the auditory nerve is tested in a preoperative electrical stimulation experiment. An extratympanic ball electrode is positioned in the meatus near the tympanic membrane or the tip of a transtympanic needle electrode is placed on the promontory or in the niche of the round window. During the delivery of electrical pulses of variable frequency and current strength, the patient is asked to describe his perceptions. For all stimulus frequencies that elicit auditory sensations, the stimulus currents corresponding to the subjective perception level and the discomfort level are determined. If the subjective test is not feasible, the functionality of auditory nerve and auditory pathway can be objectified in anesthesia by means of electrically evoked potentials of the auditory system.

The CI surgery [12.53] is performed under general anesthesia. The implant is placed in the mastoid behind the ear and the electrode array is inserted into the *scala tympani* through the round window or through an opening created immediately adjacent to it (cochleostomy). The opening of the inner ear is closed with tissue and the implant is secured mechanically. During the operation, the function of the implant and its effect on the auditory system are controlled by impedance telemetry, the recording of electrically evoked compound action potentials (TECAP), or the observation of the stapedius reflex during electric stimulation.

During the post-operative individual fitting of the speech processor, the acoustic input is disabled and the stimulation parameters are adjusted by a computer running a specific software. Within the preselected strategy, the main parameters of the individual signal processing program are the ranges of permissible stimulus strength for all electrodes. Along the device's internal stimulus intensity scale, the current amplitude and where necessary also the duration of the stimulus pulses is increased

according to a logarithmic function valid for all electrodes. From the stimulus intensities that correspond to the subjective threshold and the upper comfort level for each electrode, a mapping law is defined, which maps the acoustic input amplitude to the available electrical dynamic range (Fig. 12.36). In addition, some shape parameters of this function can be modified to affect the perception of loudness or to improve the noise reduction. The patient-specific parameters of the speech coding are based on subjective specifications. If this information is not reliable, the adaptation is supplemented by objective methods, e.g. the measurement of the electrically induced and contralaterally registered stapedius reflex, the electrically evoked auditory brainstem responses (E-ABR) or the TECAP [12.54].

During the post-operative auditory training, the patient obtains guidance and support for the processing of the new impressions. The auditory skills are tested with a test battery graded by difficulty. The success of rehabilitation can be divided into three stages. An acoustic orientation, i. e. a perception and recognition of environmental sounds, is to be expected in all patients, an effective acoustic support of lipreading by the implant can usually be achieved also by prelingually deafened patients, and finally, an open speech understanding without eye contact to the speaker and the ability to communicate via telephone is achieved generally only by post-lingually deafened patients. Speech perception in noise and reverberation remains a challenge for many implant recipients, even for bilateral implantees. Technical approaches to solving this problem are based on digital noise reduction or delay and digital overlay of the acoustic signal recorded from multiple microphones (adaptive beam forming). In this respect, as in other areas, the technical development has not yet been completed and further progress of rehabilitation can be expected.

13. Measurement Techniques in Ophthalmology

Measuremen

Albert J. Augustin

Modern ophthalmology uses numerous techniques to evaluate both function and pathophysiology of the organ. This chapter covers the major techniques used in ophthalmology. These include evaluation-techniques for the refractive part of the eye such as wavefront-analysis (Sect. 13.13), confocal laser microscopy (Sect. 13.5), as well as keratometry (Sect. 13.14) and the orbscan technology (Sect. 13.18). In addition, several methods for the exact determination of the intraocular pressure (Sects. 13.1–13.1.5) and methods to evaluate the optic nerve (13.2) in glaucoma are discussed. Imaging of the retina by means of OCT (Sect. 13.2) and angiography (Sects. 13.20 and 13.21) are important techniques in diseases of the vessel system, as well as age related macular degeneration. Electrophysiology (Sect. 13.8) including pattern techniques is mandatory to diagnose and to follow various diseases of the optic nerve head and the retina. Ophthalmologic ultrasound (Sect. 13.16) is needed for both imaging of pathologies as well as length measurement to determine the power of intraocular lenses before implantation into the eye.

13.1 Measurement of Intraocular Pressure

Subject: Tonometry is used to measure the intraocular pressure.

Measurement: Different instruments can be used: Goldmann's applanation tonometer, Schiötz's impression tonometer, noncontact-(impression) tonometer, and the Mackey–Marg tonometer. Goldmann's applanation tonometer shall be deemed to be the standard. Follow-up measurements using different methods are not advisable (the measurement results are influenced by numerous factors). In addition, the corneal thickness affects the results. Thus, thickness should be measured at all times.

13.1.1 Goldmann's Applanation Tonometry

Measurement: Goldmann's applanation tonometer is attached to a slit lamp. The clamp can vary depending on the manufacturer. The front side of the tonometer head has a standardized diameter of 3.06 mm. Fluorescent and anesthetic eye drops have to be applied before the measurement. Afterwards, the tonometer head approaches the cornea until both surface areas touch. This is done with blue light illumination. Due to a specific microsection in the measuring device two yellow semi-circles are visible in the slit lamp examination. When the pressure results in a flattening of the cornea, the two inner edges of the semicircles touch. The regulation of the pressure can be adjusted with a scroller on the tonometer clamp. Assuming an average thickness of the cornea and a normal amount of lacrimal fluid by a round area (with a diameter of 3.06 mm), the following calculation results in the IOP value: subtract the adhesive power of the lacrimal fluid from the necessary power for flattening the cornea. Equate the measured pressure with the intraocular pressure (IOP).

Indication: The intraocular pressure is an important parameter for the evaluation of glaucoma and its therapy. Applanation tonometry is a simple, elegant and – apart from certain exceptions – very precise technique to determine intraocular pressure.

Evaluation: The thickness of the cornea affects the measurement. The references contain several calculation options for the correction factor. The Orssengo–Pye-formula is mainly used to do this.

13.1.2 Schiötz's Impression Tonometry

Subject: The measurement determines the impression depth by a defined (gravitation) force effect.

Measurement: The instrument equals an invert circle. The lower fraction consists of a hand holder, a base plate, and a mobile coaxial bolt. Following the application of anesthetic eye drops, the instrument (with its base plate) is attached perpendicularly to the cornea. The deflection of the bolt can be shown on the upper fraction of the tonometer by the articulation on the scale. The measurement can be distorted by moving the tonometer slightly. It is recommended to seat the patient as flat as possible.

Indication: Schiötz's impression tonometry is used mostly for measuring intraocular pressure. The method is especially used for bedfast patients.

Evaluation: The values read off the scale are transformed to the intraocular pressure with the table attached to the Schiötz tonometer. Please consider that – depending on the insert weight – different columns are valid for IOP calculation. New impression tonometers calculate the values automatically.

Relevance: By increasing the dependency of the individual variable elasticity of the sclera and cornea such as a high myopia, the danger of an incorrect measurement is much higher than with applanation tonometry. Therefore, this method is only used in those cases where applanation tonometry is not possible.

13.1.3 Noncontact Tonometry (Air-Puff Tonometer)

Subject: The measurement determines the time that is necessary to flatten the cornea at a defined force effect (air-puff).

Measurement: The measurement occurs automatically without previous anaesthesia. Generally, the patient sits in front of the instrument like in front of a slit lamp. The patient should open their eyes wide. With reduced visual acuity the eye that not has to be examined should be covered. Corneal applanation is detected via an electrooptical system. Usually the measurement is repeated three times. An average out of the values will be calculated.

Relevance: Noncontact tonometry can be easily performed by a trained ophthalmic assistant.

13.1.4 Mackay–Marg Tonometry (Tonopen)

Subject, measurement: The measurement is possible with or without topical anaesthetics. The patient should stand up or sit on a chair. The cornea is flattened with a probe in the centre of which is a small diameter plunger that senses the ocular tension. The sterilized rubber cover is replaced for each patient, which ensures sterility. The patient should open his/her eyes widely and press the probe gently perpendicularly against the cornea.

Indication: The Mackay–Marg tonometer is used by patients with an irregular corneal surface, such as corneas following chemical burns. It is the only instrument that gives exact values in such cases.

Evaluation: A typical curve shows two spikes of the generated pressure in dependence on time. The first spike reflects the wanted intraocular pressure. The second spike reflects the necessary pressure for appplanation of the cornea with the plunger and the surrounding annular ring. The measurement should be repeated several times to calculate an average. With recent instruments such as the Tonopen the measurement will be averaged and interpreted automatically. In the end, a digital display shows the calculated value. Compared with Goldmann's tonometer the IOP values of the Mackay–Marg tonometer can be measured insignificantly higher.

Relevance: Even though the main principle of the Mackay–Marg tonometer has been known for more than 50 years, its distribution is still low. The Schiötz tonometer is likely to be replaced by other tools such as the Tonopen in the future.

13.1.5 The Pascal Dynamic Contour Tonometer (DCT)

Subject: A miniaturized piezo-resistive pressure sensor senses the intraocular pressure. The voltage that is measured by the piezo-crystal is proportional to the affecting pressure.

Measurement: The dynamic contour tonometry (DCT) is a noninvasive and direct measurement of the intraocular pressure (IOP) that is not influenced by the structural characteristics of the eye. The probe has a concave surface just a little more even than the human cornea. The measuring equals the installation and progress of Goldmann's tonometry. The tonometer is installed to the slit lamp and then applied to the cornea. Due to the concave surface of the peak the probe covers the natural corneal curvature. The tangential and bend forces should be disregarded so that the measured pressure on the cornea surface is equal to the intraocular pressure. The measured values are recorded digitally. After the measurement a chart can be evaluated with the chronological pressure sequence.

Indication: The advantage over other tonometers is the dynamic measurement over a certain period of time. With the DCT it is possible to measure the diastolic and the systolic pressure IOP and their difference to the ocular pulse amplitude. This is an indirect indicator for choroidal perfusion.

Evaluation: On average, the DCT measures a value at 3.2 mmHg higher than Goldmann's measurement. This technique is independent of the thickness of the cornea.

Relevance: It may become very important for the diagnosis and therapy of glaucoma. Scientific evaluation is ongoing.

13.2 Optical Coherence Tomography (OCT)

Subject: Optical coherence tomography (OCT) allows an in vivo description of different anatomic sections of the eye. OCT has a resolution of up to $< 10 \mu\text{m}$ longitudinal and $< 20 \mu\text{m}$ transversal.

Measurement: During the measurement the examined object is scanned automatically with an infrared light (coherence length of 830 nm). The intensity of the reflected light is determined. The temporal hesitation gives information on the distance of the scanned object.

Relevance: Retina – During the last years the OCT examination of the macula and the optic nerve head

(ONH) has been used in addition to angiography (macula) as well as in glaucoma patients. Anterior chamber – The examination of both the anterior chamber and the cornea by means of OCT is a promising alternative to ultrasound biomicroscopy.

13.2.1 OCT Macula

Indication: OCT of the macula is a standard examination in many diseases such as macular hole and macular pucker. As an upgrade to angiography OCT determines

Fig. 13.1a,b OCT (a) and angiography (b) of a diabetic macular edema

the volume (quantitation of macular edema). Using the new high resolution OCT single retinal layers may be distinguished (in vivo histology) (Fig. 13.1).

Evaluation: OCT examination of the macula gives two-dimensional pictures of the retina. The intensity

of the reflected light will be either color-coded (red = strong, blue = poor) or pictured in different levels of gray (light = strong, dark = poor). The locations of the strongest reflexion are nerve fibers, the choroid, and epiretinal membranes.

Usually, the neuro-sensory retina and the choroid have an average reflection level. Pigment epithelium damage would cause a higher intensity of the choroid underneath. The vitreous body has a low reflection level. At a strong contrast an increase in the OCT allows the imaging of vitreous body structures such vitreoretinal traction and the posterior hyaloid. Via computer reconstruction a three-dimensional image of structures can be generated. The volume of a macular edema can be calculated exactly and compared to previous examinations. Due to the higher resolution of the newest generation of OCT, three-dimensional imaging of certain retina layers can be calculated. The dimension of a pigmented epithelium elevation or the loss of nerve fibres can be imaged. The quantitation will be affected by measuring the thickness or by direct volume determination.

The standard imaging of the central retinal thickness is known as a *map*. On the *map* the macula is shown as a colored round area. The normal *map* of the retina has a blue color with a central green or yellow circle for the foveal ridge. If the retina is thickened in the center the *map* becomes red to yellow (with strongly increased values even white). Besides the color-coded images the average for certain areas (central, nasal, temporal, cranial, and caudal) of the macula are calculated in microns. They will be listed next or in combination with the *map* on the OCT printout. A retina thickness of more than 180 μm is considered as pathological.

Fig. 13.2 Visante OCT showing chamber angle, anterior chamber depth, and corneal thickness

13.2.2 OCT of the Optic Nerve Head (ONH)

Indication: As compared to other methods (HRT) or polarimetry (GDx), OCT of the ONH is a highly sensitive and very specific examination for imaging the loss of nerve fibers in glaucoma subjects. As an advantage over GDx, OCT and HRT allow the determination of the size of the ONH and the excavation.

Evaluation: Both measurement of the ONH size and excavation are done automatically. The outline of the ONH has to be done manually only for certain abnormalities of the ONH. On the printout a vertical incision through the ONH is shown. For every single incision (vertical, horizontal, and transversal) the computer indicates an ONH diameter, excavation diameter, and the width of the ONH border. Analysing every incision the

ONH areas (*disk area*) and the excavation area (*cup area*) can be determined. The relation of the two areas illustrates the *cup disk area ratio*. Besides the cup disk area ratio a cup disk horizontal and vertical ratio is stated of the instrument. The vertical cup disk ratio should be smaller at a normal formed ONH than the horizontal cup disk ratio. The measurement of the thickness of the nerve fibers works according to the idea of the layer thickness identification.

13.2.3 OCT with Visante

Indication: The OCT of the anterior chamber is similar to ultrasound biomicroscopy. It enables a precise measurement to determine the anterior chamber depth and the chamber angle. It represents an excellent in-

strument for diagnosis and evaluation of the acute angle closure glaucoma. The corneal thickness and the thickness of a cornea flap can be measured exactly before and after a refractive procedure. By diagnosing a keratoconus the Visante OCT allows a diagnostic saving and a monitoring of the process. Visante OCT allows the measurement of tumor tissue on the iris front face, but it is not as good as ultrasound biomicroscopy.

Evaluation: The examiner must determine the anterior chamber depth and the chamber angle manually. Corneal thickness is shown color-coded. Light cornea areas are shown in orange to dark red. The following parameters can be read off the table: smallest and biggest corneal thickness, as well as an average of different localizations (Fig. 13.2).

13.3 Laser-Scanning Tomography with the Heidelberg Retina Tomograph (HRT)

Subject: Laser scanning tomography allows the in vivo topography of different anatomic structures of the eye (Fig. 13.3).

Measurement: With the aid of a diode laser a two-dimensional optical cross-section of 32 focal planes (*z*-axis) can be taken. The images are used by the computer for reconstruction of the steric structures. The user must define the standard reference level and the ONH border. These two values can essentially influence the measurement to prevent causing error (especially

through the examiner); a computer model exists for pattern recognition. It automatically determines the ONH border via a combination of HRT and ophthalmoscopic images. For a higher resolution the computer uses the TruTrak software for motion artifacts. Moreover, the computer matches the position of the pictures between different measurements.

Indication: In many cases laser scanning tomography is used in the diagnosis and follow-up of glaucoma.

Evaluation: Similar to the OCT of the ONH, the following values are measured – size of the ONH, cup disk ratio, disk margin, and thickness of the retinal nerve fiber layer. In process monitoring the values can be compared to previous images. Furthermore, there is the possibility of comparing individual measurements with values of a normal population. For this purpose, a graphic image is used. It shows part of the ONH excavation and the ONH margin as the colored part of a bar. The excavation is pictured in red, the neuroretinal border in green, and the bended border in blue. Different localizations (temporal and superior, etc.) are shown.

Fig. 13.3a–c Evaluation of the optic nerve head using HRT (a, b) and OCT (c). The patient shows significant glaucomatous damage (abnormal size of the optic nerve). In Moorfield's analysis (b) the nerve is judged as pathological. Burk's (RB) and Mikelberg's (FSM) discriminant values are negative; they also indicate glaucomatous damage

Given curves cut the bars and mark the areas of the normal (predicted) and those that differ from the collective (low 95%) bar division. Moorfield's regression analysis allows a classification out of ONH diagnostics with a sensitivity for glaucoma damage at 74–90%.

Relevance: Laser scanning tomography is a popular method for an objective diagnostic documentation of ONH and the nerve fiber layer especially in daily praxis. It has big relevance in an early diagnosis and the follow-up of glaucoma patients.

13.4 Nerve Fiber Polarimetry with GDx

Subject: During the examination the retardation of polarized light is measured and the peripapillar and macular nerve fiber layer thickness is calculated.

Measurement: A dilated pupil is recommended before the measurement but not absolutely mandatory. Within some seconds an automatic measurement on 32 768 measuring points starts. The instrument combines the characteristics of a scanning laser ophthalmoscope and a Fourier ellipsometer. The retina is

scanned by a polarized infrared light (780 nm) and reflected to the pigmented epithelium (with defect to the sclera). Depending on the structure and thickness of the irradiated tissue a polarized light pervades it in different velocities. Structures with a straightened fibre orientation extend the passing time of the light with vertical polarization to the fibre direction oscillating waves. The thickness of the nerve fibre is determined by the difference between the retention periods of dif-

ferent polarized lights and with help of a histological comparison.

Indication: The technique is suitable for the determination of the peripapillary nerve fiber border and nerve fiber bunch damage. It has a sensitivity of 96% and a specificity of 93% in the early diagnosis of glaucoma damages. A glaucoma modification can be determined even before observable changes in the perimetry. It is especially qualified for a follow-up of glaucoma patients.

Evaluation: The values are transformed into a three-dimensional or false-color-coded picture. In the false-color-coded picture thick structures are marked from yellow to red and a thin from light to dark blue. According to the ISNTnorm the upper and lower nerve fibre bunches are colored red and yellow, and the temporal and nasal are colored blue. Moreover the instrument has an age and race database of standard values. With this the collected values can be evaluated. The analy-

sis occurs similarly to OCT and HRT in both a table form and graphically. In the table the calculated average values can be numerated circular and after their localization (superior, inferior). If the values are pathologic they are highlighted with red. The table also shows the standard deviation of the normal collective and the difference between both eyes. This results in the probability of a glaucoma (nerve fiber indicator (NFI) = the number). The probability of a glaucoma is low at a NFI of ≤ 30 , marginal from 30–50, and high from ≥ 50 .

Relevance: The noninvasive diagnostic procedure is suitable for judging suspect nerve fibre damage or ONH margin damage. Compared with the HRT and OCT examinations this method does not include an ONH size and excavation measurement. This measurement is fragile with both corneal or lens abnormalities, as well as by myopia and hyperopia. The development of a software module (enhanced cornea compensation ECC) can correct the aberration to some extent.

13.5 The Rostock Cornea Module (Confocal Laser Microscope)

Subject: Used for the examination of the corneal and the conjunctival layers.

Measurement: Frontal cross-section images with a maximum impression depth of about $1500\ \mu\text{m}$ and a size of $400\ \mu\text{m} \times 400\ \mu\text{m}$ are taken.

Indication: The procedure allows the imaging of keratocytes, endothelial cells, and nerve fibers in the cornea. Therefore it is suitable for a good evaluation of corneal diseases and monitoring after surgery. Furthermore, it may be used to monitor filtering bleb morphology.

Evaluation: The quantitation of the endothelial cell density happens when cells in a certain area are enumerated. All corneal layers can be imaged. Thus, it helps to obtain an early diagnosis of corneal dystrophies.

Relevance: The recent, noninvasive procedure has great potential in the diagnosis of corneal and conjunc-

Fig. 13.4 Image of the inner corneal layer using confocal optics

tival diseases. Today it is mainly used in specialized centers.

13.6 Automatic Refractometry

Subject: The quality of the optical image on the retina is measured. The lens combination with the best image results in the wanted refraction.

Measurement: The measurement works automatically and depends on the instrument; the patient may sit,

stand, or lie down. For the examination it is important that the patient looks into the distance. A picture already installed in the instrument accomplishes this. Cycloplegia is recommended for children. This helps to exclude accommodation, which would falsify the measurement.

A patient with poor fixation should cover the other eye to achieve better measurements. The measurements follow different principles. The following procedures are used: Foucault's method, Scheiner's principle, and picture measurement. In Foucault's method a punctual light is changed through a lens into a parallel light bunch. The parallel light bunch hits the eye and is combined to a point to the retina. If a poor refraction of the eye exists the point is shown as a blot or bar. The reflected light strengthens the statement. Refraction abnormality further deforms the former punctual light. An optimal refraction will reflect the light to the original point. If divergent lights of the original light source are shown they can be determined and quantified with a light detector. Different conventional lenses that could adjust eye refraction can decrease the aberration of the light source. If the aberration is not detectable the refraction of the previous lenses is equal to the wanted optimal refraction.

For Scheiner's principle a lens aperture is used that produces two punctual lights. The light rays are broken and focused through the breaking media into the eye. Depending on the distance of the two aperture plates and the refraction of the eye the light rays are focused in front or behind the retina. By the use of changing the distance between the plates the refraction can be calculated by a defined globe length.

Picture measurement process is a modification of Scheiner's principle. Reflection of an incoming light ray

generates a dot-shaped light source which is projected on the retinal surface. Because of the refraction of the eye the light rays are broken and can be focused with a lens again. Depending on the angle of incidence the light is projected in different widths on the detector. The determined distance is defined for an emmetropic eye. In myopia the distance increases, in hyperopia it decreases. The application of glasses enables the calculation of the refraction that leads to emmetropia.

Indication: An objective refraction should be part of every ophthalmological examination. Before and after a surgery (cataract surgery, refractive cornea surgery) this measurement is strongly recommended.

Evaluation: Depending on the instrument three automatic or manual measurements are needed for an exact refraction. An integrated software calculates a supposed refraction. A cause for falsification can be the *myopia of the machine*. This happens if a patient sees a blurred image and the immediate accommodation induces an increase of myopia. If astigmatism is only minimal or even nonexistent false values from up to 0.5 dpt may be determined. Characteristic of this is a strongly changing astigmatismus angle.

Relevance: Today, automatic refractometers are part of the standard equipment of every ophthalmological practice or hospital. They allow a fast and easy measurement of objective refraction. Generally, the measurements taken using an automatic refractometer can be done by medical assistants.

13.7 Visually Evoked Potential (VEP)

Subject: Visual evoked potentials are electric potential differences that are deduced from the scalp over the visual cortex after a light impulse. VEP are a special form of evoked potentials. The measuring of the time (latency) and height (amplitude) of the potential give information on the function of the optic tract. The visual stimulation of the retina happens either with a light flash (blitz VEP) or a pattern with contrast reversal (pattern VEP). In pattern VEP the pupil should be not dilated. A healthy person has latency for the primer cortical potential of 100 ms.

13.7.1 Flash VEP

Measurement: The stimulation occurs with single flashes from a xenon arc lamp. The lamp should be installed at a visual angle of 20° in front of the patient.

Alternatively, a standard flash like the GanzfeldERG (electroretinography) or a flash with an intensity of 1.5–3 cd/m² (< 1.5 Hz) can be used. The flash duration should last a maximum of 5 ms.

Indication: This method is used to measure a reduction of the transduction velocity of the optic nerve, which occurs in inflammatory disorders. Moreover, other pathologies of the optic nerve or the optic tract to the visual cortex can be detected. A comparison of both sides of the nerve response impulse is recorded and measured. The flash VEP examination is helpful in children with a profound reduction of visual acuity, media opacity, or limited compliance. An impression as to the quality of the retino-cortical transmission is given.

Evaluation: Flash lights can induce a complex answer beginning at about 30 ms and ending at 300 ms. Positive and negative peaks are numerated in order of

Fig. 13.5a,b Pattern VEP in a healthy subject for (a) the right eye (OD) and (b) left eye (OS)

their occurrence: N stands for a negative and P for a positive peak. The most important vertex is located in N2 and P2 with about 90–120 ms. Flash evoked VEP can be already evoked in infants in the 24th gestation week with a peak at 300 ms.

Relevance: Flash VEP is thought to be inferior to pattern VEP. The latency varies significantly interindividually. It is however, useful to follow patients over a certain period.

13.7.2 Pattern VEP

Measurement: The patient is seated in front of a display in a shaded room. For a period of 20 min a checkerboard pattern is presented on the display. A so called reversal impulse takes place so that in a rapid exchange the white array turns black and the black array turns white. One eye is covered. The other fixates a certain point on the monitor. Three electrodes are fixed on a certain area of the head to measure the impulses (small

needle electrodes/acupuncture needles can be punctured underneath the scalp). After that the patient should sit comfortably and fixate the specific point on the monitor.

Evaluation: The latency can vary between different measurements and this may add up to 5%. The amplitude varies up to 25%. Therefore the latency is the more sensitive parameter in VEP. The maximum amplitudes are deduced by a stimulation of 10–20 min (visual angle). With smaller or bigger impulse patterns the amplitude of the P100 component decreases. By a large impulse pattern ($> 2^\circ$) the results equal the results of the flash evoked VEP. The latency lengthens with very big and small impulse patterns ($> 15^\circ$, $> 2^\circ$). In general, the weaker the contrast of the stimulus, the smaller the amplitude and the larger the latency. Pattern VEP is one of the most important examinations in neurophthalmology. However, this method is a secondary measure. It can only confirm and support a diagnosis (Fig. 13.5).

13.8 The Ganzfeld ERG (Ganzfeld Electroretinogram)

Subject: A light evoked electrical summation answer (potential modification) of neuronal and not neuronal cells can be measured.

Measurement: With an active electrode on the cornea the ERG potentials are collected and deduced against a reference electrode on the ipsilateral tem-

ple side temporal of the outer eyelid border. For the active electrode different models can be used: Burian–Allen, Henkes, Jet, and Dawson–Trick–Litzkow, and Arden. The electrodes by Burian–Allen, Henkes, and Jet are contact lenses. They are applied with a contact gel (methylcellulose fraction $\leq 5\%$) like therapeutic

contact lens or contact lens on the cornea. When using the Burian–Allen electrode closure of the eyelid is not possible. The DTL (Dawson–Trick–Litzkow) electrode is a wire electrode. It consists of a metal coated nylon thread that is installed between the medial and lateral eyelid angle. The nylon thread should lie on the tear coating over the under eyelid border in the lower quarter of the cornea. Arden’s gold membrane electrode is fixed to the lower eyelid. Contact to the conjunctiva has to be avoided. The use of an active electrode that is fixed to the skin is not recommended. As a reference electrode a silver chloride or gold cup electrode is attached temporarily to the eyelid border. Before putting on the electrode the skin should be free of greasy secretion. Otherwise the skin resistance is much higher. Following the skin conductance should be improved with an electrode gel. After that the skin resistance should be $< 5 \text{ k}\Omega$ (between 10 and 100 Hz). For grounding a third electrode should be used. Usually the third electrode is applied to the forehead or to the earlobes and should have similar impedance to the reference electrode. The signals of the electrodes are collected during the measuring in an electrode box and isolated from the patient potentiated with the factor 1000–10 000. It is important that the incoming resistance at the amplifier is 100 times greater than the electrode resistance (active and reference electrode) and it is at least $10 \text{ M}\Omega$. The frequency width should be at 0.3–300 Hz and variably adjustable. For illustrating either an oscilloscope or an A/D changer is used. Normally today the last instrument is installed after the multiplier. The multiplier should have a scan frequency of at least 1000 Hz/channel to avoid loss of information. Standardized light stimuli (with a certain background lighting) are offered for measuring the potentials. The potentials are varied after the examination (e.g. photopic, scotopic ERG) in length, intensity, wavelength, frequency and the interval to obtain a differentiation between the cell specific summation results. For generating the light stimuli a complete area ball similar to the perimetry hemisphere is used. For an optimal illumination of the retina every ERG measurement should be done with dilated pupils. Before the examination a 20 min dark adaptation by scotopic and 10 min light adaptation by photopic ERG is necessary. The relation between the light stimulus (*standard flash* (SF)) and background lighting (complete area lightning) should be 3 : 34.

Indication: The most popular indications for the ERG are hereditary retina diseases and inexplicit view aggravations. With a discrepancy between the

ophthalmological indication and visual acuity an electrophysiological examination is mandatory.

Evaluation: The electroretinogram consists of different components. They reflect a complex answer to the different participating neurons and mechanism. The diagram is divided into: early receptor potential, a-wave, b-wave, oscillatory potentials, c-wave, and the scotopic answer. The early receptor potential (*early receptor potential* (ERP), distal PIII-wave) consists of a cornea positive component followed by cornea negative parts. They are probably associated with a voltage transformation during the photochemical process. The positive potentials (R1) are mostly generated by the outer segment of the cones. The successive negative potentials (R2) are generated by the outer segments of the rods and the cones. Generally, a measurement is hindered because an important light intensity and a special impulse condition are needed.

The a-wave is generated by the inner segments of the photoreceptors. Depending on the examination condition (scotopic or photopic), the wave is generated either by the cones or the rods. The wave develops through hyperpolarization as an effect of phototransduction cascade (sodium ionic channel closing) in the different receptors. On the cornea a negative potential develops, which is deduced from the active electrode. In the ERG diagram only the negative branch of the negative wave of the cornea is shown. The rest is superposed through the successive b-wave. The amplitude of the a-wave is measured from the baseline right at the beginning of the a-wave amplitude until the maximum negative amplitude of the a-wave. The peak time is defined as a time from the beginning of the light stimulus until the maximum of the amplitude. A determination of the slope of the a-wave is possible by a any light intensity. With this specific information on the phototransduction process can be done.

The b-wave is developed in bipolar cells. Depending on the light stimulus and the background lighting, the results of different bipolar cells can be deduced. It is assumed that – by a scopic answer and a low stimulus (light flash period $< 100 \text{ ms}$) – mainly the on-bipolar cells of the rods are pictured. A high stimulus adds the on-bipolar cells of the cones. The extra activated off-bipolar cells of the cones are mainly not substantial for the answer. When a measurement is done under photopic conditions the b-wave is shown as a complex answer of different (on- and off-) bipolar cells and further neurons. The b-wave follows the a-wave and is a positive amplitude. The amplitude of the b-wave is measured from the maximum negative amplitude of the

a-wave until the maximum positive amplitude of the b-wave. The peak of the b-wave is defined as the time from the beginning of the light stimulus until the maximum of the amplitude of the b-wave. The ascending legs of the b-wave have fast oscillating components attached. They are called oscillating potentials. They have very high frequency (100–160 Hz) and small amplitude. The maximum of these potentials is located in the inner granular layer and the inner plexiform layer. The activity of the amacrine cells and the excitation cycle (amacrine cells – bipolar cells and amacrine cells – ganglion cells) of the inner plexiform layer are supposed to be the cause for the potentials. There is no uniform definition for the determination of the amplitude of the oscillatory potential. The amplitudes are measured depending on the certain laboratory either of a previous negative minimum to the maximum peak or from a peak of the amplitude to a later minimum. It is possible to calculate an average of the amplitude. Depending on the laboratory, the evaluation can be different.

The c-wave is a summation of the cornea positive hyperpolarization of the retinal pigment epithelium and the cornea negative hyperpolarization of the Müller cells as a cause of the decrease of the extracellular potassium concentration. The measurement should be accomplished under scotopic conditions and with high intensity stimuli (light density: 10 s). Difficulties in interpretation and the risk of eyelid artifacts finally made this a more scientific tool, which is not widely used in the clinical routine. The scotopic threshold response (STR) is a cornea negative potential that can be deduced from maximum dark adaptation conditions and from poor light intensities. They should mainly generate from amacrine cells. However, in clinics this is not of high relevance. For sufficient interpretation, every laboratory should establish its own standard values. A normal distribution of the values is assumed. Thus, a median value of 5 and 95% percentile is routinely used. Consequently, subnormal are values that are out of this 5–95%-percentile. For further evaluation, the amplitudes and the peak time of the scotopic b-wave can be imaged in a graph in dependence on the intensity. The amplitude can be described as follows:

$$\frac{V}{V_{\max}} = \frac{I}{(I^n + \sigma^n)},$$

where V stands for the amplitude, I for a stimulus intensity, and σ for stimulus intensity where half maximum amplitude V_{\max} is achieved; n is the value for the slope, this can be equalized with about 1. A loss of photore-

Fig. 13.6 (a) Evaluation of the different components of the ERG (amplitudes and peak time of the a and b-waves). (b) Difference between latency and peak time

ceptors leads to a decrease of the maximum amplitude (Fig. 13.6).

Examples: For differential diagnosis typical ERG indication of retinal diseases are listed. Retinitis pigmentosa shows a decreasing amplitude and peak time changes already in an early stage of the disease even before fundus changes occur. Typically, the scotopic ERG by maximum light stimulus intensity shows a decrease of the amplitude and peak time of the a-wave. The same can be developed by an examination of the cones. With the aid of the ERG differentiation, depending on heredity pattern and characteristics, the affection and time course can be judged. In congenital Leber's amaurosis (LCA) there are only rudimentary or no answers of the receptors. Very often the ERG is pathologic and the fundus seems to be unremarkable. In cone dystrophy a rod generating ERG is normal or strongly increased (amplitudes), whereas the answer of the cone system is subnormal, or even undetectable. The cone-rod dystrophy is marked through an early progressive modification of the oscillatory potential and the rod dominated ERG. With morbus Refsum the ERG amplitude reductions are shown in both receptor types. A peak time elongation is rare. Even with a normal fundus appearance the A-beta lipoproteinemia mostly shows a strongly affected

answer of the rod system as compared to that of the cone system and only rarely a peak time elongation. With the ERG mucopolysaccharidoses can be classified. The mucopolysaccharidoses I-H (M. Pfaundler–Hurler) show a subnormal to zero ERG for both receptor types with a stronger affection of the rods. In the mucopolysaccharidoses I-S (Scheie) a pathological ERG answer of the cones and rods system is detectable until the third

to fourth life decades. The mucopolysaccharidosis II (Hunter) shows an ERG modification with an existing retinopathy. A pigment degeneration with subnormal answer of the rods and cones system in ERG is detected in mucopolysaccharidoses III-A (Sanfilippo Type A).

Relevance: In daily routine Ganzfeld ERG is one of the most important examinations for differential diagnosis of retinal diseases.

13.9 Pattern Electroretinography (Pattern ERG, PERG)

Subject: Following constant illumination the electrical answer of the central retina is measured.

Measurement: The measuring principle is similar to Ganzfeld ERG. Only active electrodes are qualified for conduction. This is the only way to image the impulse patterns. Therefore, gold membranes or DTL electrodes should be used, and the best close-addition should be switched before. During the examination the patient should look at the impulse pattern to avoid lateral eye movements and artifacts. During the measurement the signals will be augmentedly AC-linked with a factor of 10 000. The incoming resistance for the amplifier should be at least 10 M Ω and the bandpass used should have a filter of 1–10 Hz. Because this technique has to handle relatively small answer components with a size of about 8 μ V (maximum), the possibility of answer averaging (> 150) and automatic artifact suppression should be given. The latter should eliminate interfering answers of more than 100 μ V. Further processing occurs automatically through a computer determining the wanted values with interpolation. The given stimulus should match a checkerboard pattern. The size of the impulse pattern is standardized. An array should add up at 0.8° and the complete area 10–16°. The contrast between the light and dark arrays should be at least 80%. The light density for the white stimulating array should be at least 80 cd/m² at pale background lighting. The offered impulses should change with a frequency of 1–3 Hz (2–6 reverse impulses/s) at a transient PERG and 8 Hz (16 reverse impulses/s) at a steady-state PERG. The patient should be examined at neutral pupil size. For a better fixation a binocular examination may follow. To exclude falsification of the revulsion at the worse eye, the better eye should be covered in the second examination (Fig. 13.7).

Indication: The PERG reflects the activity of the ganglion cell layer. Diseases of the third neuron such as glaucoma and ocular hypertension, diabetic retinopa-

thy, optic neuritis, hereditary diseases of the optic nerve, drusen of the optic nerve, and compressions of the optic nerve can be diagnosed with the PERG. In combination with the pVEP diseases of the anterior visual pathway are evaluated.

Evaluation: Graphical imaging of the PERG results in a curve along the time axis. The curve includes two valleys and one peak, which are described as components. The first component (= N35) is a valley at 35 ms. This followed by a peak or positive component (= P50) at 50 ms. The second negative component (= N95) is at 95 ms. The components are investigated by using the following values: peak time and amplitude height. The amplitude of the N35 component is a deflection of the baseline until the first negative maximum (valley) of the N35-component. The amplitude of the P50-component is measured from the first maximum negative deflection of the curve (N35) to the highest peak of the curve. If the N35-component is not determined, an average out of the values at zero and the values from the beginning of the P50 component should be taken. The amplitude of the N95-component is either calculated from the peak of the P50-component or from the baseline of its own maximum negative deflection. The peak time matches the time period of the stimulus until the particular negative or positive maximum (N35, P50 and N95). In humans, the components are most likely generated by both neuronal and nonneuronal structures. The P50-component is generated by cells of the inner retina layers such as amacrine cells. The N95-components are mainly generated by ganglion cells, and the P50-component is generated mainly anterior the ganglion cells. A small portion of the ganglion cell layer may also contribute to the P50-component. The quotient N95 : P50 helps differentiate the location of the pathology. A combination of PERG values and pattern VEP is always reasonable for differential diagnosis. A pathological P100-latency in the pattern VEP helps to differentiate between dis-

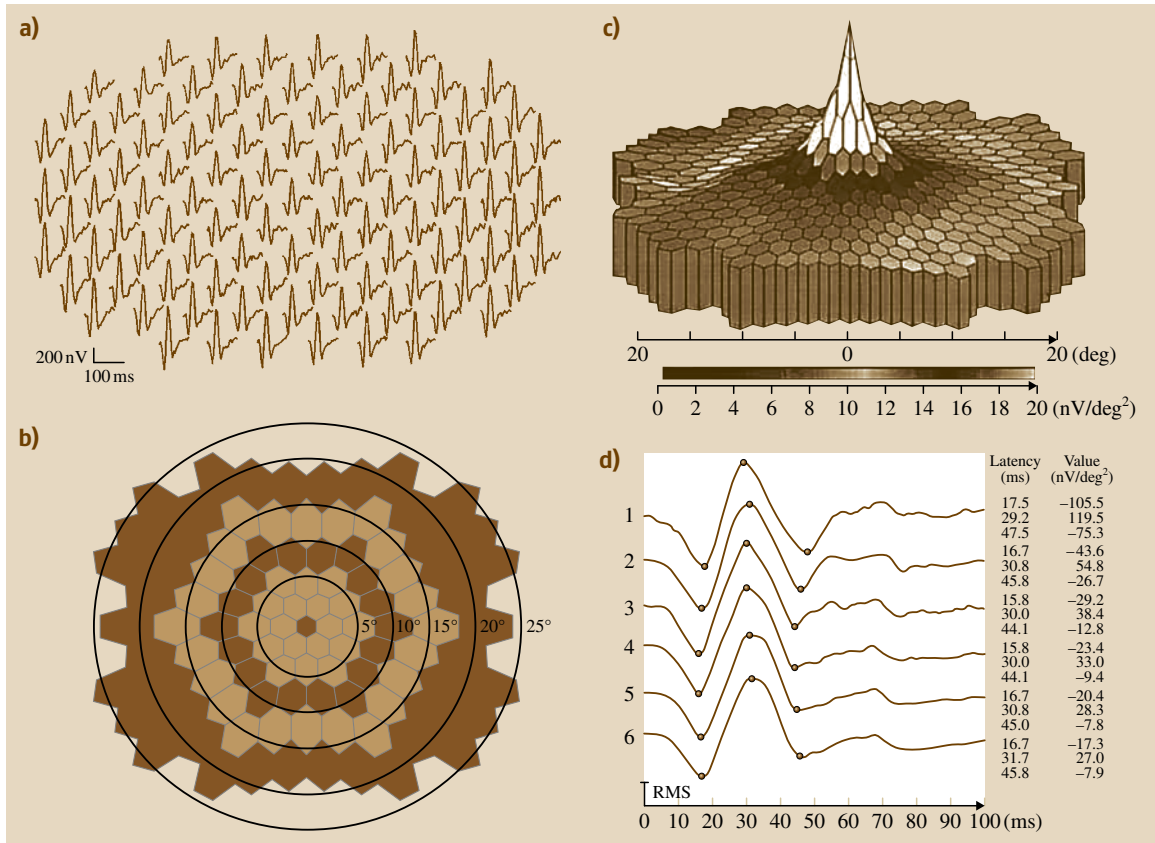

Fig. 13.7a–d Multifocal ERG. Physiological findings. **(a)** Focal ERG answers (trace arrays) calculated from 103 hexagonal stimuli in the central 25° **(b)**. **(c)** three-dimensional presentation (scalar product) of the answers shown in **(a)**. **(d)** Focal ERG answers presented in five groups around the center **(b)**. The value of the amplitude relates to the plane of the respective ring groups (nV/deg²)

eases of the optic nerve (with and without ganglion cell alteration) or retinal diseases.

Cases study: Patients suffering from open-angle-glaucoma exhibit PERG changes (reduced amplitudes) before visual field defect can be evaluated. Particularly the N95-component is affected. A compression of the optic nerve may lead to a decrease of the N95-component and the quotient N95 : P50. In rare cases, the P50-component can be reduced. Such a subnormal PERG is combined with a bad prognosis for the visual function. In diabetics a neuronal damage shown on PERG may occur even before detection of fundus changes. Such patients show reduced amplitudes, which are more pronounced with progression of the disease. Patients suffering from diabetic retinopathy who show a progression of the P50-component alteration are judged as those with bad prognosis.

PERG is qualified for a good differential diagnosis in alterations of the ganglion cell layer induced by macular diseases. Typically, the absolute values of the P50 and the N95 components are reduced in macular degeneration; however, the ratio N95 : P50 remains unchanged. In 40% of the cases diseases of the optic nerve result in alteration of the PERG. In 85% of the cases one may find an unchanged P50-component and a reduction of the N95-component. Depending on the stage of the disease, optic neuritis results in a more or less pronounced alteration of the PERG. In the acute phase (mainly in the second to the fourth week) a reduction of the amplitude of the P50-component can be found; this phenomenon is reversible. Parallel to the recovering P50-component, a reduction of the N95-component is found; this also recovers during the first 2–4 weeks. Hereditary at-

rophies of the optic nerve result in a decreasing amplitude of the N95-component and a decrease of the quotient N95 : P50. A subnormal amplitude of the P50-component is uncommon. Leber's disease shows an acute and subclinical stage before visual acuity is re-

duced and a decrease or loss of the N95-component is detected.

Relevance: PERG represents a good and efficient instrument for the evaluation of the function of retinal ganglion cells.

13.10 Multifocal ERG (mfERG)

Subject: The electroretinographical answers from different retinal areas of the central visual field (corresponding to 25° isoptere) are recorded. Both the cone system and the nerve function can be estimated.

Measurement: mfERG is similar to Ganzfeld ERG and PERG. The active electrodes can be Burian–Allen contact-lens electrodes, or DTL-electrodes. It is important that both the fixation and the visual acuity are not affected by the lens. Like in Ganzfeld ERG and PERG, a reference electrode is installed at the temporal margin of the orbit of the ipsilateral site; another electrode is placed in the middle of the forehead. The signal should be intensified from 100 000 till 200 000 and filtered with a bandpass of 10–300 Hz. Afterwards it is digitalized with a scanning rate of 16/picture frequency. From the ERG summation answers at different stimuli a local ERG answer can be extracted with m-transform-algorithms. Additional calculation models help to gain more information on the inner and outer retinal layers. The stimulation is done via a computer monitor with a picture frequency of 75 Hz. The stimulation field consists of close packed hexagonal (61, 103 or 241) arrays. In the center the size of the arrays is about 4.7 times smaller as compared to the periphery. The light density of each hexagon is modulated independently of each other according to a pseudo-randomized binary m-sequence. Within this sequence each hexagon alternates independently from each other between black and white. The average light density should be 100–200 cd/m² for bright and < 1 cd/m² for dark stimulus elements. The contrast should be at least 90% and the brightness over the entire monitor field should not vary more than 15%. The stimulation lasts about 8 min divided into parts at 60 s. During this time period a light density change of each hexagon takes place at a value of 2¹⁴ times. The measurement should be accomplished at best possible visual acuity and with dilated pupils.

Indication: mfERG is qualified for the evaluation and differentiation of macular diseases and is, therefore, a further means for differential diagnosis of visual acuity alterations and retinal changes of unknown origin.

With the aid of mfERG diseases can be detected even before morphological signs are seen. This is true for the following diseases: Morbus Stargardt, other macular dystrophies, and toxic maculopathies such as chloroquine maculopathy.

Evaluation: The graphical imaging of the mfERG can be done in many ways. The curves of each hexagon can be imaged individually in the trace array. For each hexagon a single ERG curve with two negative maximums (valleys) and a positive maximum (peak) exists. Here, the first negative maximum is described as the N1-component, the first positive maximum as the P1-component, and the second negative peak as the N2-component. The N1-amplitude is measured from the baseline to the maximum negative deflection of the N1-component. The P1-amplitude is measured from the maximum of the N1-component until the maximum of the P1-component occurs. The peak time is measured in analogy to the evaluation of the Ganzfeld ERG – from the beginning of the stimulus until the particular maximum of the curve occurs.

For facilitation of evaluation the computer creates a scalar product from the point product of the local answer and a sample. For the sample, the average focal answer of a normal population, the normalized averaged answer of the complete examination, or the area corresponding to a hexagon is used. The calculated scalar products (in rare cases the amplitude of P1) are used for one, two, or (rarely) three-dimensional pictures. The sizes of hexagons are chosen that way so that the result of each hexagon is equal. By the dividing the calculated scalar answers through the area one obtains the cone density per hexagon (nV/deg²). In a healthy patient the three-dimensional mfERG image offers an image that is pointed in the middle and surrounded by a flat sinking area. The graphical image is a simplification of the results, which may lead to a misinterpretation. Latency shifting may lead to a decrease of the scalar product, which can again change the graphical image.

However, more difficulties occur if the recording is not done adequately. The automatic evaluation would

take the measured noise as an answer and would divide this through the different array sizes and lead to a supposedly pointed mfERG image. Besides that the three- or two-dimensional evaluations of the results can also be used for the calculation of answer groups. In this case, the hexagons are combined in a ring group around the fixation center. Depending on the instrument, five to six ring groups are created. The ring groups are numbered from 1 to 6 starting from the middle. In the graph six curves are compared with each other and present a statistics with receptor density, latency, and amplitude heights per group. Besides that the mfERG can calculate a record of the time of change between light and dark. The different answers are classified in 1. kern (first order kernel) for the deduction of brightness and 2. kern (second order kernel) for the deduction of change between light and dark. As the first order kernel is considered

as an answer of the outer and middle retinal layers, the second order kernel is mostly a part of the inner retinal layers. With extraction an *optic-nerve-head-component*, a pure ganglion cell component, can be conserved.

Case study: Depending on the disease, a marred function of the central retina is expressed differently. Stargardt's disease shows amplitude reduction even before the appearance of morphological changes. Peak time changes may be found in 10% of advanced stadiums. In contrast, retinitis pigmentosa shows – besides an amplitude reduction – a distinct extension of the peak time that accumulates to the periphery. Also carrier of an X-chromosomal retinitis pigmentosa can show amplitude reduction and peak time extension.

Relevance: The mfERG is mostly a clinical tool (next to fluorescence angiography and high resolution OCT).

13.11 Electrooculograms (EOG)

Subject: The electrooculogram registers a constant existing potential on the eye. The origin of the potential is a transepithelial electrical charge difference that lies over the pigment epithelium.

Measurement: Silver chloride electrodes or light polarized electrodes such as the Ganzfeld ERG reference electrodes are suitable for the measurement. The electrodes should preferably be fixed very close to the temporal and medial eye angle. The skin should be clean and treated beforehand with a conductive paste. The impedance should be less than $10\text{ k}\Omega$ and should have a frequency between 30 and 200 Hz. For grounding an electrode should be fixed on the forehead. The deduced signal should be amplified with 5 K. An alternating current amplifier is used to avoid artifacts. The stimulation is done in analogy to Ganzfeld ERG. A stimulus light density of $50\text{--}100\text{ cd/m}^2$ is recommended. To achieve a better illumination of the retina the examination should be done with dilated pupils. If dilation is not possible, it is suggested to use a higher stimulus illuminating density ($400\text{--}600\text{ cd/m}^2$). During the measurement smooth horizontal saccades with the duration of 2–5 s should be evoked; there should be at least 10 saccades/min. Before the examination illumination of the eye (e.g. ophthalmoscopy) should be avoided. To start the examination, a 15 min preadaptation phase should be maintained. This dark period follows a light phase. At least 5 min before the beginning of the light phase the patient should start with the

saccades. At the same time the recording of the signals should start. The examination should not finish before 25 min after the beginning of the light phase. Next to this standard examination with *slow oscillation* with a slow change between dark and light, almost oscillation is established with faster changes between light and dark. Here six cycles are done throughout the light and dark phase (length: 60–80 s each). During this time the patient has to make horizontal saccades such as slow oscillation measuring.

Indication: The EOG is a noninvasive method that gives information on the function of the pigment epithelium. Therefore, the EOG can give differential diagnostic information on retinal diseases. It can be used particularly for an exclusion of pigment epithelium alterations resulting in unspecific visual acuity reduction. You may differentiate between a vitelliform Best-maculopathy and an adult vitelliform macular degeneration.

Evaluation: The deduced signal of the slow oscillation examination gives a rectangular swinging curve (per one movement of the globe). The voltage difference between the upper and lower maximum of the wave is of high interest. After dark adaptation the difference decreases until a so called dark valley occurs. For the value of the dark valley use the lowest voltage difference during the dark phase. Normally it can be measured after 11–12 min of darkness. For the determination of the remaining potential, the average from the measurement

of the beginning of the light phase should be used. After the illumination, in the first 5 min there is a steep rise in the voltage difference per bulb movement (passage). At the end of the increase the light peak is reached. The relation of the light peak to the dark valley (Arden quotient) is an important estimation scale for the EOG. Besides this there is a quotient from the light peak and the rest potential that is always smaller than the Arden quotient. Latency describes the time from the beginning of the light phase until the light peak. Next to the quotient from the light peak and dark valley, the values of the continuance potential ($\mu\text{V}/\text{deg}$) can be seen. Like any other electrophysiological examination, the

EOG needs its own standard values for differentiation of pathological indications. The almost-oscillation examination gives a voltage difference curve with changing potential peaks and valleys. Out of the six cycles a peak and valley average value is established. Out of it a quotient is formed. Additionally, an average latency is defined. The duration of the latency is called similar to the slow oscillation examination, the time between dark valley and light peak. It is possible for incorrect measurement to develop by head movement. Then by mistake a small quotient from light and dark values can develop. Therefore, it is important that the head of the patient always be in the *straight ahead* position.

13.12 Adaptometry

Subject: The time that is necessary to recognize a pattern is measured. The identification of the pattern depends on the light intensity. Through modification of the variables different adaptation times can be calculated.

Indication: Adaptometry is qualified for the diagnosis of cone and rod dysfunctions such as cone-rod dystrophy, retinis pigmentosa, retinis-pigmentosa associated syndrome, congenital night blindness, fundus albipunctatus, Oguchi's diseases, Stargardt's disease, and achromatopsia. In addition, inflammatory disorders such as posterior uveitis, intoxications with chloroquin, ethambutol, or iron oxide can be detected with the aid of adaptometry as a reduced retinal function.

Measurement: For the measurement an illuminated hemisphere like for the EOG and ERG examination is used. The examination starts in a state of brightest illumination with dilated pupils and with best corrected visual acuity. The pupil diameter should be documented before and after the examination. After 5 min adaptation time, the patient may recognize a focusing screen with a striped pattern; with the aid of a scanner the patient can inform the examiner about the identification of the pattern. The duration until the signal is registered automatically. In the following steps the test light intensity is always reduced after the identification of the pattern about a constant level (about 1.8 log units). Then an ap-

proach of test light brightness until the odor detection threshold of the patient is made. If the patient recognizes the striped pattern, the wanted threshold is reached and the process can be repeated.

Evaluation: The measured values result in a sinking curve of the noticeable light intensity (relative threshold impulse energy) along the dark adaptation time. Depending on the wavelength (green or red), the curve is steep or flat. Normally, the adaptation curve shows a biphasic progress with a characteristic bend at the crossing from light to dark. The bend, called Kohlrausch's bend, develops typically after 6–7 min; it marks the end of the function of the cones. From Kohlrausch's bend a slope of sensitivity develops just through the function of the rods. The slope of 3–4 decimal power takes place typically over 30–50 min until the absolute threshold in the adaptation is reached in the end. Pathological curves are usually monophasic, because either the cone's or the rod's part is missing in the curve.

Relevance: Adaptometry demonstrates a sensible instrument for the detection and progress of retinal diseases. It is used in both clinics as well as practice. Concerning the diagnostical power, adaptometry is inferior to Ganzfeld ERG because compliance of the patient is needed and a relative long examination time is required.

13.13 Aberrometry (Wavefront Analysis)

Subject: Measurement of the alteration of retinal imaging quality by higher order refractive errors.

For the quantification of the complete image, the following terms of definition are accomplished: wave-

front variance and Strehl ratio. The wavefront variance quantifies the modification of the entire optics. In the human eye it is depending on the pupil size. It is calculated directly from the single wavefront alterations (see the evaluation). From the wavefront variance (RMS) the optical quality can be calculated with the Strehl number (Strehl ratio). This is a value that reflects the image quality of the optics. It is calculated from the relation between the generated intensity maximum and the maximal possible intensity of the aberration free image.

Indication: In refractive surgery aberrometry is suggested to minimize calculation mistakes of higher order.

Principle: Aberrometry can be determined with the aid of different instruments, such as the Hartmann–Shack sensor, the Tscherning aberrometer, the *ray-tracing* aberrometer, and the *spatially resolved refractometer*. The Hartmann–Shack sensor is a widespread aberrometer that creates a sharp pictured focus point on the retina. This is reflected from the retinal surface so that a punctual light source is generated on the retina. This punctual light source is the origin of the spherical wavefront that is broken in a bunch of parallel light rays after the passage through the optics of the eye. With the aid of micro lenses the bunch is broken as a lot of small focal points that are pictured with a CCD camera. If the optic is optimal, the images of the single rays are located on the picture at a similar distance from each other. If this is not the case and the pictures differ from each other, the wavefront difference can be determined with the aid of the divergence of the reference position in x - and y -direction through deduction.

The Tscherning aberrometer uses a laser ray that is divided in many rays with an aperture mask. The part rays run through the optics in the eye and are projected on the retina. The resulting pattern on the retina can be observed with an ophthalmoscope lens. If the optic is optimal, all points are on the retina at an equal distance like before the passage in the eye. If this is not the case, out of the divergence in x - and y -directions the wavefront difference can be determined like with the Hartmann–Shack sensor.

With the ray-tracing sensor the eye is examined with a laser ray parallel to the optical axis. The light ray is broken by the cornea and the lens and at last hits the retina. In the case of optimal optics the light rays

meet each other at the same location on the retina. If the striking positions differ from each other it can be determined with the *position-sensing detector*. Out of the dislocation in x - and y -directions the wavefront can be calculated analogously to the previous process.

The *spatially resolved refractometer* or Scheiner aberrometer uses two laser rays. One beam is fixed and the other is movable. The fixed laser beam processes through the center of the pupil and the second light ray is movable on different positions in the pupil. At nonoptimal optics both rays hit misplaced of each other on the retina. By adjusting the incoming angle and the incoming position, the course of the ray can be changed in such a way that the rays combine on the retina. With the angle and the pupil position the wavefront can be calculated.

Evaluation: A Strehl number of 1.0 stands for an aberration-free refraction. In reality this is almost not possible. Therefore, in practice a physiological optic is seen as aberration free if the Strehl ratio is greater than 0.8.

The results are shown in dependency of the size of the pupil. Normally, a pupil diameter of 4 mm is used. The image is mostly color-coded: red describes a positive aberration (in μm) and blue a negative aberration. The colors green and yellow represent an optimal wavefront. In addition to the complete values, the wavefront variance can be calculated.

The wavefront variance is also called RMS wavefront mistake (root mean square wavefront mistake). It is a radical from the average of the square of the RMS. For evaluation the values are set in relation to the wavelength. Afterwards, the optical quality is judged with the Marechal criterium. The Marechal criterium says that the optical image is optimal if the relation to the RMS wavefront mistake to the wave lengths is smaller than $\frac{1}{14}$. If the pupil width of an eye is just as big as the relation of the RMS and the wavelength is $\frac{1}{14}$, there is a present critical pupil size.

Relevance: Aberrometry has become an important instrument in refractive corneal surgery. In this field the demand for visual quality is very high. The aberrometry is the last step for evaluating an optical image on the retina. Navigating wavefront lasik leads to a better visual acuity as compared to a normal lasik. The numbers of aberrations of higher order can be reduced.

13.14 Keratometry

Subject: Keratometry describes the measurement of the radius of curvature of the cornea in different meridians.

Examination: With the aid of a cornea-mirror the image can be examined. Both, the power and the axis of the central corneal astigmatism are measured. With the aid of a microscope the projection of the images on the cornea can be seen. The entry angle can be changed manually. At an optimum entry angle the two cornea projections are getting in contact. If the angle is too big the images are too far apart. If the angle is too small the images are partly covering each other. The entry angle

is calibrated so that the radius of the curvature can be calculated or read from the instrument.

Indication: The keratometry is important for the diagnosis of a keratokonus, for contact lens adjustment and the calculation of an intraocular lens (biometry).

Relevance: Today an automatic determination of the radius of curvature of the cornea can be achieved with modern instruments (e.g. automatic refractometer, IOL-Master, corneal topography). Therefore Javal's ophthalmoscopic keratometry or the Zeiss bomb became rare tools during the last years.

13.15 Retinoscopy or Skiascopy

Subject: The determination of the refractive state of the eye by means of a retinoscope. Retinoscopy or skiascopy is performed with the patient fixating binocularly a near object such as a letter, a word, or a picture mounted on, or held close to, the retinoscope and wearing the distance correction. No working distance lens power is subtracted or added to the finding, since the plane of regard is at the same distance as the retinoscope. The examination criteria are the observation of light-shade-phenomena in the patient's pupil. Those phenomena develop when the projection of a light beam on the retina of the patient occurs.

Measurement: The electric hand-held retinoscope projects a light-beam into the pupil of the patient. This results in a red light reflex. The examiner sits at 50 cm distance in front of the patient with a correcting glass of +2.0 dpt. This is to compensate the distance and – in the case of emmetropia – to focus the reflected light to the examination distance. By turning the skiascope around its vertical axis the examiner can observe how the light reflex drifts in the pupil. In hyperopia the light reflex moves in the same direction, in myopia it moves to the opposite. The examiner

may now change the refraction by applying correction glasses. If the correct refraction has been reached the light reflex does not move when the skiascope is turned. In an emmetropic eye the retina illuminates very shortly when turning the skiascope. This flash is called the flicker point. For the determination of astigmatism, the skiascope must be used horizontally and vertically with a bar-shaped light source. Alternatively, the retinoscope can be moved to the direction of the astigmatism axis and then vertically. The difference between both corrections is calculated. This describes the cylinder value in the direction of the astigmatism axis. Single glasses may be replaced by a bar with integrated glasses at different diopter values. For fast measurements these retinoscopy bars are very convenient when examining children. Accommodation power needs to be eliminated as with other procedures (cycloplegia).

Relevance: The usage of automated refractometers (AR) to obtain the refractive power is very popular and AR have replaced the skiascope almost completely (except for children or patients without cooperation). With the help of skiascopy the refractive status of the eye can be determined very quickly.

13.16 Ultrasound

Subject: Using ultrasound technology exact one dimensional (A-Scan) or two-dimensional (B-Scan) measurements of the length of the globe, anterior chamber

depth, or corneal thickness can be performed. An ultrasound signal is reflected from the boundary layers of different media. For calculating the distance in mm the

following formula is used

$$\text{distance [mm]} = \text{velocity of sound [m/s]} \\ \times \text{duration } [\mu\text{s}/2000].$$

The velocity of sound differs depending on the respective medium. In the vitreous body it is at 1532 m/s, in silicone oil 984 m/s. The average velocity of sound in the entire eye system of a phakic eye is at 1550 m/s.

13.16.1 A-Scan Ultrasound, Ultrasound Biometry

Indication: A-Scan technology is mainly used for the biometric measurement of the axial length. This has to be performed before cataract surgery or lens implantation. Other indications are the measurement of the thickness and the evaluation of intraocular tumors (if necessary intraorbital tumors of the anterior orbita) and the imaging of the retinal, choroidal detachments, or retinoschisis.

Measurement: An 8 MHz ultrasound probe with parallel sonic rays is held over the eye surface, which is covered with gel or water. When using water a cone is placed over the cornea. The measurement results in a two-dimensional diagram. On the x -axis the distance of the ultrasound probe is shown; the y -axis represents the intensity of the reflected sound. The measurement is made between two echo peaks that develop at the boundary of two media. Therefore, for the determination of the size the difference of the echo peaks is used. An exact measurement for ocular biometry can be made by means of the so called section biometries. It is recommended that the single sections (anterior chamber depth, thickness of the lens, and distance from the lens to the retina) be determined separately. A possible error source in biometry is the age of the patient and the deformation of the globe. If the patient is younger than 14 years, the growth of the globe must be taken into account. A staphyloma in a high myopic eye can pretend a short globe. The cooperation of the patient is very important. Eye movements may result in falsification of the axis length values. Therefore, with a subject without cooperation, the investigation should be done under general anaesthesia.

For the determination of the axial length the average has to be calculated from 4–5 measurements. In 90% of the cases the axial length of the partner eye is almost equal. If not, the complete measurement procedure should be repeated.

For the calculation of the intraocular lens the axial length value, the anterior chamber depth, the keratometry results, or the refractive error and the A-

constant are needed. Many formulas exist for this purpose. They can be divided into two main groups: physical or geometrical-optical formula that are based on a theoretical model of the eye and empiric (regression) formula that are calculated from statistical postsurgical data. The A-constant depends on the lens that is to be implanted. It varies depending on the design and material. The empirically determined formula are very precise in eyes with an axial length of $24 \text{ mm} \pm 1 \text{ mm}$. This matches the majority of the population. With a longer or shorter axial length it is recommended to use the theoretical formula, because in those cases the empirical formula is mostly not adequate.

Relevance: Ultrasound biometry has become almost completely replaced by laser interference biometry. Only in media opacities such as a mature cataracts is ultrasound biometry still used to calculate the intraocular lens.

13.16.2 Ultrasound Pachymetry A-Scan

Intention: The measurement of the corneal thickness.

Corneal pachymetry can be performed as follows: Measurement of the cornea thickness with ultrasound (20 MHz probe).

The determination of time that is necessary for the sound to passage the cornea enables the calculation of the corneal thickness.

13.16.3 Ultrasound B-Scan

Indication: The B-scan examination is suitable for a two-dimensional imaging and measurement of retinal or choroidal tumours, choroidal detachments, optic nerve head and vitreal abnormalities, as well as intravitreal foreign bodies.

Measurement: Similarly to the A-scan examination the contact surface of the probe is moistened with gel or water. When examining the anterior chamber a water bath should always be used. The graphical image is a cross-section through the eye or the anterior chamber. With the help of moveable calipers the diameter of the structures in the cross-section can be determined in all directions. After marking the areas of the structures examined, some instruments can determine certain values automatically.

Relevance: Because of its high resolution, the easy handling, lack of side-effects such as x-rays, the low costs, and the availability, the B-scan ultrasound is an important method for the for the evaluation and follow-up of many ocular changes and disorders.

13.17 Corneal Topography

Subject: The shape of the corneal surface is measured and imaged.

Measurement: There are different ways to measure the shape of the cornea. In the following, a short summary on the Placido plate and Astra-Max technique is given.

The Placido plate imaging is based on a distortion, or if needed a superposition of light rings projected on the cornea. Pictorially, the pattern on the cornea is reminiscent of a bull's eye.

Rules: The closer the circles, the steeper the cornea, or the further the circles, the flatter the cornea. The Placido plate instruments may vary with the principle of examination. There are two types of instruments that are either working proximally to the eye (*small target type*) or examining it with a certain distance (*large target type*). Both instruments have pros and cons.

The *small target* system need less light and can examine a bigger area but is sensitive to movements. Furthermore, depending on the face anatomy, the measurement may be more difficult. The *large target* system has opposite characteristics to the *small target* system. It needs more lightning, can only examine a relatively small area of the cornea but is not as sensitive to movement artifacts. The Astra-Max three-dimensional topography uses a concentrically oriented *polar grid*. The pattern is recorded and automatically worked out from three different angles. With the three-dimensional image from geometrical calculation, the flexion of the cornea over the complete cornea *limbus to limbus* can be calculated in better quality.

13.18 The Orbscan

Subject: The shape of both the cornea surface and the back face as well as the lens surface are measured. In addition, the following information is collected: anterior chamber depth, topography of the iris surface, pupil localization and diameter, angle κ , white to white distance, and the thickness of the cornea.

Measurement: The measurement is made with a movable chink of light that makes – like a slit lamp – a cross-section of the anterior eye segment. The images are made of the chink of light in less than a second and they are evaluated automatically. From the values the front and back face of the cornea can be calculated. This technology gives im-

Indication: Generally speaking, there are two fields of application for corneal topography. The follow-up of keratektasia and differential diagnosis as well as pre- and postsurgical assessment of the cornea following refractive surgery. Furthermore, pterygium-induced astigmatism can be imaged and the indication for surgery can be validated. Visual acuity alterations of unknown origin may also be further examined by this technique. Early or abortive forms of keratoconus can be identified and quantified.

Evaluation: The results are usually imaged color coded. If the corneal surface shows no astigmatism in the center a round or oval area of light-yellow to light-blue color is shown. By astigmatism a typical hourglass figure is shown. If the axis of the hour-glass figure is vertical it is called astigmatism rectus; if the figure is horizontal it is called astigmatism inversus. In oblique astigmatism the hour-glass figure is diagonal. If the hour-glass is distorted this may be judged as an irregular astigmatism. It can be a precursor of a keratoconus (lazy-eight) or induced by a scar. Other images that indicate a keratoconus is a pronounced eccentric ectasia that shows a red color on a green or dark-blue (later stage) area.

Relevance: Corneal topography is an essential measure before every refractive procedure. After surgery it is used to investigate the result. It is, therefore, mandatory in every refractive institution. It is also important for diagnosis and follow-up corneal ectasia in diseases such as keratoconus and for the investigation of new therapeutic approaches (cross-linking) (Fig. 13.8).

portant additional information on the anterior eye segment.

Indication: The orbscan is an ideal instrument especially for refractive procedures because it enables not only simple corneal topography but also a topography of the corneal back face and the lens surface. Moreover, the orbscan can determine the cornea thickness before a laser examination.

Evaluation: The evaluation is made in analogy to the diagnosis of the corneal topography, the pachymetry, and the imaging of the anterior eye segment.

Relevance: The orbscan instrument is outstanding as compared to other procedures for corneal examinations

Fig. 13.8a–e Qualitative patterns in corneal topography according to *Bogan et al.* [13.1]. (a) Round, (b) oval with slight hour-glass shape, (c) symmetrical hour-glass shape, (d) asymmetrical hour-glass shape, (e) irregular

because it can provide more information (topography, pachymetry) in one session. In pachymetry the values

vary at $\approx 23\text{--}28\ \mu\text{m}$ as compared to the ultrasound examination.

13.19 Scheimpflug Examination

Subject: Imaging and measuring all visible anterior segment structures with a computer based reconstruction of 20–50 pictures.

Measurement: The measurement is made automatically with a high-resolution camera that rotates around the eye in less than a second. Afterwards, the images

gained are calculated to a three-dimensional hologram.

Indication: Like the orbscan measurement the Scheimpflug camera is an ideal instrument for imaging and measuring different structures and proportions of the anterior segment.

13.20 Fluorescence Angiography of the Retina (Sodium-Fluorescein)

Subject: The time of the influx and the dispersion of the coloring in the retinal vessels and the choroid are imaged and documented with a specially designed fundus camera (Fig. 13.9).

Indication: Today fluorescein angiography is the standard imaging procedure in many retinal and choroidal diseases.

Implementation: For the examination about 500 mg sodium-fluorescein (10% solution in 5 ml or 5% solution in 10 ml) is given intravenously. Incoming blue stimulating light (excitation filter: 490 nm) lifts the electrodes of the molecule sodium-fluorescein to a higher energy level. Once the the electrodes slide back to the ground state green light (530 nm) is emitted. A yellow-green band elimination filter prevents a picture of the reflected blue light. The picture is usually documented digitally.

Sodium-fluorescein has a relatively low molecular weight (formula: $C_{20}H_{10}O_5Na_2$), the molecule diffuses through Bruch's membrane and the pores of the choroidal capillaries. Physiological diffusion barriers are the large choroidal vessels, the retinal vessels, and the retinal pigment epithelium.

The injection may lead to local irritations (by extravasations of sodium-fluorescein), illness, vomiting, syncope, asthmatic attack (rare). In addition, anaphylaxia (very rare) has been described. Thus, an angiography room should be equipped with the usual emergency tools.

Evaluation: *Phases of the fluorescein angiography.*

Fluorescein angiography is a dynamic procedure. Thus, the temporal process of the angiography is documented and divided into different phases. It starts at about 12–25 s (arm-retina-time) after the beginning of the injection.

- **Preatrial phase (filling of the choroid):** The filling of the choroid occurs about 1 s before the filling of the retinal vessels. It can be observed as a ho-

mogenous background fluorescence. The intensity negatively correlates with the pigmentation level of the fundus.

- **Arterial phase:** This starts immediately after the filling of the choroidal capillaries and ends with the complete filling of the arteries.
- **Arteriovenous phase:** This is marked by a complete filling of the arterioles and capillaries and ends with the beginning of a laminar filling of the veins.
- **Venous phase:** This ends with a complete filling of the veins and can be divided into an early (arterioles and venules fluoresce at a similar level) and a late venous phase (obviously less fluorescence of the arterioles).
- **Late phase (recirculation phase):** A retinal passage (filtration) has occurred. This results in a distinct decrease of the fluorescence in healthy subjects.

Hypofluorescence

Hypofluorescence can be either the cause of a blockade of the regular fluorescence or the result of a filling defect (less diffusion).

Hyperfluorescence: Hyperfluorescence can be the result of an intensified background fluorescence following a defect of the retinal pigmented epithelium. This transmission defect develops from focal RPE atrophy or missing RPE cells with the result of *uncovering* the choroidal fluorescence. It is characterized by an early hyperfluorescence. Its intensity is increasing and then fades without modification in size or shape. In addition, hyperfluorescence can occur by extravasation of fluorescein from the choroidal vessels (defect of the outer blood–retina barrier).

Defects of the retinal vessels or abnormal newly formed vessels (such as proliferations) can lead to a fluorescein leakage. In addition, staining of the tissue can be the result of dye retention. This occurs in drusen or scars and can be seen in the late phase of the angiogram.

Fig. 13.9a–f Fluorescein angiography of a healthy subject. **(a)** Infrared image; **(b)** autofluorescence, **(c)** arterial phase, **(d)** early venous phase: laminar venous phase, **(e)** late venous phase; **(f)** late phase

13.21 Fluorescence Angiography of the Retina (Indocyanine Green)

Subject: see Fluorescence angiography

Indication: ICG angiography offers the advantage of a better visibility of the choroidal vessels, a less intense fluorescence blockade by the retinal pigmented epithelium and a higher affinity to the choroid vessels. Therefore, indications are diseases originating from the choroid such as choroidal neovascularizations (CNV) in age-related macular degeneration or primary choroidal diseases (such as disorder of the choroidal circulation)

Implementation: 25–50 mg of the dye are given into 2–4 ml water (for intravenous injection). After the dye has been soluted the fluid is injected quickly. Thereafter 5 ml physiological sodium-chloride solution should be

injected. With this procedure a sharp coloring front can be achieved in the early phase. The fluorescence of ICG conforms about 4% of the sodium-fluorescein. Thus, very sensitive image detectors are required. ICG is a water-soluble tricarboyanin dye. 98% of the ICG are bound to plasma proteins. It is not metabolized but eliminated via the liver and biliary tract. It is relatively secure and has only few side effects (the mortality rate as a result of the application of the ICG is 1 : 333 333 as compared to 1 : 222 000 for fluorescein angiography). The most seen side effects are sickness (2.9%), vomiting, *flushing*, itching, rash, dyspnoea, and syncope (0.2%).

13.22 Visual Field Measurement (Perimetry)

General remarks: The visual field describes the area that can be noticed with the eye without moving it. It embraces the complete field of view from the center to the outer border. One may differentiate between the monocular and binocular visual field. Moreover, the visual field depends on adaptation as well as the size and the brightness of the observed object. In elderly subjects the size of the visual field decreases as a result of a normal aging process. For colors the visual field is smaller than for white light. Objects that are located at the edge of the field may, therefore, not be noticed as being colored.

Measurement: In all examinations the patient has to fixate a certain point and is not allowed to move his eyes. The examination must be performed separately on both sides (one eye must be covered). The automatic static perimetry is the method of visual field measurement that is used the most. At the static perimetry the patient sits in front of the perimeter in which randomly blinking light points are shown. The subject under examination fixates a light in the middle of the display. He/she should press a button whenever a light is shown in the surroundings. If the button is not pressed, the light intensity will be increased automatically and the point will be re-tested. This will be repeated to a certain intensity; if there is no answer a defect will be recorded. A subtype of the automatic perimetry is the so called blue-yellow perimetry. Here, the patient is presented a blue light in a yellowish illuminated hemisphere. It is especially sensitive to early visual field alterations.

The kinetic (Goldmann's) perimetry is the oldest method for visual field testing. Here, the person be-

ing tested sits in front of a hemisphere, very rarely in front of a flat test display. Light dots move from outward to inward (into the visual field). The moments at which the points are recognized are recorded. This test is done manually. For this examination light point at different (defined) brightness and size are used. Perception thresholds are measured, they are called isopteres. For the imaging of the blind spot one may start at 15° para-centrally and then move outwards to the margins of the blind spot. A detailed routine examination with Goldmann's perimeter should proof the outer edges with the following marks (spot sizes and intensities in chronology as indicated): V/4, I/4, I/3, I/2, and I/1. The blind spot is mostly proofed with the mark I/4. The determination of the outer margins is done with mark III/4 or V/4.

Finger perimetry (confrontation test, parallel try, comparison perimetry) is the most simple and fastest way to examine the visual field. The examiner and patient sit at distance of about 50 cm facing each other. Both cover one of their eyes with the hand so that the particular facing eye is fixed. Using the other hand the examiner moves the object (a pen) into the visual field. This is done out of every direction. The patient indicates when he sees the pen and the doctor can compare this with his own perception. Especially the outer borders and sideways deficiencies can be determined with this test. The test is fast and can be done at the bedside (Fig. 13.10).

Indication: Different diseases of the eye or the brain such as glaucoma or perfusion disorders (stroke) may affect the visual field. Defects of the visual field are de-

terminated by means of perimetry. The result is further compared to a standard result.

The blue-yellow perimetry is more sensitive than the automatic standard perimetry. Thus, this procedure allows the identification of early visual field defects such as early stages of glaucoma. For older patients the blue-yellow perimetry is not recommended. As a result of age-related lens opacification, the respective wavelengths are filtered. Therefore, blue-yellow perimetry is used for early diagnosis in younger patients suffering from ocular hypertension.

Evaluation: To judge if the visual field of the patient is normal or abnormal the results are compared to standard values of healthy persons. These are the visual field margins for the left eye for a white light stimulus: upper margin 50°, nasally 60°, lower margin 70°, temporally 95°. Usually the blind spot is located temporally between 10 and 20°. Depending on the examination (kinetic or static), the outer margin may vary because of the threshold of perception (higher for moved light sources as compared to static lighting). When doing a perimetry it is strongly recommended to always examine both

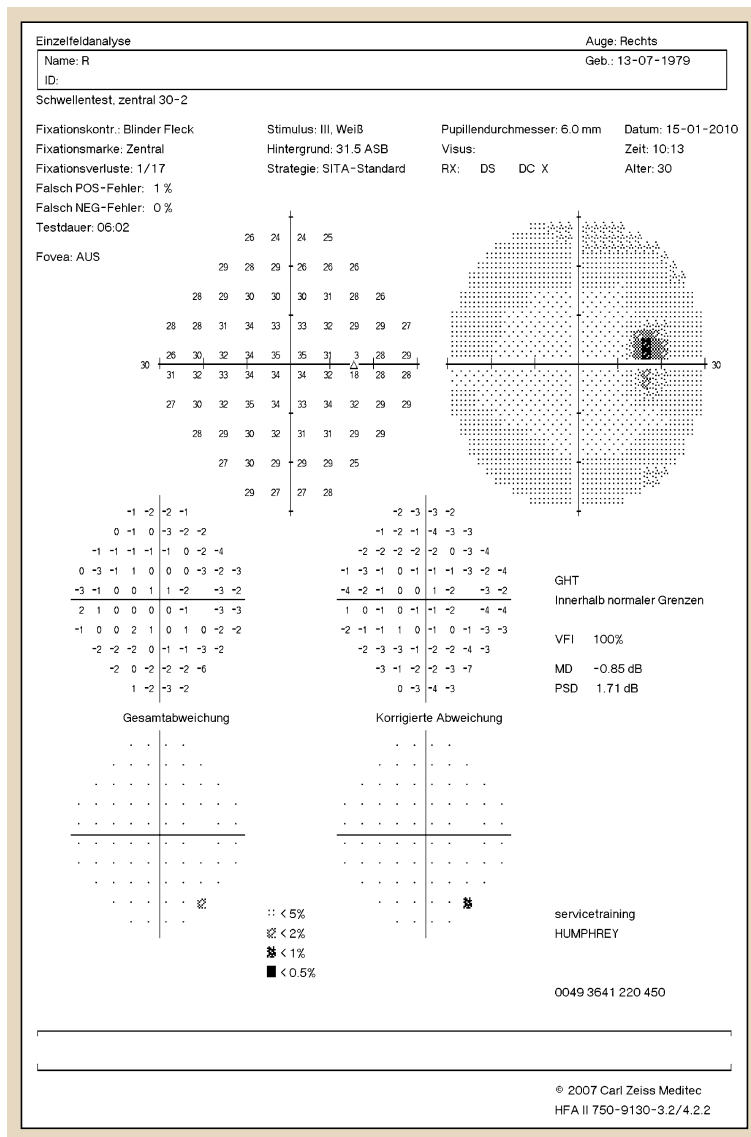

Fig. 13.10 Physiological visual field of the right eye

eyes (separately). This ensures that central (brain) damage can be differentiated from local (eye) damage. In some rare cases, the binocular visual field is measured. The results of the automatic perimetry can be imaged in different ways: look-up table, difference table, defect depth, gray scale, or shades of gray. A look-up table is a point by point printout of the threshold in decibel. The difference table is a point by point printout of the algebraic difference between the actual measured threshold and the expected or age-corrected normal values. Differ-

ences of 4 dB or less are printed normally as a symbol. Differences of 4–9 dB are marked as a small defect, of 10–19 dB as a moderate defect, and of 20 dB or greater as a deep defect. The gray scale or shade of gray is a graphical image of the measured thresholds. The complete area of the available test stimulus is divided into 9–10 intervals and each area matches a shade of gray according to a scale. Light gray tones are physiological, dark gray and black tones (exception: the blind spot) are considered pathological.

13.23 Exophthalmometry

Subject: Exophthalmometry measures the protrusion of the globe.

Measurement: Different instruments can be used – the exophthalmometer by Mutch, by Luede, and by Hertel. Hertel's exophthalmometer is the tool that is mainly used. Two movable connecting pieces touch the lateral orbital margins. The distance between the two connecting pieces is used as the base (basis line). The next step is that the examiner reads the position of the corneal apices with the deflections mirror inside the connecting pieces.

Indication: The Hertel exophthalmometer is a simple and correct method for the diagnosis of a retrobulbar

mass. Exophthalmometry is part of the basic examination procedures in endocrine orbitopathy.

Evaluation: For a follow-up the same basis is used. The distance between the orbital margins and the apex of the cornea is 18–24 mm (European subjects). A difference of more than 2 mm between the two eyes or more than 24 mm is considered pathological. A possible source of error might be a face asymmetry.

Relevance: A simple method to quantify the eye position by suspicion of protrusion of the globe. This method is a standard procedure in ophthalmology.

14. Functional Force Assessment of Skeletal Muscles

Functional Force

Paul A. Iaizzo, William K. Durfee

Measurements of muscle function and strength are essential components of many clinical neurological or physical exams, and they are important for monitoring physiological function in various animal research studies. Evaluation of muscle strength is necessary for differential diagnosis, to determine the presence of disability, to plan potential treatments, and/or to track the effectiveness of treatments. As outcomes-based medical practice becomes more prevalent, the need for quantitative outcomes assessment of muscle strength becomes even more critical. Several assessment techniques and tools are currently available, but most require a cognitively cooperative subject. Manual muscle testing is the most widely used method to assess muscle function, however its reliability and accuracy are variable. When greater accuracy is needed, instruments that provide precise readouts of resistive forces can be employed, for example, hand dynamometers, pinch grips, and

computer-controlled dynamometers. Stimulated muscle force assessment is an alternative and versatile approach for quantitative involuntary muscle torque.

14.1 The Need for Skeletal Muscle Force Assessment

There is a growing need in clinical medicine to validate the quantitative outcomes of an applied therapy. In addition, the measurement of muscle function is an essential component of most neurological and/or physical exams. In general, muscle strength is often correlated to function, potential work productivity, and/or quality of life. Muscle function becomes reduced as we age, when associated with a skeletal impairment, and as a secondary consequence of many disease processes, i.e., stroke, nerve compression, or demyelination. Therefore, assessing muscle function is an important clinical skill that is routinely used by neurologists, orthopedists, general practitioners, anesthesiologists, and occupational and physical therapists. Furthermore, the evaluation of strength is used for differential diagnosis, to determine

if an impairment or disability is present, to decide if a patient qualifies for treatment, and/or to track the relative effectiveness of a given treatment.

In a research setting, careful assessment of muscle function is often required to further our understanding of the normal or potentially impaired neuromuscular system. In such experiments, muscle forces can be assessed at the intact individual level (in vivo), in chronic and acute animal models (in situ), within isolated muscle strips or even within single myofibrils (in vitro), and at the molecular/biochemical level. In this chapter, only whole muscle testing (in vivo and in situ) will be discussed.

There are several components of muscle performance. The American Physical Therapy Association

uses various definitions to explain the characteristics of muscle function. *Muscle performance* is the capacity of a muscle to do work, and *muscle strength* is the force exerted by a muscle or group of muscles to overcome a resistance in one maximal effort. *Instantaneous muscle power* is the mechanical power produced by the muscle relative to time (muscle force times muscle velocity), and *muscle endurance* is the ability to contract a muscle repeatedly over time [14.1]. Of these performance indicators, muscle strength is the one most commonly measured when assessing the muscle function of intact humans.

In assessing muscle strength, the conditions under which the muscle contracts must be specified so that the muscle test data can be interpreted properly. The following conditions are relevant:

- *Isometric contraction* – the muscle contracts while at a fixed length.
- *Isotonic contraction* – the muscle contracts while working against a fixed load, for example, a hanging weight.
- *Isokinetic contraction* – the muscle contracts while moving at a constant velocity; generally, isokinetic contractions are only possible with the limb strapped into a special machine that imposes the constant velocity condition.
- *Concentric contraction* – the muscle contracts against a load that is less than the force produced by the muscle so that the muscle shortens while contracting.
- *Eccentric contraction* – the muscle contracts against a load that is greater than the force produced by the muscle so that the muscle lengthens while contracting.

Isometric muscle tests are the most common, as they are the simplest to perform and reproduce and, because the test conditions are well defined, they are the most appropriate for comparing results within a population. Two considerations are important when testing muscle under isometric conditions. First, because muscle force varies with muscle length, the length of the muscle must be specified when planning and reporting a muscle test. The manual muscle test has strict and well-defined rules for the subject's posture and joint positions that must be followed if one is to make clinical decisions based on the test [14.2].

Second, isometric muscle tests of intact human muscle are conducted either with the limb held in a fixed position by the examiner or with the limb fixed to

a brace or jig (Sect. 14.4). While these methods hold the limb in a fixed position, the muscle will not be strictly isometric because of tendon stretch. The mismatch between limb condition and muscle condition only causes problems when trying to infer details about muscle dynamics such as rise time or contraction speed from externally measured forces. Even if the whole muscle could be fixed at proximal and distal ends, during a twitch, the distance between *z*-lines in the myofibril will shorten, which means the sarcomeres are shortening due to internal muscle elasticity. This is why the length tension and dynamic properties of whole muscle deviate somewhat from those of the isolated sarcomere [14.3]. Nevertheless, length tension or ankle-angle/isometric-torque analyses can be done *in vivo* [14.4, 5].

Testing of intact human muscle requires that muscle output be measured external to the body and, as a result, muscle force is never measured directly. As shown in Fig. 14.1, muscles wrap around joints and attach to limbs at the proximal and distal ends. There is a kinematic relationship between the measured force and the actual muscle force that depends on the details of muscle attachment and varies with joint angle. To solve the kinematic relationship, one needs information about muscle attachment location, the geometry of the joint, and the joint angle. Such information can be readily obtained from a magnetic resonance imaging (MRI) scan, or a more generic geometry can be

Fig. 14.1 Muscles wrap around joints. Muscle force is related to external force produced by a limb through skeletal geometry of joints and attachment points (Source: Medical Internet Solutions, <http://aclsolutions.com/>)

assumed through dimensions gathered from cadaver studies [14.6, 7].

While often reported as a force, external testing of muscles more correctly should be reported as a torque. Figure 14.2 illustrates how force varies with location of the resistive load along the limb, while torque does not. Reporting muscle strength as torque about a joint eliminates this difficulty. If force is reported, the distance between the joint and the resistive load point should be measured to permit conversion to torque.

External measurement of torque about a limb joint means that all of the forces acting on that joint are measured, and that the contribution of the muscle or muscle group under study cannot be easily separated out. In other words, there are confounding forces generated by synergistic muscles; for example, when testing foot plantar flexion to determine gastrocnemius strength, the soleus may also be contributing to the measured torque about the ankle. Yet another complicating factor may be undesired activations of antagonist muscles. One exam-

Fig. 14.2 A torque of 4 is produced about a joint. It takes an opposing force of 2 to balance the torque if the opposing force is applied at *arrow 1*. If the opposing force is applied at *arrow 2*, it only takes a force of 1 to balance the torque. Thus, the perceived torque, and therefore the scoring of muscle strength, depends on where along the limb the examiner places his or her hand

ple is when you *flex your arm muscles*. In general, the resulting torque from the biceps and triceps are in balance, the arm does not move, and no external torque will be measured even though the muscles are contracting actively.

14.2 Manual Muscle Strength Testing

The simplest and most common method of assessing muscle strength is the manual muscle test (MMT). Manual muscle testing is a procedure for evaluating strength and function of an individual muscle or a muscle group in which the patient voluntarily contracts the muscle against gravity load or manual resistance [14.2, 8]. It is quick, efficient, and easy to learn; however, it requires total cooperation from the patient and learned response levels by the assessor.

The procedures for conducting the MMT have been standardized to assure, as much as possible, that results from the test will be reliable [14.2, 8, 9]. The specific muscle or muscle group must be determined, and the examiner must be aware of, and control for, common substitution patterns where the patient voluntarily or involuntarily uses a different muscle to compensate for a weak muscle being tested.

To conduct a MMT, the patient is positioned in a posture appropriate for the muscle being tested, which generally entails isolating the muscle and positioning so that the muscle works against gravity (Fig. 14.3). The body part proximal to the joint acted on by the muscle is stabilized. A screening test is performed by asking the patient to move the body part through the full available range of motion (ROM). The main test is then performed either unloaded, against a gravity load,

or against manual resistance, and a grade is assigned to indicate muscle strength.

Manual grading of muscle strength is based on palpation or observation of muscle contraction, ability to move the limb through its available ROM against or without gravity, and ability to move the limb through its ROM against manual resistance by the examiner. Manual resistance is applied by the examiner using one hand with the other hand stabilizing the joint. Exact locations for applying resistive force are specified and must be followed exactly to obtain accurate MMT results [14.2]. A slow, repeatable velocity is used to take the limb

Fig. 14.3 Manual muscle test of the iliopsoas (Source: Spokane Falls Community College, Spokane)

Table 14.1 Manual muscle test scores

Score	Description
0	No palpable or observable muscle contraction
1	Palpable or observable contraction, but no motion
1+	Moves limb without gravity loading less than one half available ROM
2–	Moves without gravity loading more than one half ROM
2	Moves without gravity loading over the full ROM
2+	Moves against gravity less than one half ROM
3–	Moves against gravity greater than one half ROM
3	Moves against gravity over the full ROM
3+	Moves against gravity and moderate resistance less than one half ROM
4–	Moves against gravity and moderate resistance more than one half ROM
4	Moves against gravity and moderate resistance over the full ROM
5	Moves against gravity and maximal resistance over the full ROM

Table 14.2 Grading of isometric manual muscle test

Score	Description
3	Maintains position against gravity
3+	Maintains position against gravity and minimal resistance
4–	Maintains position against gravity and less than moderate resistance
4	Maintains position against gravity and moderate resistance
5	Maintains position against gravity and maximal resistance

through its ROM, applying a resistive force just under the force that stops motion. The instructions to patients are to use all of their strength to move the limb as far as possible against the resistance. For weaker muscles that can move the limb but not against gravity, the patient is repositioned so that the motion is done in the horizontal plane with no gravity.

MMT grades are assigned on a 0 to 5 scale with +/- modifiers: 1 = trace score, 2 = poor, 3 = fair, 4 = good, 5 = normal (Table 14.1). Grades above 1 demonstrate motion, and grades above 3 are against manual resistance. Other comparable scoring scales exist [14.7].

A common alternative to motion-based MMT is the isometric MMT in which the limb is held in a fixed position while the examiner gradually applies an in-

creasing resistance force. The instructions to the patient are, *Don't let me move you*. The amount of force it takes to *break* the patient is used to assign a score. Scoring norms for isometric MMT are provided in Table 14.2. Because isometric MMT always involves a resistance, scores start at 3.

The assignment of scores is based on clinical judgment and the experience of the examiner. The amount of resistance applied by the examiner is also based on clinical experience and is adjusted to match the muscle being tested as well as the patient's age, gender, and body type. A major advantage of the MMT, as opposed to almost any other method, is that it can be adapted to measure the force in almost any muscle including facial muscles, tongue movements, and all of the intrinsic muscles in the hand.

While the MMT is the most widely used method to assess muscle function, its reliability and accuracy are questionable [14.10, 11]. MMT scores are least accurate for higher force levels [14.10, 12, 13]. Interrater reliability for MMT is not high, suggesting that the same examiner should perform multiple tests on one subject or across subjects [14.2]. MMT scores do correlate well with results from handheld dynamometers [14.14], implying that both are valid measures of muscle strength. However, as explained in Sect. 14.4, all tests based on voluntary activation of a muscle are prone to artifacts because of patient motivation and examiner encouragement. An additional limitation of MMT is that the scoring scale is nonlinear, making it challenging to apply longitudinally in a given patient to follow disease progression or treatment response; for example, the change in absolute muscle force between MMT scores 0 and 1 is much less than the force change between scores 3 and 4.

14.2.1 Apparatus

The appeal of the MMT is that it can be performed simply with the patient, the examiner, and a bench or table. This makes it ideal for the routine clinical environment, where specialized equipment is unavailable and time is short. It is also well suited for situations in which testing must be performed away from the clinic, for example, in nursing homes, rural areas, or remote emergency settings.

When greater accuracy of results is needed, instruments are available that provide precise readouts of the resistive force the muscle works against [14.15]. One example is a handheld dynamometer such as the one shown in Fig. 14.4. This instrument is sandwiched be-

Fig. 14.4 Handheld dynamometer. Pictured is the Lafayette MMT System (Lafayette Instrument Company, Lafayette)

tween the examiner's hand and the patient's limb, and provides a readout of force. The interrater reliability for handheld dynamometers is good when used with a standard procedure [14.16–18], as is the test–retest reliability [14.14]. While the electronic dynamometer delivers a quantitative force reading, standards relating force in Newtons to the 1–5 scoring of a MMT have not been developed because the dynamometer does

not take the size and build of the subject into account, an important, albeit subjective, part of assigning MMT scores.

Other products have been developed for specific tests of muscle strength, for example, the hand dynamometer and pinch grip devices shown in Fig. 14.5. These are easy to use and common for diagnostic tests of the hand. Despite their quantitative nature, readings between different types and brands of dynamometers can vary [14.19, 20]. Computer-controlled dynamometers offer a variety of loading conditions for muscle testing and for strengthening treatments [14.21, 22] (Fig. 14.6). Along with isometric and isotonic loading, dynamometer machines provide isokinetic conditions in which the muscle group acts against a computer-controlled resistance that moves the limb at a constant angular velocity. While these and other quantitative instruments provide accurate readings of muscle force, they are rarely found in the clinic because, for most clinical purposes, the MMT is sufficiently accurate to monitor muscle strength, is fast and easy to administer, and requires no equipment.

14.3 Advanced Muscle Assessment Methods

14.3.1 Measuring Muscle Dynamics

Muscle is a complex actuator whose external properties of force and motion result from the action of thousands of muscle fibers which, in turn, result from the action of millions of structural and active proteins whose interaction is triggered by biochemical events. While most muscle testing focuses on the overall strength of a muscle or muscle group, more sophisticated assessment can be useful for in-depth examination of muscle function, including its dynamic, kinematic, and fatigue properties.

The approach used to measure muscle function in more detail generally involves developing a mathematical model of muscle activity and then using experiments to identify the parameters of the model.

Fig. 14.7 Hill muscle model. The contractile element (CE) contains the active element with dynamics, force–velocity, and force–length properties. The series element (SE) is the inherent internal elastic element, and the parallel element (PE) represents passive connective tissue

Overviews of these methods are provided in *Zajac and Winters* [14.25], *Durfee* [14.23], *Zahalak* [14.26], *Crago* [14.27], and *Kearney and Kirsch* [14.28]. The modeler must first choose the appropriate complexity of the mathematical model. The optimum choice is a model that is sufficiently complex to reveal the behavior of interest, but not so complex that parameters cannot be identified. Generally, Hill-type input–output models [14.29, 30] are a good balance, as they capture key force–velocity, force–length, and activation dynamics at a whole-muscle level (Fig. 14.7).

Model parameters can be identified one at a time, using the approach followed by *Hill* [14.29], or all at once using modern system identification techniques [14.23, 28]. Electrical activation of the muscle is a particularly convenient means for excitation because, unlike voluntary activation, there is control over the input, an essential component for an effective system identification method. Testing can be done under isometric conditions for determining recruitment and twitch dynamic characteristics, or under arbitrary loading to find active and passive force–length and force–velocity properties.

Identification of muscle properties is most easily accomplished using isolated muscle in acute animal model studies. Here the muscle is unencumbered by joint attachments and extraneous passive tissue. Muscle tendon can be directly attached to a force sensor and placed in a computer-controlled servo mechanism to apply known length and velocity trajectories, all while being stimulated; for example, the isometric recruit-

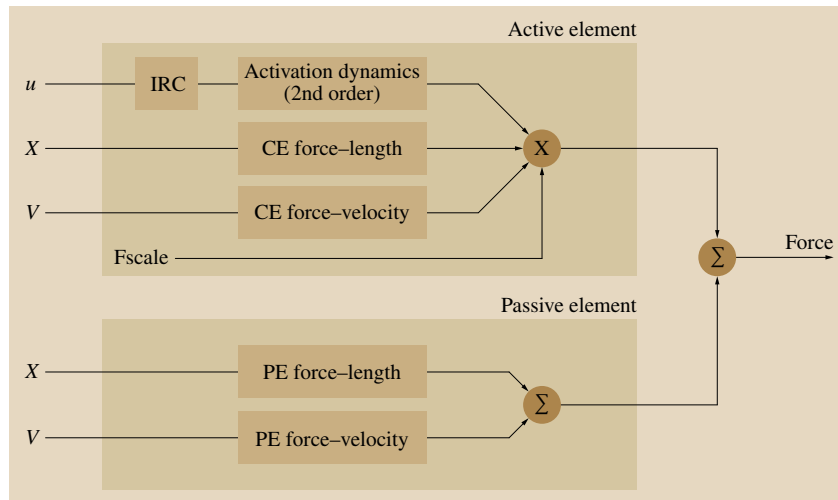

Fig. 14.8 A model that can be used for muscle property identification. The active element has recruitment and twitch dynamics which multiplicatively combine with active force–length and force–velocity properties and sum with passive force–length and force–velocity properties to produce overall muscle force (after [14.23, 24]). IRC – isometric recruitment curve; CE – contractile element; PE – parallel element

ment curve, the relationship between muscle force, and stimulus strength can be identified using either point-at-a-time or swept-amplitude methods, the latter being efficient in implementation [14.31]. Using the model shown in Fig. 14.8, active and passive force–length and force–velocity properties can be estimated using brief bouts of controlled, random length perturbations, and then verified through additional trials where both stimulation and length are varied randomly [14.23, 24] (Fig. 14.9). Simultaneous identification of active and passive muscle properties for intact human muscles is more challenging and represents an ongoing area of research [14.28].

14.3.2 Electromyogram

Contracting skeletal muscle emits an electrical signal, the electromyogram (EMG). Electrical recording of the EMG using needle or surface electrodes is an important diagnostic indicator used in clinical neurology to diagnose neuromuscular disorders including peripheral neuropathies, neuromuscular junction diseases, and muscular dystrophies. EMG is also used in research studies as an estimator of muscle activity for biomechanics and motor control experiments. The reader is referred to *Merletti and Parker* [14.32] and *Basmajian and DeLuca* [14.33] for a comprehensive discussion of surface and needle EMG used in research applications,

Fig. 14.9 Results from an isolated muscle experiment where muscle active and passive properties were identified, then the resulting model was verified against experiment data. Data were generated while the muscle underwent simultaneous, random, computer-controlled stimulation and length perturbations (after [14.24])

and to *Preston and Shapiro* [14.34], *Kimura* [14.35], and *Gnatz* [14.36] for an introduction to clinical EMG. EMG assessment is limited because it is only an indirect indicator of muscle force.

14.4 Stimulated Muscle Force Assessment

Most devices used clinically to quantify muscle force and increase objectivity rely on voluntary effort, which can be problematic. Pain, corticospinal tract lesions, systemic illness, and inconsistent motivation can significantly affect voluntarily activated muscle force. In addition, some very weak patients are unable to complete a full range of motion in voluntary force assessment tasks [14.37, 38]; for example, monitoring muscle function in patients confined to the intensive care unit is a challenge. Often such patients are on potent pain medications (e.g., morphine) and are sedated, and may have significant alterations in level of consciousness due to underlying critical illnesses [14.39, 40]. Thus, it can be extremely difficult to ask these patients to provide reproducible voluntary efforts. Even when cooperation is good, the standard measures of force assessment are qualitative. The alternative is to stimulate their muscles to contract without voluntary input.

Stimulated muscle force assessment is a versatile approach for quantitative involuntary muscle torque in humans. A muscle is activated by noninvasive nerve or motor point stimulation. A rigid apparatus is used to secure the appropriate portion of the subject's body in a predetermined position which confines movement to a specific direction, e.g., ankle dorsiflexion, thumb adduction, arm flexion, or neck flexion [14.3, 5, 41, 42] (Figs. 14.10 and 14.11). The innervating nerves or motor points of the muscle are stimulated using surface electrodes, with either a single stimulus to generate a twitch contraction or with short trains of stimuli (e.g., with 5 ms interpulse intervals) to produce tetanic contractions [14.4, 5]. Strain gauges are used to measure isometric torque and, via acquisition software, all data are displayed and online analyses are performed. Various parameters of the isometric contractions can be calculated including time between stimulus and torque onset, peak rate of torque development, time to peak

Fig. 14.10 Muscle force assessment system to determine involuntary isometric torque of the human dorsiflexor muscle. It comprises the following main components: (1) a stabilizing frame with knee supports, (2) the torque plate with mounted boot to fix the foot which can be rotated between -40° and 40° , (3) a Wheatstone bridge strain gauge system that detects the evoked torque (not shown), (4) a stimulator/amplifier unit that can supply variable stimulus pulse amplitudes and pulse durations and can amplify the voltage changes from the Wheatstone bridge, and (5) a computer with data acquisition hardware and software for recording, analyzing, and displaying all signals (after [14.40])

torque, half-relaxation time, and others (Fig. 14.12, Table 14.3).

Such information is predicted to correlate with underlying physiological conditions and/or the presence of a myopathic or neuropathic disorder. The average torque generated by healthy control subjects varies

by less than 5% with repeated testing for contractions elicited from the muscle groups studied [14.5, 41, 42]. This assessment approach has utility in a number of research arenas, both clinical and nonclinical. Specifically, it has added clinical value in diagnosing neuromuscular disorders, tracking weakness due to disease progression, and quantitatively evaluating the efficacy of a therapy [14.38, 43–47]. Compared with MMT assessment methods, measuring isometric muscle torque generated by stimulation is quantitatively objective and reliable, and increases the types of patients that can be studied, including those under sedation [14.40] (Fig. 14.10). Stimulated muscle force assessment is particularly useful when studying patients with a known genetic disorder, because it can provide important information about genotype–phenotype associations [14.38].

The general configuration of the measurement system consists of the following main components:

1. A stabilizing device that holds the subject's limb in a defined position
2. A force transducer that detects the evoked torque produced by a specific muscle group
3. Hardware devices for nerve stimulation, signal amplification, and signal conditioning
4. A computer for stimulus delivery
5. Data acquisition software for recording, analyzing, and displaying signals (Figs. 14.10–14.13).

The stabilizing device system used in most of our previously published reports to study the ankle dorsiflexors is a modification of a previously described apparatus [14.4]. This device can be configured to maintain the subject's leg in a stable position while allowing access for stimulation of the common peroneal nerve lateral to the fibular head (Fig. 14.11a). The torque about the ankle joint, produced by the dorsiflexor muscles (i.e., primarily generated by the tibialis anterior with contributions from the peroneus tertius and exten-

Table 14.3 Contractile parameters calculated from stimulated muscle force assessment

Parameter	Units	Definition
Peak torque	N m	Maximum amount of torque developed
Contraction time	s	Time from onset of torque to time of peak torque
Half-relaxation time	s	Time from peak torque to time when torque decays to half of peak torque
Peak rate of development	N m/s	Maximum rate of torque development
Peak rate of decay	N m/s	Maximum rate of torque decay
Time to peak development	s	Time from onset of torque to the peak rate of development
Time to peak decay	s	Time from peak rate of development to peak rate of decay
Half maximal duration	s	Time when the generated torque is maintained at a level of half of the peak torque
Latency to onset	s	Time from the stimulus to the onset of torque development

Fig. 14.11a–d Various applications of stimulated muscle force assessment: (a) dorsiflexor muscles in a seated individual with stimulation of the common peroneal nerve lateral to the fibular head, (b) adductor pollicis muscle following ulnar nerve stimulation, (c) activated biceps force with motor point stimulation, and (d) head stabilizing/force system to study sternocleidomastoid muscle function following motor point stimulation (after [14.5,41,42])

Fig. 14.12a,b Prototypes of the next-generation dorsiflexor stimulated muscle force assessment systems

tor digitorum muscles), is then measured. One or two padded, adjustable clamps are used to maintain stability of the leg (knee slightly flexed in supine position or flexed at 90° while seated). Modified inline skate boots of varying sizes are affixed to the torque plate and adapted for either the right or left foot. The foot and ankle can be rotated within a 40° range while secured in the skate boot. The device can also be used for subjects in supine position, in which case the support frame is secured to the upper leg proximal to the knee (Fig. 14.10) [14.40,46]. More recently, our laboratories have initiated redesigns of these devices to make them smaller, lighter, easier to position on a given subject, and have an easier user interface to the computer and data acquisition control system (Fig. 14.12).

Fig. 14.13 An example of a typical data display available to the investigator during subsequent offline analyses. Graphically displayed are the muscle torque waveform and the stimulus administered (a double pulse with a 5 ms interpulse interval). Numerically displayed are various contractile parameters. Time 0 is the time of stimulation. The red line indicates the time when half of the peak torque has been generated. The display shown is the torque generated by the dorsiflexor muscles of a normal, healthy subject

A stabilizing apparatus for the arm and hand, used to measure muscle torque of the adductor pollicis, can be attached to the main stabilizing frame (Fig. 14.11b). Using straps, the forearm can be secured to the arm stabilizing unit, which can be adjusted for varying arm lengths. The digits (2–5) are placed in the hand well, and the thumb is secured to the constructed thumb bar attached to the torque plate. Shown in Fig. 14.11c is the configuration which is used to record force generated by the biceps muscle. This approach can also measure forces in the sternocleidomastoid muscle in the anterior neck [14.42], which can be used to study the effect of therapy in patients with cervical dystonia. As for the aforementioned muscles, force can be produced by peripheral nerve stimulation or by voluntary effort. In addition, motor point stimulation of the muscle itself with large surface electrodes has been employed [14.41]. The force of the isometric muscle

contraction is obtained as change in torque applied to the instrument torque plate.

Stimulated force assessment has been used to study patients with a wide variety of disorders including amyotrophic lateral sclerosis, Brody's disease, chronic inflammatory demyelinating polyneuropathy, malignant hyperthermia, muscular dystrophy, myotonia, periodic paralysis, and nerve conduction blocks. Recently, stimulated force assessment was employed by our laboratory to evaluate athletes with potential overtraining syndrome. The new insights to be gained by employing this approach in a variety of healthcare and biomechanics applications will improve clinical understanding of underlying pathophysiologies, provide an accurate means to determine clinical outcomes, and contribute to the overall knowledge of muscle mechanics.

Stimulated force assessment has limitations. First, it depends on the ability to easily stimulate nerves with

surface electrodes so that supramaximal activation can be achieved. Many muscles, and the nerves that supply them, are deep and cannot be activated with surface electrodes. Second, the muscles must generate torque on a limb in a measurable direction. This could be a challenge, for example, with back muscles that act

on a multiple-degree-of-freedom structure. Third, it assumes no spillover of the stimulus to antagonist muscles that would contaminate the force readings. Because of these limitations, not all muscles that can be tested by voluntary force assessment methods can be tested by stimulated force assessment.

14.5 Stimulated Muscle Force Assessment in Animal Models

To emphasize the versatility of this method, a specialized version of the device was constructed and used to study ankle dorsiflexor torques in hibernating black bears in the Rocky Mountains [14.48, 49].

Shown in Fig. 14.14 are recordings made in the field; in some cases, environmental temperatures were well below freezing. Black bears (*Ursus americanus*) stay inside their winter dens for 5–7 months of the year, dur-

Fig. 14.14a,b The force assessment system used in the field to study dorsiflexor forces in overwintering black bears (a). In this approach, we found that positioning the animals on their sides provided the most reproducible results. In panel (b), one can observe that the bear fur was shaved to allow for placement of the superficial stimulating electrodes

Fig. 14.15a,b Muscle force assessment in the laboratory setting. **(a)** Right hind limb of a canine secured to a force plate to record muscle torque. In this case, the nerve stimulation electrodes with clips and electrode optimize nerve/muscle activation. **(b)** Complete system of a computer, stimulation/force transducer unit, and the limb torque unit

ing which time their body temperature drops to about $> 5^{\circ}\text{C}$ below normal and they do not eat, drink, urinate, defecate, or show any other perceptible activity [14.48].

Although inactivity in humans (i. e., as a result of confined bed rest, weightlessness, or limb immobilization) leads to atrophy of skeletal muscle, loss of muscle tone, and impaired strength, the black bear does not suffer similar deterioration. We found that overwintering black bears lose less than 23% of their strength over 130 days, unlike humans who are weakened by a 90% strength loss over the same period [14.48]. When we employed stimulation protocols to study muscle fatigue behavior as we previously used in humans to diagnose mitochondrial myopathies [14.45], we observed that black bear fatigue profiles did not alter during the hibernation period [14.49]. Additionally, muscle contractile properties, including contraction time, half-relaxation time, half-maximum value time, peak rate of development and decay, time to peak force development, and time to peak force decay, did not change, indicating that obvious alterations in whole-muscle function occurred over the winter. This study further supported our findings that black bears have a high resistance to atrophy despite being subjected to long-term anorexia and limited mobility [14.48, 49].

Our group has also designed and constructed force assessment systems that have been used to study force properties in various animal models for muscle disorders. Additionally, we have used these methods to evaluate drug and anesthetic effects, hypermetabolism (e.g., malignant hyperthermia), and compartment syndrome. Shown in Fig. 14.15 is the device that we have developed to perform muscle force assessment in large mammalian models (canine and swine) in the laboratory setting; as with the human systems, it is important to stabilize the leg.

Most methods to assess murine (mouse) muscle function are highly invasive and do not allow for long-term testing in a given animal. Our laboratory de-

Fig. 14.16 **(a)** Device setup employed for noninvasively studying leg force properties in a mouse, **(b)** leg setup and electrode placements, and **(c)** online LabVIEW program display of measured forces (after [14.50])

scribed a novel murine assessment system developed to measure skeletal muscle contractile properties on multiple occasions over time in intact animals [14.50] (Fig. 14.16). In control mice, we measured less than 8% day-to-day variability and also detected a difference ($p < 0.003$) in peak twitch tension (P_t) due to cardiotoxin-induced muscle damage.

Duchenne muscular dystrophy (DMD) is a devastating disease caused by degeneration of striated muscle

due to the absence of dystrophin. In this study, when control mice were compared with dystrophic mice (MDX), differences in normalized torque and P_t per body weight were detected ($p < 0.003$). The use of stimulated muscle force assessment in mouse models will be useful for investigators testing the efficacy of novel therapies for DMD because it can noninvasively take measurements at different time points and can sensitively detect differences in function due to pathology.

14.6 Conclusion

The assessment of a patient's muscle strength is an important vital function. Strength assessment is necessary for determining distribution of weakness, disease progression, and treatment efficacy. The particular assessment approach utilized is dictated by the clinical circumstance or the severity of illness. Several assess-

ment techniques are currently available to the healthcare provider and researcher, each with their unique attributes. As outcomes-based medical practice becomes the norm, the need for quantitative outcomes assessment of muscle strength will grow, and stimulated muscle force assessment may become increasingly important.

Digital Radi

15. Digital Radiography

Lothar Heuser

Digital imaging was developed and initially used in astronomy. Computed tomography (CT) was the first digital modality used in radiology, followed by magnetic resonance imaging (MRI), digital subtraction angiography (DSA), and phosphor storage plates (computed radiography, CR).

A digital image consists of a certain number of picture element cells called pixels which are arranged like a chess board in rows and columns. Matrix sizes range from 512×512 up to 4000×4000 pixels. The grey levels are stored as binary numbers in a range of 8–16 bits (= binary digits).

In conventional film/intensifier screen radiography, the film fulfills all the roles of detector, display medium and long term storage. In digital radiography, separate units for detection or data acquisition, display, and storage are required.

There are certain advantages to the digital image, including lossless reproduction and duplication, and postprocessing, i. e., window setting, enlargement, edge enhancement, as well as subtraction and integration procedures. Advantages in workflow management are transport over networks and connectivity to radiology (RIS) and hospital information systems (HIS).

as well as their special applications, are described in particular in this chapter.

15.1 Historical Background

Ever since the discovery of x-rays, film has been used as the imaging medium in projection radiography. Digital imaging techniques were developed for astronomical photography and analysis. Computed tomography (CT),

invented in 1973, was the first radiological modality which used digital imaging techniques. This was enabled by the development of more powerful, less space-consuming computers and the fall in prices of micro-

electronic devices. Compared with recent systems, processing speed and capacity were very low. Therefore, the first scanners, dedicated to skull and brain imaging, used a small imaging matrix of 64×64 pixels. In the first whole-body scanners, the matrix was extended to 128×128 pixels. Spatial resolution was significantly lower as compared with conventional x-ray films, but the dynamic range, i. e., contrast resolution, was more than a hundred times higher.

The introduction of this new technology caused a new problem: in conventional x-ray technology the film was both image detector and long-term storage simultaneously. Rapid-access media for long-term storage of CT data did not yet exist. Due to the low capacity of hard-disc drives, CT data had to be stored on magnetic tapes. The latter were not suitable for long-term storage and had the additional disadvantage of delayed access to stored images. Therefore, CT images had to be copied to Polaroid films and to conventional x-ray films.

Magnetic resonance tomography (MRT) was the second digital imaging modality introduced to clinical radiology, in 1976. Data acquisition was different from CT, but the algorithms for image reconstruction were similar. The image matrix was also quite small, and conventional x-ray films were used for storage.

Secondary digitization of fluoroscopic images led to the development of digital subtraction angiography (DSA), in 1981. The capacity and performance of computers had extended in the meantime, and the imaging matrix could be expanded to 512×512 pixels. Digital fluoroscopy, the variant without subtraction, used a matrix of 1000×1000 and later even 2000×2000 pixels. The dynamic range was 10 bit, corresponding to 1024 gray scale steps.

Digitalization of conventional projection radiography was achieved by the introduction of digital image

plates in 1984, which used cassettes with the same formats as conventional x-ray films.

Digital image plates were developed from image intensifier screens used together with x-ray films. In intensifier screens, absorbed radiation energy is completely converted to light, whereas in image plates that use storage phosphors the absorbed energy can be stored and then released by a laser readout process (photostimulable luminescence). Matrix size was 2000×2000 in the first system, with dynamic range of 10 bit. Although the spatial resolution of photostimulable phosphor plates was significantly worse compared with conventional film–screen combinations, monitors able to display the full 2000×2000 pixel matrix did not exist at that time. Therefore, images had to be printed out on conventional films for analysis and storage. The hardware required for image processing was quite expensive, and there were no options for dose reduction. These obvious disadvantages hindered the early spread of computed radiography. After expansion of the matrix to 4000×4000 pixels, photostimulable image plates could be used for all diagnostic purposes.

The introduction of flat-panel detectors in 2000 led to the development of fully digitalized x-ray systems. Due to their better dose quantum efficiency (DQE), dose reduction could be achieved as compared with conventional film–screen combinations. Further advantages were the instant availability of images and the avoidance of transport of the cassettes to the reading station. The matrix consisted of 3000×3000 pixels.

Today, digital imaging technology is realized in the majority of radiological departments, creating a filmless workflow. Technical advances and price reductions of hardware and storage media are the reasons why digital imaging now does not suffer from any disadvantages compared with conventional film-based imaging.

15.2 From Analog to Digital Image

In an analog image, the fluoroscopic screen or the film serves as the detector. The generated signal is proportional to the radiation dose. Within the first 100 years of the discovery of x-rays, the conventional detectors consisting of film and intensifier screens were optimized. For fluoroscopy, image intensifier systems were developed. Both resulted in a marked decrease of radiation dose.

15.2.1 Spatial Resolution, Dynamic Range, and Dose Quantum Efficiency

Spatial resolution, grayscale dynamic, and dose quantum efficiency are the most important criteria for a digital image detector system. Optimized film–screen combinations with light emission adapted to the color of the film base were regarded as the most dose-effective

Fig. 15.1 Gradation curve of the film (0 – fog; I – toe; II – linear part; III – shoulder; IV – solarization)

detector systems. There was a reciprocal relationship between sensitivity and spatial resolution, i.e., the larger the grain size of the intensifier screen, the higher the sensitivity and the worse the spatial resolution. X-ray film contains 220 000 silver bromide grains per

cm², which serve as picture elements. The dynamic range (latitude) of the film is limited by the maximum optical density that can be generated by exposure. The special criterion of the film is its gradation curve (Fig. 15.1). Proportionality between the radiation dose and attenuation exist only in section II of this curve. This results in about 40 gray levels. Special low-grade films can display up to 80 gray levels.

Digital images do not suffer from this limitation. They utilize a matrix of discrete numerical values to represent the image. This set of picture element cells (pixels), which are arranged like a chessboard in rows and columns, is called the matrix (Fig. 15.2). Used matrix sizes range from 512×512 (262 144) up to 4000×4000 pixels (Fig. 15.3). The gray levels are stored as binary numbers in a range of 8–16 bits (binary digits). Smaller numbers of gray scale levels (8 bit) are used for ultrasound imaging and laser film printing, and 10–14 bits are used for digital fluoroscopy and digital radiography. Since monitors can display only 64 gray levels (6 bit) and the human eye can resolve only 16 gray levels (4 bit), special window settings are

required to display the whole latitude of a digital image [15.1].

15.2.2 Differences Between Analog and Digital Images

Organization

In conventional film screen technology the film serves as detector, display medium, and storage medium. These three functions are separated in digital technology. Image intensifiers, photostimulable phosphor plates, and flat-panel detectors with direct or indirect conversion are used as detectors. They all generate analog electric signals that have to be converted into digital signals by an analog-to-digital converter (ADC). The raw data of the digital image are specially processed for perception by the human eye and can then be displayed on a monitor. For short-term storage, a hard-disc drive (HDD) in the processing unit is used, while for long-term storage the data have to be transferred to a redundant array of independent discs (RAID) or saved onto a magneto-optical disc, compact disc (CD) or digital versatile disc (DVD).

Digital Image Parameters

As mentioned above, the gray scale dynamic range of a digital image is significant larger than that of film. However, the spatial resolution of film is significant better; for example, a 30 × 40 cm image plate contains 16 000 000 pixels in a 4000 × 4000 matrix. An x-ray film of the same size contains 264 000 000 grains of silver bromide that serve as picture elements. Since the overall resolution is a product of spatial resolution and latitude, all relevant details can be displayed on digital images. Expanding the matrix causes additional problems: First, computer performance and storage capacity have to be improved. Second, if all other parameters stay unchanged, the signal-to-noise ratio (SNR) decreases, as shown in Fig. 15.4. To com-

Fig. 15.4a,b Effect of image matrix on noise. (a) Enlarging the image matrix size to 64 pixels. (b) 16-pixel matrix. The number of image points without information increases from 6 to 50

pensate for this disadvantage, tube loading, the DQE of the detector system, or the readout process can be altered.

Many studies have compared exposure levels and image quality in conventional and digital radiography. In conclusion one can state that:

- Using equivalent exposure, diagnostic information from digital radiography is superior to conventional radiography.
- For equivalent image quality, digital radiography requires less exposure than conventional radiography.

Digital radiography has certain advantages in terms of exposure. The gray levels of the image are normalized (signal normalization), and the brightness of an image does not depend on the absorbed dose (Fig. 15.5). Therefore, there is no loss of contrast in case of over- or underexposure, unlike in conventional films, and un-

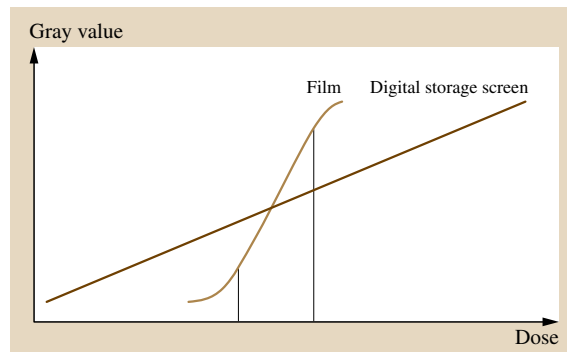

Fig. 15.5 Signal behavior with films and with digital storage screens

Fig. 15.6a–d Illustration of a skull specimen with four different exposure doses (a–d). Image (d) was obtained using a radiation dose 500 times higher than image (a). Image brightness and contrast remain constant under exposure doses that vary by several orders of magnitude. An excessively high dose (d) can no longer be recognized visually based on the brightness or contrast of the image ▶

der special conditions the exposure dose can be reduced (Fig. 15.6). However, too much reduction of dose will certainly result in increased noise and loss of detail information (Fig. 15.7). On the other hand, overexposure results in an unnecessarily elevated dose to the patient but is not seen directly in the digital image, unlike on conventional films.

Image Reproduction, Image Processing, and Image Postprocessing

The storage of a digital image as a binary-coded dataset has many advantages: Lossless reproduction and duplication are possible. Brightness and contrast can be adjusted for optimal perception by the viewing eye, which may be very useful in case of large differences of contrast or attenuation. Image processing means gray scale processing, edge enhancement, as well as subtraction and integration of frames. A main application is DSA.

In summary, digital imaging has the following fundamental differences from conventional cassette-based film–screen systems [15.2]:

- Decoupling of image acquisition, presentation, and storage, requiring further investments in workstations, storage devices, and picture archive and communication systems (PACS)
- Large dynamic range, with no effects of over- or underexposure
- Brightness and contrast can be modified independently of the absorbed dose of the digital system
- Risk of unrecorded overexposure due to signal normalization
- Image quality and detail resolution depend on the quality of the detector and display systems.

Fig. 15.7a,b Signal normalization in digital radiography. Radiographs of a femur specimen. (a) The dose was halved while keeping the other radiation parameters constant. The brightness remains unchanged, but there is a noticeable increase in image noise and a decrease in recognizable details ▶

15.3 Digital Imaging Systems in Radiology

Figure 15.8 shows a comparison of the different digital detector systems used in radiology.

15.3.1 Digital Image Intensifier Radiography and Conventional DSA

In digital fluoroscopy and conventional DSA, an analog image is generated on a fluoroscopic screen and is enhanced by a factor of 300 by an image intensifier. It appears rotated by 180° and demagnified on the output screen. Conversion into an analog video signal is performed either by a tube operated camera (Vidicon) or charge-coupled device (CCD) chip. So far, this forms a complete x-ray image intensifier chain. The analog signal is then converted into a digital signal by an ADC and sent to a processing unit (Fig. 15.9). For a long

time, display on a monitor required reconversion to an analog signal. Today, digital monitors are available for direct display. Matrix sizes are 1000 × 1000 for a series of frames and 2000 × 2000 for single images. Compared with conventional film–screen technology there are advantages in terms of image processing, reproduction, duplication, as well as transport and archiving. Spatial resolution is limited by the resolution of the image intensifier and the matrix size.

In conventional DSA the image is also generated in a conventional intensifier chain and digitized. Processing is performed as a mask technique, with the first frames of a series prior to contrast injection serving as masks that are subtracted as single or integrated images from the frames after contrast injection. In this way, structures that are common to both the mask and post-

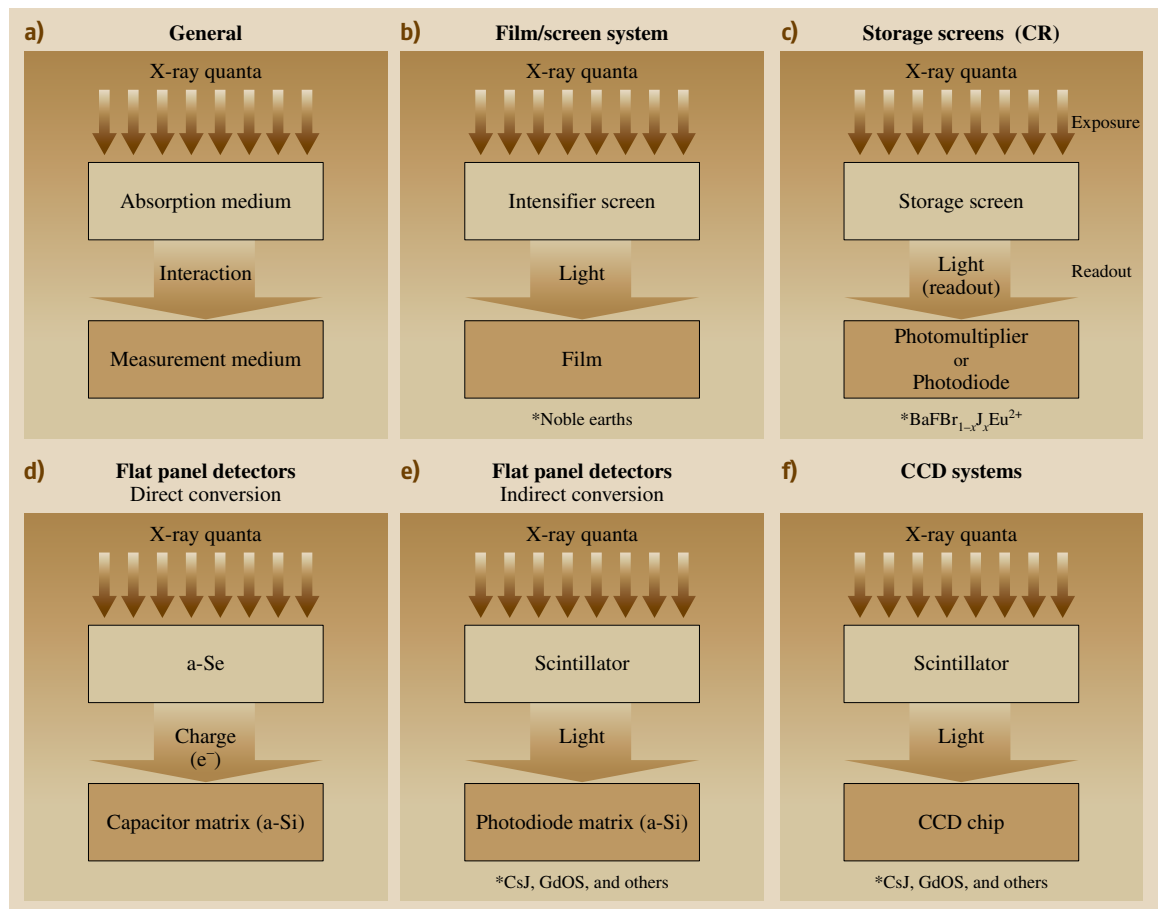

Fig. 15.8a–f Comparison of the various detector systems and their working principles (after [15.3])

Fig. 15.9 Schematic illustration of digital image intensifier radiography. The analog image is generated in an x-ray image intensifier–television chain, and is then digitized by an analog-to-digital converter (ADC). Image processing takes place on a computer. Thereafter, transmission and storage can proceed. Conversion back into an analog signal (digital-to-analog converter, DAC) is required if the image is to be displayed on analog media (after [15.4])

contrast image are removed. The resulting (subtracted) image contains just the contrasted vessels (Fig. 15.10). The difference signal is additionally amplified, which results in enhanced contrast. Since the images are stored as binary digital datasets, the whole process is performed in real time and circulation of contrasted blood can be watched on a monitor.

This technique yields the following advantages:

- A reduced amount of contrast medium is required compared with film angiography, with a corresponding reduced risk of contrast-induced adverse effects
- Display of vessels without overlay of other structures, which is especially useful in the skull base where arteries cross dense bony structures
- Utilization of negative contrast media such as carbon dioxide for vascular imaging (Fig. 15.11), which can be used in patients with contraindications for iodine contrast media.

DSA is sensible to voluntary and involuntary movements (heart beats, bowel movements) of the patient.

These cause a shift of the structures that undergo subtraction between the mask and postcontrast images. The resulting artifacts can degrade image quality to such a degree that vessel analysis becomes impossible. There are two solutions to this problem: remasking and pixel shift. In remasking, a different mask, probably closer to the contrast frames, is chosen. By using this technique, the time interval for movements is reduced, resulting in fewer artifacts. Movements after contrast injection cannot be eliminated by this method. Using the pixel-shift method, the mask and contrast images are shifted with respect to each other by pixels or subpixels until the anatomic structures match up. In most cases, this technique leads to a marked improvement in image quality.

15.3.2 Digital Storage Screens

Digital phosphor storage plates have a similar structure to intensifier screens. The storage medium (for example, BaF) is applied as a powder on a polyester base. However, in contrast to intensifier screens, in phosphor

Fig. 15.10 Schematic illustration of mask technology (*top row*) and original images (A. carotis interna) in DSA

Fig. 15.11 (a) Digital subtraction angiography with CO₂ in a patient with kidney transplant. (a) Unsubtracted image after injection of 50 mL CO₂. (b) Subtraction image. The quality of vascular imaging is comparable to that with positive x-ray contrast medium. This method is suitable for patients with contraindications to iodine-containing contrast media

image plates only a small fraction of the released electrons are converted to visible light. The major part of the generated free electrons are stored at a high energy level. This is achieved by the phosphor being doped; i. e., it contains impurities of another element (europium) which modifies the crystal lattice structure, forming electron traps. Instead of falling back to their ground state by emitting fluorescent light, the electrons ex-

cited by exposure to x-ray quanta remain at a higher metastable energy level (Fig. 15.12). This state persists for several hours. In the readout unit, the screen is removed from the cassette and scanned point by point by a fine laser beam. The electrons now emit fluorescent light and return to their stable original state. The emitted light is measured by photomultipliers, converted into electric signals, and digitized (Fig. 15.13). After the

Fig. 15.12 Schematic illustration of energy changes during the exposure and readout process of a digital luminescent screen

readout process, the screen is erased with bright visible light and loaded into the cassette for the next exposure. As in conventional intensifier screens, the system suffers from the problem of the reciprocal relationship between sensitivity and image sharpness; i. e., a thicker conversion layer is more sensitive, but the increased scattering of light quanta results in lower image sharpness. This scattering by the luminescent layer needs to be minimized as far as possible, which is achieved partly by dyeing it and partly by using special binders (e.g., a synthetic resin varnish).

The computer generates a raw data image, which is processed further using special programs. Depending on the type of processing, the result is either an image

similar to the one obtained using conventional film or a version with edge enhancement. Moreover, steeper or flatter gradients can be created through special look-up tables (LUT). Whereas early systems started with a 2k matrix, matrix sizes of 4k are common today. The system is used both in x-ray cassettes and as a built-in device in complete x-ray units (e.g., chest imaging systems for standing patients). The detector's input dose is 2.5 μGy , i. e., comparable to that of a screen-film system of sensitivity class 400 [15.2].

The advantages of this method are:

1. The use of normal cassette formats allows direct replacement of film cassettes by digital cassettes

Fig. 15.13 Schematic illustration of the readout process of a digital storage screen. The laser beam's point-by-point scanning releases the trapped electrons, and the light emitted as a result is fed to the photomultiplier either directly or by means of a mirror. It is converted in the photodetector into an electric signal

Fig. 15.14 Schematic illustration of the readout process using the dual scanning method. Unlike a simple readout process, the luminescent screens have a transparent carrier layer such that the readout process can be performed by photomultipliers on both sides

without the x-ray facility having to be upgraded or converted.

- Signal normalization always results in correct exposure, i.e., the brightness and contrast remain unchanged even under large dosage jumps. Major dose reductions, however, are not possible with these systems with the exception of a few situations, as increased noise causes loss of image details.

A further development of this method consists in *dual scanning* (Figs. 15.14, 15.15). By using a transparent carrier material, readout is possible from both sides with an additional photomultiplier, which leads to better SNR and a 40% DQE increase [15.5, 6].

Storage Screens with Needle Image Plates (NIP)

Instead of a powder as the luminescent material, a further development of storage screen technology uses CsBr needle crystals (Figs. 15.16, 15.17). The luminescent light is guided inside the crystal needles, which function as optical fibers, thus minimizing lateral diffusion of the light. The detector layer is correspondingly thicker, thereby increasing dose efficiency while maintaining the same spatial resolution. During the readout process, there are further benefits due to deeper penetration of the laser readout beam into the luminescent layer, which ultimately reduces image noise [15.7]. Since the configuration and arrangement of the crystal are very similar to those of planar image detectors, the

DQE is improved. This results in a dose decrease of up to 50% compared with powder image plates [15.7, 8].

15.3.3 Digital Flat-Panel Detectors (Planar Detectors)

Flat-panel detectors are built-in components of x-ray units. This means that the detector is connected online to the computer using either a cable or a wireless system [wireless local area network (WLAN), Bluetooth, etc.]. Whereas cassettes with digital storage screens, similar to screen-film cassettes, have to be removed from the cassette holder after exposure and transferred to the reading device, in direct radiography with flat-panel detectors the image is available within a few seconds. Two types of flat-panel detectors have been developed: with direct and indirect energy conversion. In direct energy conversion, x-ray quanta are converted directly into an electric signal, whereas in indirect energy conversion fluorescent light is generated, then converted into electric signals by photodiodes. The feature common to both methods, however, is an active matrix made of capacitors and thin-film transistors (TFTs), consisting of amorphous silicon and acting as a switch for spatial coding (Fig. 15.18).

Detectors with Indirect Energy Conversion

Incoming x-ray quanta generate visible light in a scintillator made of cesium iodide or gadolinium oxysulfide.

This light is converted into electric signals below the scintillator in a matrix of photodiodes made of amorphous silicon. One problem with this method is posed by scattering of light in the scintillator, leading to signal spreading and thus adversely affecting spatial resolution. This problem, however, can be minimized by forming the cesium iodide (CsI) crystals in the shape of needles, so that they behave like optical fibers and permit directional transmission of light. Systems with indirect conversion (optodirect systems) show the highest quantum efficiency among all digital detectors in the field of skeleton radiology (55–70 kV) (Fig. 15.20). At 70 kV, the DQE can reach 65%. The detector input dose required for posterior–anterior chest x-rays is in the range of 1–1.5 μGy , which is comparable to a screen–film system of sensitivity class 800.

Detectors with Direct Energy Conversion

The direct method dispenses with the intermediate step of light conversion. Electric charges are generated directly through the absorption of x-rays in the 500 μm converter layer made of amorphous selenium. The schematic layout of such a detector is shown in Figs. 15.18 and 15.19.

An applied high voltage causes electron–hole pairs generated by the x-rays to separate. Under the selenium layer there is a matrix of collecting electrodes, which define the individual pixels. Below each electrode there is a capacitor for charge storage and a switching tran-

Fig. 15.15 The Fujifilm FCR PROTECT CS readout unit. The system operates with four drawers for different cassette formats

Fig. 15.16a,b Scanning electromicrographs of the conversion layers of a conventional screen with powdered luminescent material (a) and a needle crystal screen (b). The crystals behave similarly to optical fibers and reduce light scattering. They have a better DQE

Fig. 15.17 Agfa DX-G readout unit for needle crystal screens and conventional luminescent screens

sistor for readout. The DQE of systems with direct conversion (electrodirect systems) is lower in this range, but in the range 20–30 kV it is higher. In addition, these systems have the advantage of higher signal in

the case of small, high-contrast structures, therefore being especially suitable for digital mammography. However, they are used in automated chest x-ray workstations also, despite the poorer DQE in the hard beam range.

The first direct detectors used in radiology were CCD systems. Since CCD chips are only 2–4 cm² in size, the recording format needs to be decreased correspondingly with a lens or with fiber optics, which leads to considerable reductions in dose efficiency and image quality. Alternatively, CCD chips can be mounted in a linear array, and the image compiled sequentially from full-format rows (the slot-scan method). This slot technology decreases the scattered radiation to such an extent that a grid can be dispensed with. The resulting decrease in dose compensates as far as possible the lower DQE encountered in CCD technology [15.9].

The advantages of direct detectors over storage plate systems consist of higher dose efficiency (at least in the case of powder-coated storage plates) and in a higher performance speed, enabling display of the recorded image within a few seconds, which facilitates monitoring of critical patients and enables a higher examination frequency (Fig. 15.21). Nowadays, there also exist mobile devices with a portable detector which transmits

Fig. 15.18 Illustration of the active matrix and the characteristics of a detector with indirect energy conversion

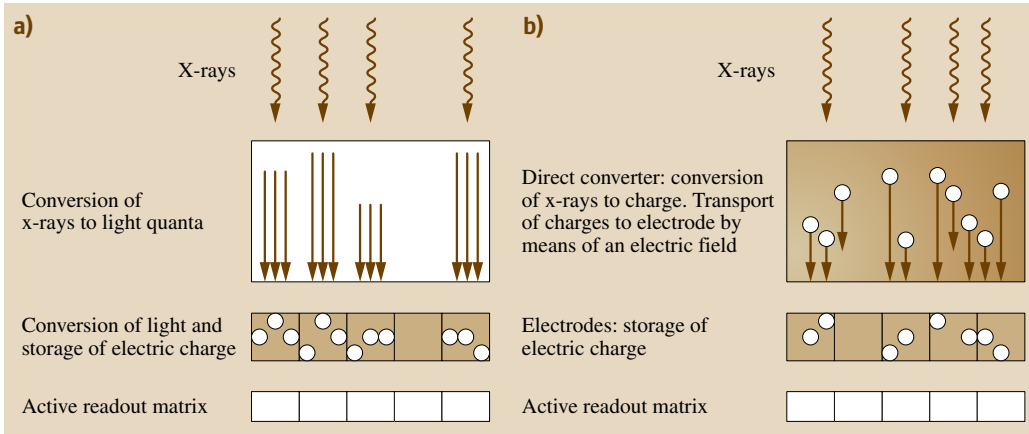

Fig. 15.19a,b Schematic illustration of the working principle of planar detectors with indirect (a) and direct (b) energy conversion (after [15.10])

image data either over a cable or using a wireless system. Thus, when x-rays are taken in the operating theater or in the intensive care unit, this information is made available directly afterwards. On the downside, this system suffers from higher procurement costs (by a factor of 3–4).

Flat-Panel Detectors for Fluoroscopy and Angiography

Flat-panel detector technology has advantages when compared with image intensifiers also, and has displaced them in newer angiographic units. Depending on the field of application (interventional radiology, neuro-radiology, cardiology), detectors are available in various sizes, as single- or dual-plane systems.

As in static radiography, flat-panel detectors for angiography and fluoroscopy exist as detector types with indirect and direct x-ray conversion, as already described above. For the x-ray spectrum used in angiography and fluoroscopy, cesium iodide (CsI) offers considerable advantages as compared with selenium due to the higher atomic number of the elements involved. This means a higher DQE and results in a better signal-to-noise ratio. The technical requirements imposed on flat-panel detectors for dynamic applications are significantly greater than those in static radiography. In particular, the demands in DSA, dual-plane x-ray serial angiography, and fluoroscopy in terms of minimizing the dose pose special challenges for DQE, image readout speed, and the temporal resolution of dynamic

Fig. 15.20 Signal intensity as a function of quantum energy for direct energy conversion with amorphous selenium (Se) and for indirect conversion with cesium iodide (CsI) and gadolinium oxysulfide (Gd₂O₂S). It is evident that the latter detector has a better signal yield in the kV range for skeletal diagnostics, whilst the selenium detector is superior to detectors with indirect energy conversion in the mammography soft beam range

Fig. 15.21a,b Planar detector (TrixeLL) in the Siemens Axiom Aristos x-ray unit. The advantages of direct radiography are evident. The image appears on the monitor a few seconds after exposure

flat-panel detectors. One of the main problems is the readout process, which should be made as short as possible to avoid blurring through movement during the exposure. The duration of the readout process, however, affects the DQE. Pixel sizes lie between 150 and 200 μm . Image frequencies range from single images to 60 frames/s (in pediatric cardiology).

Compared with conventional x-ray image intensifiers, flat-panel detectors offer several technical advantages [15.10], such as:

- Homogeneous image quality across the entire image area (no distortion, by the Earth's magnetic field)
- Better imaging in high contrast (e.g., catheter tips, guide wires, etc.)
- Higher linear dynamic range (C-arm CT)
- Better transmission of contrast differences [higher modulation transfer function (MTF)]
- Higher DQE
- Square or rectangular geometry of the x-ray-sensitive surface [advantageous for three-dimensional (3-D) reconstructions]
- Low volume and therefore geometrical layout (Fig. 15.22) can be used in environments with strong magnetic fields (magnetic navigation).

C-Arm CT (Planar Detector CT, PD-CT)

The first reports on attempts to acquire projection data across a 180° fan beam angle go back to 1997–2001 [15.11, 12]. They were performed with C-arm systems equipped with conventional image intensifiers. The smaller dynamic range, image distortions, and susceptibility to interference from magnetic fields during rotation limit the performance of image intensifiers as detectors for CT systems and prevent their use for classic CT-type applications such as imaging of soft-tissue structures [15.13]. Therefore, image intensifier-based systems have been used only for high-contrast imaging and for 3-D rotation angiography (3-D DSA) [15.11, 12, 14, 15]. It may be assumed that these systems will gradually be replaced by PD-based C-arm CT systems (Fig. 15.23), since

Fig. 15.22 C-arm angiography unit with planar detector (Axiom Aristos, Siemens). The physical dimensions of the detector are small

Fig. 15.23 (a) Rotation angiography image of the A. carotis interna. (b) 3-D reconstruction with the image of a small aneurysm (*arrow*)

Fig. 15.24a,b Circumscribed cerebral hemorrhage with conventional CT (a) and with C-arm CT (b). The image quality of the C-arm CT is virtually identical to that obtained using the conventional method (after [15.16])

they offer higher dose efficiency and better image quality.

Generation of 3-D DSA images through PD-CT during an intervention is already very common [15.16–18]. Compared with image intensifier-based systems, PD technology offers significantly better soft-tissue imaging, resulting in images similar to spiral CT (Fig. 15.24).

PD-CT is also referred to as cone-beam CT. It requires special image reconstruction methods, due to the pronounced divergence of the lateral rays. The reconstruction method of choice is the Feldkamp al-

gorithm [15.19]. In principle, high image quality can only be ensured for the central layer corresponding to the central beam. Image quality decreases for regions outside the central layer, and artifacts increase with increasing distance from it. These artifacts are generally referred to as cone-beam artifacts [15.20]. To avoid them, accurate reconstruction algorithms are necessary, in general requiring high computing power and not yet being practical for everyday applications. However, their eventual use is becoming ever more realistic with ongoing advances in computer technology.

15.4 Digital Image Processing

The raw data image generated by the detector is inadequate for imaging purposes. Artifacts must be elimi-

nated and the information processed in order to generate a high-quality image. This requires robust programs that

Fig. 15.25a,b Effect of image processing. (a) The raw image data from a digital cassette (CR)/direct radiography (DR) system cannot be utilized diagnostically. (b) After processing with MUSICA 2 software (Agfa), imaging of bone and soft tissue contrast is optimized

provide constant brightness and contrast and that are adapted to the specific organ of interest (Fig. 15.25).

In planar detectors, there exists the problem that the crystals are not of uniform length (production tolerances) and, for this reason but also due to other errors, provide variable signal intensities. These distracting effects are eliminated by flat fielding, in which all the pixels are allocated individual correction factors. Offset effects associated with pixels are captured with dark-field images (image data acquisition without radiation) and corrected also. Differences in pixel sensitivity and variations in the signal amplification of pixels can be corrected with flood field images (image data acquisition with constant, homogeneous radiation across the entire detector area). The greatest challenge for image processing software consists in the identification of those pixels that require correction [15.21]. Nonfunctioning pixels are easy to identify (through appropriate limits being placed on the offset and gain), using the specified procedures. Partially functional pixels and those with nonlinear response are not affected by these methods. If, on the other hand, the offset and gain limits are set too narrowly, normal pixels are falsely identified as defective. Another very widely used method for eliminating bad lines (line artifacts) or speckle noise caused by pixel defects is the median filter [15.22], where the defective pixel is replaced by the median of the neighboring pixel values.

15.4.1 Frequency Filtering

Digital image processing is used, on the one hand, to compensate for the nominally lower spatial reso-

lution of digital systems (MTF restoration), and on the other, to exploit the intrinsic advantages of digital detectors; for example, in chest x-rays, as a result of digital reduction of the dynamic range [dynamic range reduction (DRR) or dynamic range compression (DRC)], good contrast is maintained in the lungs and improved transparency and contrast are obtained in the mediastinum [15.3]. This overcomes an inherent drawback of conventional radiography, namely the inverse relationship between contrast and dynamic range. In addition, appropriate filtering creates the effect of local contrast enhancement, which facilitates recognition of low-contrast structures but allows image characteristics to deviate more strongly compared with conventional x-ray images. For this reason, such procedures for local contrast enhancement or structure emphasis (frequency modulation) should normally be used cautiously.

As a general rule, the same image processing algorithms are used for flat-panel detectors as for storage screen systems. However, there exist differences depending on the manufacturer, both in terms of features and standards and in terms of the underlying filtering. In chest x-rays in particular, it is important to adjust the image processing characteristics of different imaging systems and manufacturers uniformly where they operate alongside each other, so as not to impair the image analysis in control examinations. In systems with blurred mask filtering, a large filter kernel should be selected for dynamic compression and harmonization and only a low weighting factor (0.5) used. DRC, DRR, and comparable algorithms are mostly not as susceptible to processing errors as edge-emphasizing filters. The latter, in particular, can distort the image characteristics

(excessively emphasizing vascular structures) and then mask spot or area shadows.

15.4.2 Multifrequency Filtering

Multifrequency filtering is offered nowadays by many companies, e.g., as multiscale image contrast amplification (MUSICA) by Agfa, UNIQUE by Philips, or multiobjective frequency processing (MFP) by Fuji. These are complex image processing methods that permit contrast enhancement while taking into account the original contrast and the size of the object being imaged (spatial frequency composition) [15.23–26]. By selecting the filter parameters appropriately, low-contrast structures (hard to recognize in the original image) can be enhanced and high-contrast ones (those that are easily recognizable) reduced in contrast accordingly [15.4]. In summary, through multifrequency filtering, the low image noise in direct radiography makes it possible to optimize display of even the smallest or low-contrast structures without limiting the resolution by superimposed image noise [15.27].

15.4.3 Dual-Spectrum Radiography (Energy Subtraction) and Temporal Subtraction

Two different techniques have been developed for energy subtraction: the single-exposure dual-detector and the dual-exposure single-detector techniques.

In the single-exposure dual-detector technique, there is only one exposure on two detectors positioned

one behind the other, separated by a filter (Cu). This creates one exposure with an unfiltered spectrum and a corresponding percentage of low-energy quanta, and one with a hardened spectrum in which the higher-energy quanta predominate.

The dual-exposure single-detector technique needs only one detector. Two exposures are made, one at tube voltage of 120 kV and a dose corresponding to a 400 system, and one at 60 kV and a dose corresponding to a 1000 system. This technique has been employed in chest x-rays for detection and characterization of calcified loci [15.28–30]. Although this results in diagnostic advantages compared with conventional x-rays, so far this technique has failed to enter routine practice, since it does not solve the main problem in the diagnosis of focal pulmonary lesions, namely distinguishing between benign and malignant ones.

Temporal subtraction has been used to assess new lesions and changes that have occurred since the last examination, relying on direct comparison with previous x-rays [15.31]. After using software algorithms developed specially to achieve optimally artifact-free subtraction (iterative image warping), changes appear in the differential image as dark (increase) or bright (decrease) spots. Temporal subtraction has proved to be of benefit in the detection of isolated focal lesions and of low-contrast, multifocal, blotchy changes, and in the follow-up of extensive changes [15.32, 33]. Low-contrast lesions and lesions in obscured locations (e.g., infraclavicular) were diagnosed more efficiently by employing this technique.

15.5 Image Communication and Archiving

A further advantage of digital image technology is that digital datasets can be transmitted over data lines. The corresponding global standard data format is called diagnostic imaging and communication (DICOM). The transmission speed depends on the network's bandwidth. One must remember that transporting conventional films involves human resources, and that these resources are in short supply in today's hospitals. This creates difficult issues even for emergency staff. The problems multiply when moving x-ray bags between various departments or hospitals by post, by taxi, or by means of public transport. Therefore, image transmission over a data network from the imaging system to the referring physician is the only practical solution for

achieving an efficient workflow. This has led to the development of local data networks in hospitals and medical practices. Regional networks that link medical institutions exist also and are being constantly expanded.

A similar situation applies to archiving of images. Conventional films require the building of heavy archival systems that take up considerable space. Bearing in mind that rapid developments in CT and MRI have increased the number of individual images by a factor of 10–100, it is easy to see that neither budgets for films nor space for the growing archives are available. The digital archive requires only a fraction of the space taken up by conventional systems. The initial high costs needed for storage media have long since

dropped to such an extent that digital archiving always comes ahead in any comparison. The real advantage for staff arises from the fact that images in a digital archive are sorted alphanumerically and can be retrieved at any time. The time-consuming search for films, e.g., for a particular therapy – the critical point in bygone days – is no longer required.

Special picture archive and communication systems (PACS) have been developed for radiology. They are designed to support not only image communication and archiving, but also the workflow in radiology departments. This means that such a PACS needs to be able to do more than just storing, archiving, and distributing the data generated by the various imaging modalities. What is needed, rather, is interfacing and communicating with the radiology information system (RIS) and/or the hospital information system (HIS). Communication with the RIS and HIS takes place across an HL7 interface, while interfacing to the modalities is via special DICOM protocols. Normally, the workflow proceeds as follows.

15.5.1 Example 1 – Hospital Outpatient or Patient at a Doctor's Surgery

1. The patient's first contact is the central admission counter. Here, the master data are recorded and sent by the HIS to the RIS. In the case of an ambulatory practice, the master data are entered directly into the RIS.
2. The radiology job is generated in the RIS, and sent via the DICOM worklist server to the appropriate modality, where it appears on the worklist. Depending on the system and configuration, a prefetching order is also sent to the archive server to fetch any previous examinations of the patient.
3. The master data are sent automatically to the modality, so that the examination can be performed.
4. Once the examination is completed, the generated images are sent to the PACS and the examination data to the RIS.
5. The radiologist's workstation normally consists of three monitors: two for image viewing and one for RIS data, which enables analysis of images stored in the PACS and comparison with previous examinations or other modalities. Other add-ons include digital dictation and voice recognition, also implemented in the RIS.
6. Images and diagnoses can be stored on a CD/DVD and given to the patient. Hard copies on film or paper can also be made.
7. Images are stored initially on the PACS server, where they are kept for a period that depends on the particular requirements (e.g., 3–5 years). At the same time, they are copied into a long-term archive and saved there in the form of a compressed dataset. Image data and diagnoses can also be saved in the PACS together with the images. The corresponding originals, however, are also saved in the RIS.

15.5.2 Example 2 – Hospital Inpatient

With the master data available, notification is sent via an order entry module in the HIS. The data are sent to the RIS, where they can be inspected. Using this interface it is possible to confirm the indication or to reject the order, if the circumstances require this (indication, missing laboratory results, etc.). If the job is approved, the sequence is as in example 1 from step 2.

Once the examination has been completed and the findings approved, they are sent from the RIS to the HIS to be entered into the electronic patient file, where they are archived together with the rest of the patient's data (laboratory tests, surgery reports, outpatient and discharge letters, etc.).

Computed Tomography

Thorsten M. Buzug

In this chapter, historical milestones of computed tomography (CT) (Sect. 16.2), recent technology with a focus on generation and detection of x-rays (Sect. 16.3), as well as image reconstruction (Sect. 16.4) are discussed. Furthermore, the chapter includes aspects of applications (Sect. 16.5), dose exposure in computed tomography (Sect. 16.6), and a brief overview on special CT developments (Sect. 16.7). Since this chapter gives a review, the interested reader is referred to recent literature on computed tomography including a detailed discussion of CT technology in the references section.

16.1 Background

Research in computed tomography is still as exciting as at the beginning of its development during the 1960s and 1970s; however, several competing methods exist, the most important being magnetic resonance imaging (MRI). Since the invention of MRI during the 1980s, the phasing out of CT has been anticipated. Nevertheless, to date, the most widely used imaging technology in radiology departments is still CT. Although MRI and positron emission tomography (PET) have been widely installed in radiology and nuclear medicine departments, the term tomography is clearly associated with x-ray computed tomography. In the USA, com-

puted tomography is also called computerized axial tomography (CAT).

Computed tomography has evolved into an indispensable imaging method in clinical routine. It was the first method to noninvasively acquire images of the inside of the human body that were not biased by superposition of distinct anatomical structures [16.1–4]. This is due to the projection of all the information into a two-dimensional imaging plane, as typically seen in planar x-ray fluoroscopy. Therefore, CT yields images of much higher contrast compared with conventional radiography. During the 1970s, this was an enormous

step toward the advance of diagnostic possibilities in medicine.

Some hospitals have actually replaced their conventional shock rooms with a CT-based virtual shock room. In this scenario, imaging and primary care of the patient takes place using a CT scanner equipped with anesthesia devices. In a situation where fast three-dimensional imaging of a trauma patient is necessary (and it is unclear whether MRI is an adequate imaging method in terms of compatibility with the patient), computed tomography is the standard imaging modality. Additionally, due to its ease of use, clear interpretation in terms of physical attenuation values, progress in detector technology, reconstruction mathematics, and reduction of radiation exposure, computed tomography will maintain and expand its established position in radiology.

Recently, interesting technical, anthropomorphic, forensic, and archeological as well as paleontological

applications of computed tomography have been developed. These applications further strengthen the method as a generic diagnostic tool for nondestructive material testing and three-dimensional visualization beyond its medical uses. Magnetic resonance imaging fails whenever the object to be examined is dehydrated. In these circumstances, computed tomography is the three-dimensional imaging method of choice.

Today, whole-body scans as well as imaging of very small vessels, for instance, vessels of the feet, belong to clinical routine (Fig. 16.1). Furthermore, the preoperatively acquired CT image stack can be used to synthetically compute projections for any given angulations. A surgeon can use this information to get an impression of the images that are taken intraoperatively by a C-arm image intensifier. Therefore, there is no need to acquire additional radiographs and the artificially generated projection images actually resem-

Fig. 16.1 Whole-body scans can be performed with the latest generation of CT systems, including multislice detector systems. Even very small vessels of the feet can be precisely visualized (courtesy Philips Medical Systems)

ble conventional radiographs. Additionally, the German Employer's Liability Insurance Association insists on a CT examination in severe accidents that occur at work. Therefore, CT has advanced to become the stan-

dard diagnostic imaging modality in trauma clinics. Patients with heavy trauma, fractures, and luxations benefit greatly from the clarification provided by imaging techniques such as computed tomography.

16.2 Milestones of Computed Tomography

Conventional x-ray imaging suffers from the severe drawback that it only produces two-dimensional projections of a three-dimensional object. This results in a reduction in spatial information (although an experienced radiologist might be able to compensate for this). In any case, a projection represents an averaging. The

result of the averaging can be imagined if one were to overlay several radiographic sections on the light box for diagnosis. It would be difficult for even an expert to interpret the results, as averaging comes along with a considerable reduction in contrast, compared with the contrast present in one slice.

Fig. 16.2a,b Conventional planar x-ray leads to low-contrast images that do not allow clinical diagnostics involving soft tissue (a). The figure shows the cranial bone (left), in which details of spatial structures in the brain cannot be recognized. In the image of the knee (right), even bone structures have low contrast. This low contrast is caused by the averaging process during the x-rays' passage through the body. The first attempts to create radiographic slices of the human body were carried out using conventional or analog geometric tomography, also referred to as tomosynthesis if the acquired x-ray images are digitally postprocessed (b)

Figure 16.2a shows conventional images of the cranium (left) and of the knee (right). These images show the high attenuation of x-rays within, for example, the cranial bone and most notably around the dental fillings. The small differences in attenuation that characterize soft tissue, however, are not visible at all. The morphology of the brain, in particular, is completely lost in the averaging process. In the knee, even the bone structures are imaged with poor contrast due to the superimposition.

16.2.1 Analog Geometric Tomography and Tomosynthesis

In the 1920s, the desire to undo the averaging process that characterizes conventional x-ray radiography led to the first tomographic concept. The word “tomography” itself is composed of two Greek words: *tomos* (slice) and *graphein* (draw). The use of the word “tomography” was considerably influenced by the Berlin physician *Grossmann*, whose Grossmann tomograph was able to image one single slice of the body [16.5].

The principle of the conventional or analog geometric tomography method is illustrated in Fig. 16.2b. During image acquisition, the x-ray tube is moved linearly in one direction, while the x-ray film is synchronously moved in the opposite direction. For this reason, only points in the plane of the center of rotation are imaged sharply. All points above and below this region are blurred, more so at greater distances from the center of rotation. Hence, this method can be interpreted as *blurring tomography*. It is called *tomosynthesis* if there is digital postprocessing of the projection images.

The blurred information above and below the center of rotation does not disappear, but is superimposed on the sharp image as a kind of gray veil or haze. Therefore, a substantial reduction in contrast is noticeable. However, the gain in quality compared with a simple radiograph is clearly visible in the example of the tomosynthetically acquired slice sequence of the knee in Fig. 16.2b [16.6, 7].

Due to the increased availability of electronic x-ray detectors, tomosynthesis systems are currently regaining scientific attention [16.8]. In modern systems, projection images are measured during movement and stored digitally using an image intensifier system. This allows subsequent image reconstruction that is superior to the analog blurring technique.

A related method, called *orthopantomography*, is now widely used in dental radiology. In this method, a panoramic view of rows of teeth is produced on an

imaging plane that is curved to follow the jaw. However, sophisticated trajectories allow reconstruction of slices by geometric tomography as well. Nowadays, the term tomography, despite competitive modalities such as magnetic resonance imaging (MRI) or positron emission tomography (PET), is still most commonly associated with computed tomography (CT) or, more precisely, with x-ray CT.

16.2.2 Generations of CT Systems

Computed tomography avoids the superimposition of blurred planes and produces such high contrast that even soft tissue can be imaged well. The resulting leap in the quality of diagnostic imaging led to the enormous success of CT. Historically, four distinct generations of CT have emerged. Their classification relates to both the way in which x-ray tubes and detectors are constructed, and the way that they move around the patient. Figure 16.3a–d illustrates the different generations schematically.

First-Generation CT

The first generation of CT involves an x-ray tube that emits a single, needle-like x-ray beam, which is selected from the x-ray cone by means of an appropriate pin-hole collimator. This geometry is referred to as *pencil beam*. A single detector is situated on the opposite side of the measuring field and the x-ray tube. The detector is moved synchronously along with the x-ray tube. This displacement is linear and is repeated for different projection angles γ (Fig. 16.3a). Depending on the specific attenuation properties of the tissue, the intensity of the x-ray is attenuated on its path through the body.

The amount of x-ray attenuation is measured by the detector and subsequently digitally recorded. For each angle γ , this step yields a simple, one-dimensional radiograph. However, from this initial radiograph, it is still not possible to determine the spatial distribution of the tissue attenuation coefficients. It is clear that, to determine the location of two consecutive objects on one projection line, the situation needs to be viewed sideways as well. This is the approach taken by CT, which views an object from all sides, since the projection angle is varied from 0° to 180° .

The first CT scanner, built by the company Electric and Musical Industries Ltd. (EMI), was based on this principle. In 1972, *Hounsfield* realized the scanner in the EMI central research laboratories [16.9]. For his invention, he jointly won the Nobel Prize for medicine together with Allen M. Cormack in 1979. The first ex-

Fig. 16.3a–d First-generation CT devices are equipped with a pencil beam and a single detector. These are moved linearly, and the configuration is rotated through different projection angles (a); CT scanners of the second generation have one x-ray source with fan-beam geometry, as well as a short detector array. The x-ray fan is created from a conical x-ray source by means of a slit-shaped collimator (b); the third generation of CT scanners has a substantially larger angle of the x-ray fan and a longer detector array, such that the entire measuring field can be x-rayed simultaneously for one single projection angle (c), and the fourth generation has a stationary closed detector ring (d)

periments by Hounsfield were performed in 1969 with a radioactive americium source that was linearly displaced along with the detector. Hounsfield collected data from 0° to 180° necessary for image reconstruction. The first reconstruction of a two-dimensional slice took 9 days – a clinically unacceptable processing time. However, for the first time, a two-dimensional slice image could be achieved that did not originate from averaging or blurring information, as in the conventional geometric tomography mentioned above. Figure 16.4 shows a very early EMI CT head scanner of 1972.

The first commercial scanners from EMI had a narrow focused x-ray beam and a single sodium iodide (NaI) scintillation detector. This pencil-beam principle, which is not practiced any more, is of fundamental importance as its mathematical methods for reconstruction can be understood most easily. Indeed, the mathematical methods of more modern geometries can be obtained

from the pencil-beam geometry using suitable coordinate transformations. Figure 16.4a shows one of the first tomographs of the first generation produced by Siemens in 1972.

The subsequent rapid development of CT has been, and still is, driven by three essential goals: reduction of acquisition time, reduction of x-ray exposure, and, last but not least, reduction of cost. Throughout the course of optimizing these factors there are several historical stages, which are briefly described below.

Second-Generation CT

The computed tomograph of the second generation has an x-ray source with a narrow fan beam and a short detector array consisting of approximately 30 elements (Fig. 16.3b). However, since the aperture angle of the fan beam is small, the x-ray tube and detector array still need to be translated linearly before the projection angle is adjusted for another projection. In the earliest of the

Fig. 16.4a–d Development steps of CT. (a) 1972: EMI head scanner (first generation); (b) 1974: Siemens Siretom (first generation); (c) 1975: Philips Tomoscan 200 (second generation); (d) 2005 Philips Brilliance (third generation)

second-generation scanners, the angle of the fan beam was about 10° .

Despite the need for linear displacement, the acquisition time was reduced to a few minutes per slice, as the detector array could measure several intensities simultaneously. However, the measuring field was still small. For this reason, and due to their long acquisition times, first- and second-generation scanners were mainly restricted to use in imaging the cranium. Figure 16.4b (right) gives an idea of the scale of the measuring field. The cranium can be fixed in the scanner and shows no large intrinsic movement during the acquisition time (relative to the spatial resolution that could be achieved at the time).

This is certainly not the case when imaging the area of the thorax or the abdomen, as the intrinsic movements of the heart and lung, as well as the movement of the diaphragm and soft organs of the abdomen, produce artifacts in the reconstructed images. The mathematical methods of reconstruction demand that all points of one slice are x-rayed from all angles from 0° through 180° . One object moving out of the imaging plane during rotation of the x-ray tube, due to patient movement, will inevitably result in errors in image reconstruction. Such image errors, referred to as motion artifacts, are described in detail in Sect. 16.4.4.

Third-Generation CT

The main goal of developments in the 1970s was to reduce acquisition time to less than 20 s. This was intended to give enough time to acquire an image of the abdomen with minimal error, while the patient held their breath. A major step toward achieving this goal was an extension of the second generation's fan-beam concept, i. e., the introduction of a substantially larger angle of the x-ray fan and a correspondingly longer detector array. Figure 16.3c shows a schematic illustration of this principle of third-generation scanners. Nowadays, the angle of an x-ray fan beam is typically between 40° and 60° and the detector array is usually constructed as an arc with between 400 and 1000 elements. In this way it is now possible to simultaneously x-ray the entire measuring field, which is currently wide enough to cover the torso, for each projection angle γ . As a result, the third generation of CT systems can completely abandon linear displacement of the x-ray tube.

The acquisition time for third-generation systems is reduced considerably, since continuous rotation can take place without interruption for linear displacement. The majority of CT scanners currently in use are fan-beam systems of the third generation. Figure 16.4c and

d show two CT scanners of the second and third generation from 1975 and 2005, respectively.

Fourth-Generation CT

The fourth generation of CT scanners does not differ from the third generation with respect to the x-ray tube. The fan-beam source also rotates continuously around the measuring field without any linear displacement. The difference is in the closed, stationary detector ring with up to 5000 single elements. The x-ray tube rotates either outside (Fig. 16.3d) or inside the detector ring.

If the x-ray tube is outside the detector ring, it is necessary to prevent the x-rays from radiating through the detectors from behind. Therefore, the detector ring is dynamically tilted away from the path of the tube. In this way, the line of sight between the tube and the appropriate section of the detector ring only passes through the patient (and patient table) and not through the electronics behind the detectors.

Fourth-generation tomographs establish *inverse fans*, which are centered on detectors rather than on the x-ray focus. An inverse fan is also referred to as a *detector fan*. An inverse fan can be very dense, limited only by the sampling rate at which individual detectors can be read out. As a result, unlike third-generation tomographs, this scanner is not limited to the spatial resolution of a single fan beam.

16.2.3 Spiral CT

Another development, which was a great leap forward in capability from that of the third generation, led to what is identified by *Bushberg et al.* [16.10] as the sixth generation of tomography scanners. This refers to the introduction of slip-ring technology, which enables spiral or helical sampling.

As the x-ray tube must be continuously supplied with energy, the rate of circular movement was previously limited by the attachment of an electric cable, which was mounted on a spool. In this process the cable was unwound in one direction and carefully wound up in the other. This represented a huge obstacle to the reduction of acquisition time. The x-ray sampling unit had to stop and start again after a certain angle of rotation.

Although data could be collected throughout both clockwise and counterclockwise rotations, limits were placed on high velocities due to the increasing torsional moment. This problem was solved by the introduction of slip-ring technology. In this technology, the energy is provided via sliding contacts situated between the outside of the sampling unit, in what is called the *gantry*,

and the rotating sampling unit. This enables the sampling unit carrying the x-ray source and, in the case of third-generation scanners, the detector array to rotate continuously. As a result of slip-ring technology, rotation frequencies of two rotations per second, i.e., *subsecond scanners*, are nowadays commonplace.

However, there are also smaller, more compact devices, in which the sampling unit is independent from an external energy supply during rotation, making use of accumulators. An example is given by the mobile Philips Tomoscan M CT scanner, where accumula-

tors are mounted on the rotating sampling disk and a capacitive radiofrequency (RF) link is used for data transfer.

The slip-ring innovation enabled a new acquisition technique. Along with a continuous motion of the patient table through the sampling unit, it became possible to measure data in the shape of a spiral (strictly speaking, the x-ray tube trajectory is a helix). The spiral CT technique was demonstrated successfully using a prototype by *Kalender* in 1989 [16.11]. The spiral CT technique is discussed in more detail in Sect. 16.4.3.

16.3 Computed Tomography Technology

Computed tomography systems consist of a *front-end*, i.e., the scanner unit, and a *back-end*, i.e., the control console and viewing station. All components of the front-end, i.e., the x-ray tube, x-ray filter, aperture unit, collimator, detector system, high-voltage generator, cooling system, data-acquisition system (DAS), slip ring, patient table, motors, motor controllers, as well as mechanical components, are highly developed today. However, due to their key position in the system, only two main components of the front-end will be discussed here: the x-ray tube and the corresponding detector system. For a detailed discussion of the physics of x-ray generation, photon-matter interaction, x-ray detection, and photon statistics the reader is referred to [16.4].

16.3.1 X-Ray Generation

X-ray radiation is of electromagnetic nature; it is a natural part of the electromagnetic spectrum, with a range that includes radio waves, radar and microwaves, infrared, visible and ultraviolet light, to x- and γ -rays. In electron-impact x-ray sources, the radiation is generated by deceleration of fast electrons entering a solid metal anode and consists of waves with a range of wavelengths roughly between 10^{-8} and 10^{-13} m. Thus, the radiation energy depends on the electron velocity v , which in turn depends on the acceleration voltage U_a between the cathode and anode. In medical diagnostics, acceleration voltages are chosen between 90 and 140 kV, for radiation therapy they lie between 10 and 300 kV, and for material testing they can reach up to 500 kV.

Electrons are emitted from a filament, which is directly heated to approximately 2400 K to overcome the binding energy of the electrons to the metal of the fila-

ment. Filaments are usually made of thoriated tungsten with a melting point of 3683 K. Due to their thermal energy, electrons are boiled off from the filament. This process is called thermionic emission. To produce a small electron focus on the anode, the trajectories of the accelerated electrons must be controlled by electron optics. The focusing device is a cup-shaped electrode (frequently named a Wehnelt cylinder) that forms the electric field near the filaments such that the electron current is directed to a small spot on the anode.

While the acceleration voltage determines the energy interval of the x-ray spectrum, the intensity of the generated x-ray spectrum or the number of x-ray quanta is solely controlled by the anode current. The acceleration voltage and the anode current can be controlled by the user.

With the entry of accelerated electrons into the anode, sometimes also called the *anticathode*, several processes take place close to the anode surface. Generally, the electrons are diffracted and slowed down by the Coulomb fields of the atoms in the anode material. The deceleration results from the interaction with the orbital electrons and the atomic nucleus. As known from classical electrodynamics, acceleration and deceleration of charged particles creates an electric dipole, and electromagnetic waves are radiated. Usually, several photons emerge throughout the complete deceleration process of one single electron. It can happen, however, that the entire energy eU_a of an electron is transformed into a single photon. This limit defines the maximum energy of the x-ray radiation.

Due to the fact that the slowing down of electrons in the anode material is a multiprocess deceleration cascade, a continuous distribution of energies is produced, the so-called *bremstrahlung*. Since the free electrons

are unbound, their energy cannot be quantized. The continuous *bremsstrahlung* is superimposed by a characteristic line spectrum, which originates from direct interaction of fast electrons with the inner shell electrons of the anode material. If an electron on the K-shell or K-orbital is kicked out of the atom by a collision with a fast electron, i. e., the atom is ionized by the loss of an inner electron, an electron of one of the higher shells fills the vacant position on the K-shell. As the inner shells represent states having lower potential energy than the outer shells, this process is accompanied by the emission of a photon. This process creates sharp lines in the x-ray spectrum that are characteristic fingerprints for the anode material.

It should be noted at this point that the image quality of CT specifically suffers from the fact that x-ray attenuation is a complicated function of wavelength. The details of the functional behavior are given in the next section. Generally, one has to bear in mind that a low-energy x-ray, i. e., radiation with a longer wavelength, is more strongly attenuated when passing through matter than high-energy x-ray. (Low-energy quanta are generally undesired in x-ray imaging. They increase the dose to the patient, but do not contribute to imaging, because they are almost totally absorbed by the human body.) As a consequence, the center of the polychromatic x-ray is shifted to higher energies (harder radiation). This is the origin of what is called beam hardening, which produces artifacts in the reconstructed images.

Generally, a flat metal filter measuring a few millimeters is mounted onto the x-ray tube. The filtering of the useful beam reduces the number of x-ray quanta while increasing the average energy of the radiation. This prehardening of the radiation reduces beam-hardening artifacts during image reconstruction and the dose to which the patient is exposed.

Unfortunately, the quantum efficiency of the conversion from kinetic energy into x-ray radiation, for a tungsten anode (W , $Z = 74$) working with an acceleration voltage of $U_a = 140$ kV, is roughly on the order of $\eta = 0.01$. This means that 99% of the kinetic energy is transferred locally to the lattice, heating up the anode. As a result, CT x-ray tubes have serious heating problems.

Since it is the energy deposition in the target volume that produces the heat load, the tube current and the duration of exposure, or more precisely the product of current in milliamperes and exposure time in seconds, are two important parameters of the practical scan protocol that the radiologist has to choose appropriately. The heat capacity of an x-ray tube is measured

in *heat units*. Therefore, for several decades, rotating anode disks have been used to distribute the thermal load over the entire anode. The anode target material is rotated about the central axis, and therefore new, cooler anode material is constantly rotated into position at the focal spot [16.12]. In this way, the energy of the electron beam is spread out over a line, called the focal line, rather than being concentrated at one single point. In Fig. 16.5a–c a modern Philips MRC 600 x-ray tube is shown. A liquid-metal-filled spiral-groove bearing allows very high continuous power compared with conventional ball bearings. Often, a heat exchanger is placed on the rotating acquisition disk to cool the anode.

Ideally, x-rays should be created from a point source, because an increase in source size will result in a penumbra fringe in the image of any object point. The size and shape of the x-ray focus seen by the detector determines the quality of the resulting image. The effective target area, called the optical focus, depends on the orientation of the anode surface that is angulated with respect to the electron beam. The projection of the focus shape onto the detector must be minimized to obtain a sharp image. However, this surface angle increases the tube power limit, because it allows the heat to be deposited across a relatively large spot while the apparent spot size at the detector will be smaller by a factor of the sine of the anode angle [16.12]. The image quality is degraded by a large focus diameter, due to significant partial shadow areas of each object point. The mathematical expression that measures the image quality is called the *modulation transfer function* (MTF). A large angle between the incident electron beam and the anode surface normal is generally not desired, because there is a certain probability that the electrons will be elastically reflected from the surface and thus not contribute to x-ray generation. The probability of this backscattering effect increases as the atomic number of the anode material increases and as the angle between the surface normal and the anode rotation axis decreases.

Typically, the x-ray focus diameter for diagnostic tubes is found to be between 0.3 and 2 mm. The penetration depth of electrons into the anode depends on the kinetic energy and the anode material and can be found to be up to $30 \mu\text{m}$. The radiologist may have the option of choosing between two focus sizes. This is technically realized by focusing the electron beam onto two target points with different anode orientations. In some systems the spatial resolution of the detector can also be doubled by switching between two foci during data acquisition. This concept is called a flying focus.

Fig. 16.5a–f Modern high-power x-ray tube (a,b) and schematic illustration of a modern x-ray tube with a rotating anode disk (c), schematic illustration of a multislice detector (d), a detector unit of a 64-row CT system (e), and the realization of a $41 \times 41 \text{ cm}^2$ flat-panel detector with 2048×2048 pixels (f)

A second effect that influences imaging quality is caused by the anode surface. X-ray beams leaving the anode tangentially to the anode surface are reduced in intensity when arriving at the detector. This intensity reduction is due to the self-absorption of photons by the anode, caused by the microscopic roughness of the anode surface. The x-ray intensity decreases gradually with a reduction in the angle between beam and anode surface. This effect, which is called the *heel* effect, grows during the lifetime of any x-ray tube, because the roughness of the anode surface increases due to erosion by electron bombardment along the focus line. In modern CT systems the cone of the utilized x-rays is becoming larger and larger. Therefore, it is important to know the radiation characteristics of the anode, because the basic assumption of the imaging principles of fluoroscopy and of CT reconstruction is that the object to be scanned is illuminated homogeneously. Slight deviations from a homogeneous beam profile can be compensated for by specially formed filters mounted on the x-ray tube and by detector calibration.

16.3.2 Detector Systems

Typically, x-ray quanta are not measured directly, but are detected via their interaction products (for example, emitted photoelectrons). The overall detection efficiency is primarily determined by the geometric efficiency (also called the *fill factor*) and the quantum efficiency (also called the *capture efficiency*). The geometric efficiency refers to the x-ray-sensitive area of the detector as a fraction of the total exposed area, and the quantum efficiency refers to the fraction of incident quanta that are absorbed and contribute to the signal. The overall detection efficiency is the product of the geometric and the quantum efficiencies.

Gas Detectors

X-ray radiation is able to ionize gases. This fact was discovered very early in the last century and led to the development of the well-known Geiger–Müller counter. In the first tomographic experiments carried out by Cormack and Hounsfield, the Geiger–Müller counter was used as a detector in pencil-beam geometry. In the early days of clinical CT, gas-based detector arrays were also manufactured for what are known as third-generation scanners in fan-beam geometry. Even today, some scanners using high-pressure xenon are in use. The photoelectric interaction, $h\nu + \text{Xe} \rightarrow \text{Xe}^+ + e^-$, describes the first part of the detection process chain. Xenon ions and electrons are attracted by high volt-

age to a cathode and an anode, respectively. A series of alternating cathode and anode pairs forms the detector array [16.4]. The current produced by recombination is a measure of the x-ray intensity entering the detector.

A weak quantum efficiency (a low probability for photoelectric absorption) can be compensated for by high-pressure and tall ionization chambers. Another advantage of tall chambers is improved directional selectivity of the detector element. Since the ionization probability is proportional to the travel length of x-ray quanta inside an element (one cathode–anode block), detection of x-ray quanta with an oblique entrance will be suppressed. In this way, a tall detector element has built-in collimation. However, the septa between detector elements are insensitive regions that will decrease the geometric efficiency of the detector.

Scintillation Detectors

Today, almost all modern CT systems are equipped with scintillator detectors. Such a detector essentially consists of two main components: a scintillator medium and a photon detector. In a first step, the short-wave x-ray radiation entering the detector is converted into long-wave radiation (light) inside the scintillation material. Typical scintillator materials used are cesium iodide (CsI), bismuth germanate (BGO), and cadmium tungstate (CdWO_4). The choice of material is critical and depends on the desired quantum efficiency for the conversion from x-ray to light and on the time constant for the conversion process, which determines the *afterglow* of the detector. For very fast fluorescence decay, i. e., a very small time constant, as required by modern subsecond scanners, ceramic materials made of rare-earth oxides such as gadolinium oxysulfide ($\text{Gd}_2\text{O}_2\text{S}$) are used.

On the rotating sampling unit, the series of detector elements is arranged in a circle segment with the x-ray source at its center. In Fig. 16.3c this is schematically shown for a third-generation scanner. X-rays that have been scattered may undergo deflection through a small angle and finally reach the detector. This detection is undesired because it reduces the contrast of the image. To suppress the measurement of scattered x-ray quanta, collimator lamella are attached to each element. Such an antiscatter collimator grid is directed toward the x-ray focus to filter out photons not traveling in the line of sight between the x-ray source and the detector. Without an antiscatter grid, the image quality would be significantly reduced.

However, there is an obvious disadvantage of the antiscatter grid. To block an oblique entrance of scat-

tered x-ray photons effectively, a minimum lamella thickness of 0.1 mm is required. In practice, the detector elements have a total geometric efficiency of about 50–80% [16.13]. This decreased fill factor leads to an undesired reduction in spatial detector resolution.

Solid-State Multislice Detectors

Crystal- and ceramic-based solid-state detectors described in the previous section can be extended to multirow or multislice detector systems. The key feature of such multirow arrays is a maximum effective x-ray-sensitive area. This feature is quantified by the fill factor, which is explained below. Xenon high-pressure gas detector array systems cannot be easily extended to flat area detector systems. Therefore, all modern multislice CT systems are based on solid-state scintillation detectors.

In Fig. 16.5d, a cone-beam detector system is shown schematically. In contrast to detector systems in technical CT systems, for example, in micro-CT (where flat-panel detectors are employed), almost all clinical CT systems are equipped with cylindrical detector units. As illustrated in Fig. 16.5d, the multiarray system forms a cylindrical barrel with the x-ray source as its center. If the number of rows of such multislice detector systems is chosen to be very high, the orientation of the respective x-ray fan inside the cone beam, relative to the axial slice, becomes significant, and the requirements of image reconstruction increase. However, modern CT systems are equipped with cone-beam sampling units due to improved spatial resolution and faster image acquisition. Image reconstruction in cone-beam systems is discussed in Sect. 16.4.

Different technical configurations of multislice detector systems are available today. Usually, detector units can be partitioned and combined. This flexibility is achieved by the electronic interconnection of pairs of detector segments leading to a desired slice thickness.

Solid-State Flat-Panel Detectors

Without reconstruction mathematics that are adapted to the cone-beam situation, image artifacts arise for higher x-ray fan angulations, even in a 16-row detector system. This leads to clinically unacceptable image quality. In any case, the reconstruction algorithms used for the cone-beam geometry need to be revised for practical implementation. Therefore, a logical step forward is to leave multirow detector arrays and move in the direction of real flat-panel detector systems, which have recently become commercially available. However, they were not originally designed for use in CT systems, but rather

to compete with established radiography systems using film cassettes, computed radiography cassettes, and image intensifiers.

Each sensor element of a flat-panel detector consists of a photodiode and a thin-film transistor (TFT). Both are made of amorphous silicon on a single glass substrate. The pixel matrix is coated with an x-ray-sensitive layer. Multichip modules are used as readout electronics at the edge of the detector field. The x-ray-sensitive coating is, for instance, a cesium iodide layer. The basis is the single glass substrate with a silicon matrix of 2048×2048 sensors, each $200 \mu\text{m}$ in size. The monolithic structuring is done with thin-film technology such that a composition of a set of medium-sized subpanels, which have undesired dead zones at the interfaces, potentially producing imaging artifacts, is not required. A final cesium iodide (CsI) coating forms the scintillator layer of the detector.

The CsI layer is applied directly onto the pixel matrix by a physical deposition process. The production technique is known from semiconductor production. Physical and chemical processing steps, i. e., the combination of photolithography and further etching phases, are applied to produce the finely structured detector elements. This leads to an x-ray-sensitive detector field with a desired high fill factor, i. e., the ratio of the *x-ray-sensitive area of the detector* to the *total area of the detector*.

X-ray quanta entering the detector are converted into visible light in the upper CsI scintillator layer. The light photons are guided to the photodiodes of the next processing layer. The photons are absorbed, thereby producing an electric charge in the photodiodes that is proportional to the intensity of the x-ray radiation.

During detector exposure, the electric charge is integrated and stored in the detection element, which acts as a capacitor. The actual readout process is initialized by the thin-film transistor, which switches the charge to the readout electronics via a data link. There, amplification and analog-to-digital conversion are performed on the same chip, resulting in fast operation with low noise. In Fig. 16.5f, a preassembly, raw detector with ribbon-cable data links [16.14] is shown. Its 4194304 pixels are integrated onto a $41 \times 41 \text{ cm}^2$ active area.

A highly desired system property of the digital scintillation detector system is linear dynamics over a wide range of illumination. In this way, high- and low-dose applications have the same contrast information, i. e., excellent contrast resolution. Film systems are capable of imaging objects with high contrast within a very narrow exposure range only. If the object is over-

underexposed, the contrast of the image can easily be too low. Due to the linear response characteristic curve of the digital system, it is robust against over- and underexposure. However, within the range of low-contrast imaging, flat-panel systems do not achieve the quality of the dedicated CT detector systems described in the sections above [16.13].

In addition to a linear detector dynamics characteristic, another important advantage of the flat-panel detector is its excellent spatial resolution. To optimize the spatial resolution, CsI is evaporated onto the matrix so that direct contact between the scintillation material and the carrying photodiode matrix is established. This manufacturing step is designed in such a way that CsI grows anisotropically, forming needles on the matrix. If x-ray quanta are converted into visible light inside the CsI structure, the emerging photons are, in all likelihood, traveling along the needles, because they act

as a fiber-optic cable. In this way, photons are guided directly onto the photodiode or in the opposite direction.

The photons that are traveling in the opposite direction face a mirror on the top side of the CsI layer that ensures that eventually almost all photons find their way to the photodiode. This light guidance effect of the CsI fiber structure is the reason for the high quantum efficiency of digital flat-panel detectors. The x-ray-sensitive CsI coating can be made very thick to obtain high quantum efficiency and also to suppress broad photon scattering, which would reduce the spatial resolution. The scintillation light is bundled by the CsI fibers onto a small point on the photodiode matrix. However, an isotropic CsI layer must always find a compromise between high quantum efficiency and high spatial resolution. Figure 16.12b in Sect. 16.7 shows a prototype volume or cone-beam CT equipped with a flat-panel detector.

16.4 Image Reconstruction

The fundamental problem of computed tomography can be easily described: Reconstruct an object from its shadows or, more precisely, from its projections. An x-ray source with a fan- or cone-beam geometry penetrates the object to be examined, such as a patient in medical applications, a skull found in archeology, or a specimen in nondestructive testing (NDT). In so-called third-generation scanners, the fan-shaped x-ray beam fully covers a slice section of the object to be examined. Depending on the particular paths, the x-rays are attenuated to varying extents when passing through the object; the local absorption is measured with a detector array.

Of course, the shadow that is cast in only one direction is not an adequate basis for determination of the spatial distribution of distinct structures inside a three-dimensional object. To determine this structure, it is necessary to irradiate the object from all directions. Let $p_{\gamma_i}(\xi)$ represent the attenuation profile of the beam as a function of the x-ray detector array coordinate ξ under a particular projection angle γ_i . If the different attenuation or absorption profiles are plotted over all angles of rotation γ_i of the sampling unit, a sinusoidal arrangement of the attenuation or projection integral values is obtained. In two dimensions, these data $p_{\gamma_i}(\xi)$ represent the Radon space of the object, which is essentially the set of raw data. From a mathematical point of view, image reconstruction in computed tomography is the task of computing the spatial structure of an object from the shadows that it casts. The solution to this problem is

complex and involves techniques from physics, mathematics, and computer science. The described scenario is referred to as the inverse problem in mathematics.

In computed tomography, the meaning of the mathematical term *inverse problem* is immediately apparent. The spatial distribution of attenuating objects that produce the projection shadow is not known a priori. This, actually, is the reason for acquiring the projections along the rotating detector coordinate ξ over a projection angle interval of at least 180° . It is an inversion of integral transforms. From a sequence of measured projection shadows $\{p_{\gamma_1}(\xi), p_{\gamma_2}(\xi), p_{\gamma_3}(\xi), \dots\}$, the spatial distribution of the objects, or more precisely the spatial distribution of the attenuation coefficients $\mu(\xi, \eta)$ within a chosen section through the patient, must be estimated.

In 1961, the solution to this problem was applied for the first time to a sequence of x-ray projections by which an anatomical object had been measured from different directions. Allen MacLeod Cormack (1924–1998) and Sir Godfrey Hounsfield (1919–2004) were pioneers of medical computed tomography and in 1979 received the Nobel Prize for medicine for their epochal work during the 1960s and 1970s.

16.4.1 Fourier-Slice Theorem

Depending on the path η which the x-ray quanta take through the body – starting at the x-ray tube $\eta = 0$ and

Fig. 16.6a–g From the raw data to the reconstructed image. Sinogram of attenuation or projection values (a), high-pass-filtered projection values (b), backprojection of the filtered projection (c), accumulation of all backprojections of the high-pass-filtered (d) and the native (e) projection profiles; data acquisition of spiral CT (f), row-data interpolation for spiral CT (g) ▶

ending at the detector $\eta = s$ – the intensity of the rays will be attenuated differently. After taking the logarithm of the intensity measured on detector element ξ the sum of attenuation values $p_\gamma(\xi)$ is obtained along the x-ray path for the projection angle γ .

The x-ray source rotates around the object to be examined, penetrating it with x-rays. The sum of attenuation values, the so-called projection integral $p_\gamma(\xi)$, is measured and saved for each angle. Therefore, the projection integral – plotted over all angles – takes a sinusoidal course (Fig. 16.6a). This plot that collects the raw data of the measurement is called a sinogram and represents the Radon space of the object, named after the Austrian mathematician *Radon* [16.15].

The key theorem that describes the relation between the Fourier transform of the projection integral and the Fourier transform of the desired image is the Fourier-slice theorem. One is interested in the spatial distribution of attenuation values $f(x, y) = \mu(\xi, \eta)$ having measured only the projection data $p_\gamma(\xi)$.

The Fourier-slice theorem ensures that the one-dimensional Fourier transform $P_\gamma(q)$ of the measure projection integral $p_\gamma(\xi)$ can be identified with a radial line in the Cartesian Fourier space $F(u, v)$ of the object $f(x, y)$ drawn at the angle γ of the corresponding measurement, with $u = q \cos \gamma$ and $v = q \sin \gamma$. Filling the Fourier space in that way over all angles γ leads to a complete Fourier representation of the object, which can be reconstructed in principle by an inverse two-dimensional Fourier transform. For a detailed discussion the reader is referred to [16.4].

16.4.2 Filtered Backprojection

The Fourier-slice theorem is not directly implemented due to some interpolation problems that would arise. In today's CT systems, so-called filtered backprojection is widely used. Within this method, which is also called the convolution method, the projection integral data $p_\gamma(\xi)$ are digitally filtered. Figure 16.6a,b shows how this is done in the frequency domain. The linear weighting $|q|$ of the Fourier-transformed projection profile $P_\gamma(q)$ is essentially a high-pass filter. Consequently, the filtered projection profile $h_\gamma(\xi)$ shows the changes along the profile only. The result of the high-

pass filtering of the measured attenuation profile $p_\gamma(\xi)$ is illustrated in Fig. 16.6b. It can be seen that the sinusoidal structure of the data is preserved. However, due to the high-pass filtering, only changes of $p_\gamma(\xi)$ are represented by $h_\gamma(\xi)$.

This filtered profile $h_\gamma(\xi)$ is projected back in the direction γ of the measurement of $p_\gamma(\xi)$. In Fig. 16.6c this is exemplarily demonstrated for a single backprojection angle γ . Obviously, a single filtered backprojection alone does not represent the image of the object. However, the errors of one direction are consistently compensated by accumulation of the backprojections of all available views in the interval $\gamma = [0, \pi)$.

The concept for reconstruction of the tomographic image $f(x, y)$ from the projection values $p_\gamma(\xi)$ is demonstrated by a successive backprojection. In Fig. 16.6d the intermediate results of the reconstruction process of a tomographic abdomen image are shown for an increasing number of projection angles $N_p = \{1, 2, 3, 10, 45, 180\}$. This sequence reveals that a sufficiently high number of projection angles is needed to reconstruct the image of the object. In Fig. 16.6e the intermediate results of the simple backprojection, i.e., the direct backprojection of the measured projection integral $p_\gamma(\xi)$, is shown. This naive strategy leads to a blurred image independent of the number of backprojection angles.

When CT images are compared, it is important to know the exact weighting function within the filtered backprojection. The linear weighting with $|q|$ as described above is the mathematically ideal case. In practice, the filter is often less progressive in the high-frequency domain. The actual type of weighting can be chosen at the console of the scanner. The operator is asked to choose a filter kernel from a filter bank including a variety of gradually changing weightings from *very sharp* to *very smooth*. The optimal choice of a filter kernel is always a compromise between a high noise level with fine spatial resolution and smooth images with low spatial resolution [16.4].

16.4.3 Raw-Data Interpolation for Spiral CT

A first step toward a true volume image is the so-called spiral CT method (Sect. 16.2.3), which was proposed by

Kalender in 1989 at the annual Radiological Society of North America (RSNA) conference [16.11].

The inadequacies of the simple slice stack produced by conventional CT are easy to understand. Due to the preset collimation, each slice has a certain width, which is also referred to as the slice thickness. Within this slice thickness the intensity is weighted with its sensitivity profile – given by the source intensity distribution inside the collimation and the detector sensitivity profile – and then averaged.

This averaging process is a problem in all cases in which the object is characterized by boundaries which are angulated with respect to the axial slice, i. e., where structures to be displayed quickly change in the direction of the table feed. In these cases, the averaging process results in a step-like slice stack so that the structure to be displayed has a staircase-like appearance. The development of slip-ring technology, which has already been briefly discussed in Sect. 16.2.3, made it possible to rotate the sampling unit, i. e., the tube and detector array system, continuously. If the table feed is kept constant during the rotation, then the x-ray source rotates around the patient on a spiral path; strictly speaking, this movement describes a helical trajectory (Fig. 16.6f).

This orbit interpretation is based on a coordinate system attached to the patient table, since the x-ray source does of course still run along a circular path. The spiral path only arises from the patient's view. With this concept, complete projection data acquisition of an object is possible, and the scan time for a volume could be considerably reduced in comparison with conventional tomography.

Indeed, it is remarkable that spiral CT technology works at all. An essential requirement for the reconstruction methods described in Sects. 16.4.1 and 16.4.2 is the completeness of the raw data. This means that an object in the measurement field can only be reconstructed if all points of the object are illuminated from all sides, i. e., over 180° . This condition is the reason why artifact-free conventional CT scans of the heart are practically impossible because the heart motion shifts parts out of the slice to be reconstructed while the sampling unit rotates around the heart.

Thus, the projection data to be used for the reconstruction process do not fulfill the consistency condition. Rather, the differences between the projection data of a complete cycle should only be caused by the change of perspective. The reconstructed tomogram is thus impaired by motion artifacts, which will be described in detail in Sect. 16.4.4.

In spiral CT scanners, the motion of the objects to be reconstructed is in fact the decisive innovation compared with conventional CT scanners. The object to be examined is no longer scanned in a single plane. The reason for this is that, due to the continuous patient table feed, the source trajectory is not a closed circular orbit. Therefore, a complete set of raw data is not available for the reconstruction process – the data are inconsistent in terms of Sect. 16.4.1.

The key idea governing the reconstruction process of the spiral CT method is based on the assumption that the missing data of one slice can be completed by interpolation (Fig. 16.6g). If this has been done, then the two-dimensional reconstruction procedures described in Sect. 16.4.2 are again available without any restriction. Figure 16.6g shows the simplest principle of a slice interpolation. The helical rise, i. e., the path along which the table is moving during one 360° rotation of the sampling unit, will be denoted with s here.

One may now select an arbitrary slice position z_r because no preferred axial position regarding the data basis exists due to the constant table feed. For the selected slice there initially is only a single projection angle γ_r for which the projection dataset $p_{\gamma_r}(\xi)$ is available. The projection data $p_\gamma(\xi)$ of all other projection angles must be provided accordingly by means of interpolation. For this purpose, the data that have not been measured under the other required projection angles in the selected slice position z_r must be interpolated on the basis of the closest neighboring angles of the helical trajectory that have actually been measured. Contrary to conventional CT, one has to consider the table speed v as a function of the rotation frequency $1/T_{\text{rot}}$ of the sampling unit. This yields the table feed per rotation or the helical rise $s = v/T_{\text{rot}}$. If one includes the width or thickness of the x-ray fan d defined by the collimator, then these parameters are usually combined to define the new scan protocol parameter pitch $p = s/d$.

16.4.4 Artifacts

Artifacts are image errors that may emerge due to a variety of reasons. Artifacts can originate from a simplification of the reconstruction method – to date usually the filtered backprojection – which assumes monochromatic radiation or continuous representation of the projection signal. Artifacts may also stem from the use of special sampling technologies and detector arrangements, or simply from defective detector elements. Corrective actions may only be taken if the causes of such artifacts are known. Such countermeasures are in

fact very important, since the filtered backprojection has the disadvantage that artifacts are projected back over the entire image so that the overall diagnostic value of the image is reduced or completely destroyed. In this section a brief overview of CT artifacts is given [16.4].

Partial-Volume Artifacts

If a detail of an object consists of a sharply contrasted boundary, the limited resolution of a detector system of course becomes particularly noticeable. The boundary will usually not be located directly at the edge between one detector element and another. Therefore, the x-ray intensity at the corresponding element that has to image this boundary will be linearly averaged over the detector width $\Delta\xi$. Due to this averaging step, the object is blurred. Due to the superposition of filtered backprojections from all directions, this inconsistency leads to artifacts within the reconstructed image which are visible as streaks from the origin of the inconsistency along the backprojection path. Partial-volume artifacts are thus observed, for instance, as ghost lines that extend, particularly, from straight object boundaries. This is due to the fact that the backprojections from the other directions are not able to consistently correct an erroneously detected value, which has been projected back over the entire image. As a countermeasure, the beam may be collimated finely and the corresponding artifacts will be reduced.

Beam-Hardening Artifacts

X-rays produced by electron-impact sources, where fast electrons are entering a solid metal anode, cannot be monoenergetic or monochromatic. In Sect. 16.3.1, the different spectral x-ray components have been introduced, such as the continuous spectrum of the bremsstrahlung (from fast electrons decelerated by the Coulomb fields of the atoms in the anode material) and the characteristic emission lines. Radiation attenuation does not only depend on the path length but is also a function of the specific, wavelength-dependent interaction between x-rays and the material concerned. The reconstruction is in this case – similar to the partial-volume artifact described above – impaired by the nonlinearities which occur here. The beam-hardening artifact is caused by the nonlinear relation between the attenuation values μ and the measured values of the projection p . If an x-ray beam with broadband energy spectrum passes through an object, the spectrum changes along the path. This is due to the fact that different bands of the frequency spectrum are differently attenuated, depending on the specific attenuation

coefficients $\mu = \mu(\xi, \eta, E)$ of the material being radiographed. In general, low-energy, i.e., soft, x-ray beams, are more strongly absorbed than high-energy, hard x-ray beams. This is the reason why this effect is named hardening of the x-ray spectrum and the corresponding image error is named the beam-hardening artifact. Similar to the partial-volume artifact, the beam-hardening artifact can be explained by the inconsistency of the individual projection values from different directions, which cannot complement each other correctly within the filtered backprojection method. One corrective method applied in virtually all CT scanners consists of filtering the soft radiation next to the source, i.e., before the radiation reaches the tissue. This may, for example, be done with thin aluminum or copper foils, and for a single material with known properties, it is of course possible to correct for beam hardening computationally.

Metal Artifacts

One known problem in CT is the appearance of metal artifacts in reconstructed CT images. Low-energy x-rays are attenuated more strongly than high-energy x-rays. Recall that the absorption is given by $\alpha \propto Z^4 \lambda^3$. Due to the Z^4 dependence, this beam-hardening effect is prominent for metals that are introduced into the human body, such as dental fillings or hip prostheses, and leads to inconsistencies in the Radon or projection space. These inconsistencies observed in the integral attenuation values are due to the polychromatic x-ray spectrum produced by the x-ray tube. Additionally, without applying the dual-energy principle, the total attenuation of the x-ray intensity is an a priori unknown combination of the photoelectric effect and the Compton effect. This often leads to artifacts in the reconstructed images in the form of dark stripes between metal objects with light, pin-striped lines covering the surrounding tissue. Besides beam hardening, another origin of metal artifacts is a higher ratio of scattered radiation to primary radiation, causing a low signal-to-noise ratio (SNR) in the metal shadow. This effect will be discussed in the next section. However, inconsistent projection data can also be repaired with surrogate data created by interpolation or be treated as missing data in order to ignore the inconsistent data in a statistical approach. The problem with interpolated surrogate data is that they always include residual inconsistencies due to missing information during interpolation. On the other hand, within the missing data approach, a brute-force method is applied to eliminate inconsistencies. However, the problem with this strategy is that the reconstruction

actually suffers from voids in the projection data. Recently, it has been shown [16.16] that both strategies may be combined. A weighted maximum-likelihood expectation-maximization (MLEM) approach can be used to reduce the influence of the residual inconsistencies from interpolation in such a way that optimal imaging quality is obtained by optimizing the compromise between residual inconsistencies and data voids.

Motion Artifacts

So far it has been assumed that the morphology in the slice to be reconstructed does not change during data acquisition. However, if one also has to take into account the temporal variation of the attenuation coefficient $\mu = \mu(\xi, \eta, E, t)$, one faces the problem of image reconstruction with a changing data basis; that is, the data measured during the rotation are inconsistent. As a countermeasure, one fundamental goal for engineers developing new CT scanner generations is the acceleration of data acquisition, particularly with respect to the time constants related to anatomical and physiological motions. The presently used scanners are multislice subsecond CTs, which, however, are not able to display perfect radiographs of beating hearts without electrocardiogram (ECG) triggering.

Sampling Artifacts

As in general in any signal processing task, Shannon's sampling theorem must not be violated in CT. This applies to both the reconstruction of an axial slice and the subsequent reconstruction of three-dimensional (3-D) data presentations by slice stacking (Sect. 16.5.3). Subsampling of a signal also results in the typical aliasing artifacts. An inherent sampling problem discussed in [16.4] arises particularly for a detector array with a rectangular sensitivity profile of the single detector elements, namely that the individual elements would have to be arranged at half the distance of their own width. As this requirement cannot be met due to obvious technical reasons, one makes use of an elegant mechanical trick. The corrective action, which is nowadays used to prevent aliasing, is based on either the quarter detector shift or the so-called *flying focus* of the x-ray tube.

Electronic Artifacts (Ring Artifacts)

There are several electronic defects that can deteriorate the image and in most cases destroy it. The most famous, or rather notorious, electronic defect is the failure of a detector channel. In third-generation CT scanners,

such a detector defect will result in prominent so-called ring artifacts. As the x-ray source and the detector array are tightly joined at the sampling unit, the failure of an individual detector element, or the corresponding processing channel, becomes specifically visible. During the filtered backprojection the virtual lines connecting the corresponding detector element and the x-ray source, which are sometimes called defective beams, form the tangents of a circle. This means that all values outside the circle are seriously affected by this artifact. Inconsistencies with the measured values of the corresponding other projection directions in fact arise for each point of each line. Due to the backprojection, all image areas are again affected by the artifact.

Scatter Artifacts

For the detector element located in the unscattered, direct beam path, in principle it does not make any difference which physical mechanism of interaction actually reduces the intensity. Other detector elements located outside the direct line of sight may in fact be impaired by certain interactions. Particularly in the area of strongly attenuating anatomical objects such as the shoulder, abdomen, and pelvis, the measured values may be distorted due to scattered radiation. These scattered x-rays may become a considerable part of the overall signal. Whereas the scattered radiation is almost the same for all projection angles, it is very different for the wanted signal. In projection directions in which highly absorbing objects are located one after another, the wanted signal may become extremely weak, so that the scattered radiation dominates the signal. Within the filtered backprojection, inconsistencies then arise from this projection direction, which result in streak artifacts. With regard to the interfering radiation caused by scattering reaching the detector, third-generation CT scanners are superior to fourth-generation CT scanners. The detector array of such scanners is designed such that the row of detector elements is arranged on a circular segment with the x-ray source located at the circle center. It is therefore possible to collimate the radiation by septa so that scattered radiation – with an incident angle into a *false* detector element, which is larger than a threshold angle – is effectively shielded. The critical angle is determined by the length and the spacing of the detector segments. In fourth-generation scanners the detectors are located on a circle, the center of which is the isocenter of the measurement field. An x-ray source, to which a detector collimation might be focused on successfully, obviously cannot be located there.

16.5 Scan Planning and Applications

In the following sections, some important practical aspects of computed tomography (CT) will be discussed. Among others, these aspects concern scan planning, data processing, and representation – particularly gray value scaling. In particular, scan planning plays an important role in clinical applications of CT, since scans cannot be arbitrarily repeated due to the system-inherent radiation dose to which the patient is exposed.

Therefore, it is furthermore not only important to plan the scan properly, i. e., to prepare the image acquisition, but also to be informed about how the image data may be represented, i. e., how to postprocess the acquired data appropriately to maximize the information that is available from the images by means of modern visualization techniques.

16.5.1 Scan Planning

The first and most important step in planning a CT scan is the acquisition of an overview scan, which is called a topogram (Siemens), scanogram (Philips), scout view (General Electric) or pilot scan by the different manufacturers. To acquire this overview scan, the rotation of the sampling unit is stopped at a desired angle. In principle, any angulation is possible, but typical positions are *anterior–posterior* (a.p.), i. e., x-ray examination from the patient’s front to the patient’s back, and *lateral*, i. e., x-ray examination from the side.

During acquisition of the overview scan, the patient table is continuously moved through the measuring field. Figure 16.7a exemplarily shows images resulting from an a.p. and a lateral overview scan. The resulting images are quite similar to conventional x-ray images. However, both imaging techniques differ in that a parallax in the axial direction of the patient does not occur for the overview scan because of the minimal divergence of the x-ray beam due to slice collimation.

By means of the a.p. overview scan, it is possible to plan and program a particular slice plane, the slice thickness, and the number of slices or the volume. When using the lateral overview scan it is also possible to program special slice orientations by appropriately tilting the entire gantry. This is especially useful in skull radiographs and spinograms to exclude sensitive organs (e. g., eyes) from the scan. Figure 16.7a shows an a.p. overview scan of a thorax. Here, axial slices with a thickness and distance of 8 up to 10 mm are typically scanned. If the lumbar vertebrae are to be examined, the gantry must be tilted such that it is adapted to the ori-

entation of the individual vertebral bodies. Figure 16.7a also highlights that this is the only possibility for acquiring planar images of, for instance, the intervertebral disks.

Figure 16.7b,c shows two different orientations of the skull. If one aims to acquire coronal skull images, it is necessary to place the patient appropriately on the table. In Fig. 16.7b, a lateral overview scan of the patient can be seen. The patient is lying on his abdomen with his head heavily hyperextended. This hyperextension of the head is indeed required due to the limitations in the angle of gantry tilt. Two tomographic slices are shown on the right in Fig. 16.7b. Such radiographs are frequently used either to diagnose chronic sinusitis or to evaluate bone fractures. In slice 1, artifacts due to dental fillings can clearly be identified. Slice 2 shows a section of the frontal calvarium of the skull with spongiosa. Both slices allow unobstructed paranasal sinuses to be discerned. In comparison, axial images without gantry tilt are shown in slices 3 and 4 of Fig. 16.7c.

16.5.2 Hounsfield Units and Gray-Value Mapping

In CT, the attenuation values μ from (16.1) are usually represented as gray values. In this context, an approach developed by Hounsfield has proven to be appropriate and is nowadays commonly used. Here, the attenuation values are transformed onto a dimensionless scale and are related to the attenuation value of water. The definition of these CT values reads

$$\text{CT value} = \frac{\mu - \mu_{\text{water}}}{\mu_{\text{water}}} 1000. \quad (16.1)$$

In honor of Hounsfield, the unit of these values

$$[\text{CT value}] = \text{HU} \quad (16.2)$$

is called the Hounsfield unit (HU). On this scale, the CT value of -1000 HU is assigned to air and the CT value 0 HU to water. In principle, this is an open-ended scale, but in practice it ends at ≈ 3000 HU. The range of 4000 HU overall can be captured quite well by means of 12-bit gray-value images. This scaling is arbitrary, but nevertheless has practical consequences. Since the attenuation values of almost all organs – except the bones – are quite similar to those of water, the difference from the attenuation value of water that is given by (16.1) is of per mill.

Fig. 16.7a–c Preparation of an overview scan to plan the slice plane position (a). With a fixed tube detector position, the table is continuously moved through the gantry. This produces projection images similar to x-ray fluoroscopy. Two geometries are typically used: lateral – the patient is x-rayed from the side; anterior–posterior (a.p.) – the patient is x-rayed from the front to the back. Lateral overview scan for planning the slice position of head tomograms (b,c). Due to the limited tilt of the gantry, the patient has to be bedded face-down and with his head hyperextended to the neck to be able to acquire a coronal representation of the facial cranium (slices 1 and 2). In comparison, axial images without gantry tilt (slices 3 and 4)

Radiologists are accustomed to considering CT values as absolute values which can unequivocally be assigned to the organs. Deviations of these CT values for certain organs indicate pathology. Section 16.4.4 already pointed out the dependence of the x-ray attenuation on the wavelength of the radiation and the potential artifacts arising from this. This problem, which emerges in the case of all CT scanners used for diagnostic imaging, is a consequence of the usage of polychromatic radiation spectra.

While passing through the body, the spectral distribution of the radiation changes such that unequivocal assignment of attenuation values is actually not possible. Nevertheless, the view of the radiologists is largely justified, since most organs behave like water with regard to radiation physics. Therefore, it is possible to correct the beam hardening for these objects by means of a calibration measurement performed with a water phantom. Thus, for the CT values of soft tissue, the definition of the Hounsfield value is directly linked to the tissue density ρ . In this context, Fig. 16.8b is of special interest because different organs and organ changes can be readily distinguished.

It is sensible to divide the whole Hounsfield scale into diagnostically relevant intervals as shown in Fig. 16.8. Figure 16.8a shows a histogram of the relative frequencies of the CT values of an abdominal slice. The accumulations of air, the foam plastic of the patient bed, as well as the fat and the organs can be seen. In the representation of the tomographical slice of the parenchymatous organs, the problem arises that many organs are mapped into overlapping intervals of CT values. Therefore, a sound diagnosis is actually not easy; thus, textures of organs are also important in clinical practice.

The human visual system cannot resolve the complete dynamic range from -1000 HU up to 3000 HU with 4000 gray-value steps. This is the reason why, in practice, gray-value discriminations of only 256 or 512 steps are resolved on display devices.

Recent studies have shown that the human observer is able to discriminate between 700 and 900 shades of gray for the available luminance range of current medical displays and in optimal conditions [16.17]. To be able to detect differences between organs that have rather similar visual representations in their attenuation, it is necessary to map the respective anatomically sensible Hounsfield interval appropriately to the perceptible gray-value range. For this, one uses the piecewise linear function

$$G = 255 \cdot \begin{cases} 0 & \text{for CT value} \leq \text{WL} - \frac{\text{WW}}{2} \\ \text{WW}^{-1} \left(\text{CT value} - \text{WL} + \frac{\text{WW}}{2} \right) & \\ 1 & \text{for CT value} \geq \text{WL} + \frac{\text{WW}}{2} \end{cases}, \quad (16.3)$$

where WW denotes the window width and WL the window level.

Figure 16.8b,c shows the corresponding piecewise linear function for a bone window (WL = $+300$ HU, WW = 1500 HU) and a soft tissue window (WL = $+50$ HU, WW = 350 HU), as well as their effects on the representation of an abdominal tomogram. Density differences in the spinal process are visible only in the bone window, but differentiation of the soft tissue is hardly possible due to the large width of the window. In the soft tissue window, organs such as the liver and the kidney can be distinguished quite well. However, in this relatively narrow window, all CT values above $+225$ HU are displayed undifferentiated as white areas.

Figure 16.8a also exemplarily shows the results of applying different windows to an image slice of the thorax. Again, the relative frequency of the CT values is given. These images are especially challenging, since lung tissue, soft tissue, and bone tissue might be interesting from a diagnostic point of view. For the classification of the areas, three windows turned out to be quite useful. Thus, the lung or pleura window (WL = -200 HU, WW = 2000 HU), which allows the lung tissue with its low density to be differentiated, is added to the already mentioned soft tissue window and bone window.

16.5.3 Three-Dimensional Data Representation

In the previous sections, the reconstruction of two-dimensional images has been considered. However, today, medical applications of computed tomography are mainly related to three-dimensional imaging. In a first step, a stack of two-dimensional slices must be acquired. A conventional technique is given by a sequential procedure where the patient, lying on the patient table, is moved slightly in the axial direction of the scanner, i.e., the scanner's z -axis. The table then stops and a complete raw data set of a single slice is measured. The stack of tomogram slices is subsequently used to compute the three-dimensional representation of the depicted anatomy. This procedure is called *secondary reconstruction*.

Fig. 16.8a–c Attenuation values in Hounsfield units **(a)**. The data are compiled from the collections in [16.18]. The principle of windowing. The complete interval of practically sensible Hounsfield values (HU), ranging from -1000 HU up to 3000 HU (relative frequency of the values for the abdomen area – *lower left*), cannot be recognized and distinguished by the human visual system. Therefore, the different anatomically interesting Hounsfield intervals have to be mapped to appropriate grayscale intervals that can be differentiated. The *lower right* image provides the characteristic curves for two anatomically relevant windows. The *upper* images show the result of the bone window **(b)**: $WL = +300$ HU, $WW = 1500$ HU) and the soft tissue window **(c)**: $WL = +50$ HU, $WW = 350$ HU)

As for the surface visualization method, it is necessary to select a gray value threshold representing the surface. In this context one has of course a certain degree of freedom, as different objects may be visualized as long as their Hounsfield values are clearly different from one another. The gray-value isosurface will then be illuminated with a virtual light source so that the corresponding light reflections can be computed to display the result.

An alternative visualization method of 3-D CT data is multiplanar reformatting (MPR). MPR is used to show angulated sections through the three-dimensional stack of slices. Typically, the principal sections (the sagittal, coronal, and axial slices) are presented to

the radiologist. In Fig. 16.9e, a coronal reformatting is shown.

Figure 16.9b,c illustrates the volume rendering technique. This method assigns a physical light reflection and scattering value to each voxel (spatial pixel). The computer is then used to illuminate this *data fog* with a virtual light source and to model the optical impression artificially. To do so, real reflection and scattering of light is simulated. If bones, organs, and contrast-media-enhanced vessels are assigned different optical properties, interesting insights into the pathological status of the patient can be gained. In a postprocessing step, certain tissue types can be suppressed. In Fig. 16.9d, for example, bone is eliminated by a spe-

Fig. 16.9 (a–d) Angiographic image acquisition with CT (CTA). (a) *Maximum-intensity projection* (MIP), (b) volume rendering, (c) zoom into the knee and visualization from the back, and (d) virtual bone elimination with the bone removal technique. (e–i) Three-dimensional representation of the abdomen. (e) Coronal reformatting, (f–i) volume and surface rendering, (g) virtual endoscopy of the intestine together with (i) the representation of the virtual endoscopy trajectory, and (h) virtually opened intestine in cylindrical coordinates

cial bone removal technique for better visualization of the vessel tree.

An alternative to volume rendering is surface rendering, as illustrated in Fig. 16.9f–i. The individual shades of gray of the layers (images) in the data stack represent the degree of physical attenuation of the x-ray beam. In a clinical context, deviations from the normal distribution of these values may indicate pathological changes in the patient.

During visualization, it is possible to visualize certain ranges of values and to selectively suppress others. If the viewer chooses a constant gray value, i. e., a threshold, all spatial points with this value may be displayed in space as an isosurface. This surface is approximated by triangles using a technique called triangulation. Then, the mosaic of triangles is again illuminated and displayed using the virtual method described above. The larger the number of mosaic pieces

Fig. 16.10 (a) Perfusion measurement for stroke patients, (b) visualization of lung emphysema, (c) CT angiography of the cranial vessels, and (d) imaging of a coronary stent

chosen for the reconstruction of the surface, the more lifelike the result.

In addition to the three-dimensional representation of organs or bone surfaces, which may be interactively rotated on the computer screen, an interior view of hollow organs and airways of contrast-enhanced vessels can be produced. In this way, virtual flights into the body – for example, into the bronchial tubes or the intestine – can be visualized. In Fig. 16.9i, a virtual insight into the human intestine is shown. The value of such a three-dimensional diagnostic approach lies in the reduction of the large amount of data otherwise inherent to the hundreds of single slices.

16.5.4 Clinical Applications

The final section of this chapter describes the broad variety of clinical applications of modern CT imaging by means of some examples. In Fig. 16.10, four typical applications are illustrated. Important fields of application are summarized in the following.

- *Brain perfusion:* The blood flow in the brain (cerebral blood flow, CBF), blood volume in the brain (cerebral blood volume, CBV), mean transit time (MTT), and peak time of the bolus maximum (time to peak, TTP) are acquired and displayed as colored overlays on the relevant CT slices. In this way, colored maps of tissue vitality give indications of an acute or chronic infarct (Fig. 16.10a).
- *Liver perfusion:* Arterial and portal measurements of perfusion in liver studies.
- *Tumor perfusion:* Characterization of known lesions via their perfusion.

16.6 Dose

The gain in diagnostically valuable information accompanying the advent of computed tomography was considered to be exceptional. This is one of the main reasons why the applied dose was not considered to be of vital importance during this developmental stage. Based on the number of devices currently installed in Germany and an average of 3500 examinations per year, an annual total number of several hundreds of millions of slices can be estimated to be acquired each year.

This approximately lies within the same range as the total number of standard projection radiographs acquired in clinical practice. Considering the different

- *Lung measurement:* Diagnostics of lung emphysema (Fig. 16.10b); automatic detection of lung nodules.
- *Calcium scoring:* Quantification of coronary calcification.
- *Vessel analysis:* Visualization of vessel trees (Fig. 16.10c); analysis of stenoses and aneurysms; planning of stents.
- *Cardio CT:* Identification and quantification of stenoses; planning of stents and visualization of implanted stents (Fig. 16.10d).
- *Virtual endoscopy:* Three-dimensional CT data as a basis for anatomical interior views of hollow organs (Fig. 16.9i) and contrast-enhanced vessel trees.
- *Trauma:* Fast imaging of the entire body for diagnostics of accident injuries.
- *Dental planning:* Three-dimensional reconstruction and slices through the maxilla and mandible as a planning basis for implantation of prostheses for the oral surgeon.
- *Planning of radiotherapy:* Three-dimensional CT reconstruction as a basis for dose planning in the radiation therapy of tumors.
- *Image-guided surgery:* Three-dimensional CT reconstruction as a basis for planning and navigation of surgical interventions.
- *Interventional imaging:* Visualization of a surgical instrument tip during a biopsy.

In particular, perfusion measurements show that today CT is on its way towards becoming a functional modality. This technique allows the blood flow to be measured after contrast media injection into different organs.

types of radiological examinations (x-ray examinations), one immediately becomes aware of the following discrepancy. Although CT examinations represent only about 4% of all radiological examinations, their share of the total dose amounts to $\approx 35\%$. In short, CT accounts for the largest portion of medically related x-ray exposure.

Considering new generations of CT scanners, such as spiral multislice CT, the applied dose indeed is not reduced. In fact, it is more likely that the dose applied during one single imaging session will increase. This is mainly due to the fact that, in modern

scanners, longer sequences and thinner slices can be easily measured [16.19]. Initiated by reports about unnecessarily high x-ray exposure in pediatric CT examinations [16.20], which were actually performed on the basis of the same scanning protocols as were used in human adults, a high sensibility concerning the applied dose has emerged among both manufacturers and users. Recent developments such as automatic exposure control take the problem of dose into account. With this technology, one can easily adjust the dose according to the anatomy of the patient or likewise take into account whether the individual under examination is an adult or an infant.

Figure 16.11a schematically illustrates that one initially has to differentiate patients according to their physique and between infants and adults. If we adopt the same tube current–time product for infants as is used in scan protocols for adults (Fig. 16.11a, left), the obtained intensity of the x-ray at the detector and thus the applied dose, with respect to the achievable diagnostic quality (i. e., the $\text{SNR} = \mu/\sigma$), is unnecessarily high. Therefore, in the case of a pediatric examination, it indeed is reasonable to decrease the anode current to a level that allows a comparable diagnostic quality to be obtained as achieved in the examination of an adult (Fig. 16.11a, right). Such automatic exposure control (AEC) can be steered by means of the scanogram.

Figure 16.11b illustrates dynamic adaptation of the x-ray tube current or dose with respect to the anatomical situation observed along the axial z -axis (longitudinal dose modulation). In anatomical areas in which, as known a priori, low attenuation of the x-ray intensity is to be expected (for example, within the lung area) the tube current and thus the dose can be lowered, without decreasing the image quality. If all areas are imaged with the same tube current, this will result in either dose rates that are too high or noise levels that are too strong.

Figure 16.11c illustrates dynamic adaptation of the tube current across the projection angle γ to the integral attenuation of the radiated body area (angular dose modulation). At all sections through the body, which are oval rather than circular, the angular dose modulation is to be applied. In particular for image acquisitions of the shoulder, strong dose modulation is to be used.

Another possibility for dose reduction arises in cardiac imaging. In Fig. 16.11d, a trigger sequence of an ECG-triggered image acquisition of the heart is depicted. Since data are only acquired within the resting phase of the beating heart, the overall dose can be significantly reduced, provided that the tube current is switched off outside the data window. This effec-

tive and efficient procedure is called temporal dose modulation. Figure 16.11e shows the effect of the combination of longitudinal and angular dose modulation on the attenuation of the x-ray beams and on the tube current.

Apart from device-related measures for reduction of radiation exposure, for which the manufacturers bear responsibility, there is a set of user-related measures which also affect the applied dose. The quantities and their connection to the dose, adjustable in the scan protocol, are given in the following. For a detailed discussion on radiation exposure in CT, one is referred to the book by Nagel [16.19].

- *Current–time product (mAs product):* Dose and mAs product, i. e., the product between the x-ray tube current and acquisition time, have a linear dependence. However, the standard deviation, i. e., the image noise, increases proportionally to the inverse of the square root of the mAs product.
- *Acquisition time:* At constant x-ray tube current, the dose increases linearly with acquisition time. However, the mAs product is always to be considered as a total, so that, at a constant dose, the acquisition time can be reduced along with simultaneously increasing the tube current. Thereby, the image noise is unaffected; however, motion artifacts are less likely to occur at short acquisition times (Sect. 16.4.4).
- *Tube voltage:* With increasing tube voltage U_a (Sect. 16.3.1), the efficiency of the x-ray tube as well as the penetration of the radiation are increased. The intensity of the radiation increases with U_a on average following a power of 3.5. With deeper penetration of the radiation, the image contrast obviously decreases. However, this is more than compensated for by the better quantum statistics. Therefore, the image quality generally is improved – obviously at the expense of a higher dose being applied to the patient. If the voltage is, for instance, increased from 120 to 140 kV, in order to reduce the dose whilst maintaining image quality, the mAs product must be reduced by 40%. Thus, a dose reduction of $\approx 15\%$ is obtained [16.19].
- *Thickness of the object to be imaged:* For infants and frail patients, one has to bear in mind that a smaller mAs product has to be adopted. Due to lower attenuation, the statistics of the x-ray quanta are still as good as for adults or heavier patients. Correspondingly, image quality is not affected. For heavier patients, an increase in x-ray tube voltage is prefer-

Fig. 16.11a–e Active methods for dose reduction [16.19]. **(a)** Automatic exposure control (AEC) differentiates between heavier and thinner patients. **(b)** The longitudinal dose modulation – a dynamic adaptation of the tube current or dose to the anatomical situation. **(c)** Angular dose modulation – a dynamic adaptation of the tube current or dose to the shape of the axial body section. **(d)** Temporal dose modulation. **(e)** Combination of longitudinal and angular dose modulation. (IQ – image quality)

able to an increase in the mAs product, since the increase in radiation exposure is less intense.

- *Slice thickness*: The slice thickness can typically be adjusted by means of a tube sided collimator from 1 up to 10 mm. Thereby, the slice thickness does not affect the dose if the same body section is to be measured. The advantage of a finer slice sequence is the reduction of partial-volume artifacts as well as step artifacts occurring on coronal or sagittal reformatting of the image. The disadvantage is that, at a finer collimation, fewer x-ray quanta will reach the detector such that the image noise will correspondingly increase. If the image quality is to be kept constant, the mAs product and thus the dose will have to increase inversely proportionally to the slice thickness.
- *Pitch factor*: A pitch factor of $p = 1$ means that, in the case of a rotation of the sampling unit through 360° , the patient table is moved linearly by a length equal to the adjusted slice thickness (Sect. 16.4.3). If $p < 1$, the individually measured slices have a larger overlap, such that the image quality is increased. However, this results in an increased dose. Accordingly, if $p > 1$, the dose can be reduced. In theory, an artifact-free image reconstruction should be possible up to a pitch of $p = 2$. With this, the scanning length is increased such that, for the same mAs product, fewer x-ray quanta are available for the image formation of a coevally larger body section. Therefore, the image noise increases.
- *Scanning length*: If the imaged body section is enlarged, the dose applied to the patient will increase accordingly. This is expressed by means of the effective dose or the dose-length product. The number of slices always has to be limited to the diagnostically relevant section, which has to be specified in the overview scan (Sect. 16.5.1).
- *Filter kernel*: The choice of the respective filter kernel at first glance does not directly influence the dose. However, as described in Sect. 16.4.2, the choice of the high-pass filter of the filtered backprojection does indeed affect the image resulting from the reconstruction, since the choice of the filter ker-

nel represents a trade-off between noise and spatial resolution. If one wants to reduce the noise while maintaining high spatial resolution, this is only possible at the expense of an increase in dose. Thus, it always depends on the diagnostic question as to whether an appropriate choice of the filter kernel can be used for dose reduction.

- *Window width*: The window width (Sect. 16.5.2) used for adjusting the display of the CT images does not initially have a direct influence on the dose. However, the higher the contrast selected by constricting the window width, the stronger the noise present in the images. Conversely, it is possible to smooth the image by enlarging the window width. If there is a contrast reserve due to the diagnostic question, smoothing of the visualization can already be incorporated during the planning step. This will decrease the mAs product and thus the radiation exposure.
- *Field of view (FOV)*: When using a very small FOV, i. e., a very strong detail magnification, as a general rule, a very sharp reconstruction filter has to be used. This is due to the fact that the magnification of the section under examination is chosen because a locally more detailed image needs to be analyzed. This immediately has consequences for the image noise, which can only be reduced with an increase in the mAs product and, therefore, an increase in the applied dose.

Finally, it should be mentioned that the progress toward smaller detector elements also influences the dose. It can be shown that, for constant signal-to-noise ratio, the dose increases with the inverse fourth power of the detector element size, as described in detailed in [16.4]. If in the formula of Brooks it is assumed that $b = d = \Delta\xi$ for the sampling distance at the center of rotation and for the slice thickness, respectively, then, in consideration of the definition of the signal-to-noise ratio $\text{SNR} = \mu/\sigma$, one obtains the relation $D \propto (\text{SNR})^2/(\Delta\xi)^4$. Obviously, this limits a further reduction of the size of the detector elements, since the dose may not be arbitrarily increased.

16.7 Special System Designs

In the last few decades, special CT imaging designs have been developed for certain applications, and this chapter concludes with a brief review of five of these.

For coronal imaging, the problem of motion artifacts (Sect. 16.4.4) arises with the conventional CT imaging concepts described above. Third-generation CT systems

therefore require ECG-triggered data acquisition, because with respect to the time constants of heart motion, even subsecond CT scanners without ECG-triggered data acquisition are too slow.

For this kind of clinical application, electron-beam computed tomography (EBCT) has been developed and will be described below in Sect. 16.7.1. Furthermore, a short description of volume or cone-beam CT – often abbreviated as VCT or CBCT, respectively – will be given in Sect. 16.7.2. These systems are subsequent steps beyond multislice CT (MSCT). However, if very small object details in the micrometer range must be imaged, the spatial resolution of conventional clinical CT is insufficient. For this task, special micro-CT systems have been developed (Sect. 16.7.3). Since nuclear imaging is able to visualize the metabolism of a patient, and x-ray transmission computed tomography gives complementary morphological information, a consequent idea is the combination of both modalities into so-called PET-CT scanners, which will be introduced in Sect. 16.7.4. In the last section (Sect. 16.7.5), a system extension to include two sampling units, i. e., two x-ray tubes and two corresponding multislice detector arrays in a so-called dual-source system, is described.

16.7.1 Electron-Beam CT

If there is a need for extremely short acquisition times, the concept of moving sampling systems must be left behind entirely. One approach to achieving this is the use of electron-beam computerized tomography (EBCT). This type of CT was developed for cardiac imaging.

In EBCT, there is no longer a localized x-ray tube rotating around the patient as in conventional CT technology. Instead the patient is situated, in a manner of speaking, *inside* the x-ray tube. An electron beam is focused onto wolfram target rings, which are arranged in a half circle around the patient, and generates the desired x-ray fan beam upon impact with the wolfram target. The x-ray irradiation is measured with a stationary detector ring. Such systems have mainly been sold to cardiologists by the company Imatron. The electron-beam technique is able to acquire an image slice in 50 ms. Figure 16.12a shows a diagram of an EBCT system as well as an illustration of a modern Imatron system. Further technical details can be found in [16.22].

Fig. 16.12 (a) Electron-beam CT, (b) volume or cone-beam CT, (c) PET-CT, and (d) dual-source CT [16.21]

16.7.2 Volume CT

There has so far not been a common definition of the generations of development of CT. In [16.10], scanners equipped with a cone-shaped x-ray beam and a plane detector are referred to as the seventh generation. However, even within the cone-beam scanner itself, one needs to distinguish between systems that use only a small cone opening, as in the case of a multislice (multiline) detector system or indeed a symmetric x-ray cone. In particular, the necessary reconstruction methods differ extensively between these systems. To understand the motivation behind the development of cone-beam CT systems, recall that the step from the pencil-beam to the fan-beam concept came along with the advantages that the x-ray source was exploited more effectively, and that there was a reduction in acquisition time. The efficiency of the energy transformation in the generation of x-ray radiation is just about 1%.

As the heat produced inside the x-ray tube essentially defines the physical capacitance, and therefore limits the measuring time, the next straightforward step in the development of CT scanners involved the use of a cone-shaped x-ray beam, which is already produced in the x-ray tube. Both the pencil-beam and the fan-beam geometry are created by means of appropriate pinhole or slit collimators, which reshape the original x-ray source intensity profile, reducing efficiency.

Technologically, there are three important problems that had to be solved before the successful application of cone-beam geometry to CT imaging. First of all, a flat-panel detector, which did not exist at the time, had to be introduced to replace the line or multiline detector arrays. Second, the huge amount of raw data that quickly emerge on subsecond scanners in particular had to be transferred from the rotating sampling unit to the image reconstruction computer. The bandwidth required for the data transfer poses a challenge even today. Third, there is the problem of reconstruction, whose mathematics is slightly more sophisticated compared with the two-dimensional methods.

Figure 16.12b schematically shows the cone-beam geometry of an imaging system with a planar detector (flat-panel detector, Sect. 16.3.2). The planar detector geometry was first applied for technical applications in micro-CT, since the required charge-coupled device (CCD) chips were only available for this geometry. Figure 16.12b shows a prototype of a so-called volume CT (VCT) developed by General Electric Medical Systems.

16.7.3 Micro-CT

Recently, micro-CTs, which essentially comprise a miniaturized design of the cone-beam CTs mentioned in the previous section and which are typically used for nondestructive, three-dimensional microscopy, have become commercially available. The x-rayed measuring field, often as small as 2 cm^3 in volume, is so small that medical applications might seem to be ruled out. Indeed, these scanners are more commonly used for material testing and analysis, but medical applications are on their way to taking center stage. An example in human medicine is the analysis of trabecular structures in bones. Micro-CTs are also ideal scanners for radiological examinations of small animals [16.23]. Micro-CTs are often produced as desktop devices and have a measurement chamber that is entirely shielded by lead walls against scattered x-ray beams, so that no further means of protection are necessary. The object to be examined is placed on a rotating specimen disk, which is controlled by a stepper motor.

The two most crucial components of micro-CTs are the x-ray tube and the two-dimensional detector array. In particular, it is the size of the focus and the size of the detector elements that, apart from the mechanical accuracy of the rotary motion, determine the spatial resolution. Therefore, micro-CT systems need a micro-focus x-ray tube. An x-ray focus size of $b_F < 10\ \mu\text{m}$ is desirable. Unfortunately, when using such a small target area for the electrons, the anode current cannot be very large. The current is typically less than $100\ \mu\text{A}$. Since the current controls the intensity of the x-ray spectrum, there are certain constraints with respect to the materials being examined.

A 12-bit x-ray charge-coupled device (CCD) chip with a pixel matrix of 1024×1024 or higher may be used as a detector, which can be connected to a scintillation crystal by fiber optics. The size of the picture elements typically has an order of magnitude of around $b_D < 10\ \mu\text{m}$. SkyScan specifies a resolution of about $10\ \mu\text{m}$. As micro-CTs are cone-beam x-ray systems, three-dimensional reconstruction methods are required to calculate the images [16.24].

16.7.4 PET-CT

With the exception of contrast-enhanced angiography and perfusion techniques, CT, on its own, is only able to provide morphological information, i. e., information on the shape of objects. On the other hand, positron emission tomography (PET) provides informa-

tion on metabolism, i. e., the biomedical function of an anatomical region [16.25]. CT, however, is based on the attenuation of x-ray radiation. Different organs, having different absorption properties, are therefore only imaged according to their shape, and the patient is considered to be passive during imaging.

In PET, the patient is injected with a radioactively marked *tracer*, which is metabolized inside the body. One very important tracer is 2-(fluorine-18)-fluoro-2-desoxy-D-glucose (^{18}F -FDG), which can be used to trace glucose metabolism. This is especially important for oncology studies, since, due to their faster metabolism, the ^{18}F -FDG uptake of tumors exceeds the uptake of nonmalignant tissue. Compared with ordinary glucose, ^{18}F -FDG differs in the presence of the tracer atom. As such, it behaves like glucose only at the beginning of the metabolic chain. Thereafter, the molecule is detected but not catabolized any further, leading to an accumulation of the tracer inside the tumor.

^{18}F -FDG is a positron emitter, so wherever the tracer accumulates, the process of positron annihilation is intensified; i. e., upon collision with an electron, the positron entirely dematerializes, becoming two gamma-ray photons that fly away in opposite directions. These gamma-ray photons are then measured by two detectors, located opposite each other, in what is called a coincidence measurement. By means of, for instance, filtered backprojection or statistical reconstruction, the location of the dematerialization can be reconstructed, and tumors are represented as *hot spots* inside the image.

An interesting approach to imaging diagnostics is the combination of both morphological and functional imaging methods. The goal of displaying function along with morphology in a single image has been realized for some time using methods of image registration. Registration is an image processing step that must overcome problems caused by the different positioning of the patient in the two different scanners and changes resulting from the time that passes between the two acquisitions.

In the case of combined techniques, the patient is successively scanned using the different imaging modalities. Using a combined PET-CT scanner, such as, for instance, the *biograph* from Siemens (Fig. 16.12c), the images are acquired almost simultaneously, with the patient effectively in the same position, so that the location of a tumor relative to the surrounding anatomy can be displayed immediately.

16.7.5 Dual-Source CT

Figure 16.12d shows a recent development in the field, the so-called dual-source CT. Two complete sampling units, both of which consist of an x-ray tube and a detector array, are installed perpendicular to each other. Best images of the beating heart are obtained when the acquisition interval is set to the diastolic phase. Since the patients are usually agitated, this resting phase of the heart is often so short that motion artifacts are inevitable. Usually, images have to be acquired across 180° , in order to obtain a complete raw dataset within the relatively short resting phase of the heart. However, when employing a sampling unit taking advantage of the dual-source technology, only a rotation of about 90° is necessary. Thereby, the sampling time is halved, such that motion artifacts are significantly reduced. If one wants to abandon the administration of beta blockers, which are used to lower the pulse, artifact-free image reconstruction by means of a single source scanner is no longer possible. Here, the strength of the halved acquisition time becomes apparent. Using these modern dual-source subsecond scanners a temporal resolution can be achieved that only differs by a factor of 2 from the acquisition speed achieved by electron-beam CT. Considering the applied dose, the ECG-supported triggering of the acquisition window is of great importance. Here, compared with the standard CT scan protocol in which the tube current is not modulated, a dose reduction of up to 50% can be achieved.

Ultrasound D

17. Ultrasound Diagnostics

Rudolf Götz, Frank Schön

Today, ultrasound diagnostics is an important imaging method in virtually all medical fields. The fact that it is quick, simple and in particular cost-efficient plays a major role in this. Further advantages are provided by the mobility and the broad spectrum of use of modern ultrasound diagnostic systems. Not least, these properties and also the absence of ionizing radiation make its use indispensable these days.

According to data from the German Electrical and Electronic Manufacturers' Association (Zentralverband der Elektrotechnischen Industrie – ZVEI), the ultrasound market for new devices has a sales volume in Germany of approximately €200 million per year. Approximately 50% of this volume is from acquisitions in clinics and hospitals, and approximately 50% is from doctors in private practices. The distribution of sales between the different specialist fields gives the following pic-

ture: approximately 30% gynaecology, approximately 30% internal medicine and approximately 20% cardiology.

The high density of devices used in everyday diagnostics is due to there being a large number of different technical and applicative methods (Table 17.1) and a number of different industrial suppliers. Ultrasound diagnostics has partly replaced or supplemented other methods, such as conventional x-ray diagnostics but

Table 17.1 Overview of the advantages and disadvantages of imaging methods

	Ultrasound	CT	MRI	X-ray	Angio	Nuclear medicine

also computer tomography (CT) and magnetic resonance imaging (MRI).

In contrast to these methods, ultrasound is a so-called real-time method. The organs being investigated are displayed on a monitor in real time in this sectional

imaging technique. They therefore correspond to a tomographic sectional image familiar from CT and MRI. Ultrasound imaging thus differs substantially from the method of looking through the body in a conventional x-ray examination.

17.1 Basic Physical Principles

17.1.1 Principle

The following explanations regarding the generation of ultrasound images follow theoretical considerations and are presented in an idealized form. They are based on physical principles which are intended to be presented to the reader in a way which is simple and easy to understand. The actual generation of ultrasound images is much more complex, however. An essential part of image generation is based on the phenomenon of scattering, which makes the process which actually takes place much more complicated, and this will only be referred to here in passing. It will not be discussed in further detail in the text below.

In ultrasound diagnostics, the transmitter and receiver are combined in the ultrasound probe. The probe is connected to the ultrasound unit via a cable, thereby enabling very free positioning of the ultrasound probe on the body and thus also virtually any desired examination plane and slice orientation.

In contrast to the x-ray method, which is a transmission method, ultrasound is a so-called reflection method. The ultrasound probe transmits a short ultrasound pulse which penetrates the body and is partially reflected at interfaces, e.g. between liver and kidney. Once the pulse has been emitted, the unit switches the ultrasound probe to receive mode. The ratio of transmission to reception time is approximately 1 : 1000.

The reflected components of the sound wave transmitted are then recorded by the ultrasound probe and fed to the unit for further processing. With the exception of the continuous wave method (Sect. 17.3.2), ultrasound

units therefore basically work with what is known as the pulse method. This principle is also wide-spread in the natural world and is used, for example, by bats, dolphins and other animals for orientation.

17.1.2 Generation of Sound Waves

Special, cut piezoelectric crystals are used to generate sound waves. These synthetic crystals are manufactured industrially, for example from fractions of barium titanate, lead zirconate, lithium compounds or other ceramics. These are subject to what is known as the piezoelectric effect, which was described by the brothers Jacques and Pierre Curie using crystals of tourmaline. As soon as a voltage is applied to a crystal of this nature, it changes its form or geometry. Depending on the polarity of the voltage, dilatation or contraction of the piezoelectric crystal occurs.

If a high-frequency alternating current is therefore applied, then it oscillates at precisely that frequency and generates high-frequency sound waves. If the alternating current applied is at a correspondingly high frequency, this produces ultrasound waves which are no longer audible to humans (Fig. 17.1). In the receive mode, however, sound waves impinging on the crystal are converted into an electrical alternating current which is then processed further by the unit (Sect. 17.3).

17.1.3 Reflection

On the way through the tissue, components of the transmitted sound wave are reflected at interfaces between different organs and sections of organs. The energy of the waves which are reflected is determined in each case by the differences in the so-called wave impedance (Z) of the individual organ parts and sections scanned. There is more or less reflection at these multiple interfaces depending on the relationship between the individual wave impedances, on the angle of impact with respect to the interface and on the surface texture (scattering).

Fig. 17.1 Frequency ranges

In order to contribute towards the generation of an image, the reflected wave must have sufficient energy as energy is also lost on the return path to the crystal. The ideal reflected component is approximately 1%, which corresponds to a reflection coefficient of $R = 0.01$. Higher reflection coefficients result in a greater loss of energy of the propagated wave overall, thus resulting in insufficient penetration of the ultrasonic beam into deeper tissue.

The reflection coefficient is by definition between 0 and 1, where $R = 0$ means that there is no reflection taking place and $R = 1$ corresponds to total reflection. The reflection coefficient R is calculated from the wave impedances of the two media which form the interface (Fig. 17.2). The difference between the two wave impedances is crucial here.

As can be seen from (Fig. 17.3), the wave impedance of air is vastly different from that of human tissue, with the result that there is a high reflection coefficient of nearly $R = 1$ and total reflection occurs. An interface with air is therefore an obstacle to ultrasound which cannot be overcome. In order to achieve the best possible transmission from the probe to the body without any loss of energy, ultrasound gel is used as a coupling medium. On account of its very high water content, the gel conducts sound well and should ensure air-free contact with a reflection coefficient of roughly $R = 0$.

However, it is not only air but also metal parts, bones and calcium particles which can present problems that produce virtually total reflection. This explains acoustic shadows behind bones, gall stones or endoprostheses, for example.

17.1.4 Spatial Mapping – Transit Time

The spatial mapping of the scanned tissue and reflecting interfaces is done by measuring the transit time from transmission of the pulse to receipt of the respective reflected components. Early echoes means that the waves have been reflected by interfaces close to the ultrasound probe. Late echoes means that the waves have been reflected by interfaces a long way from the ultrasound probe. This difference in time is represented on the monitor display by a corresponding distance between the pixels in the sound beam direction. However, this presupposes knowledge of the speed of sound conduction in the tissue, which is assumed to be on average 1530 m/s (Fig. 17.4). Since different tissues also have different wave impedances, this average is inevitably a generally accepted compromise and is used in standard commercial ultrasound units.

Fig. 17.3 Various reflection coefficients

Fig. 17.4 Sound wave travel speed in tissue

Only very modern ultrasound units take into account these differences in the speed of travel of the sound waves when calculating the ultrasound images and compensate for the differences in the transit time, either manually with intervention by the user or else automatically.

17.1.5 Penetration Depth, Axial Resolution and Frequency Ranges

It is not only the number of reflecting interfaces and their reflection coefficients but also the frequency of the sound waves which influence the penetrative power of the sound waves. Higher transmission frequencies lose more energy over the same travelling distance than lower transmission frequencies and thus achieve a shorter penetration depth than lower frequencies.

Fig. 17.5 Illustration of two reflectors at different distances

Fig. 17.6 Frequency ranges of diagnostic ultrasound

However, high frequencies have an advantage in terms of the axial resolution on account of their shorter wavelength (λ). In a theoretical best-case scenario, the minimum wavelength for separate imaging of two interfaces is a single wavelength. A frequency of 5 MHz, for example, gives a wavelength of 0.3 mm, whereas a frequency of 10 MHz corresponds to a wavelength of 0.15 mm. More individual interfaces can therefore theoretically be resolved at 10 than at 5 MHz (Fig. 17.5).

As can be seen in the figure, a pulse packet does merely not consist of a single wave with a positive and negative amplitude but also includes attack and, in particular, decay amplitudes. These lengthen the overall pulse packet by several oscillations. In modern high-end units on the market, a considerable degree of technical complexity is sought after in order to control the transient phenomena in the crystals. The aim is to generate the shortest possible pulse packets, ideally with only a single sine pulse. This can only be achieved through precise knowledge of the respective crystal characteristics of the ultrasound probe and with appropriate control using customized electrical pulse lengths and pulse forms. As a result of this *electrical behavior* of the crystals, pulse packet lengths are achieved which are nearly the size of a single wavelength. The theoretical resolution of 0.15 mm at 10 MHz can therefore approximately be achieved, as mentioned in the example above.

The axial resolution is thus proportional and the penetration depth is inversely proportional to the frequency. For practical applications of ultrasound, this provides a necessary compromise between the desire for high axial resolution and a good penetration depth.

Figure 17.6 gives an overview of the different frequencies used to produce images of different organs.

17.1.6 Influencing Factors: Pressure and Temperature

As already mentioned, the speeds at which sound waves pass through a medium are primarily dependent on the material properties of the medium. A change in the atmospheric conditions of temperature and pressure likewise influence the propagation velocity of the ultrasound pulse. Both an increase in temperature and a rise in pressure go hand in hand with faster propagation of sound waves.

In this context it is significant that the ultrasound pulse itself exerts positive and negative pressure in periodic alternation on the transmission medium. This means that the ultrasound pulse itself influences the sound-conducting properties of the medium with its

pressure fluctuations. These effects on the medium and the resulting interactions continuously change the properties of the ultrasound pulse during the propagation through the tissue. This change has an effect on the signal quality and can be put to technical use.

17.1.7 Second Harmonic

During the course of time of a sinusoidal wavelength, the periodic pressure fluctuation triggered by the ultrasound pulse leads to a regularly changing sound propagation speed. The positive half-wave (pressure) moves with greater speed than the negative half-wave, with the result that the negative-going edge of the positive sound wave becomes increasingly steep as the distance from the sound source increases (Fig. 17.7).

A similar phenomenon can be observed in sea waves on the beach. The lower section of the wave, which is close to the sea bed, moves more slowly because it is braked by the ground which is getting closer all the time. The upper section of the wave is largely uninfluenced by this and thus moves more quickly. At some point, this effect becomes so great that the crest of the wave *falls* forwards, as it were, and the wave breaks.

The pulses from an ultrasound unit emitted into the body also experience this deformation on their path through the tissue. Whereas the sound wave still exhibits a virtually sinusoidal pressure curve when it is

close to the crystal, as the distance from the crystal increases the shape of the wave increasingly resembles a saw-tooth. The higher the intensity of the sound emitted, the earlier and more pronounced this deformation. Every nonsinusoidal oscillation can be broken down into multiple sinusoidal oscillations of different frequencies by means of Fourier analysis (Fig. 17.8).

The saw-tooth-like shape of the changing pulse contains firstly a sinusoidal fundamental wave (a), furthermore a sinusoidal oscillation with a relatively low amplitude and half wavelength (b), and also other sine oscillations with constantly decreasing amplitudes which correspond to an integral quotient of the fundamental wavelength (c). These high-frequency components are also known as harmonic frequencies. This *harmony of sound* is familiar to us all from music, as the generation of sounds in musical instruments is subject to similar principles.

Conventional signal processing suppresses the higher-frequency signal components, so that the dominant fundamental of each reflected signal is primarily used for imaging. In the method known as *second harmonic imaging*, however, the first overtone (second harmonic) is isolated and used to obtain an image. The fundamental (first harmonic) and all other overtones are filtered out and are not used further.

Using the second harmonic frequency has a number of advantages. The main advantage is the significantly

Fig. 17.7 Change in the shape of a sound wave as a result of nonlinear sound velocity

Fig. 17.8 Transformation of a nonsinusoidal oscillation into various sinusoidal oscillations

clearer differentiation between liquid and solid tissues. The reason for this is the more pronounced saw-tooth-shaped signal deformation in solid structures (tissue) and the lesser degree of deformation in liquid tissues, in which virtually no reflected harmonic waves are generated. Some companies therefore also refer to this technique as tissue harmonic imaging. Another advantage of using harmonics is that the amplitude of the interfering side lobes which occur automatically at the fundamental frequency is too low to generate overtones.

Tissue harmonic imaging is therefore a technique which reduces artifacts in the ultrasound image and makes it possible to more cleanly and clearly delimit liquid-filled cavities in particular, such as the amniotic cavity, the bladder, the cardiac cavities or cysts. These days it is also used in devices in virtually all price ranges.

17.2 Visualization of the Blood Flow and Vascular System

17.2.1 Doppler

In addition to calculating the depth of a reflecting interface, the pulse reflection method generally used in ultrasound also provides the possibility of detecting a moving structure and measuring its speed. This is possible due to technical processing of the reflected signals, which differs from the method described before of determining the transit time and which, in addition to displaying the tissue morphology, also enables functional diagnosis of moving tissue volumes and liquids (blood, muscle, urine).

17.1.8 Broadband Harmonics

One disadvantage of using the second harmonic is that the reflected second harmonic has less penetrative power as a result of the doubling in the frequency. Because these waves must cover the distance to the ultrasound probe, however, the depth of field of the ultrasound image which can be displayed is overall reduced. Use of this technology should therefore be left to the user, who differentiates depending on the organ being investigated by switching the unit on and off.

Some modern high-end devices provide another possibility for using harmonic signals, however. In addition to the harmonics already described, Fourier analysis also shows so-called half-waves (subharmonics) with half the fundamental frequency of the transmission pulse.

The simultaneous use of half-waves and second harmonics to calculate an image compensates for the disadvantage of the short depth of field because of the lower frequency of the half-wave and its better penetrative power. The reception and processing of these signals place high demands on the frequency spectrum of the ultrasound probe which can be effectively used and also on the signal processing electronics. In general, the ultrasound probe and the piezoelectric crystals used in it have optimized frequency ranges due to their material and design. The broadband capability of the ultrasound probe is indispensable for the simultaneous reception of half-waves and harmonics and is crucial to the quality of this reception. In high-end devices, this technology is found under the name broadband harmonics.

This method is named after the Austrian physicist Christian Doppler and is based on the phenomenon, which we know from everyday life, that the frequency of sound of a moving object changes according to its speed and direction. Everyone is familiar with the phenomenon of the changing sound of a passing ambulance which has its siren turned on. This phenomenon is known as frequency shifting.

The measurable change in frequency between the emitted and the reflected signal, which in ultrasound is called the Doppler shift or the Doppler frequency shift (f_D), is proportional to the speed of the moving struc-

Fig. 17.9 Formula for describing the Doppler effect (f_1 transmission frequency, f_2 reception frequency, Δf measured Doppler shift, v speed of the target particle, φ angle of incidence between the sound beam direction and the direction of movement of the target particle, c sound velocity)

ture. The relationship between the Doppler shift and the speed of the target particle is illustrated in Fig. 17.9. The speed of the movement can be calculated by determining f_D in the ultrasound unit and with the aid of the known variables of sound velocity, transmission frequency and reception frequency.

A fundamental problem in the practical Doppler measurement is its reliance on angles. As can be seen in Fig. 17.9, there is a connection, dependent on the angle φ , between the moving structure and the position of the observer. Extreme cases are, firstly, direct measurement in or against the direction of movement ($\varphi = 0^\circ$) and, secondly, measurement at right angles to the direction of movement ($\varphi = 90^\circ$). In the first case, f_D corresponds to the actual speed, whereas in the second case the result given by the correction factor ($\varphi = 90^\circ$, which gives $\cos \varphi = 0$) does not give a measurable speed.

For practical use, it holds that an angle of between 0° and no more than 60° to the direction of movement should be used when using the Doppler technique.

17.2.2 B-Mode

In the B-mode, too, visualizations of the blood flow are also possible to a limited extent, since the reflection coefficient of blood is approximately 1000 times lower than that of tissue. On certain conditions (immediate proximity to the blood-conveying organ, slow-flow phenomenon, haematocrit, etc.), the blood flow is visualized spontaneously, which is known as spontaneous flow or spontaneous echo.

However, by subtracting two consecutively recorded image lines and subsequently superimposing them

with one of the noncontrast lines, modern signal processing technology provides the possibility of imaging the movement of the reflecting structures which takes places between the two recordings. The advantage of this method (B-flow) is that it does not rely on angles. The spatial resolution of the illustration of the flow is dependent on the resolution of the B-image, however, and this can have a negative effect on the diagnosis. This method is therefore currently much less widespread than the Doppler method.

17.2.3 Ultrasound Contrast Medium

Depending on the medical indication and in order to achieve an accurate representation of the organ perfusion and the perfusion dynamics, ultrasound contrast medium is increasingly used in diagnosis. Ultrasound contrast medium is applied intravenously, passes largely unaffected through the lungs and is then pumped into the muscles and organs by the left heart in a highly diluted solution with the blood. Ultrasound contrast medium is composed of countless tiny gas bubbles with a diameter of between 2 and 4 μm and reflects ultrasound which is beamed in significantly better than the natural corpuscular constituents of the blood. There is also a second effect, which increases the visualization of the gas bubbles and therefore of the blood: the gas bubbles are considerably smaller than the spatial dimension of the sound waves.

In the compression wave of an ultrasound pulse, areas of elevated and reduced pressure periodically surround each bubble completely. In the area of elevated pressure, bubbles are compressed. Conversely, bubbles in the low-pressure area dilate. On account of these rhythmic changes in volume, the bubbles become a source of sound as they begin to oscillate. However, the acoustic pressure of the initial sound field and the change in diameter are not in a linear relationship with one another. If the pressure doubles, for example, the bubbles do not reduce in size to the same degree. As a result of this nonlinear oscillation and the slight difference in the size of the individual bubbles, they emit a broadband frequency spectrum back to the ultrasound probe. Just like the wave breaking on the beach, this broadband, nonsinusoidal signal can be understood as the sum of multiple sinusoidal single frequencies (Fig. 17.8). The second harmonic (Fig. 17.8) is usually particularly pronounced here, meaning that it can be selected in the receiving component of the ultrasound unit and used for the

imaging. This method is known by the term contrast harmonic.

The so-called mechanical index (Mi) measures the mechanical effects of the sound waves on tissue and contrast medium bubbles

$$Mi = \frac{p^-}{\sqrt{f}}$$

Here, Mi is the mechanical index (dimensionless), p^- is the negative acoustic pressure (MPa) and f is the transmission frequency (MHz).

At a low Mi and thus a low acoustic pressure, bubbles still behave in a linear fashion, and at higher acoustic pressures their behaviour becomes nonlinear and they generate harmonics.

17.3 Equipment Technology

17.3.1 The Basic Design of an Ultrasound Unit

The fundamental components of an ultrasound unit are the devices shown in the diagram (Fig. 17.10).

The combination of these components constitutes a medical device which is approved in accordance with the respective applicable regulations, which satisfy EU and international agreements. Any change to these components or their parts (e.g. repair with a structural change, such as recoating of an ultrasound probe) means that this approval is automatically rescinded.

Ultrasound Probe

Specific ultrasound probe designs are available for different fields of use. They differ essentially in the design of the crystal array. The standard designs described in the section below can be found in different sizes, widths and radii of curvature, and in a wide variety of other ultrasound probe designs. The shape of the housing differs depending on the intended use of the respective *instrument*.

Base Unit with A/D Converter

The base unit of a modern ultrasound unit is essentially composed of two parts. The interface between

Table 17.2 Types of probes and their application

Organ	Application	Type of probe
Brain	Transcranial	Sector
Brain	Intraoperative/burr hole	Convex/sector
Pituitary	Transnasal	Linear, flexible
Thyroid, neck vessels	Transcutaneous	Linear
Heart, aorta	Transthoracic/transesophageal	Sector
Lung, mediastinum	Endobronchial ultrasonography (EBUS)	Convex
Pleura	Transcutaneous	Convex/sector
Breast	Transcutaneous	Linear
Spine	Intraoperative	Linear/convex

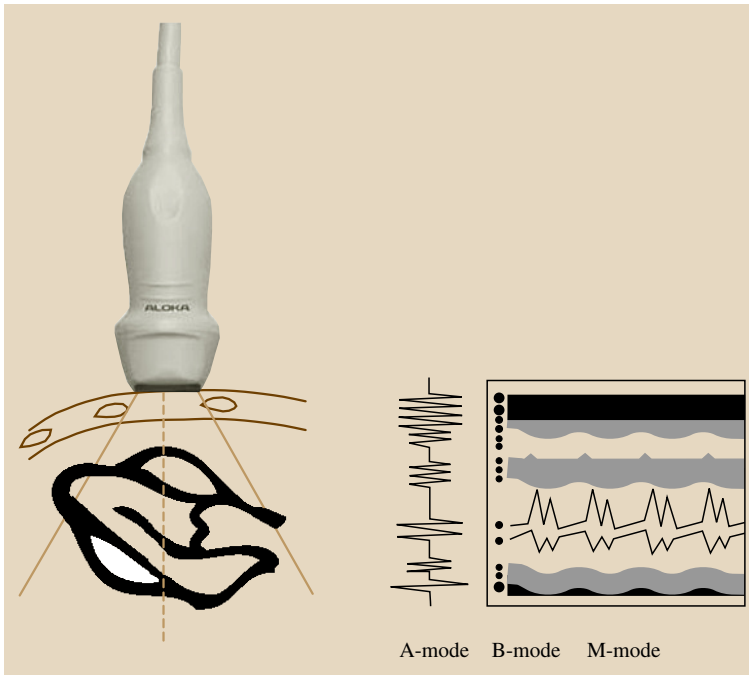

Fig. 17.11 Diagram of A-mode, B-mode, and M-mode

the analogue-functioning ultrasound probe and the digital processor is in the analogue/digital (A/D) converter. The purpose of the A/D converter is firstly to generate all of the electrical pulses and pulse sequences required for steering the sound beam and also to receive the reflected signals and convert them to digital form. It thus becomes clear that the image quality in particular is heavily dependent on the quality of the A/D converter.

The base unit also has the task of scan conversion (spatial mapping of the scan lines recorded) and further processing the digitized signals by means of image processing. Other functions include the operator-controlled computer dialogue, provision of measuring and calculation programs, as well as archive functions and generation of signals for viewing units (monitors) and interfaces.

Monitor and Interfaces

Today, digital flat-screen monitors are predominantly used. Only a few ultrasound units still work with conventional video signals. The interfaces for data

transmission, printer control and archiving which are normally used today are also digital.

A-Mode

Historically, the A-mode method (amplitude mode) was the first ultrasound method used. It has been almost exclusively replaced in the medical field by the methods described below, as the diagnostic value of the A-mode is very limited. Measurements of depths and distances can only be carried out at a single point.

Along the sound propagation line, signals reflected through media boundaries are displayed as individual peaks on the depth scale depending on the transit time – the pulse reflection method (Fig. 17.11). The value of the amplitude is dependent on the ratio of the wave impedances between the media boundaries.

B-Mode

In the B-mode (brightness mode), the display of the A-mode signal is modified such that the reflected signal is no longer displayed as a peak but rather as an indi-

vidual, depth-dependent (transit time) pixel. The value of the amplitude is represented by the brightness of this pixel, so that a line is generated with points of varying brightness. The simple B-mode method cannot be used diagnostically. However, it was the basis for the development of the M-mode and the 2-D B-mode.

M-Mode

The *M-mode* (*motion mode*) is produced by the horizontal deflection (time axis) of a B-mode line and storage and display of the resulting images. The M-mode is intended to be used for the diagnosis of moving organ parts, such as cardiac valves or cardiac muscle. It stands out in this area in particular due to its high time resolution, as just one individual line is repeatedly scanned.

2-D B-Mode

The 2-D B-mode method (two-dimensional brightness mode) is these days the most important sectional imaging technique in ultrasound diagnostics and is generally referred to as B-mode. The image is produced by quickly stringing together a number of individual B-mode lines (scanning lines) horizontally to give a flat 2-D image. Here, the image geometry is determined by the relative arrangement of the individual B-mode lines. It is also dependent on the design of the ultrasound probe. As in the traditional simple B-mode, the brightness of the individual pixels is determined by the amplitude of the reflected signals. Today, at least 256 shades of grey are required as standard.

Digitally Encoded Ultrasound

The practical applications of ultrasound require a necessary compromise between the desire for high axial resolution and a good penetration depth. Digital encoding of ultrasound pulses significantly improves this compromise, with the benefit of better penetration.

During transmission, a typical digital encoding is superimposed on the ultrasound pulse as an identification pattern. This encoding can also be detected in the ultrasound pulse after it has been reflected at the different interfaces in the patient's body, with the result that, when processing the reflected signals in the ultrasound unit, the encoded pulses can be separated from unencoded, unwanted signals (e.g. noise, artifacts). This means that only those signals which include the relevant individual code are processed further.

An example from the natural world shows that the same principle is used by bats. The individual encoding

of the transmission pulses emitted by a bat allows it to identify its own pulses from a wide number of pulses from other bats. Every individual bat is therefore able, despite a large number of other pulses, to move about safely in space with its own signals.

In addition to the encoding, signal compression also takes place, making it possible to produce an encoded transmission signal with a lower level of energy, which can then form a signal with a higher level of energy again at a later point as a result of adding together the individual digital pulses.

Two fundamental advantages of digital encoding emerge from this:

1. Unwanted signals are suppressed.
2. The useful signal is amplified.

Unwanted signals such as noise and artifacts are suppressed, and at the same time the useful signal is amplified and raised above the ambient noise level. At the same frequency and thus also at the same resolution, the effects mentioned bring about an increase in the penetration depth. This significantly reduces the problem of achieving a high resolution whilst at the same time obtaining a high penetration depth. This method does not put us in a position to be able to do away with the compromise between frequency (resolution) and penetration depth. A significant improvement in the situation is possible, however.

17.3.2 Doppler Ultrasonography

As outlined in the introduction to the fundamental principles, Doppler ultrasonography is used to detect blood flow. Different methods can be used technically:

- Pulsed-wave (PW) Doppler
- High-PRF Doppler
- Continuous-wave (CW) Doppler
- Color Doppler.

With Doppler ultrasonography, a distinction is also drawn on the basis of whether a device operates solely in the Doppler mode or whether it operates in the so-called duplex mode by superimposing a B-mode. In *duplex mode*, the scanning point (*sample volume*) at which the velocity of blood flow is measured is displayed in B-mode. The anatomical mapping at the point of the velocity measurement is therefore defined precisely. A Doppler device for use in duplex mode must also include all the technology for generating a B-mode.

Fig. 17.12 Duplex Doppler, B-mode with sample volume (*left*), and PW spectrum (*right*)

PW Doppler

The pulsed-wave (PW) Doppler technique uses the pulse reflection method and also the A-, M- and B-mode imaging methods. The processing of the transit time information is used here to determine the sample volume position. Reflected signals from the sample volume are not used to display an image but rather to measure the velocity according to the Doppler principle.

Similar to the M-mode, the time profile of the velocity of blood flow is displayed on the monitor. The position of the sample volume can be changed and positioned accurately by sight in duplex mode (Fig. 17.12).

The maximum velocity of blood flow which can be measured using PW is limited by the repetition frequency of the pulses (PRF). By using other, additional sample volumes, this limitation – which results from what is known as aliasing – is shifted into a velocity range which is no longer diagnostically relevant.

High-PRF Doppler

The PW Doppler technique is limited by what is known as *aliasing*. Above a certain frequency and velocity of blood flow, this causes incorrect display (alias display) of the Doppler signal, which can lead to incorrect interpretation of the flow direction.

This effect is dependent on the frequency of the pulse (scanning frequency or pulse repetition frequency (PRF)), which should be as high as possible. An artifact such as this can be observed in Western films, for example, when the carriage wheels suddenly appear to rotate

backwards because the scanning frequency (television frame frequency) is too low.

The high-PRF Doppler technique which should be found in all modern duplex systems was developed to avoid this effect of aliasing while maintaining the depth selectivity. It allows the aliasing cut-off frequency to be shifted upwards by increasing the PRF. The price paid for this is multiple sample volumes, which results in a slight restriction in the depth selectivity.

The use of duplex systems with automatic switching from PW to high-PRF is a useful addition to the pure PW mode.

Today, duplex devices should include frequency analysis in order to make it possible to detect pathological flows in the characteristics of the Doppler spectrum displayed. The Doppler signal is broken down and displayed in its individual frequency components by Fourier transform or similar methods (Fig. 17.8).

When the angle of incidence is known, frequency components can be equated with velocity components. Further information about the velocity is thus obtained. The most important here is the information about the degree of turbulence, which gives insights into pathological flow.

CW Doppler

The CW Doppler (continuous wave) technique is the only ultrasound method which is not a pulsed method. Two physically separate crystals, a transmission crys-

tal and a reception crystal, are accommodated in a probe and operate simultaneously. Whereas one crystal constantly transmits, the second crystal continuously receives the reflected signals. Alternatively, it is also possible to use groups of crystals, e.g. in a phased array ultrasound probe.

Due to the continuous transmission, depth mapping is no longer possible, however, as it is not possible to measure pulse transit times. The velocities measured are rather divided along the entire path of the measuring beam. The resulting advantage is the ease with which it is possible to measure high velocities of blood flow, such as those which are to be found in high-grade stenoses. The disadvantage of this method compared with the PW Doppler technique is the lack of depth selectivity.

Color Doppler

The industrial development of the first color Doppler in Japan (ALOKA, 1985, SSD-880) was an important step in the development of ultrasound diagnostics.

The color Doppler is in principle a PW Doppler. Here, it is not just a single sample volume which is used but several hundred. These sample volumes are combined in lines to form an extensive two-dimensional Doppler image. The Doppler image is superimposed in the correct position on the black-and-white B-mode image. These two images can be viewed together in real time in the real-time mode.

In order to be able to distinguish the Doppler information from the morphological black-and-white information (B-mode), it is displayed with color-coding (Fig. 17.13).

A generally accepted illustration of the direction of flow is given with the colors red (towards the ultrasound probe) and blue (away from the ultrasound probe). However, it must be mentioned that there is no additional standardized color coding system. In the individual color Doppler systems, too, various color coding systems (color charts) can be accessed which more or less follow subjective preferences.

The effect of aliasing mentioned above occurs as an artifact in the color Doppler technique, too. This has the effect that, in the middle of a flow which is color-coded blue, for example, a red spot appears which is completely surrounded by blue (Fig. 17.14). This can be seen when the maximum velocity which can be displayed is exceeded at precisely this point. The color then *turns* into the other color.

As it is obviously impossible for a *red island of reverse flow* to suddenly appear in the middle of a blue flow, the user can easily identify this phenomenon as aliasing.

The velocity (cut-off frequency) above which aliasing occurs is called the Nyquist limit

$$\text{Nyquist limit} = f_{\text{Ny}} = \frac{\text{PRF}}{2} .$$

Fig. 17.13 Color Doppler with aliasing

Fig. 17.14 Vascularization in the fetal brain, imaged using eFlow technology

Aliasing can even be useful here in that it shows us the point in the blood flow with the highest velocity. In order to measure the highest velocity, we position the sample volume at this alias position. Using the color Doppler technique it is then possible to detect and pinpoint the extent of pathological flows such as jets and to locate small vessels in real-time mode.

If the color Doppler technique is also added to the duplex mode so that the B-mode, color Doppler and Doppler spectrum are all displayed, this is referred to as the triplex mode.

Power Doppler

The term *power Doppler* is understood as meaning another version of the color Doppler technique. It is also known by the following synonyms:

- Amplitude Doppler
- Color angio
- Power color, etc.

The power Doppler technique also uses the Doppler shift to image blood flow. However, it does not display the velocity of the flow using color-coding, but merely shows the amplitude of a point of movement in the received signal detected by the Doppler shift present. The amplitude represents the number of reflectors (mainly erythrocytes) and is not displayed in the normal color Doppler technique. The power Doppler is generally more sensitive and can more easily detect slow-moving blood particles. It therefore fills the vaso-

lar lumen better than the normal color Doppler is able to, as the low amplitudes of the available signal information are not sufficient for further analysis with the normal color Doppler.

High-Resolution Modern Color Doppler Techniques

At this point it is worth mentioning a further development of the power Doppler technique which is known by various different names (e.g. eFLOW, dynamic flow, etc.). In some modern units, the method can be found with markedly higher spatial resolution values (<0.3 mm). It is extremely well suited for accurate, two-dimensional illustration of the vascular lumina through which blood is actually flowing. This method is of advantage particularly in the case of slow velocities or small vessels and when imaging a complex organ vascularization, but also in the case of stenoses.

It is made possible using modern pulse generators (beamformers) which shorten and optimize transient phenomena in transmission pulses. This makes extremely short pulses possible, which enable a higher spatial resolution.

Tissue Doppler Imaging

A special Doppler technique has become established for imaging the heart, and this technique does not color-code the blood flow but rather the cardiac tissue, which is to say the cardiac wall (myocardium). This is referred to as *tissue Doppler imaging* (TDI). Since the move-

Fig. 17.15 Tissue Doppler imaging (TDI)

ment in the myocardium is considerably slower than that of the blood, low-pass filters are necessary here instead of the high-pass filters which are customary in the blood flow Doppler. This technology enables conclusions to be drawn regarding the velocity of individual segments of myocardium (Fig. 17.15) and thus allows specific diagnosis in the case of disorders concerning the movement of the wall, e.g. as a result of a myocardial infarction or diastolic dysfunction. Additional information can be found in the further reading.

17.3.3 Types of Probes

The types of probes used today are primarily divided into two groups. Mechanical probes and electronic probes, or combinations of the two, are almost exclusively used.

Mechanical Probes

Today, these are still used for special applications (e.g. radial technique, skin diagnostics). Here, the deflection

Fig. 17.16a–c Sound field geometry of various types of probes

for generating a two-dimensional image is carried out by a small electric motor in the ultrasound probe.

Electronic Probes

Electronic probes are used far more frequently, and we know these as linear, convex and sector scanners. They differ in principle due to their deflection geometry and their deflection method (Fig. 17.16).

The deflection of the ultrasonic beam is realized electronically by time-shifted activation of a large number of crystals; no mechanical wearing parts are used whatsoever. The maximum transmission frequency is usually approximately 15 MHz.

Linear Probes. The simplest form of an electronic probe is the linear scanner. It consists of a large number of crystals arranged next to one another, and depending on the size of the probe it can contain up to approximately 400 crystals (Fig. 17.17).

A scanning line is always constructed using several crystals, and in this case six crystals lying next to one another are used, for example. This group of active crystals is also called an array, which has given us the frequently used term linear array. Each crystal is activated by an electronic pulse and transmits a sound wave which merges with the others to form a wave front. As a result of various physical effects, a sound field with a focal constriction is generated in the typical sound field geometry illustrated (solid line). Another six crystals are then activated, forming the next (dashed) sound field. According to the same principle, the next (dotted) sound field is then generated in turn, and this is repeated in the direction of the arrow until a complete image can thus be constructed from the reflected pulses. In order to generate a real-time display with 20 images per second (20 Hz), all of the processes described must have taken place within approximately 1/20 s.

Fig. 17.17 Scanning principle of a linear probe

Fig. 17.18 Phased array principle

Convex Probes. In the *convex probe*, also known as a curved array, the same method is used. The only difference here is that the crystals are not arranged on a linear contact surface but on a convex contact surface. Different radii of curvature are available for different fields of use (Fig. 17.16b).

Sector Probes. In the electronic sector, also called a phased array, considerably fewer crystals are used than in the linear or convex array. The electronic activation is carried out with a time shift or phase shift, which is where the term phased array comes from. However, this is no longer done from the outside in but continuously from one side to the other, with the result that an oblique wave front is generated (Fig. 17.18). Changing the activation at an appropriate speed achieves an oscillation in the beam, which in turn produces a two-dimensional image in the form of a sector.

The advantage of sector probes can be clearly seen from the example of avoiding rib shadows (Fig. 17.19), as the small contact surface of the sector probe enables examination through the intercostal spaces.

A disadvantage of the sector technique is caused by the divergence of the ultrasonic beams at greater depths, which results in the lateral resolution becoming increasingly poor in deeper tissues. The gaps which appear are filled in by the device using interpolations.

17.3.4 Focusing

The focal constriction, mentioned above, is important in all electronic probes, and this is known as the focal area. The narrower the sound field in this focal area, the better the lateral resolution of the system, that is to say in the lateral direction, perpendicular to the sound propagation direction. The diameter of the ultrasonic beam in the focal area depends on the different electronic focusing techniques of the device. Resolution values cited by the

manufacturers usually relate to the focal area. The focal position is also crucial, however. Ideally, the focal position should be precisely where the organ to be examined is located. This is where the biggest advantage of electronic probes over mechanical probes is to be found: the possibility of shifting the focal position electronically.

Dynamic Focusing

In dynamic focusing, the crystals are no longer all activated simultaneously; instead, the outer crystals are activated first, followed by the central crystals. The position of the focus is determined by the time-shifted activation between the outer and inner crystals (delay line). In addition, in electronic probes it is possible to use multiple focal zones simultaneously, which makes it possible to produce a sharp image over virtually the entire depth of field, although this comes at the expense of the image frequency. This is called dynamic focusing (Fig. 17.20). The image regions of the individual focal zones are recorded one after the other using a buffer memory and are finally combined to form a complete image which is focused throughout (Fig. 17.20b).

Modern devices have up to ten focal zones, but only four of these are usually used simultaneously for dynamic focusing because, as already mentioned, the use of a buffer memory reduces the image frequency. When using conventional array technology, this focusing technique is only possible in the longitudinal direction of the ultrasound probe, however, and only affects the lateral resolution.

Slice-Thickness Focusing

At right angles to the ultrasound probe, and thus also at right angles to the section plane, the scanning lines are only focused at a depth which is dependent on the shape of the crystals. Both at close range and at distant range, the ultrasound can propagate relatively uncontrollably. The actual two-dimensional sound field therefore also extends in an unwanted fashion at right angles to the section plane. This unwanted extent is called the slice thickness.

As a result, very small vessels, cystic hollow bodies or low-echo lesions are not intersected exactly in the middle, and every scanning beam also records echogenic structures which are behind or in front of the small structures. Other echo signals from exactly this depth therefore impinge on the ultrasound probe, and these cannot unambiguously be attributed to the small structure (Fig. 17.21a). Only in the focal area is the extent of the slice thickness of the sound field so small that no tissue parts outside of the small structure are affected.

Fig. 17.19a,b Comparison of sector and linear probes

Fig. 17.20a,b Principle of dynamic focusing

The matrix array technique is a new ultrasound probe technique which also provides electronic focusing at right angles to the section plane and thus provides a reduced and uniform slice thickness from close range to about 25 cm.

Conventional ultrasound probes consist of a single row of piezoelectric crystals lying next to one another and therefore also only permit focusing in this single

lateral plane. The matrix array ultrasound probe has a two-dimensional arrangement of up to approximately 1000 tiny square crystals which can be activated selectively. Electronic focusing as described by time-shifted activation of the individual elements is therefore not only possible in the lateral plane but also perpendicular to it (elevation plane). This technique largely eliminates slice thickness artifacts (Fig. 17.21b) and also enables

Fig. 17.21 (a) Conventional technique versus (b) matrix array

very small structures to be visualized without artifacts and with a high resolution.

Another positive effect of the matrix array technique is the considerable improvement in the penetrative power on account of the reduction in beam diver-

gence and thus the increase in the energy density which accompanies it at the same time. It allows higher ultrasound frequencies to be used while maintaining the same penetration depth, thus enabling an improvement in the frequency-dependent axial resolution.

17.4 Three-Dimensional Ultrasound (3-D, Real-Time 3-D)

The development of three-dimensional ultrasound technology took into account the needs of many users for three-dimensional imaging of anatomical structures. The objective was among other things to simplify and improve the diagnosis of structures which can often only be assessed with difficulty in 2-D images.

17.4.1 Acquisition Techniques

Modern ultrasound diagnostics can also record and display three-dimensional blocks of data. To this end, a third dimension perpendicular to the 2-D plane is added to the two-dimensional (B-mode) ultrasound images and processed as a 3-D data set.

In everyday clinical practice, 3-D technology was only able to establish itself with the development of efficient computer processors, which enabled a true real-time 3-D display. When 3-D technology emerged in the 1980s, computing times were still in the region of hours. As a result of precisely this real-time capability of the systems, 3-D technology has recently also become known and marketed as 4-D ultrasound.

Hands-Free Technology Without Position Sensors

This simple technology uses the conventional 2-D ultrasound probe, which is moved or panned as uniformly as possible by the examiner parallel to the 2-D plane or around a fixed point in order to record an image sequence. The number of images to be recorded which will later be used to reconstruct the 3-D data set is specified before the procedure is begun (Fig. 17.22). This hands-free technology does not allow accurate three-dimensional mapping, however, as the distance actually recorded is not known and there is no guarantee of a precise and straight recording movement. This also means that no measurements can be made and volumes cannot be determined.

Hands-Free Technology with Position Sensors

This hands-free technology is a development of the technology without position sensors and is used to avoid the disadvantage of undefined recording. By attaching a position sensor to the 2-D ultrasound probe, constant

Fig. 17.22 Data block from multiple parallel sectional images using 3-D hands-free technology

determination of the position of the ultrasound probe and thus spatial mapping of the individual 2-D images becomes possible. Data sets recorded in this way allow measurements to be made and volumes to be determined.

The position detection can be achieved using different techniques and position sensors. In addition to sensors in the electromagnetic field, infrared, ultrasound and acceleration sensors (gyro sensors) are also used. These forms of sensor technology all have their own

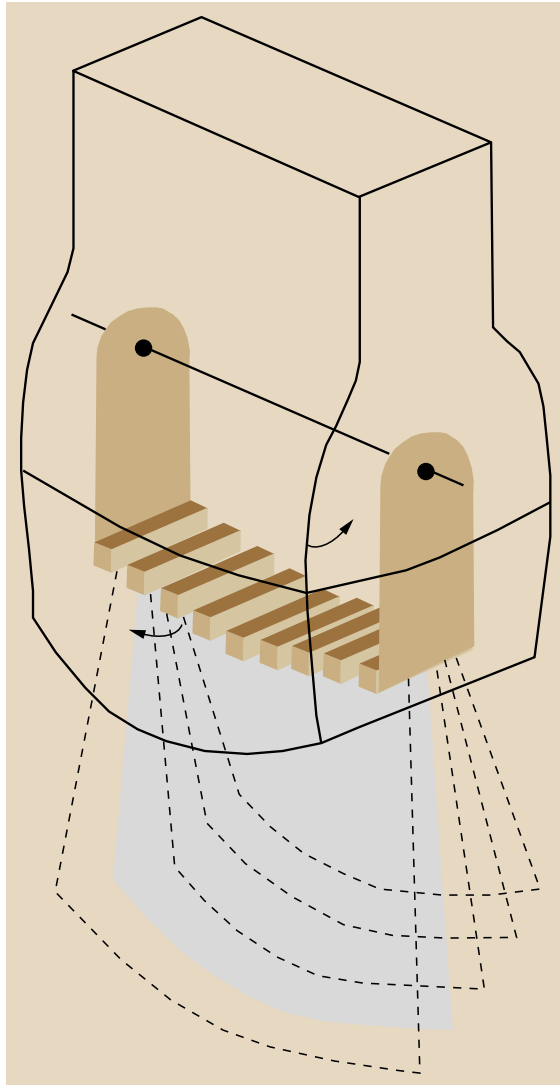

Fig. 17.23 Integrated 3-D/4-D ultrasound probe with mechanical deflection

methodological advantages and disadvantages. The disadvantages predominantly have an adverse effect on the spatial resolution.

Integrated 3-D Ultrasound Probe with Motorized Deflection

In order to overcome the problems described with hands-free technology and ensure simple handling, motor-driven 2-D crystal arrays have been combined with mechanical displacement transducers which en-

Fig. 17.24 3-D frustum of a pyramid, generated with a matrix phased array ultrasound probe

able reproducible recording of a 3-D data block. The array oscillates in a special liquid-filled ultrasound probe housing and scans the anatomical structures repeatedly at such a speed that a real-time representation of the volume can be calculated (Fig. 17.23).

This type of ultrasound probe is currently primarily used in gynaecology to image the foetus, as it achieves very good resolution with integrated convex arrays.

Integrated 3-D Ultrasound Probes with Electronic Deflection

This smaller and lighter construction manages without mechanically moving components. As with the matrix array ultrasound probe, the array of these probes consists of a two-dimensional, usually square arrangement of tiny piezoelectric crystals which can be activated selectively. According to the principle of the sector phased array method, the crystals are electrically activated at different points in time, so that the scanning beam forms a narrower or wider angle with respect to the array surface. By time-shifted activation of the respective crystal rows and columns, unlike with the conventional phased array ultrasound probe the direction of the beam can be determined in both horizontal axes (Fig. 17.24).

This type of ultrasound probe is currently used primarily in cardiology, as it is predestined for intercostal use due to its small contact surface.

17.4.2 3-D Reconstruction

Irrespective of the scanning method, in all 3-D methods all of the sectional images acquired are lined up during

Fig. 17.25 Surface 3-D

the scanning process such that their positions and angles are correct, providing a three-dimensional data set.

This spatial data block represents the basis for all further calculations. Different display calculations are used here:

- Surface display
- Multiplanar display
- Transparent display.

Surface Display

Surface display requires a considerable difference between the wave impedances of the tissue structures (change in impedance), which generally exists between liquid and solid structures. In order to visualize the desired interfaces, it must be possible to clearly delineate the object under examination from its surroundings.

These conditions can often be found when performing diagnosis during pregnancy, as the skin of the foetus is demarcated from the amniotic fluid by a considerable change in impedance.

Specific algorithms for representing surfaces in 3-D data sets (rendering) and further calculations from the graphical image processing, such as the generation of artificial shadows, for example, allow a display which is photorealistic (Fig. 17.24).

Multiplanar Display

This technology allows the examiner to image section planes which cannot usually be displayed from an ap-

plication point of view. It is possible to simultaneously display multiple sections through an organ or structures which are at any desired angles with respect to one another. The examiner thus gains the possibility of better visualizing anatomical or pathological structures spatially, measuring them and determining their volume.

Transparent Display

By using filtering, it is possible to suppress faintly reflecting structures to the advantage of structures which reflect signals strongly. This allows clear 3-D imaging of bones, for example, which is usually necessary when searching for anomalies in the foetal skeleton.

17.4.3 New and Additional Technologies

This section gives an overview of particular new technologies which have started being used in recent years in ultrasound technology:

- Extended field of view
- Trapezoidal technique
- Steered compound imaging (real-time compound imaging)
- Speckle reduction
- eTracking.

Extended Field of View

The term extended field of view (EFOV) is understood as meaning the extension or widening of the 2-D

Fig. 17.26 Scrotum imaged using extended field of view

imaging plane. By shifting the ultrasound probe in its longitudinal axis, an extended two-dimensional image is generated.

This does not involve extending the information in the 3rd plane (perpendicular to the 2-D plane) as is the case with 3-D, but rather extended the 2-D plane itself. Using image processing algorithms, matching sections of the respective individual images are lined up together using pattern recognition, and these individual images therefore produce a calculated, new and coherent picture of the organ structures (Fig. 17.26).

This technology is also known by other trade names: SieScape, Freestyle, LOGIQ View, Panoramic Ultrasound, etc.

Trapezoidal

With the trapezoidal technique, the width of the sound field of a linear probe is extended. By time-shifting the activation of the outer groups of crystals (phasing or steered beam principle), a trapezoidal sound field is generated (Fig. 17.27).

This technology is known by other names, such as Virtual Convex, for example.

Steered Compound Imaging (SCI)

The conventional electrical activation of linear and convex array ultrasound probes has the effect of emitting a transmission pulse at right angles to the surface of the ultrasound probe. Anatomical structures or interfaces running parallel to the ultrasonic beam are struck by the

ultrasonic beam either tangentially or at a very acute angle. Under these conditions, the portions of the ultra-

Fig. 17.27 Extension of sound field using trapezoidal technique with linear probes

Fig. 17.28
Image optimization using steered compound imaging

sonic beam reflected in the direction of the ultrasound probe are very low. These structures therefore appear only faintly or not at all. The scanning beam also barely reaches the structures lying distal to these interfaces, because the majority of the energy of the ultrasonic beam is deflected by reflection.

In addition to the known lateral edge shadows artificial inhomogeneities also appear in the distal structures and interfaces. The consequences of these phenomena can be reduced if the structures being examined are sounded not just from one direction but from different directions using beam steering (phasing) and the resulting sound reflections are superimposed using image processing to form a compound ultrasound image. Usually, three consecutive images are generated, which have been recorded in a range between -30 , 0 and $+30^\circ$ (Fig. 17.28). Modern devices furthermore also allow angle steering, adapted according to requirements, in various intermediate stages which makes it possible to image different depths of field. Every reflecting interface is therefore optimally sounded from different directions.

This technology is also known by other trade names, such as Realtime-Compound-Imaging, SonoCT, Cross-Beam, etc.

Speckle Reduction

Because of their physical properties, ultrasound images are always accompanied by noise. The signal-to-noise ratio is in the region of approximately 1.9 and can only be visually and subjectively improved by corresponding image processing. As a result of the constantly increasing computational power of computers, further image-processing steps can be added after the actual acquisition of signal data. Special algorithms allow image characteristics to be emphasized and changed. This includes image homogenization and the accompanying subjective noise suppression, and also, for example, edge enhancement of adjacent organ structures.

These image-processing measures can in many cases aid fast and easy diagnosis, but they are not always and exclusively of use, as both false positive and also false negative image information can be generated. The trained operator should therefore always be free to decide on their use and also their degree of use.

Vessel Distension Analysis (Echo Tracking, eTracking)

The growing awareness of relationships between cardiovascular diseases and vascular function and also

Fig. 17.29a,b Vessel distension analysis using eTracking

vascular mechanics has meant that diagnostic parameters can be raised by means of a series of different technical methods (ultrasound, tonometry, plethysmography, etc.).

Ultrasound can be used to calculate a number of relevant parameters, such as the pulse wave velocity (PWV), vascular elasticity (β -Index), augmentation index (AIx) and arterial function (FMD), from the vascular distension. The distension is determined in real

time by analysing the raw data signal. Using specialist software, the movement of moving organ structures is followed by user-defined points along an ultrasonic beam (tracking). This is done with a high level of temporal (1 kHz) and spatial precision (1/16 of the wavelength).

A development of this analysis method is based on the simultaneous and colocated detection of the velocity of the blood flow using Doppler technology. This

allows further parameters to be calculated, e.g. pulse wave propagation or wave intensity, which describe the

coupling between the heart and the vascular system downstream (Fig. 17.29a,b).

17.5 Operation of an Ultrasound Unit

17.5.1 General Conditions

Operation of an ultrasound unit has today become standard in most medical fields. Some important general conditions should be observed and are detailed below.

Documentation

The operator of an ultrasound unit is generally required by the accounting body and by legal authorities to document findings.

All suppliers of ultrasound equipment provide relevant advice and solutions on request for the analogue and digital storage of data and images for the findings. In the simplest scenario this includes thermal printers or internal digital memory with CD/DVD/USB storage or export interfaces, such as the vendor-neutral DICOM (digital communication in medicine) standard for network-based archiving of still images or image sequences and measurement data.

The DICOM standard not only governs the archiving of medical image data as well as other modalities such as CT and MRI, but also provides further functions and procedures which support work-flow (e.g. work list, print, structured report, etc.).

Application-Specific Additions and Upgrades

Modern digital ultrasound units allow additional hardware or software to be installed to extend the scope of use of the unit. This includes, for example, units for simultaneous ECG recording, memory upgrades, specific analysis programs (stress echo, contrast medium assessment, TDI evaluation, analysis of the vessel distension and pulse wave velocity, etc.).

In addition to these device-specific upgrades, there is also always the possibility of extending the intended use of a device with additional ultrasound probes.

Maintenance and Repair, Updates

The ultrasound unit manufacturers provide recommendations for safe operation and warnings against improper use of units and probes. The user should find this information in the safety instructions provided with the equipment documents.

Important: in line with the Medical Devices Operator Ordinance (Medizinische Betreiberverordnung,

MedBetreibV), the operator of an ultrasound unit has certain duties to ensure the safety of the systems used. To this end, the ultrasound unit manufacturers and retailers offer tailored maintenance and inspection agreements which conform to the law support service for their customers. These contracts often also include the option of insuring against damage to the units and probes. There are also offers for regular updates of the device software.

Hygiene

In general, the operator should inform him or herself about possible legal hygiene regulations in the context of the planned examinations. In addition, the guidelines of the professional associations include recommendations regarding hygiene which should also be observed.

For the cleaning of units and also the cleaning, disinfection and sterilization of ultrasound probes and auxiliary equipment, such as puncture adapters, the manufacturers provide information about the methods to be used and approved cleaning, disinfection and sterilization agents.

Safe Use of Ultrasound Diagnostics

According to current scientific knowledge, the diagnostic use of ultrasound which complies with standards does not have any unwanted side effects. However, it is recommended that the Doppler mode be used cautiously, particularly for the purpose of foetal examinations. Because ultrasound energy is absorbed and converted into heat at the transition between tissues in bony structures, it is not possible to rule out cell-damaging effects with certainty. It is therefore imperative that the recommendations of the relevant professional associations are observed.

Medical Infrared Imaging

Gerald C. Holst, Thorsten M. Buzug

This chapter describes passive as well as active thermal methods and their applications in medicine. To keep the body temperature at a constant level, excess heat is released by evaporation, convection, conduction, and radiation. Evaporation of sweat is the most obvious mechanism. Its effectiveness depends upon the ambient temperature and relative humidity. Convective cooling is most noticeable when standing in front of a fan. Conduction occurs when physically touching an object. Conductive cooling depends on the temperature difference between the object temperature and the skin temperature. Feverish patients are sometimes immersed in cool water. Radiative cooling is a function of the skin temperature and the environmental temperature. It is experienced when placing your hand in a freezer. An infrared (thermal) imaging system is calibrated to provide surface temperature. Local variations in skin temperature is a function the above quantities as well as metabolism (cancers and exercise), inflammation, circulatory

disturbances, and skin condition (scabs, moles, and hair).

18.1 Background

Variations in skin temperature are related to local metabolic differences. These variations may be normal (e.g., during exercise) or abnormal (e.g., presence of cancer). Temperatures may be measured with either a contact or noncontact device. Contact devices include the common liquid-in-glass thermometer, resistance thermometer, and thermocouple. Noncontact devices may be either a nonimaging or imaging infrared (IR) system. A nonimaging system (such as a radiometer) simply measures the radiation. The system's calibration converts the output voltage to a temperature value. Imaging systems create a two-dimensional image of the skin. As with the radiometer, the IR imaging system measures the radiation that appears to emanate from the skin.

What is most striking about IR imaging is that it is one of the few modalities which is noninvasive and contactless. Recently, this was manifested in a case where feverish individuals potentially infected with severe acute respiratory syndrome (SARS) were identified among a huge number of persons in airport security areas by their facial temperature profile. However, since its invention it has been conjectured that medical infrared imaging is a functional imaging modality (infrared functional imaging, IRFI) that can be used to visualize pathologically increased metabolism by its temperature signature. Especially for some types of cancer, detection of tumors follows the thermographic paradigm that the strong growth of malignant tumors is accompanied by an

increase of metabolism, leading to a conspicuous thermal signature. Since cancer cells have a high metabolic rate, a localized elevated skin temperature may warrant further tests for the presence of cancer.

IR imaging can be expected to yield sensible results in cases of inflammation processes, arthritis, rheumatism, circulatory disturbances, any cases of allergy with skin symptoms as well as burning and scalding, frostbite, monitoring the success of skin transplantation, etc. For qualitative measurements, IR images are also used in pain diagnostics. An overview of the general causes of fluctuations of skin temperature that can be measured with IR camera systems can be found in [18.1].

Although the medical community has known about IR imaging for years, there is now significant renewed interest. The medical IR imaging community is small compared with the overall nondestructive testing (NDT) community (SPIE has hosted *Thermosense* since 1978 [18.2]). Increased temperature is an indicator of potential failure in electrical power distribution and machinery [18.3]. Industries such as automobile, petrochemical, die casting, and paper manufacturing use IR imaging systems for process control [18.3]. Numerous manufacturers have developed IR imaging systems for NDT. These calibrated systems lend themselves to medical applications.

18.2 Infrared System Design

Due to the atmospheric spectral transmittance, electronic imaging system design is partitioned into seven generic spectral regions (Fig. 18.1) of which four are associated with thermal imaging systems. The ultraviolet (UV) region ranges in wavelength from 0.2 to 0.4 μm . The visible spectral region ranges in wavelength from 0.4 to 0.7 μm . Televisions and electronic still cameras operate in this region. The near-infrared (NIR) imaging spectral region spans $\approx 0.7\text{--}1.1\ \mu\text{m}$. Image intensifiers, starlight scopes, and night-vision goggles operate in this region. The first infrared imaging band is the short-wavelength infrared (SWIR) imaging band, which covers approximately 1.1–2.5 μm . The second infrared band is the mid-wavelength infrared (MWIR) spectral region that covers $\approx 2.5\text{--}7.0\ \mu\text{m}$. The third

infrared band is the long-wavelength infrared (LWIR) spectral band. It covers the spectral region from ≈ 7 to 15 μm . The fourth infrared band is the far-infrared (FIR) or very long-wave infrared (VLWIR) region. It applies to all systems whose spectral response extends past 15 μm . The MWIR and LWIR regions are sometimes called the first and second thermal imaging bands, respectively. Note that SWIR, MWIR, and LWIR are generic terms; for example, a LWIR system's spectral response can be anywhere in the LWIR region (e.g., 8–14 μm , 7.5–10.5 μm , 8–12 μm , etc.).

For convenience, targets are labeled as either hot or cold with respect to the immediate background. For MWIR and LWIR systems, the term thermal is misleading. IR imaging systems do not sense warmth or

Fig. 18.1 Representative atmospheric transmittance as a function of wavelength λ over a 1 km path length. The transmittance varies with temperature, relative humidity, and airborne particulates. Note the nonlinear wavelength scale

Fig. 18.2 Representative calibration (25–34 °C). The temperature scale can be adjusted to any value

cold (they are not thermometers) but rather the radiation emitted by an object. Hot refers to a target that appears warmer than its immediate background and cold means that the target appears cooler than its immediate background.

The detector output is simply a voltage. After calibration, a specific voltage level represents a temperature value. This voltage can be mapped into pseudocolors. Consistent with human feelings, cold objects are represented as blue and hot objects as red (Fig. 18.2). Whether the output is displayed on a grayscale or as pseudocolors is a matter of personal preference. However, pseudocolors generally facilitate image interpretability.

18.2.1 Detectors

The detector is the heart of an imaging system because it converts infrared radiation into a measurable electrical signal and converts target spatial information into electrical temporal information. Current terminology lists detectors generically as cooled or uncooled. Within each category, there are many different types of detectors. Early IR imaging systems contained only a few detectors, necessitating scanning mechanisms. Current systems are staring arrays that contain 320×240 detectors or 640×480 detectors. With the smaller array (320×240), data interpolation creates a 640×480 output to be consistent with most displays.

Cooled Detectors

LWIR photon detectors must be cooled below 100 K, with 77 K considered a typical temperature. These temperatures can only be reached with a mechanical cooler or with liquid nitrogen. Many MWIR detectors can operate at 200 K, and this temperature can be easily achieved with a thermoelectric cooler (TEC). TECs appear to have an infinite lifetime, whereas mechanical coolers degrade over time. Coolers add cost and bulk, and consume power.

InSb, a high-quantum-efficiency MWIR detector, has replaced the low-quantum-efficiency Pt:Si detector. Although generally labeled as HgCdTe, it is a mixture

($\text{Hg}_{1-x}\text{Cd}_x\text{Te}$). By varying the ratio, the spectral response can be tailored to the MWIR or LWIR region. The most popular is the LWIR detector with a peak response near $12 \mu\text{m}$. A filter is used to limit the response to the LWIR region. The quantum-well infrared photodetector (QWIP) is based upon mature GaAs growth technology. The response can be tailored from 3 to $19 \mu\text{m}$. The LWIR version typically has a spectral response from 8.3 to $10 \mu\text{m}$. The responsivity and noise are temperature sensitive, so QWIP devices are typically cooled to less than 60 K.

Uncooled Detectors

Microbolometers with either VO_x or $\alpha\text{-Si}$ coating can operate at room temperature and therefore are called uncooled devices. Although called uncooled, these devices may have a TEC to stabilize the detector temperature. Uncooled devices are lightweight, small in size, and easy to use. Because they use very low power, they lend themselves to handheld, battery-operated devices. Uncooled detectors generally have much lower responsivity than cooled detectors.

18.2.2 Performance Metrics

Thermal sensitivity refers to the smallest temperature differential that can be detected. It depends upon the light-gathering properties of the optical system, the detector responsivity, and the system noise. A laboratory measure of thermal sensitivity is the noise equivalent differential temperature (NEDT). It is also called the noise equivalent temperature difference (NETD) or noise equivalent temperature (NET). Generally, the NEDT for cooled detectors is less than 10 mK and may be as high as 100 mK for uncooled sensors.

Spatial resolution provides valuable information regarding the finest detail that can be discerned. It is usually specified by the instantaneous field of view (IFOV) and is also called the detector angular subtense (DAS)

$$\text{IFOV} = \text{DAS} = \frac{d}{l_f}, \quad (18.1)$$

where d is the detector linear dimension and l_f is the system's effective focal length. The field of view (FOV) is simply the IFOV multiplied by the number of detectors.

The minimum resolvable temperature (MRT) is a composite metric that combines thermal sensitivity and spatial resolution [18.4]. It is used primarily to characterize military systems and, as such, has less value to the medical imaging community.

18.2.3 Image Processing

Many cameras have built-in image processing capability. Indeed, we can say the modern thermal imaging system is a microcomputer with a detector attached. Cameras come with a large variety of image processing software. For temperature-measuring devices, typical

18.3 Infrared Physics

A comprehensive infrared physics equation is quite complex. For simplicity, it is assumed that the skin radiates isotropically and that the radiant exitance follows Planck's blackbody law. Reflectance of ambient radiation can significantly affect the target signature. For convenience, skin reflectance is assumed to be essentially zero.

18.3.1 Planck's Blackbody Law

The spectral radiant exitance of an ideal blackbody source, whose absolute temperature is T , can be described by Planck's blackbody radiation law

$$M_e(\lambda, T) = \frac{c_1}{\lambda^5} \left(\frac{1}{e^{(c_2/\lambda T)} - 1} \right) \text{ W}/(\text{m}^2 \mu\text{m}). \quad (18.2)$$

where $c_1 = 3.7418 \times 10^8 \text{ W } \mu\text{m}^4/\text{m}^2$ and $c_2 = 14388 \text{ } \mu\text{m K}$. As shown in Fig. 18.3, as the absolute temperature increases, the spectral radiant exitance increases at shorter wavelengths. A blackbody must be heated to 600 K before it appears to glow (heated to incandescence). Equivalently, visible imaging systems can only sense the radiation from sources whose temperature is greater than 600 K. Clearly, only an IR imaging system can detect skin temperatures (nominally around 310 K).

Fig. 18.3 Planck's spectral radiant exitance as a function of wavelength for different temperatures T

built-in functions include isotherms, color rendition, spot temperature measurements, temperature profile, and area-weighted temperature. Area-weighted functions are also called region-of-interest (ROI) functions. Most systems offer emissivity correction that allows the user to enter both the target emissivity and the surrounding temperature.

18.3.2 Camera Formula

When viewing an ideal target, the camera formula provides the system output voltage

$$V_{\text{SYS}} = G \int_{\lambda_1}^{\lambda_2} \frac{R_D(\lambda) A_D}{4F^2} M_e(\lambda, T) d\lambda, \quad (18.3)$$

where G is the system electronic gain, $R_D(\lambda)$ is the system spectral response (detector spectral response multiplied by the optical spectral transmission), A_D is the detector area, and F is the f -number (the focal length divided by the aperture diameter). The limits of integration depend upon the spectral response of the system (e.g., MWIR or LWIR)

What is of interest is the difference between a target and its immediate background

$$\begin{aligned} \Delta V_{\text{SYS}} &= G \int_{\lambda_1}^{\lambda_2} \frac{R_D(\lambda) A_D}{4F^2} [M_e(\lambda, T_T) - M_e(\lambda, T_B)] d\lambda. \end{aligned} \quad (18.4)$$

Although the differential voltage is proportional to the radiant flux difference, it is convenient to specify the flux difference between a target and its immediate background by an equivalent temperature difference ΔT . Using a Taylor series expansion for the flux difference and keeping the first term (valid for small temperature differentials)

$$\begin{aligned} \Delta V_{\text{SYS}} &\approx \left(G \int_{\lambda_1}^{\lambda_2} \frac{R_D(\lambda) A_D}{4F^2} \frac{\partial M_e(\lambda, T_B)}{\partial T} d\lambda \right) \Delta T \\ &= k_{\text{CAL}} \Delta T. \end{aligned} \quad (18.5)$$

The partial derivative is called the thermal derivative and must be evaluated at the background temperature.

Fig. 18.4 Planck’s spectral radiant exitance difference from 37 °C (310 K)

The bracketed term is a calibration term that is unique for each type of IR imaging system. After calibration, the output voltage differential is proportional to ΔT . The differential voltage is mapped into an intensity or pseudocolor. Figure 18.4 illustrates the differential radiant exitance for small skin temperature increments above 37 °C (310 K). While there is more differential signal in the LWIR, MWIR systems perform equally well; they just have different calibrations.

18.3.3 Emissivity and Reflectivity

By Kirchhoff’s law, when an object is in thermal equilibrium with its environment, the absorption $\alpha(\lambda, T)$ is

equal to the emissivity $\varepsilon(\lambda, T)$. This leads to the popular saying that good absorbers are good emitters. Real blackbodies do not emit all the radiation described by (18.2) but only emit a fraction of it. The ratio of actual radiant exitance to the theoretical maximum is the emissivity. The radiation that appears to emanate from a target is actually a combination of emitted and reflected radiation. Expressed as a ratio,

$$\varepsilon(\lambda, T) + \rho(\lambda, T) = 1 . \tag{18.6}$$

For an ideal blackbody, $\alpha(\lambda, T) = 1$ and $\rho(\lambda, T) = 0$. For nonideal blackbodies, the amount of radiation that appears to emanate from the target is

$$\varepsilon_T(\lambda, T_T)M_e(\lambda, T_T) + \rho_T(\lambda, T_T)M_e(\lambda, T_{AMB}) , \tag{18.7}$$

where T_{AMB} is the effective ambient temperature. The apparent background radiation is

$$\varepsilon_B(\lambda, T_B)M_e(\lambda, T_B) + \rho_B(\lambda, T_B)M_e(\lambda, T_{AMB}) . \tag{18.8}$$

For example, when imaging an expected tumor, ε_T is the skin emissivity over the tumor and ε_B is the emissivity of *normal* skin. The reflective component makes calibration difficult. In the next section it is shown that skin emissivity is sufficiently high that the reflective component can be neglected in many situations.

18.4 IR Imaging in Medical Applications

For bare skin, $\varepsilon \approx 0.98 \pm 0.01$, and this tends to be independent of skin color [18.5]. While hair does not affect skin emissivity, it acts as an insulator which prevents accurate skin temperature measurements. Neglecting reflection (i. e., assuming $\varepsilon_T(\lambda, T) = \varepsilon_B(\lambda, T) \approx 1$) introduces a small error in temperature measurement. While this error is considered minor, it is appropriate to discuss *apparent* temperature differentials rather than absolute temperature differences ΔT . While quantitative imagery is always desired, qualitative differences may suffice. It is advisable to have a baseline image

(Table 18.1). This is called differential infrared thermography (DIT). The difference can be magnified by subtracting the baseline image from the desired image.

Very often IR imaging is the interpretation of subcutaneous processes from the cutaneous temperature distribution. As shown in Fig. 18.5, as the tumor depth increases, lateral heat flow provides a larger hot area than the actual tumor. Furthermore, the edges are diffuse, making precise location difficult. Core temperature (37 °C) is generally held constant for depths larger than 20 mm, and therefore the thermographic paradigm holds for near-to-skin processes only.

Table 18.1 Image pairs for qualitative imaging

Desired image	Baseline image
After or during exercise	Resting before exercise
After or during smoking	Before smoking
Potential tumor on left breast	Right breast (assumed normal)

Fig. 18.5 Heat diffusion

Table 18.2 Local temperature signature of certain pathologies

Medical condition	Apparent ΔT (K)
Inflamations (e.g., rheumatism, arthritis)	1–2
Vascular diseases (e.g., thrombosis)	1–2
Breast cancer	1.5–4
Malignant melanoma	2–4

Although local temperature increases are relatively small [18.6] (Table 18.2), these values can easily be measured with current IR imaging systems. Image quality is considered very good when the signal-to-noise ratio (SNR) is greater than 10 and excellent when

$SNR > 40$ ($SNR = \Delta T / NEDT$). For the values listed in Table 18.2, both cooled and uncooled systems will provide adequate SNR. For subtle changes ($\Delta T < 0.5$ K), a cooled system may be required.

Finally, surface scabs and certain moles act as insulators and thus prevent heat from reaching the surface. Here, the area will appear cold compared with normal skin. Mathematically, this is a negative ΔT but is commonly reported as a positive ΔT .

It is important to recognize that reflectivities in the visible and the IR are usually different. Infrared imagery will always look different than visual imagery. Features seen in thermograms may or may not be present in visual images. It is prudent to record both visual and infrared imagery.

18.5 Specific Applications

Skin variations may be measured either passively or actively (also called passive thermography and active thermography). This far, this chapter has described passive temperature methods. High metabolic rate appears as an elevated skin temperature. For surface insulators (e.g., moles), the active method is preferred. Here the mole and surrounding skin is either heated or cooled and the time history of the temperature is measured (e.g., natural thermoregulation). The *normal* skin will reach *normal* temperature before the mole does.

18.5.1 Circulatory Disturbance

As an example of a prominent circulatory disturbance, Fig. 18.6 shows the effective cooling of a hand of a person smoking a cigarette. This qualitative example shows the vascular narrowing and the subsequent reduction in blood perfusion associated with smoking. For this image sequence a simple (MWIR) line-array detector scanner (NEC TH5104 Thermo Tracer) was used. This camera employs a detector array of 255×223 pixels and a temperature resolution of $NEDT = 100$ mK. Obviously, smoking restricts the blood flow as a result of vasoconstriction. As a consequence of the reduced blood flow, the metabolic rate is reduced and, with lower metabolic rate, the hand cools to ambient temperature.

18.5.2 Sports Medicine

Figure 18.7 shows the temperature distribution on the femoral skin during exercise testing on a bicycle ergometer. After 2.5 min at rest, the subjects underwent

a load-graded exercise test. Brake resistance (measured in watts) was increased every 3 min, thus increasing the workload up to the submaximal condition corresponding to 65% of the maximal heart rate value. The recovery phase was defined as the time necessary to restore the rest heart rate by means of recovery exercise and rest. With blood demand from the working muscles there is skin vasoconstriction and skin surface cooling. As the muscles stop working and the recovery and the restoration phases start, thermoregulatory control is invoked to limit body temperature increase. Here the skin vessels dilate to increase heat conduction to the skin.

Figure 18.7 highlights the results of Merla et al. [18.8], who recorded images every minute during exercise and the recovery phase. The images were

Fig. 18.6a–d Cooling of a male hand as a result of vasoconstriction due to smoking. *Blue* represents cold and *red* represents hot. For the measurement the NEC TH5104 Thermo Tracer was used, shown in the *left image* [18.7]. Image (a) is before smoking. Images (b–d) were taken at 2 min intervals after smoking (courtesy IASTED and ACTA Press)

Fig. 18.7 Variation of the thigh skin temperature during exercise on a bicycle ergometer. The barely visible vertical temperature scales next to each image are identical to Fig. 18.2. Note that the skin temperature is less than the core temperature (37°C) (after Merla [18.8]). The temperature scale (blue to red) is 30 to 38 K

taken with an AEG camera AIM 256 Pt:Si (MWIR). Its detector array consists of 256×256 pixels and has a temperature resolution of $\text{NEDT} = 100 \text{ mK}$.

These sports-medical measurements were correlated with the corresponding oxygen intake. It was shown that the degree of skin cooling and the thermoregulation depends on the individual fitness level of each subject. Currently, the extent to which IR imaging is able to estimate the hemodynamics of the thigh muscles is being studied.

18.5.3 Skin Cancer

In the last 30 years the number of patients diagnosed with skin cancer has increased dramatically. However, there is no appropriate and sound way to decide non-invasively if a skin tumor is benign or malignant. Generally, the diagnosis is made with Stolz's traditional ABCD rule of dermatoscopy based on the four main criteria or lesion parameters: asymmetry, border, color, and diameter, with a semiquantitative score system [18.9, 10]. Frequently, this method is improved by computerized scanning methods based on polarized light surface microscopes [18.11]. With both methods a suspicious spot has to be observed over a period of

time to obtain a reliable result, i. e., the evolution of the spot is important, which refines the ABCD method into the ABCDE method [18.10].

For the time being the only way to get an accurate diagnostic finding is an invasive histological examination. IR imaging may avoid redundant excision of tissue and potentially enables detection of malignant melanoma at an early stage. Thanks to the facts that malignant melanoma has higher consumption of glucose caused by a higher level of metabolism and augmented branching of blood vessels, so-called angiogenesis, the temperature should differ from surrounding healthy tissue. Associated with the increased demand of energy, it is conjectured that malignant melanoma shows a higher temperature ($2\text{--}4 \text{ K}$) than its surrounding skin [18.6]. Infrared imaging has a high potential to detect the beginnings of angiogenesis, when cancer cells first try to develop their own blood supply, which is a necessary step before they can grow rapidly and metastasize. Other types of skin cancer (e.g., basalioma) will behave differently due to an encapsulation strategy of the tumor.

For screening of suspicious moles, a clinical protocol has been proposed that consists of an IR imaging sequel after provocation of the skin area by cool-

Fig. 18.8 Thermoregulation sequence of a basal-cell carcinoma (basalioma) after forced cooling [18.12]. The boreholes of the circular plate are used as fiducial landmarks for motion compensation. The temperature pattern of the marker does not disturb landmark detection (courtesy IEEE)

ing [18.12]. To be accepted into clinical routine a simple, reproducible measurement protocol of the thermographic image acquisition and patient preparation has to be set up. To get the characteristics or temperature signature, respectively, the relevant skin area has to be provoked. Generally, two directions are possible with active thermography. On one hand the skin can be warmed up or, on the other hand, the skin can be cooled down. One major risk of the warming method is that the protein denaturation process starts when the skin temperature exceeds 42°C . For that reason the cooling-down method is used to produce a substantial temperature difference within a few minutes.

The cooling is carried out using direct contact with cooled gel packs. An area of about 10 cm by 10 cm is cooled to 20°C . After this patient preparation step, the signature of the thermoregulation process is recorded by the LWIR FLIR SC 3000 camera. The QWIP detector array consists of 320×240 pixels. It can resolve temperature differences as low as $\text{NEDT} = 30\text{ mK}$.

During thermoregulation the tumor shows up as a cold spot compared with surrounding tissue (Fig. 18.8). A difficulty in the evaluation of the thermoregulation process is that a spot cannot be automat-

ically detected on the basis of the temperature image alone, because at the starting point of thermoregulation the entire skin region of interest has a homogeneous temperature distribution (20°C).

To overcome this problem a circular marker with boreholes used as fiducial landmarks is attached to the skin and a normal digital photograph is taken prior to the thermographic session (see the inset to the temperature regulation graph in Fig. 18.8). By assigning the corresponding marker borehole location of each IR image with the respective digital image, motion of the patient can be compensated. This is important because a small motion in an image acquisition with a macroscopic lens can cause errors in the correlation between the frames of the thermographic sequence (details of the image sequence registration process can be found in [18.7]). Without stable motion compensation, automated comparison of the temperatures of skin and spot is not possible.

The signature of the curves is exponential. However, focusing on the thermoregulation of the spot, it can be seen that there is synchronous warming to 32°C in the first 90 s. As can be seen in Fig. 18.8, the temperature of the basalioma increases more slowly

than the surrounding healthy skin when the temperature exceeds 32 °C. The basalioma is not visible in the temperature image during the first 90 s of the recording; however, it is clearly recognizable in the end. One possible explanation for the lower temperature is based

on the physiological characteristics of a basalioma. A basalioma is created from cells which can produce an isolation layer, as already mentioned in the study by *Maleszka et al.* [18.13], who saw this effect for psoriatic arthritis [18.14].

18.6 Limitations of IR Imaging in Medical Applications

While the physical principles of infrared imaging are clear there are a variety of problems one has to cope with in medical applications of thermographic imaging. Typical sources of errors in diagnostic imaging are given in the following list:

- Complexity of an exact model of the medical thermoregulation process. Even the simple bioheat equation of *Pennes* [18.15]

$$\rho c \frac{\partial T}{\partial t} = \nabla(k \nabla T) + c_b w_m(T) \rho_b (T_a - T) + Q_m + P(z, t), \quad (18.9)$$

where ρ , c , and k are the density, specific heat, and thermal conductivity of tissue, respectively, c_b is the specific heat of blood, ρ_b is the density of blood, T is the local tissue temperature, T_a is a reference temperature (typically arterial blood temperature), t is time, Q_m is the metabolic heat production per volume, and $P(z, t)$ is the heat deposited per volume due to spatially distributed heating. In this general form, w_m is a function of temperature to include the specific case of temperature-dependent perfusion [18.16] which is an ill-posed problem, because of:

- Patient-dependent variability of the thermoregulation process due to different biofeedback time constants
- Spectral specification as well as accuracy and resolution of the infrared camera
- The lack of a definition of a standard in active thermography concerning the methodology of thermal excitation or provocation
- Vagueness of determination of thermal characteristics of skin cancer, i.e., variation of the emissivity coefficient of suspicious moles
- Only the surface temperature is imaged
- Unknown relation between thermoregulative time constants and the amount of applied energy in active thermography
- Inhomogeneity and speed variation of energy transfer in active thermography
- Spurious reflection of background radiation
- Insufficient patient acclimatization before imaging (patient-induced uncertainty, e.g., time of patient's most recent warm meal, as well as ambience induced, e.g., unstable thermoregulation of the examination room, etc.).

For a discussion of some of these points see *Nowakowski* [18.17].

18.7 Summary

Undoubtedly, infrared imaging or thermography is an effective medical screening modality. However, if a tumor inside the breast is actually resulting in a specific heat signature on the breast skin, then, in most cases, the tumor is in an advanced state. Therefore, cancer diagnosis using IR imaging should be restricted to some special types of skin cancer. Currently, several studies are underway to examine the suitability of IR imaging as a screening modality for skin cancer. It is expected, for instance, that a malignant melanoma will show

a faster temperature increase than its surrounding tissue. This assumption is motivated by the fact that this kind of cancer has a very active metabolism and possibly angiogenesis. However, the basalioma shows the opposite behavior because it is encapsulated from the surrounding tissue. A point which should be mentioned again is that one can only see the temperature distribution on the surface of the human body. IR imaging cannot directly reveal the inside of a body. A further discussion of technical difficulties can be found in [18.17].

Endoscopy

19. Endoscopy

Martin Leonhard, Klaus–Martin Irion

Endoscopy has an established position in modern medical diagnosis and treatment. The advantages of endoscopy are important for all those involved and are decisive for the success we enjoy today: for the doctor it means improved diagnosis and treatment; for the patient it means minimally invasive approaches, reduced trauma, reduced risk of infection, quicker wound healing, and often, shorter stays in hospital; and as a result for the hospital and society this translates into reduced costs. This general statement can also be looked at in considerably more detail for individual indications, but that is not the purpose of this chapter. The age of purely diagnostic endoscopy is far behind us. Endoscopy is either replacing open surgery and microsurgical procedures or now exists in competition with them in a wide range of fields. In this respect, medical and medical technological advances are occurring continuously, and there appears to be no end to this development in sight. The field is seen as highly innovative with new approaches emerging continually, of which, however, only some will prove to be both a financial and a clinical success.

19.1 Basics

Endoscopes can either be introduced through natural orifices (mouth, nose, ear, esophagus, trachea, urethra, rectum, vagina or even the tear duct in the eye or the lactiferous ducts of the breast) or via small, artificial incisions in order to reach the organs of the abdominal cavity or enter joint spaces.

Successful endoscopic concepts always reflect the challenge between the maximum possible reduction of trauma associated with the surgical approach, by reducing the external diameter of instruments on the one hand, and, on the other, the maximum image quality and possibility for manipulation and interventions which favor larger telescopes and large instruments or working channels. In addition, the general parameters are defined by human anatomy and technological capacity.

19.1.1 Terminology

Endoscopy concerns the visualization of concealed body cavities, as is clear from the Greek roots of the word *ἔνδοσ* (*endos*, Greek: inside) and *σκοπεῖν* (*skopein*, Greek: to look). Endoscopy is a medical technology and not a clinical speciality in its own right. Today it is daily routine in many medical fields [e.g., gastroenterology, abdominal surgery, urology, gynecology, sports medicine, ear–nose–throat surgery (ENT), pneumology] – in fact there are only a few fields in which endoscopy is not represented.

The names of different endoscopic procedures are generally composed of the term for the organ which is the object of the investigation, followed by the suffix “scopy”, e.g., gastroscopy, laparoscopy, cystoscopy, hysteroscopy, arthroscopy, laryngoscopy, and bronchoscopy, to give a selection of examples from the fields listed above.

Seen from this angle, names such as *resectoscopy* and *videoscopy* are inappropriate, although we encounter them from time to time. These terms are derived from instruments or types of endoscope. In this case, the instrument concerned is the resectoscope (an instrument from urology and gynecology), or the videoscope, which can now be found in a wide variety of applications and describes an endoscope which, amongst other things, is equipped with a distal image sensor.

The term *keyhole surgery* is often employed in scientific journalism as a striking term for endoscopy, which restricts the possibilities of endoscopy to purportedly secretive observation. On the contrary, thanks to the modern possibilities for using images in the

training of doctors and when informing the patient, endoscopy has, in fact, become very transparent and with its diverse treatment possibilities has advanced far beyond the boundaries of optical diagnosis. We regard the term endoscopy as being established; the surgical element of endoscopy is often referred to as minimally invasive surgery (MIS). We thus use these terms throughout.

19.1.2 Endoscopy and the Strengths of Optical Perception

When we are faced with a complex situation, the first thing we want to do is *to get a picture* of it. When we have correctly understood something, we say “I see.” This idiomatic representation brings the optical sense and our sight into the focus of our perception. It is not merely coincidence that sight is our most important sense. The retina is one of the few places in the body where the cellular bodies of neurons can be found outside of the actual central nervous system. Based on the image processing which occurs in the retina, we can regard this from a technical point of view as a type of optical coprocessor.

For the purposes of our discussion, optical image formation is based in principle on three components [19.1]:

1. illumination with visible light,
2. an object with characteristic absorptive and reflectance properties, in special cases with fluorescence and other effects; these properties modulate the illumination light,
3. observation with photosensitive and color-sensitive sensors, either our eye or a semiconductor sensor, and processing in the retina and in the brain or technical means of image processing.

This list already identifies two central components of endoscopy for us: high-quality illumination and imaging. The details of the endoscopic image chain are discussed in Sect. 19.2.3.

Magnification and Resolution

With the naked human eye we can see objects of approximately 0.1 mm, using optical aids such as a microscope this can even be extended to view structures in the submicrometer range. Special endoscopic procedures can be used to view structures measuring just a few micro-

meters. In principle, it can be asserted that with modern endoscopic equipment the accuracy of detail and resolution of the image considerably surpasses the perception during open surgery and thus allows the doctor to work more precisely. This is also due to the characteristic that, at a short distance from the object, endoscopes have a magnifying effect. Furthermore, this advantage is reinforced by the continuous improvement of optical and electronic systems, most recently by the introduction of high-definition (HD) camera systems.

The resolution of an endoscopic system depends on the optical parameters. As a result, image enlargement with optical zoom is associated with an increase in the information gained, while a *digital* zoom is not.

Color Vision

Our color vision provides us with an additional dimension that other imaging procedures such as magnetic resonance imaging and ultrasound do not offer. In normal observation conditions, the human eye cannot differentiate between more than 256 grey levels (8 bits) [19.2], whereas the endoscopic image delivers 10 bits in three color channels. This is particularly important with respect to the fact that the doctor must differentiate between a multitude of red tones in tissue.

This is not to be confused with procedures such as color Doppler ultrasound, in which a further measured variable (flow speed) is superimposed over the grey value image via a false-color representation.

Significance of Surfaces

One obvious weakness of light is that it cannot penetrate tissue deeply and can only visualize surfaces. Our internal organs are composed of manifold internal surfaces, which have been made accessible by the use of endoscopes. In addition, a multitude of pathological changes occur on surfaces, making endoscopy a very effective diagnostic and treatment procedure. A carcinoma, commonly referred to as cancer, is a malignant tumor originating in epithelial tissue, which can be found on the (internal or external) surface.

It is important to understand that surface structures can be visualized considerably better and more precisely with optical procedures than with other imaging procedures thanks to the color rendering and the excellent spatial resolution. As a result, with the current technical possibilities, all procedures of virtual endoscopy via computed tomography (CT) and magnetic resonance using interpolation procedures only appear to be as accurate but are in practice considerably inferior to optical procedures.

Perception and Processing of Visual Stimuli

The biological aim of sight is to recognize objects, dangers, and surroundings, not primarily to act as an optical or spectral recording system. When it comes to recognizing what is visible in an image, the human observer is usually superior to technical procedures.

Goethe, a well-recognized German poet, focused intently on colors, sight, perception, and their complex interaction. His argument of cause and effect, i.e., *one only sees what one knows*, was expanded by *Berci* in his ground-breaking work *Endoscopy* [19.3] in 1976 into *what ones sees should become known and documented*. Even today this remains a central pillar of endoscopy. Image processing and recognition is one of the tasks for which we are still searching for a final solution.

However, current research is also focusing on the advantages of optoelectronic and biophotonic procedures over pure imaging with white light in order to achieve better, i.e., more objective, tissue differentiation [19.4].

Classification

Information which we cannot see, such as ultrasound, magnetic fields, and x-rays, must first be converted into something that we can understand. The preferred solution is an optical image, which is why these procedures are often referred to as medical imaging modalities, even though the original information cannot be *seen* at all, but is rather measured. Endoscopy is generally not defined as an imaging modality in standard nomenclature, although based on modern endoscopy this is a point which could definitely be discussed further.

19.1.3 Challenges

Sight

Endoscopy has deprived the doctor of a direct view of the site of examination or operation. Although in the meanwhile resolution has been improved to such an extent that it considerably surpasses conventional sight, stereoscopic vision remains limited.

Haptics

The digital (*digitus*, Latin: finger) feeling and *grasping* of organs with the fingers is another important sense which could be relied upon in open surgery but which is now translated by long instruments and thus barely perceivable.

Manipulation

The space available to move and manipulate is restricted by the choice of access; appropriate planning and ex-

perience are required to compensate for this. Complex procedures are sometimes performed with expensive telemanipulation systems, although this can normally not be justified from an economic point of view. In addition, the desire for miniaturization restricts the size of instruments (e.g., forceps), which can result in longer interventions.

Conclusion

The restrictions placed on the senses of sight, touch, and to a certain extent, smell as well as the restricted manipulation possibilities which a doctor is prepared to accept in endoscopy must also be clear to the engineer when designing new instruments so as not to broaden this deficit even further. The target should be to open up possibilities with endoscopy which were previously not available.

19.1.4 History

The desire to look into concealed body cavities goes back thousands of years. There is written evidence that instruments for proctoscopy were in use in ancient Egypt [19.5], and specula have been retrieved from Pompeii dating from the first century AD. Technical possibilities and medical advances were mutually dependent. A few milestones are listed here to serve as examples; more detailed information can be found in, for example, *Reuter's* work on endoscopy [19.6]:

1806 Philipp Bozzini builds the first instrument for introducing light into body orifices, his so-called *Lichtleiter* (light conductor), in Frankfurt (Germany) [19.7].

- 1868 Adolf Kußmaul (Freiburg, Germany) performs the first gastroscopy on a sword swallower using an open tube and a candle.
- 1877 Max Nitze (Berlin, Germany) uses an optical lens system and a glowing platinum wire for illumination.
- 1902 Georg Kelling (Dresden, Germany) performs diagnostic laparoscopy on two female patients.
- 1912 The Dane Severin Nordentoft reports for the first time on knee arthroscopy. Kenji Takagi (Tokyo) begins performing arthroscopy with a cystoscope in 1919, and Otto Bircher in 1921 in Aarau (Switzerland).
- 1929 Heinrich-Otto Kalk (Berlin, Germany) is seen as a true pioneer of diagnostic laparoscopy through his work.
- 1934 John C. Ruddock (Los Angeles, CA) describes laparoscopy as a valuable diagnostic method.
- 1950 Publications on gynecological laparoscopy begin to appear: Raoul Palmer (Paris, France, 1950), Hans Frangenheim (Wuppertal, Germany, 1958).
- 1958 Basil J. Hirschowitz presents a flexible gastro-scope, which still features a distal light bulb (University of Michigan, MI, USA).
- 1959 Harold H. Hopkins (Reading, UK) patents a rod lens system that dramatically improves image transmission in endoscopes; the invention is introduced in rigid endoscopes in 1965 by Karl Storz.
- 1963 Karl Storz introduces illumination with glass fibers in the endoscope as a new technology (cold light).
- 1985 Erich Mühe in Böblingen (Germany) performs the first laparoscopic cholecystectomy (removal of the gallbladder).

19.2 Endoscopes and Endoscopic Accessories

Modern endoscopy systems are composed of a variety of components. Basically, these core components serve to generate light and illuminate the intracorporeal treatment area optimally while producing images which are then relayed out of the body and visualized optimally. Alongside purely endoscopic visualization, numerous instruments and devices are also required to enable minimally invasive treatment. In principle, one differentiates between rigid and flexible endoscopes.

19.2.1 Light Sources and Illumination

Light transmission has been performed in both rigid and flexible endoscopes via optical fiber bundles since the 1960s. Physically, the transmission of light via a light conducting fiber is based on the principle of total internal reflection between the core and the sheath of the individual glass fiber. Halogen, halide, and xenon light sources are employed as extracorporeal light sources.

This light, focused via the proximal plug, is coupled into the endoscope. Recently, the first light-emitting diode (LED)-based light sources have also become available for endoscopic applications.

The quality of any illumination must be comparable to sunlight. One criterion is the color temperature of a light source, which is based on quantum-mechanical considerations on the radiation of ideal, black bodies. The color temperature of the sun is the same as its surface temperature of approximately 6500 K. A further measured variable is the color rendering index, which is a measure of the quality of the color reproduction.

Light sources based on xenon high-pressure short-arc lamps are now the standard light sources for endoscopy, both in the field of flexible endoscopy and in minimally invasive surgery. These systems are characterized by a very homogeneous white light spectrum and high light intensity. Due to the excellent focusing possibilities, xenon light systems can be used just as efficiently in large- and small-caliber endoscopes. The color temperature comes very close to that of daylight; the color rendering index is excellent. Systems with 180 W are now sufficient for almost all endoscopic applications. The light is guided from the light source over an orderless glass fiber bundle (light cable) to the endoscope by means of total reflection in the glass fiber.

With technical advances in the field of LEDs, the first super-bright semiconductor elements are now available, which can also be used in endoscopic illumination. The advantage of this technology lies in the considerably longer lifetime of the illuminant, the high efficiency factor (i. e., less heat generated), and the small dimensions. This means that, alongside self-contained light sources, LEDs can also be installed distally and proximally in endoscopes. The current disadvantage of this lies in the inhomogeneous white light spectrum and the poor focusability of LEDs in small cross-sections of glass fibers.

19.2.2 Imaging: Endoscopes and Image Sensors

Today, endoscopic image transmission is performed optically, fiber-optically or optoelectronically depending on the type of endoscope. The common element in all endoscopes is a distal objective, which determines the direction of view and the image field.

The image field of an endoscope or the numerical aperture (NA) of the endoscope objective is dependent on the refraction index of the ambient medium. If an

examination, for example, a cystoscopy, is performed in an aqueous medium, for the same optical conditions, the image field is smaller than in applications in air or in CO₂, as is the case in laparoscopy.

Rigid Endoscopes

In traditional rigid endoscopes, images are transmitted completely optically via a lens system. In this field, the so-called rod lens system of Hopkins has managed to win widespread recognition because of its outstanding quality. Transmission systems based on rod-shaped gradient lenses have failed to gain ground. Alongside rigid endoscopes with fixed, standard directions of view at 0°, 12°, 30°, 45°, 70°, 90°, and 120°, rigid endoscopes have recently been introduced which feature adjustable directions of view [19.8]. This has the advantage of being able to adjust the direction of view during an intervention without changing the external contours of the endoscope.

Image Transmission with Glass Fiber Bundles

Image transmission over ordered optical fiber bundles occurs primarily in *flexible endoscopes*. Today we differentiate between so-called fully flexible image waveguides and semiflexible image waveguides. While semiflexible image waveguides are predominantly used in semiflexible mini-endoscopes and micro-endoscopes (Fig. 19.1) due to their small-caliber variants of approximately 1 mm (35 000 pixels) or less, traditional flexible fiber endoscopes with flexible image waveguides are increasingly being replaced by optoelectronic endoscopes.

Electronic Image Sensors

Miniature charge-coupled device (CCD) and also complementary metal-oxide-semiconductor (CMOS) image sensors are integrated in the tip of the endoscopes with an objective lens and signal processing technology, delivering electronic images with resolutions many times that of fiber endoscopes. In gastroenterologi-

Fig. 19.1 Marchal miniature endoscope sialendoscope (Source: Karl Storz)

cal applications, almost all traditional fiber endoscopes have already been replaced with videoendoscopes.

Video Technology

The first flexible videoendoscopes over 20 years ago featured black-and-white image sensors; the hollow organ was illuminated with sequential red–green–blue (RGB) light, and the compilation of the three color separations was used to calculate and visualize an endoscopic color image continually by means of image conversion. Modern videoendoscopes have color CCD and/or CMOS image sensors with on-chip RGB color filters or color filters for complementary colors (Fig. 19.2).

Video technology is an elementary component of endoscopy. This is not just applicable to the field of flexible videoendoscopes (Fig. 19.3), for which miniaturized image sensors are primarily installed distally, but also to rigid endoscopes, and particularly in the applications of minimally invasive surgery. The use of high-quality, proximal camera systems makes it possible to reproduce the extremely high transmission quality of Hopkins rod lens systems almost perfectly.

Endocameras: 1-Chip and 3-Chip

Proximal endocameras are equipped with one or three image sensors and usually have parfocal zoom objec-

tives (Fig. 19.4). Color rendering is considerably better in 3-chip cameras than in 1-chip systems.

While 1-chip and 3-chip camera systems in standard phase alternating line (PAL) or National Television System Committee (NTSC) standard versions did not come close to the resolution limits of rod lens telescopes, these limits are almost being reached by the latest 3-chip HD endocameras. Alongside the HD endocamera, the remaining components of the transmission elements such as the control unit, monitors, and digital recorders have also been adapted to the high-resolution standard. There is thus no technical reason standing in the way of HD camera systems penetrating the market. The HD requirements are specified by television. There are transmission standards with 1280×720 p (progressive) and 1920×1080 i (interlaced). The progressive standards (1280×720 p/ 1920×1080 p) only are applied to cameras or monitors. Modern HD image sensors with CCD and CMOS technology satisfy these standards.

Stereoendoscopes

Although the image quality of today's endoscopic systems is extraordinarily high, particularly when performing endoscope-assisted MIS interventions surgeons sometimes miss the depth perception offered

Fig. 19.2 Distal construction of a videoendoscope with miniaturized electronic image sensor (Source: Karl Storz)

Fig. 19.3 Videocystoscope with distal electronic image sensor

by their visual system in open operations. There was thus the desire from very early on – as with stereomicroscopy – for stereoendoscopes.

Stereoendoscopes compile endoscopic image information from two different spatial directions – similar to the human eyes. This stereo image pair is delivered to the eyes of the beholder separately via special visualization units.

The first patent for a stereoendoscope was awarded in 1905 [19.9] and was built jointly by Berlin urologist S. Jacoby (Germany), a student of Max Nitze, and

Fig. 19.5a,b Jacoby stereocystoscope (1904) (Source: Reuter, Endoscopy) (drawing adapted)

the Berlin company Louis & Heinrich Loewenstein in 1904 (Fig. 19.5). It was not until the mid 1990s that a number of manufacturers introduced stereovideoendoscope systems for minimally invasive surgery onto the market. None of these systems proved successful. Studies showed that three-dimensional vision was possible

Fig. 19.4a,b High-resolution 3-chip endocamera IMAGE1 HD (a) endoscope and 3-chip CCD camera head (b) camera control unit (CCU)

over the monitor, but the associated disadvantages such as lower resolution, lower color rendering, less image transparency, and less light meant that operations could not be performed any more efficiently.

Even autostereoscopy systems were offered which did not have any real three-dimensional (3-D) information. Improvements in visualization of 3-D information in particular are necessary for stereoscopy to achieve acceptance. One approach is to make the image not only visible from two perspectives, but also to visualize it volumetrically using different focus levels [19.10].

19.2.3 Video Chain

Having dealt with the fundamental components of the light source, light cable, endoscope, and electronic image converter, the following will introduce the term *video chain*. As in every chain, it is important that all links are strong and of high quality, as the overall result of a good endoscopic image is determined by the weakest link in this chain.

It is often the *small* things which can bring a high-quality system to its knees. It is thus particularly important to pay attention to all coupling and connection points, for example, as regards cleanliness of optical surfaces. In the same way, electrical connections and signal cables must be checked carefully for kinks or damaged connections which can affect the result. When choosing a video signal, the highest available quality should be selected.

In the video chain, the endoscopic camera (image converter) is followed by the monitor and optionally the image and video documentation system or telemedicine possibilities.

19.2.4 Monitors

Today, thin-film transistor (TFT) monitors are used almost exclusively in the visualization of endoscopic images. Their quality has increased considerably in recent years. The change in the operating theater away from cathode-ray tube (CRT) monitors towards flat-screen monitors around 2005 occurred at a time when the image reproduction of flat-screen monitors was still considerably below the possibilities offered by CRT monitors. The aura of the new, the expectation that this deficit would be resolved, and the weight advantage, which allows easy and flexible positioning of the screen, paved the way for this premature technological change.

Important criteria when selecting a good monitor are excellent color rendering, as large as possible a viewing angle, and very low latency, i. e., no delay between the operator's actions and visualization thereof on the monitor. In particular the latter point represents an important difference in comparison with monitors for nonmedical applications. In contrast to monitors for other imaging modalities, in endoscopy excellent color resolution is decisive – particularly with respect to the color tones of human tissue. Technical specifications are good for an initial comparison, but true performance and differences between units only become visible in a direct comparison in the operating theater.

19.2.5 Image and Video Documentation

In the beginnings of endoscopy, image documentation was an almost secretive art, as only the examiner was in a position to view the examination field. However, the wish to share this view with fellow examiners was expressed from early on.

Today, the doctor is obliged to document pathological findings and the properly performed operation in image or digital video form. The commonplace, high-quality, electronic image sensors available today make excellent image documentation possible. Of course, an important factor when recording images is that there is optimal visibility and that the site is well irrigated.

Digital archiving of still images is standard today. Because, in general, an electrical connection exists between the recording unit and the image sensor and thus at least indirectly with the patient, the documentation unit must be designed as a medical device. Conventional consumer products are not permitted.

Additionally, systems tailored especially to medical applications allow the doctor to record images systematically and specifically for the intervention being performed and then to prepare these in the corresponding surgical reports. The units must be simple to handle, and in particular, images must be simple to capture [19.11]. There are a number of different systems on the market, which in some cases are tailored to very specific medical applications (Fig. 19.6).

Alongside the capture of still images, documentation of video sequences is playing an increasingly important role. With the increased requirements vis-à-vis resolution, video sequences in HD format (720 p, 16:9) in MPEG2 can achieve data rates of approximately 12 Mbit/s or memory requirements of 90 MB/min. For 1080 p, approximately 20 GB is required per hour of recording time.

Fig. 19.6a,b Clinically approved system for digital storage of patient, image, and video data. This model is tailored to orthopedic applications: **(a)** AIDA compact ortho, **(b)** documentation mask for the surgical protocol of partial resection of a medial meniscus

The integration of patient-related (image) data in existing hospital information systems (HIS) and picture archiving and communication systems (PACS) is becoming ever more important and should be delivered by high-quality endoscopic image and video memory systems (Sect. 19.3).

19.2.6 Telemedicine in Endoscopy

Broadband data links now allow us to transmit endoscopic video images to any location. This can be in order to get a second opinion or for teaching purposes; it could be to a location within the same hospital or even another continent. The possibility to interact with the recipient is important, either simply via speech or even additionally via graphic interfaces (telestration). For telemedical applications in endoscopy, it is very important that image transmission be temporally synchronized.

19.2.7 Endoscopic Instruments

Alongside the endoscope, which takes care of optical imaging, endoscopy requires a range of further instruments for insertion and manipulation.

Access Instruments

Flexible endoscopes are generally used without further insertion aids. If required, a lubricant may be applied and/or local anesthetic administered. This applies to gastroscopes, colonoscopes, cystoscopes, nasopharyngoscopes, bronchoscopes, etc. These flexible endoscopes are inserted under visual control.

Rigid endoscopes are usually inserted via an insertion tube, which is referred to differently depending on the application. Rigid endoscopes are usually inserted under local or general anesthetic.

To examine the bladder in urology, a single *shaft* is required for a diagnostic procedure and a double shaft system for a surgical intervention, whereby the continuous irrigation provides clear visibility and removes resected tissue or liquid clouded by blood.

In laparoscopy, access to the abdominal cavity (peritoneum) is achieved using a Veress-needle. This step allows, once the peritoneum has been insufflated with gas (CO₂), the creation of a working space without visual control. A rigid endoscope is then introduced via the trocar which is equipped with a sharp trocar mandrel. Additional instruments can then be introduced into the operating region via other trocars under visual control.

Manipulation Instruments

Depending on the application, endoscopy allows the use of a wide variety of instruments which can be used to manipulate tissue, such as exploratory probes, grasping forceps, dissectors, retractors, scissors, hooks, suction and irrigation catheters, resection loops, needle holders, staplers, and clip applicators. Figure 19.7 shows examples of different grasping forceps and a complete set for laparoscopic partial nephrectomy. The range of different instruments is enormous; the leading manufacturers offer several thousand different instruments for the most diverse medical indications.

Dimensions of Minimally Invasive Instruments

The dimensions of the instruments are once again subject to two parameters: As minimally invasive as

Fig. 19.7a,b Laparoscopic grasping forceps. (a) A selection of different jaws, and (b) an endoscopic set for laparoscopic partial nephrectomy

possible, and as effective as possible as far as optical image and mechanical manipulation are concerned. For this reason, purely diagnostic instruments are generally more slender and are used without or only under local anesthetic; surgical treatment endoscopes are usually larger in diameter and normally require general anesthetic. The typical diameter of minimally invasive instruments ranges from 10 to 5 mm, which can be seen as standard in laparoscopy, through to 1.9–3.5 mm for minilaparoscopy instruments. Minilaparoscopy is a rediscovered method originally used in internal medicine for liver diagnosis. The approach was first elected by the internists Georg Kelling, Heinrich-Otto Kalk, and John C. Ruddock at the beginning of the 20th century.

Instruments which are introduced into the working channels of flexible endoscopes generally have a diameter ranging from 2.2 to less than 0.5 mm.

19.2.8 Preparation of Endoscopes and Instruments

The significance of hygiene and proper instrument processing has been becoming ever more important in recent years, particularly due to new versions of pathogens which are not sufficiently deactivated by the traditional and often manually performed methods of instrument decontamination and thus potentially pose a hidden risk of human-to-human transferral of infectious microorganisms via surgical instruments. A further reason for this is the ever smaller and more complex nature of instruments, which accordingly places higher require-

ments as regards the creation of a hygienically sterile state. In principle, all instruments contaminated with microorganisms, particularly invasively and minimally invasively employed instruments, can cause infections. It is thus essential that they be subjected to a safe, validated reprocessing before being reused [19.12].

The reprocessing cycle usually consists of the following steps:

- Cleaning, defined by bioburden reduction by 1–4 log levels (bioburden reduction to 10^{-1} – 10^{-4} of initial contamination).
- Disinfection with bacteria reduction to 10^{-4} – 10^{-5} .
- Or high level disinfection (bacteria reduction to 10^{-6}), if appropriate for the procedure and surgical instrumentation.
- Sterilization with bacteria reduction to 10^{-6} (killing 99.9999% of bacteria or leaving just one out of one million alive).
- Sterilization process with a double safety factor (so-called *overkill* processes with bacteria reduction to 10^{-12}) which destroys all forms of microbial life.

Cleaning

Cleaning is primarily the mechanical depletion of contaminations, for example, by brushing the surfaces, rinsing, and/or auxiliary use of ultrasound. The effectiveness can be boosted through the use of chemical agents based on enzymes, aldehydes, and other active agents. Thorough cleaning is essential before (high level) disinfection and sterilization because inorganic and organic materials that remain on the surfaces of the

instruments can interfere with the effectiveness of these processes.

Disinfection

Disinfection is based either on the use of chemical substances with the corresponding spectrum of activity or on the action principle of the thermal denaturing of organic compounds with the help of water at a temperature of 93 °C or higher, which fully coats the surface of the instrument.

In the meanwhile it has become commonplace to perform these procedures in automated washer-disinfector machines, whereby the parameters relevant for success, such as the concentration of the chemicals, their exposure times, and the temperature, are controlled and monitored accordingly. This avoids the possibility of human error. The reduced handling of contaminated instruments and aggressive chemicals thanks to such fully automated processes also helps to protect staff.

High Level Disinfection. High level disinfection (HLD) is a process that eliminates all pathogenic microorganisms, with the exception of bacterial spores. HLD is normally accomplished using a chemical disinfectant solution.

Sterilization

Following properly performed cleaning and disinfection, the instrument is subjected to sterilization depending on the application at hand. The internationally preferred procedure, in health care facilities due to sterility assurance and cost efficiency, remains steam sterilization (autoclaving) with moist heat (pressurized saturated steam) at a temperature of 134–137 °C (272–279 °F) for an exposure time of 3–5 min, which is subject to different regulations in each country (in the USA, AAMI ST 79) [19.13].

For instruments declared as thermolabile (based on the materials used) there are a number of alternative, low-temperature sterilization processes available such as traditional gas sterilization with ethylene oxide or formaldehyde. Additionally, there are also newer processes available which are based on hydrogen peroxide (H₂O₂), peracetic acid or ozone, which must be assessed and selected for the individual goods to be sterilized in terms of their efficiency, suitability, and material compatibility.

Care

An additional, important aspect in the scope of the reprocessing process of a medical device is service and care, which are usually performed as part of the func-

tional check after successful cleaning/disinfection but before sterilization, and which serve to ensure the functioning and value retention, particularly for instruments with moveable parts. In this step, the moving parts are oiled locally with a silicone-free instrument oil which is biologically harmless (biocompatible) and does not hinder the selected sterilization process (e.g., steam penetration through the care agent film to the surface beneath). The instrument is operated several times to ensure distribution of the care agent within the joint.

Structural Design

Reprocessing of medical devices is a complex process, the success of which is dependent on multiple factors including, importantly, the instrument itself and its mechanical design layout and also the selection of the materials used.

Requirements and Directives

On the topic of hygiene, the legal and regulatory parameters require qualified processes and staff who are suitably trained and qualified.

Cleaning [19.14], disinfection, and sterilization [19.15, 16] are subject to a multitude of field-specific recommendations [19.17], international standards, and national regulations and represent a continuous challenge for both users and manufacturers of medical devices.

19.2.9 Peripheral Units

Alongside the units for videoendoscopic image capture and documentation, a whole range of additional units for assisting surgery are required.

Insufflators and Suction/Irrigation Systems

All MIS interventions performed in the abdomen require the creation of a pneumoperitoneum, which allows organs and tissues to separate slightly and become visually and instrumentally accessible while the abdominal wall remains closed. Gas insufflators are used for the generation and maintenance of the pneumoperitoneum. The regular changing of instruments and suction, e.g., of liquids, result in continuous pressure and volume losses, which place great demands on modern gas insufflation units. The units should provide a maximum flow rate of 30 l/min and not exceed an intra-abdominal pressure of 15 mmHg. To avoid hypothermia in patients undergoing longer interventions, the new generation of units have an integrated module for warming and/or moistening the gas.

Alongside the insufflation of gases it is often necessary in MIS interventions to irrigate the operating site or the lens with liquid or remove blood and tissue remnants. In addition, efficient irrigation can also be used for hydrodissection, i. e., to dissolve adhesions. Modern suction and irrigation systems unite both requirements.

Energy Application Systems

A therapeutic effect is achieved by applying energy in order to cut, separate, initiate hemostasis, coagulate, disintegrate calculi, and for many other actions.

High Frequency

Amongst other things, high-frequency (HF) current (Chap. 34) is used to create thermal effects endoscopically (Fig. 19.8). This can be used to dissect soft tissue and coagulate existing hemorrhaging under endoscopic visual control. There is a general differentiation between monopolar and bipolar HF electrosurgery. Monopolar technology is used most often in endoscopy.

Laser

Lasers have been used in medicine since shortly after their technical implementation at the beginning of the 1960s. Different media allow different laser wavelengths in the visible, infrared, and ultraviolet ranges of the spectrum. Depending on the wavelength, pulse duration, and interaction duration, it is possible to achieve a truly characteristic interaction in the tissue [19.18]. Important interaction partners are water and hemoglobin, the absorption properties of which define how deeply the light penetrates (Chap. 29). Lasers are used widely in ENT [19.19] and urology [19.20], where

they are employed for lithotripsy, for tumor coagulation, to separate stenoses, and for prostate enucleation.

Laser light is transmitted in endoscopy via flexible, thin glass fibers; for special applications in the far infrared, mirror systems (CO₂ lasers) are also used. Recent years have seen these systems become ever more compact and also very service-friendly thanks to the use of laser diodes.

Other Energy Delivering Systems

With photodynamic therapy (PDT) an endoscopic tumor treatment is possible which exploits the interaction of (laser) light, oxygen, and a photosensitizer that accumulates selectively in malignant tissue [19.21].

Energy can also be withdrawn endoscopically using *cryoprobes* to destroy tumor tissue by localized supercooling, or be delivered in concentrated form using *ultrasound* to separate tissue.

Systems for Further Interventional Procedures

As endoscopy is very multifaceted, special interventional systems are used for the most diverse of applications. These include

- implants such as endoluminal stents or occluders, which can be introduced endoscopically,
- motorized instruments used to ablate bone and hard tissue (shavers, drills) or to cut soft tissue (morcellators).

19.2.10 Endoscopy Workstations

Endoscopy workstations are tailored to the requirements of the respective application.

Fig. 19.8 High-frequency units (monopolar/bipolar) with an endoscopic instrument set for transurethral resection (TUR)

Fig. 19.9a,b Two different endoscopy workstations: (a) compact system for outpatient departments with camera control unit, light source, monitor, keyboard, and suction/irrigation pump (Gastropack), (b) equipment trolley for the operating theater additionally with HF surgery system, insufflator, and still image and video archiving system

For clinical outpatient departments, emergency medicine, and even doctors' practices specializing in endoscopy, the focus is on a compact system which is fundamentally concentrated on illumination and image rendering. Biopsies and minor interventions are possible. These systems are light and easy to transport, and have been available on the market for quite some time (Fig. 19.9a).

Day clinics, which usually perform routine operations endoscopically and under general anesthetic, and

fully equipped operating theaters in hospitals require a larger range of treatment options. As a result, a modular concept is called for, exactly calibrated to the needs at hand. The components are installed on a mobile equipment trolley and can be positioned at the required location in the operating theater. Mobility over greater distances is also possible to some extent (Fig. 19.9b).

Newly designed operating theaters are now predominantly equipped with fully integrated workstations (Sect. 19.3).

19.3 Integrated Operating Theaters

As a result of the rapid development in minimally invasive surgery, there is now a wide variety of devices in the operating theater in comparison with the past. The operation and handling of these systems, which are often from different manufacturers, have thus become more and more complex and time consuming. In addition, the surgeon requires a considerable amount of time to document all the points relevant to surgery and compile a report. On top of all this, the surgeon is continuously being confronted with more complex MIS interventions, and time budgets are always being cut. These increasing requirements can only be satis-

fied by improving the ergonomic handling of units and instruments and comprehensive computer-assisted documentation and data provision [19.22]. The design of system workstations and new concepts for integrated operating theaters set benchmarks for the logistical harmonization of operating activities, reduce stress for the surgeon and assistants, and thus reduce operating and changeover times.

System integration allows, amongst other things, central control and operation of endoscopy units and further devices capable of being integrated such as HF units, operating tables, operating lamps, and operating

light cameras, as well as documentation systems and the telemedicine unit via a central touch-sensitive monitor (touchscreen) directly from the sterile area and/or at the nurse's workstation [19.23]. There is also the possibility to preset start configurations for the system parameters and telemedicine basic settings with personal or intervention-specific presets, so that the units set themselves automatically when the respective configuration is selected. This saves time on the one hand and contributes to quality assurance on the other. The user interfaces of the integrated devices are represented one-to-one on the system's user interface. Users thus do not have to familiarize themselves with a new concept. Alongside the realistic user interface for each individual unit there is also a freely definable overview display of the most important unit parameters. The individual, selected units can also be controlled from this display mode. In addition, the visualization of unit parameters as well as alarm and status messages from the operating system is realized in a section of the touchscreen clearly visible to the surgeon.

A further dimension of operating room (OR) integration is data management, which results from the obligatory documentation requirement. In this respect, the systems offer all necessary functions for holistic,

accurate documentation of all endoscopic and open interventions. User-friendly entry systems allow the simple capture of still images, video sequences, and spoken commentaries on findings and operative interventions directly from the sterile area by simply activating the touchscreen, a footswitch or the camera head buttons.

A digital imaging and communications in medicine (DICOM) interface can be used to give the system access to DICOM worklists available on the hospital network, which allows rapid transfer of patient data.

Alongside system integration and data management, audio and video technology for communication and data transfer also form part of the holistic concept of an optimally integrated operating solution. The different video signals from endoscopic and room cameras as well as from the PACS and HIS systems can also in principle be connected and routed as required and even telecommunicated, thus allowing them to be displayed outside of the operating theater. Audio and video technologies are also controlled via the touchscreen at the nurse's workstation. The man-machine standard interfaces often already feature intelligent voice-controlled systems.

The focus on integrated OR systems (Fig. 19.10), which is increasing productivity and efficiency in many surgical procedures, has put hospital administration in

Fig. 19.10 Fully integrated operating room OR1 Karl Storz (Source: Karl Storz)

a position to see the operating theater as an important source of income. In terms of profitability, the operating theater has become a decisive factor in the success of a hospital.

These integration technologies have been recently complemented by efficient OR management systems. Efficient OR management is based on the harmonization of all processes and integrated components combined with the possibility to connect seamlessly with the hospital information system. Such a system (e.g., Orchestrion [19.24]) makes it possible to optimize the planning of operations and staff schedules, and ensures efficient flow of information between the operating theaters and the hospital information system. By

optimizing the way in which the operating theater is used, the hospital achieves smoother processes and is thus in the position to offer patients a higher quality of treatment. This tool is helpful in preplanning of operations and coordinates and controls the use of available OR resources. It is thus an important element in the development of strategies for optimal utilization of limited resources. Thanks to the implementation of standardized interfaces, these tools can be easily integrated into the existing information technology (IT) structures of a hospital. The modular design of the system can be adapted to suit the individual requirements of every hospital and offers a dynamic platform to be able to integrate future developments and improvements.

19.4 Medical Applications

Endoscopy is employed in a wide variety of medical and surgical disciplines for diagnosis and treatment. It is routinely used in, amongst others, the different sub-disciplines of ear–nose–throat medicine, pneumology, gastroenterology, abdominal surgery, urology, gynecology, and also sports medicine.

Users are found in all strata of the healthcare system, from specialists to ambulatory healthcare centers and day clinics as well as all types of hospitals from primary health care to university hospitals.

19.4.1 Most Common Procedures

The most common surgical endoscopic interventions are arthroscopic interventions, endoscopic sinus

surgery, laparoscopic gallbladder removal, transurethral resection of bladder tumors, and benign prostate tissue (BPH) [19.25]. Hernias, bariatric surgery hysterectomy, and appendectomy are some of the most common surgical procedures, although they are only partially performed endoscopically. Additionally, in 2008, more than 16 million diagnostic endoscopic examinations were performed in the US.

19.4.2 Special Procedures

The following illustrates some special endoscopic applications to demonstrate the potential and particular possibilities, but by no means does it claim to be exhaustive.

Fig. 19.11 Miniaturization in endoscopy using pediatric urology as an example. *Top*: resectoscope for tissue ablation with HF current, shaft diameter 3.7 mm; *bottom*: cystoscope shafts (Source: Karl Storz)

Fig. 19.12 Spinal system for treatment of disc herniations and spinal canal stenoses (Source: Karl Storz)

19.4.3 Miniaturization

Endoscopes can be miniaturized so that they are suitable for operations on children and newborns. To give an example, we cite the incision of the closed ureteral orifices in a newborn baby with hydronephrosis, whereby a small scalpel is introduced via a delicate pediatric cystoscope and used to remove an anatomical anomaly (Fig. 19.11). Today it is even possible to operate endoscopically on the fetus while it is still in the womb. Other applications for mini-endoscopy include examination of the tear duct in the eye, salivary ducts in the mouth (Fig. 19.1), lactiferous ducts in the breast or the fallopian tubes. This is where the finest, flexible fiber-optic endoscopes with diameters of 0.3 mm to approximately 1 mm come into use.

19.5 Tissue Differentiation

As discussed in Sect. 19.1.2, illumination is modulated by the illuminated tissue and perceived by an image sensor. A variety of procedures now make it possible

19.4.4 Controlled Access

In some medical applications it was previously not possible or usual to work under visual control. In terms of more minimally invasive and safer accesses, endoscopic assistance has become established in anesthesia and emergency medicine in recent years in attempts to find the right access in cases of difficult intubation.

Endoscopic examination of the uterus (hysteroscopy) is also on the advance in this respect, particularly for performing targeted biopsies or removal of polyps, in comparison with blind curettage. This is driven by improved reimbursement and new indications such as transcervical sterilization. Even if hysteroscopy could be used without causing pain and without anesthesia by any specialist in a practice, enhanced training and logistics is needed to support this procedure in an office environment.

19.4.5 Alternatives to Surgical Microscopes

In the fields where surgical microscopes are used, endoscopic procedures are gaining ground. Endoscopic procedures are becoming increasingly popular in laryngeal surgery, neurosurgery, and in delicate operations in spinal surgery (Fig. 19.12). The depth of field of endoscopic systems is considerably larger than with microscopes. Moreover, endoscopes can be used to look around corners, which is not possible with microscopes as a result of the large working distance.

19.4.6 Gastroenterological Endoscopy

Possibilities to examine the digestive tract are offered by a wide range of extremely differentiated endoscopy systems which can be coupled with ultrasound, zoom or fluorescence procedures. In addition, a piggyback procedure is used for examination of the bile ducts, in which a small-caliber endoscope is introduced through a large-caliber duodenoscope. Gastroscopy and colonoscopy are amongst the most commonly employed diagnostic procedures. Fig. 19.13 shows a typical, flexible endoscope from gastroenterology with a distal image sensor.

to gather information about the tissue, being considerably more detailed than the information offered by the colored white-light image.

Fig. 19.13a,b Flexible videocolonoscope with distal, high-resolution solid-state image sensor: (a) video cart, (b) close up look of videocolonoscope, CCU and lightsource

19.5.1 Molecular Imaging/ Fluorescence Endoscopy

Molecular imaging is one of the great beacons of hope in the field of cancer research and early detection, as it makes pathological changes visible at the cellular level. Fluorescence-based endoscopy systems are also of great importance as optical detection units. The procedure itself uses the distinct metabolism of abnormal cells to display fluorescent substances accumulated in the tumor via a molecular mechanism. This optical form of molecular imaging, in which the suspicious area in the endoscopic image lights up in color,

was initially used in bladder cancer with great success [19.26].

Carcinomata in situ with a thickness of just a few micrometers ($< 30 \mu\text{m}$) can be visualized with this technique at a very early stage (Fig. 19.14). No other imaging procedure is in a position to do this.

Nowadays, the procedure is also used for numerous other organ systems. The target of various initiatives in molecular imaging is to have new disease-specific marker substances and tailored detection systems available in the future. This can only occur through cooperative alliances between pharmaceutical companies and device manufacturers.

Fig. 19.14a,b Endoscopic cystoscopy of small exophytic tumor with small satellite tumors: (a) photodynamic diagnosis (PDD) mode, (b) white light (Source: Karl Storz)

19.5.2 Infrared Endoscopy

Infrared endoscopy, i. e., endoscopic representation of image information in the infrared range, has been on the wishlist of diagnostic medicine for many years. For example, it could be used to recognize inflammatory conditions better. However, this target is subject to technological limitations. Endoscopic capture and transmission of near-infrared (NIR) light from 650 nm up to approximately 1000 nm and a maximum of 2000 nm is possible with existing technologies. Image transmission beyond that cannot be achieved with standard optically transparent lenses.

Current research and development activities have thus concentrated on the NIR range. Attempts are being made, amongst other things, to determine perfusion following transplants or visualize enteroanastomotic insufficiencies at an early stage. For intraoperative examination of the anastomosis following intestinal resection, the surgeon has visual and manual control available in open surgery; in laparoscopic interventions, however, only visual, endoscopically assisted control under white light is available. For better control of intestinal perfusion, *Carus et al.* [19.27] first employed intraoperative fluorescence diagnostics for laparoscopic colorectal anastomosis. The basis for these applications is the NIR-transmitting endoscope as well as cameras and optical contrast agents, which are excited by special excitation light to exhibit NIR fluorescence. The intravenously administered marker indocyanine green (ICG) is excited to fluoresce in the infrared region at around 830 nm on exposure to red light. The diagnostic principle has been used since the 1960s to examine the retina, and as a result ICG is approved for the most diverse of applications in many countries. It is hoped that use of ICG fluorescence laparoscopy technology will significantly reduce the relatively high rate of anastomotic insufficiencies in the colon and rectum.

Technically, the ICG fluorescence system is based on an endoscopic 300 W xenon light source, into the light path of which an ICG excitation filter can be swung alternately. As a result of this deep red excitation light, the presence of ICG in blood can be detected as NIR fluorescence even in deeper tissue structures. This fluorescence is detected by an imaging laparoscope via an observation filter, separated from interfering light rays, and converted into an electronic image signal by a special camera which is sensitive to the NIR range. A type of false-color coding is used to convert the infrared (IR) fluorescence information to a visible range and display it on the monitor. Optionally, one can

swap between the standard white-light mode and the IR mode.

19.5.3 Zoom Endoscopes, Endomicroscopes

Today, histological microscopic examination is the gold standard for assessing tissue with regard to its nature or malign degeneration. There has long been a desire to be able to perform this laboratory examination in situ at the time of the operation.

As early as 1980, *Hamou* [19.28] described a procedure in Paris in which he dyed the tissue to be examined with methylene blue and then viewed it with a rigid endoscope, which normally delivers a standard wide-angle image or, in contact with tissue and by altering the optical focus level, an endoscopic image with 150× optical magnification. This allowed the recognition of the size of the cell nuclei and anomalies in the cell structure. The procedure was commercialized by Karl Storz under the term contact endoscopy and used in the detection of cervical dysplasia and to examine the larynx. The procedure did not become widely used. Today, magnification endoscopy has found a new impetus in gastroenterology.

The optical magnification of extended tissue structures superimposes the information of many tissue layers on top of each other. Recent years have seen the further development of procedures from microscopy which can be used to produce a defined slice level endoscopically using the confocal principle. To do this, one requires either a distal microscanner or a proximal scanner, which is technically demanding. Alternative procedures are visible on the horizon, but clinical evidence is not yet available.

19.5.4 Ultrasound Endoscopes

Endoscopy is an unrivalled procedure for assessing the surfaces of organs. Ultrasound technology is used to assess deeper structures and processes. Endoscope-assisted ultrasound examinations allow tissue characterization and conclusions about deeper layers, which remain invisible in purely endoscopic observation. Piezoceramic ultrasound elements are integrated either as individual elements or in the form of an array into the tip of the endoscope and emit short, high-frequency ultrasound pulses into the tissue. These sonic pulses are reflected by tissue interfaces and other tissue inhomogeneities at different penetration depths, captured by the same ultrasound element again, converted into electrical signals, and transmitted to an

evaluating processor unit. The information from various ultrasound echograms is compiled to create so-called ultrasound B-mode images (brightness images) and visualized for the doctor for further evaluation on the monitor. The frequencies of endosonographic systems are currently in the range 5–30 MHz. Earlier electromechanical scanner units have now been exclusively replaced by electronically controlled array transducers (linear/radial scanners). Interventional operations in particular, e.g., fine-needle biopsies, can be performed under endosonographic control.

19.5.5 Optical Coherence Tomography

Optical coherence tomography (OCT) can be seen as an optical equivalent to ultrasound imaging. The basic principle of OCT is based on white-light interferometry. In this, an arm with known optical path length is used as a reference to the measuring arm. The interference of the signals from the two arms provides a pattern, which one can use to determine the relative optical path lengths within a depth profile. In a one-dimensional raster scan, the ray is then directed transversally in one or two directions, which allows one to record a two-dimensional (2-D) or 3-D tomogram.

Today, OCT is routinely used in ophthalmology; in endoscopy, current applications are still experimental (Fig. 19.15), mostly on the larynx and in the bladder. The penetration depth is around 2 mm.

19.5.6 Virtual Chromoendoscopy

Differentiation between benign and malignant structures is an important aspect of endoscopic diagnostics. To improve conclusions with regard to tissue characterization and tissue differentiation, the application of coloring methods with, e.g., methylene blue, toluidine blue, and indigo carmine has been common for many years. Similar contrast accentuations are achieved by

Fig. 19.15 (a) Endoscopic OCT images in false-color rendering. Healthy urothelium (*a* urothelium, *b* lamina propria, *c* muscularis propria); (b) muscle-invasive lesion, the layer structure is no longer identifiable, scale 1 mm (Source: A. Goh, S.P. Lerner, Baylor College of Medicine, Houston)

the use of acetic acid, for example, in early detection of carcinomata in the cervix, esophagus, and oral cavity.

Several years ago these technologies were joined by spectral image processing technologies, which can be used to perform special real-time color analyses of videoendoscopic images. We differentiate between purely software-based systems (virtual chromoendoscopy) (Fig. 19.16) and systems which visualize a combination of narrowband illumination with specific, electronic color assignment (narrowband imaging, NBI). The idea behind the spectral processing techniques is to improve the recognizability of special structures by limiting optical image information to a narrowband range in comparison with the whole visible spectral range, thus suppressing less relevant spectral information. For this reason, the wavelengths which are of greatest interest in endoscopic examinations are those which correspond to the range in which the blood pigment hemoglobin displays the highest absorption. These lie in the blue between approximately 410 and 440 nm and in the green between 530 and

Fig. 19.16a,b Virtual chromoendoscopy: (a) white-light image of the palate, (b) defined vascular structure (Source: Karl Storz)

580 nm. Restriction to such spectral ranges allows contrast accentuation between tissue regions with higher and lower hemoglobin concentrations. This allows for

better differentiation of vascular structures near to the surface. Pathological structures, e.g., in the region of the esophagus, are easier to identify.

19.6 Further Future Developments

Alongside the procedures for tissue characterization (Sect. 19.5) there are a whole host of further innovative approaches. The first clinical implementation has already occurred, but for the most part clinical acceptance cannot yet be foreseen.

19.6.1 Natural Orifice Transluminal Endoscopic Surgery – NOTES

For some years now there have been intense discussions in surgical and gastroenterological circles about further reduction of the trauma associated with the surgical approach. It is starting to look possible to cross the boundaries between internistic gastroenterology and abdominal surgery. To do this, it is accepted that a previously intact organ structure (e.g., the stomach or vagina) will need to be penetrated surgically. In contrast to trauma associated with the surgical approach through the abdominal wall, however, this is seen as acceptable by the protagonists.

Operating via natural orifices appears possible. NOTES stands for natural orifice transluminal endo-

scopic surgery. The aims were laid down in 2005 in a white paper [19.29] led by *Rattner* and *Kalloo*. To date, amongst other things, gallbladders and appendices have already been removed from patients transgastrially (via the stomach) and transvaginally [19.30] (via the vagina). We can assume that, by the beginning of 2010, over 500 patients have undergone NOTES procedures across the world. A large percentage have been performed on women transvaginally, as this approach has been well known for a long time and the access site can be closed easily in open surgery without any problems. In principle, the transgastric approach is preferred, but no satisfactory method of closing the stomach wall has yet been found. Some of the operations are performed as hybrids with the help of a laparoscopic port.

The very high initial expectations placed on instruments and surgical techniques have still not been met. Nevertheless, some technological innovations have been realized in this regard.

Figure 19.17 shows the ANUBISCOPE from Karl Storz as an example. It is used for transgastric appli-

Fig. 19.17a,b Flexible, interventional platform for performing transgastric operations, ANUBISCOPE with three working channels, two of which can be angled for triangulation of flexible working instruments. The two half-shells can be moved: when closed they serve as an atraumatic introduction and dilation aid; when open they act as a retractor and secure the operating region against the nonvisible region. **(a)** Whole system, **(b)** distal close-up with coagulation hook, grasping forceps, and suction catheter (Source: Karl Storz, FDA approval pending)

cations with total reflection option (210° angle in four directions). This is a platform with a flexible shaft; the working channels are larger and intended for flexible instruments, which can be angled and used to manipulate tissue accordingly. Triangulation, which is not possible in traditional, internistic endoscopy, is made possible here by the instruments which can be angled. The special mechanism on the tip of the endoscope allows atraumatic introduction as with a blunt trocar in laparoscopy (closed state), and in the operating area, thanks to the open position of the half-shells, offers protected operating, stabilization of the instruments, and their triangulation. A third working channel can be used to introduce further instruments such as an articulating catheter for suction or as a guide for a laser fiber.

It is still too early to sum up the history of NOTES, as it is far from finished.

19.6.2 Single Port

Once the enormous challenge of NOTES (Sect. 19.6.1) became apparent to physicians and engineers working at companies active in the field, they began to search for alternative innovations. The idea of reducing the trauma associated with the surgical approach and not leaving any scars was expanded on so that work should only be performed via a single laparoscopic site or a single port. As a matter of preference, the umbilicus was suggested as the approach, because this would at least avoid creat-

ing a new scar (the umbilicus being, to a certain extent, a natural scar).

A multitude of different terms were developed, which although they might differ slightly in the details, all basically follow the same principle. *Single-port laparoscopic surgery* refers to an approach port which can accommodate several instruments (Fig. 19.18).

Despite its potential advantages, the procedure is associated with considerable ergonomic restrictions and limitations, as it is more difficult to perform laparoscopic interventions via this procedure and it demands extraordinary dexterity and expert knowledge on the part of the surgeon. The Dundee ENDOCONE system was realized as an integral insertion–instrument–retraction system to resolve this problem and facilitate the performance of single-port operations. The system features curved, instruments in order to enlarge the operating space between the surgeon's hands.

19.6.3 Simulation

The establishment of minimally invasive surgery (MIS) brought with it an increase in training requirements for new endoscopic techniques. Hand–eye coordination training with endoscopic instruments using simple in vitro models is not sufficient for basic MIS training. Intensive courses using in vivo large-animal models have been necessary to date in order to teach prospective MIS surgeons the requisite instrumental interactions and manoeuvres. The availability of high-performance

Fig. 19.18a,b Single-port approach systems and instruments display various differences, particularly when it comes to their shape. **(a)** CUSCHIERI ENDOCONE, **(b)** X-CONE consisting of two half-shells, which are locked together via a seal (Source: Karl Storz)

computers and graphic processors means that it is now possible to produce virtual simulators, which on the one hand present the operating site relatively realistically and, on the other hand, can already simulate the interactions between the instruments and the soft tissue almost as in real life. The requirements vis-à-vis real-time performance and image resolution are largely met.

There are different simulators for the different specialities, e.g., urology [19.31], gynecology, visceral surgery, colonoscopy, etc. The simulator system for abdominal surgery comprises a monitor, a control unit, a simulation personal computer (PC), a patient torso with trocar modules including tactile force feedback, and endoscopic instruments (Fig. 19.19).

The available training scenarios offer the possibility to practice the individual techniques such as handling of the endoscopic camera, the endoscopic grasping forceps, and a suction/irrigation handle, etc. Combinations can also be trained. The variation of the individual scenarios happens via different difficulty levels and different directions of vision (0° , 30° , 45°) on the one hand, and different laparoscopic views on the other, which are varied within the simulation but are also dependent on the position of the trocar modules, which can be placed in almost any position on the patient module.

The simulators offer an easy-to-use user interface. All possible actions are described within the interface with text or additionally with images, so that the user can start with the system directly. The user can choose between different scenarios, tasks, and difficulty levels. In addition, there is usually also an integrated student-teacher system. Individual students then have the possibility to create user accounts in which the results of the training scenarios are saved. This presents the opportunity of monitoring training progress. Additionally, the teacher can view the results of all the created user accounts via his login.

19.6.4 Endorobotics

Robots are stationary or mobile machines which perform specified tasks according to a defined program. One possible task is the use in medical environments to move or position instruments or visual systems. Problematic, however, in the medical environment, is the autonomous movement of such a system. Today we do not speak of robots, but of handling systems, which operate under direct interactive control of the surgeon. In endoscopy, one currently differ-

Fig. 19.19 Virtual MIS simulator for laparoscopic interventions

entiates between two types of *robot systems*. Firstly, there are so-called telemanipulation systems, which are used to position and activate endoscopic instruments and endoscopes by remote control. Secondly, wireless videocapsules are sometimes referred to as endorobots, as they pass through the gastrointestinal tract as an autonomous endoscopic visualization system, compiling corresponding image information for transmission to the outside (Sect. 19.6.5).

The following describes endoscopic telemanipulation systems [19.32–35]. The first attempts at telemanipulation systems were made by a team led by Taylor [19.36]. A positioning system for laparoscopes was launched onto the market in the mid 1990s by Computer Motion, Inc. [19.37]. Speech input was used to guide the endoscope in the abdomen and position it. This system was later superseded by the Da Vinci telemanipulation system from Intuitive Surgical. The Da Vinci system is composed of a control unit with stereo monitor and, on the patient side, a three-armed instrument positioning/activation unit and a positionable stereolaparoscope. During laparoscopic interventions, the surgeon sits at the control console and moves the instruments on the operating table from this position. The software-assisted 3-D visualization provides the doctor with a detailed, 3-D view of the operating field and a great depth of field. The doctor controls the instruments from the control console using control elements. In doing so, the exact movements of his wrist, hand, and fingers are acutely enacted by the remote-controlled

instruments. The camera-assisted laparoscope can be moved and positioned in the body; simultaneously, the image section can be magnified. This provides the surgeon with optimal vision over the operating field. The operating and, in particular, the performance of critical manoeuvres are facilitated for the doctor, but due to the high cost of the system and the extensive time and effort needed pre- and postoperatively, the system has only enjoyed success in a single MIS application.

19.6.5 Capsule Endoscopy

The endocapsule contains an image sensor, an illumination unit based on mini LEDs, and usually a localization element which can be used to determine the position of the capsule in the gastrointestinal tract. An external control unit receives the image information and saves it in the form of a series of pictures spanning several hours. In addition to the visualization of the esophagus, this type of wireless endopill diagnostics allows inspection of the entire small intestine in sufficiently good image quality. This new procedure is easy to perform, very patient friendly, and considerably more informative than conventional radiological intestinal contrast agent examinations. Prior to capsule endoscopy, there was no satisfactory way of visualizing the small intestine, be it endoscopically or radiologically. A number of systems are currently available on the market.

However, capsule endoscopy is still not an alternative to videogastrosocopy or videocolonoscopy for examining the stomach or colon. This is due to the fact that there is no way of controlling the movement and direction of the pill and that there is no possibility for direct treatment when the respective findings are detected.

Current research activities are thus concentrated on the remote control of endopills [19.38].

19.6.6 Endonavigation

The first steps in researching endonavigation were taken at the end of the 1980s in paranasal sinus surgery [19.39, 40]. The position of endoscopic paranasal sinus surgery instruments was compiled in three dimensions and then visualized in a preoperatively recorded three-dimensional CT data record. Position detection is effected via the instrument tip; the instrument itself was held in a holding arm with six degrees of freedom; the position was then determined by an angle encoder system [19.41]. Further developments at the

Fig. 19.20 Endonavigation system SURGICAL COCK-PIT (Source: Karl Storz)

beginning of the 1990s allowed so-called *noncontact* navigation systems. Camera systems detect the position of instruments based on reflectors mounted on the instruments (Fig. 19.20). Such systems have managed to make a place for themselves in neurosurgery, orthopedic surgery, and paranasal sinus surgery. As optical position detection of the instruments occurs via the extracorporeal portion of the instrument, use of these navigation systems is only possible in combination with rigid instruments and/or endoscopes.

The use of innovative electromagnetic-based navigation systems has now made it possible to detect the intracorporeal position of (flexible) instruments. This requires the integration of a miniaturized coil element in the instrument. The advantage lies in the possibility of determining the intracorporeal position, i. e., the localization of flexible instruments and endoscopes [19.42]. An associated disadvantage is that ferromagnetic materials around the measurements can lead to measuring errors. In the future, navigation techniques in combination with other sensor technologies will facilitate new endoscopic visualization and documentation techniques [19.43, 44].

Cone-Beam Computed Tomography and Navigation

Dirk Schulze, Gerhard Hoffmann

Cone-beam computed tomography (CBCT) is a rather new image modality which is now especially in use in dentistry and ENT surgery. Image acquisition comprises a rotating system of x-ray tube and detector deploying 200–600 fluoroscopic image from an examination object. Image reconstruction starts subsequently where mainly filtered back projection and its modifications are used. The reconstructed dataset is displayed in specialized viewers. Moreover these DICOM (digital imaging and communications in medicine) stacks can be used for purposes in image guided surgery.

20.1 Technical Background of Dental Digital Volume Tomography

Since the late 1990s, devices for cone-beam computed tomography (CBCT) have been used, but already one decade before, the very first clinical prototypes had been applied for angiographic applications.

Finally, adaptations of used detectors as well as the available processing power in combination with radiographic tubes applied in dentistry resulted in a practicable design of CBCT systems.

In contrast to fan-shaped ray beams used in conventional computed tomography, CBCT utilizes conical or pyramidal ray beams. The area-shaped absorption reliefs resulting from exposure are captured by flat-panel detectors and visualized by special three-dimensional imaging algorithms (Fig. 20.1).

20.1.1 Data Acquisition

In CBCT systems, a conical or pyramidal projection geometry is used, with its shape depending on the respective aperture system. A displacement of this system in the z -axis as found in spiral computer tomography (CT) is currently not applied. Therefore, the recording system rotates around the object with a fixed z -axis. The extent of rotation is currently determined by conventional imaging algorithms – as a rule, rotation angles of $\pi + \phi$ (where ϕ is the cone or pyramidal angle of the beam) to 2π are used. For extension of the field of view (FoV), rotation may take place both horizontally and eccentrically; however, in the majority of appliances,

Fig. 20.1 Comparison between fan-beam and cone-beam radiation geometry

centric revolution is carried out. On the orbit described, between 200 and 600 radioscopies (fluoroscopies) of the object are acquired within 10–20 s. For instance, depending on the device and the recording mode, the effective exposure time is between 20 and 50 ms per projection. Moreover, continuous, unpulsed exposures

Fig. 20.2 CBCT device. Infinitely adjustable FoV: 5×5 to $24 \times 19 \text{ cm}^2$ (Source orangedental)

are carried out as well. For legal reasons, the tube parameters are globally subject to substantial fluctuation ranges; in general, however, tube voltages between 80 and 120 kV and a tube current between 0.5 and 10 mA are applied [20.1].

The actual acquisition of the absorption relief is done by flat detectors or detectors coupled with image intensifiers, e.g., charge-coupled device (CCD) sensors. This creates fluoroscopies of the examination volume for each position of the orbit. As flat detectors, arrays of amorphous silicon are used that are coupled to a scintillator (e.g. CsI, GdO) via glass fibers. X-ray quanta hitting the scintillation layer create light quanta that produce a proportional quantum of electric charge in the detector layer. According to the detector configuration, they are collected line by line, analog/digital converted, and spatially encoded. Apart from this indirect detection, application of arrays of amorphous selenium also allows the use of direct quantum detection [20.2]. As far as image intensifier systems are concerned, signal amplification is connected upstream of detection, which is achieved by chain-linking of secondary electron multipliers. This procedure, which has been known for about 60 years, produces high output signals even in the event of small input signals; however, at the same time the dose decrease associated therewith directly leads to a deterioration of the signal-to-noise ratio as well [20.3]. This is why image intensifier systems are still used to a limited extent in dental CBCT.

In many cases, it is currently already possible to vary the acquired section (field of view) of the examination volume, providing FoVs between 4×4 and $24 \times 20 \text{ cm}^2$ [20.1]. In terms of perspective, variable FoVs represent the most futureproof systems for the user, since acquisition may be controlled according to indication and unnecessary radiation exposure can be avoided by fading out uninteresting areas (Fig. 20.2).

20.1.2 Data Reconstruction

Fluoroscopies collected (raw data) may be reconstructed to an imaging volume via different mathematical algorithms, with the modified Feldkamp algorithm being the most frequently used. This represents a three-dimensional (3-D) modification of the filtered back-projection (FBP) method known from computed tomography (CT). In this process, the recorded information is back-projected into the acquisition zone, folded back mathematically. The overlapping of all back-projections results in a three-dimensional reflection of the absorption occurring during acquisition. The blur occurring

during this process is adjusted by filtering, which at the same time helps to improve the contrast. In the event of strong absorptions, for example, due to metallic filling materials or implants, typical artifacts arise within this reconstruction algorithm, spreading out across the overall image in a linear or lamellar way [20.2]. Image quality may be improved by iterative procedures.

Algebraic reconstruction (ART) represents another, more complex kind of image reconstruction. In this process, the absorption information is decomposed in matrices, and the original absorption values are reconstructed by systems of equations (Fig. 20.3). If carried out exactly, these arithmetic operations are substantially more complex than FBP and therefore are not yet regularly applied.

In general, data reconstruction in the meantime is done on specialized graphics processor units (GPU), leading to a reduction of reconstruction time to below 1 min. Reconstruction is frequently done on isolated reconstruction processors, delivering the result to a review station or a server.

Depending on the kind of detector, the result of reconstruction is a spherical (round detector) or cylindrical (rectangular detector) volume. Unlike in classic

CT, in CBCT this is composed of isotropic voxels (Fig. 20.4). According to the absorption, a grayscale value can be assigned to each individual voxel. The assignment of grayscale values on a histogram is based on primary instrument calibration. There are substantial differences between CBCT systems which should be considered in subsequent data processing. Since the result of reconstruction in CBCT is usually a volume file, subsequent decomposition of the dataset in individual layers across the length of the z -axis is required.

20.1.3 Data Evaluation

Evaluation of reconstructed data is done either in viewing programs provided by the manufacturer or in software applications of third-party distributors or classic digital imaging and communication (DICOM) viewers. Usually, a view of all three spatial planes is offered in the form of secondary multiplanar reconstructions (MPR). Frequently, there is a complete three-dimensional representation in a further window, with the MPR representing the diagnostically substantial information value, since they allow exact inspection of any anatomical field marker or pathological change

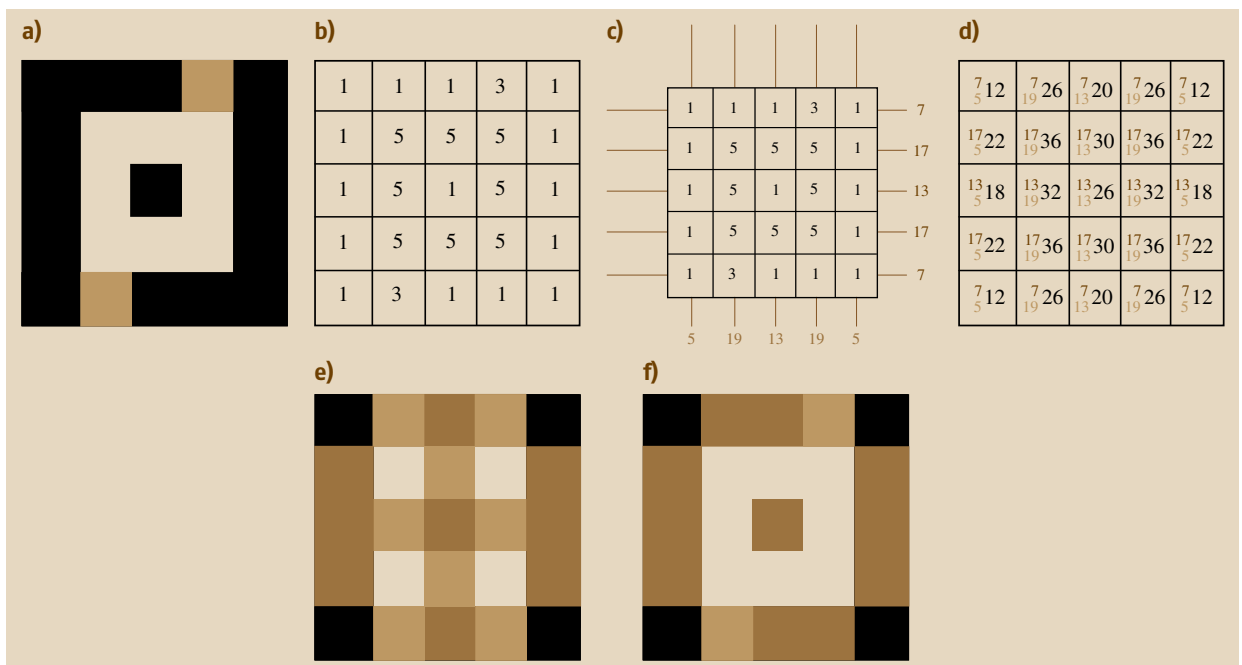

Fig. 20.3a-f Principle of filtered backprojection (a-f). (a) Examination object, (b) numbers representing absorption values of the object, (c) two projections and their results row by row and column by column, (d) back projected values and their sums, (e) image representing the sums, (f) image after filtering

Fig. 20.4 Difference between isotropic and anisotropic voxels

in the acquired volume. Moreover, analysis of these datasets requires specialized MPR in dentistry. For example, free, non-axis-related MPR are created along the dental arch to provide a panoramic view of all the teeth. Historically, this kind of reconstruction is above all attributable to the fact that, for assessment of changes of the teeth, the periodontium, and the bone, dentists usually fall back on panoramic tomography. In a further step, it is then possible to create transversal representations positioned at right angles to the reconstruction axis, showing a cross-section through the respective jaw. Depending on the bit depth, the grayscale representation along a histogram is distributed into several hundred grayscale values. However, since this represents an inadequate number for the human eye, adequate imaging is achieved by displacement of the center

of representation and a limitation of the number of grayscale values (windowing). In so doing, it must be considered that, due to the exposure parameters used, CBCT provides a poorer representation of the soft tissue than classic CT. A further spreading of absorption values of different soft tissues such as fat and muscles is only achievable by increasing the dose. Therefore, CBCT currently remains reserved for diagnostics of high-contrast structures.

The decisive advantage over projection radiography of course is the generally available three-dimensional localization by different MPR levels.

Pathological changes and geometrically exact information can only be documented and transported by screenshots or different report functions (according to software).

Three-dimensional reconstructions are frequently realized using the volume rendering technique (VRT). Within this system, the overall dataset of the volume is reconstructed to another object, which may be modified manually in its position and transparency. At the same time, modification of the grayscale values is possible by overlapping of color spectra, i.e., using a color lookup table (CLT).

Metric analyses as used for planning of implants or for measuring spatial requirements are subject to inherent measurement errors in dental CBCT, albeit substantially smaller than in classic CT. Since a voxel represents the smallest information unit in a CBCT dataset, measurement is only possible between at least two voxels. In the ideal case, a measurement may coincide with the length of a voxel edge. In the worst case, measurement may take place between the two furthestmost points. There is an incremental measuring error which, in the ideal case, is already considered by the viewing software.

20.2 Areas of Application of Dental CBCT

Structured use of CBCT required a scientifically based analysis of existing data records [20.1, 4, 5]. Therefore, guidelines for application of CBCT have been available since April 2009, authorized by the German Society of Dental, Oral and Craniomandibular Sciences (GSDOM). The following indication areas are defined individually.

20.2.1 Preservative Dentistry

In the event of unfilled teeth, high-resolution CBCT examination achieves the sensitivity of film-based or

digital intraoral recordings [20.6, 7]. However, metal artifacts as well as artifacts due to the hard substance of neighboring teeth occur in the neighborhood of metal restorations, making approximal caries diagnostics in clinical applications impossible [20.8]. Therefore, CBCT is hardly suitable for caries diagnostics, particularly of approximal lesions.

The following indication areas within the individual specific fields in which a CBCT examination may be carried out are currently under discussion or are already evidence-based.

Endodontics

- Apical changes in the event of existence of clinical abnormalities, if they are not detectable on two-dimensional recordings or spatially correlatable [20.9, 10].
- Root fractures, since for purely mathematical reasons their identification is safer than using two-dimensional imaging [20.11].
- Root resorption, e.g., following dental trauma [20.12] (Fig. 20.5).

Periodontics

- Visualization of the osseous periodontal situation, thanks to the excellent representation of the three-dimensional periodontal morphology [20.13–15].

20.2.2 Prosthodontics

In prosthodontics, CBCT provides additional possibilities for diagnostics and therapy planning. In the future, CBCT data in combination with digital data from intraoral scanners by integration in planning software may provide additional possibilities for therapy planning in the sense of a virtual setup. At the time of guideline creation, evidence-based data regarding this subject were available only to an insufficient extent or not at all. Currently, the following areas of indication for

prosthodontics are becoming apparent where a CBCT examination may take place:

- Additional information regarding diagnostics of tooth abutment significance (root surface, furcation findings, etc.).
- Visualization of quantitative and qualitative bone material available (implant-supported dental prosthesis, removable prosthetics).
- Representation of nerve exit points (implant-supported dentures, removable prosthetics).
- Diagnostics of osseous diseases of the temporomandibular joint [20.16–20].
- Virtual planning of implant-prosthetic restorations [20.21].
- Linking of 3-D data to the construction software of computer-aided design (CAD)/computer-aided manufacture (CAM) systems (e.g., for CAD/CAM-manufactured drilling templates, long-term temporary appliances or definitive denture).

20.2.3 Functional Diagnostics and Therapy

In the area of diagnostics and therapy of craniomandibular dysfunctions, clinical and instrumental diagnostic procedures are complemented by imaging procedures. Within this process, tomographic x-ray procedures

Fig. 20.5 CBCT dataset 12×8.5; root canals are clearly visible (Source orangedental)

principally are exclusively conducive to the representation of osseous changes in the region of the temporomandibular joint. Several scientific studies have revealed that use of CBCT achieves at least the same results as when using classic or computed tomographies of the temporomandibular joint [20.16, 22, 23]. With regard to quantitative analyses, CBCT shows very good consistency with actual measurements at macroscopic-anatomic preparations [20.24, 25].

For representation of cartilage structures, magnetic resonance imaging remains the procedure of choice, more so as osseous contours are also represented in three-dimensional (3-D) cross-sections. Currently notable main indications for CBCT in temporomandibular joint diagnostics are:

- Exclusion of primary temporomandibular joint diseases
- Recording of differentially therapeutically relevant findings (extent of erosive processes of the condyles, sclerosis, position of condyles, malpositions of the condyle in the mandibular fossa).

20.2.4 Surgical Dentistry

In dental surgery, CBCT predominantly serves for diagnostics of osseous (pathological) findings and spatial conditions that have been partly described already under the other special fields. At present, the possible fields of application becoming apparent within the special fields where CBCT may be used for x-ray diagnostics are:

- Root fractures (although with signs indicating that sensitivity for fresh fractures may be reduced immediately after trauma) [20.26, 27]
- Fractures of alveolar processes [20.26]
- Intraosseous pathological changes such as odontogenic tumors or larger periapical osseous lesions [20.28]
- Positional anomalies of teeth
- Preoperative tomographic diagnostics during planned surgical removal of (partly) retained wisdom teeth. Use of CBCT may be suitable here if the spatial positional relationship between the mandibular canal and the wisdom tooth cannot be interpreted with sufficient security based on already existing, conventional radiographs or is estimated to be critical [20.29, 30]. Based on its low impact in terms of therapeutic benefit, however, routine application prior to removal of wisdom teeth is not recommended [20.31].

20.2.5 Implantology

In implantology, CBCT is predominantly used in therapy planning, typically for visualization and measurement of the initial osseous situation as well as for visualization of three-dimensional implant prosthetic treatment planning (i.e., templates). This requires a metric measurement whose accuracy depends on the actually achieved spatial resolution, the contrast resolution, and the signal-to-noise ratio. Identification of the measuring points has a decisive impact on the measuring accuracy as well. All published data are based on in vitro examinations which do not show any blurring artifacts due to patient movements. For linear measuring sections typical in implantology, maximal relative errors of 3–8% have been established [20.32, 33]. For a measuring section of 10 mm this means a possible inaccuracy of approximately 0.5 mm.

Based on these recordings, using software it is possible to simulate and evaluate planned implants, superstructures, augmentations, incisions, dentures, and prosthetics. Values and findings gained in this way may be used for planning of possibly exact, prosthodontically oriented positioning of implants with the best possible utilization of the available bone material. Moreover, it is possible to detect deficits in the existing tissue range and to anticipatorily recognize the necessity of augmentations/distractions/implant-preparing measures and where appropriate plan corresponding measures. Transfer of spatial information from the planning system to surgical reality takes place via computer-based manufactured transfer and drilling templates or using direct instrument navigation. In vitro, axial deviation of up to 4° and linear deviations of up to 2.4 mm are stated [20.34]. Related in vivo data barely exist, although a preliminary analysis based on a very small number of cases states maximal linear deviations of 6 mm and 11° axially [20.35]. So far, there exist few valid data concerning clinical application of CBCT-supported implantation using drilling templates. However, first results have shown good conformity of CBCT planning with the clinical situation [20.36]. In the future, it is likely that CBCT may be used directly for intraoperative navigation procedures as well [20.37]. In principle, these processes require observation of system-immanent possible inaccuracies and keeping to safety margins, to avoid injury of sensitive neighboring structures.

Since, due to the high absorption of a titanium implant, there arise hardening artifacts in the further beam path, an evaluation of the direct peri-implantary region

as well as of the region between implants in the direction of the beam path is possible only to a very restricted extent.

20.2.6 Cranio-Maxillofacial Surgery

In addition to the surgical fields of application of dental surgery and implantology already mentioned, CBCT may be applied in cranio-maxillofacial surgery for the following indications, for instance [20.38]:

- Odontogenic tumors [20.39]
- Anomalies of bone pathology and structure particularly in the event of osteitis, osteomyelitis, and osteoporosis
- Maxillary sinusitis
- Salivary stones
- (Osseous) temporomandibular diseases
- Craniofacial traumatology
- Representation of the spatial course of intraosseous structures (osseous nerve and vascular channels)
- Diagnostics and surgical planning in the event of complex malformations (Fig. 20.6).

20.2.7 Orthodontics

In general, children are subject to increased risk of suffering consequential damage due to ionizing beam

exposure. This should be absolutely, and of course increasingly, considered in orthodontics, and the indication must be adapted accordingly [20.40].

Although knowledge is currently based on a relatively low level of evidence, the following orthodontic indications are currently becoming apparent for which CBCT-based diagnostics could be recommendable:

- Diagnostics of anomalies of tooth findings.
- Diagnostics of anomalies and dysplasia of dental roots.
- Differential-diagnostic assessment of tooth eruption disorders.
- Representation of the periodontal bone material for prognostic assessment of planned tooth movement.
- Diagnostics of craniofacial malformations.

Even if existing CBCT datasets in principle are suitable for calculation of two-dimensional (2-D) cephalograms, they are only convenient as a starting point for intended 3-D cephalometry, because of the inevitable loss of information [20.13, 41]. Fundamental work has already been presented [20.27, 42, 43].

Particularly with regard to the frequently juvenile patients, the choice of a suitable radiographic examination procedure requires special consideration of radiation protection. Possibilities for dose reduction must be exhausted (e.g., reduced optical resolution, re-

Fig. 20.6 CBCT, 20×19 dataset, overview image for surgery (Source: orangedental)

duced exposure angles, reduced number of projection recordings). Moreover, examination procedures without any ionizing radiation should be considered as an alternative.

20.2.8 Technical Restrictions of the Procedure

Unlike classic CT, CBCT imaging is substantially more sensitive to patient movements. They may be initiated by random movements such as, e.g., during swallowing, or due to constant tremors.

This may have a lasting effect on the quality of the overall volume dataset, while in CT only one (in the event of sequential acquisition) or a few axial layers (in the event of spiral acquisition) are concerned. At the same time, differentiated representation of soft tissues using CBCT is impossible. However, a huge advantage of this procedure is the comparatively low occurrence of metal artifacts, enabling also diagnostic assessment of structures within a layer near metal fillings, while in conventional CT metal artifacts may render whole layers unusable.

20.2.9 Dose

Depending on the system and the imaged volume, beam exposure (effective dose) is between 30 and 150 μSv , sometimes even lower.

Even if applying *low-dose* protocols, conventional CT systems currently cannot achieve the spatial resolution of CBCT systems.

20.2.10 Navigation

Navigation combines recording of preoperative data of a patient with his intraoperative position. In such a way, it is comparable to the methodology known from the global positioning of vehicles or other objects.

Fundamentally, one distinguishes between active and passive navigation.

In the case of active navigation, real-time data to support a surgical intervention are displayed on a separate monitor or even shown in the operating field (augmented reality) [20.44]. At the same time, it is possible to bring *active* instruments into the navigation window. At an additional stage of extension, situational changes of tissue qualities can be communicated to the user via haptic (*forced feedback*) mechanisms to decide on the operative procedure [20.45].

In the event of passive navigation, preoperative data are exclusively used for planning a therapeutic intervention. As a result, computer-assisted planning, e.g., may be stored in the form of a template or a splint and released via CAD/CAM procedures. This object is then applied during surgery as a positioning guide or success control; there is no direct back-coupling as in active navigation.

20.2.11 Prerequisites for Navigated Procedures

Acquisition of a preoperative or pre-interventional dataset is absolutely required for navigation [20.46, 47]. Acquisition essentially takes place using slice-imaging procedures such as CBCT, CT, and/or MRI, with all datasets being able to be merged with each other as well. Prior to data acquisition, data registration in the navigation or planning software at a later stage should be considered, insofar as it may be required to introduce reference markers. Moreover, it is necessary to adapt the quality of the gained cross-sectional data for further applications (radiation beam length, necessity of soft-tissue information).

20.2.12 Further Processing

The cross-sectional data gained from the above-mentioned modalities is imported in planning surfaces and converted for processing. As a rule, the voxels are tetrahedronized here or abstracted in similar procedures; in general, this is called segmentation. All information that is not essential is dismissed from the dataset, and only interesting data are processed. There exist different algorithms for segmentation; for example, it is possible to filter data according to their absorption values (threshold method) [20.48]. Apart from this, there are also other methods available that are substantially more subtle (watershed algorithm, marching cubes) [20.49]. Finally, all of them lead to an anatomic model which is generated from the cross-section dataset and shows a considerably lower data volume than the original dataset.

20.2.13 Registration

With regard to registration, one distinguishes between active and passive navigation procedures. For passive procedures, the segmented datasets are usually collocated using models (plaster models in special articulators or other appliances), so that transfer of

software-assisted implementations such as drillings to the model or model-supported templates becomes possible. Since the information transfer is taking place a priori here, this process is called passive navigation. The resulting information, e.g., in the form of a positioning or drilling template, is then implemented in the operative situs.

For active navigation, the prepared data are adjusted to the patient's position in a quasi-live way. This process may require integration of reference markers, which are recorded on the spot for triangulation using infrared cameras and used for collocation of the dataset. Moreover, there exist systems using existing anatomic landmarks for data matching [20.50, 51]. However, in comparison with passive navigation, corresponding implementations are carried out intraoperatively

and therefore are substantially more cost intensive. However, this enables real-time analysis of preoperatively gained data and so allows minimally invasive interventions and a particularly protective procedure. Furthermore, use of intraoperative three-dimensional data acquisition is possible here, as currently available with so-called three-dimensional C-arms, to provide the preoperative dataset with a live update and investigate the preoperative planning in detail [20.52].

Consequently, navigation procedures are subject to a number of modifying influences, making accuracy in the submillimeter range currently almost impossible. Furthermore, careful selection of the preoperative imaging procedure, exact planning, and choice of suitable reference objects are indispensable for successful navigation.

21. Interventional Radiology – Angiography

Intervention

Doris Pommi

Interventional imaging in radiology and cardiology needs systems with enhanced imaging capabilities and cutting-edge technology. After the definition of digital subtraction angiography in Sect. 21.1, its range of application is described in Sect. 21.2. The advantages of interventional radiology procedures are outlined in Sect. 21.3 on the basis of existing angiography systems. Section 21.4 give an overview on trends in interventional radiography.

21.4.3	Hybrid Applications	420

After radiologists had learned how to visualize the vascular system under x-ray fluoroscopy and contrast media, they had the idea of treating vascular diseases with special angiography catheters in the same way. While the catheter was first used for applying contrast media only, it now served as a tool for transporting and placing different therapeutic *devices*, implants, and chemotherapeutic substances such as balloon catheters, endoprostheses (stents), and chemoembolization material. For this procedure, image guidance and monitoring played a decisive role. So, from merely diagnostic radiology, interventional radiology evolved. Therefore the angiography suite, compared to other imaging modalities (like computertomography, magnetic resonance tomography, etc.), will be used more and more

for interventional procedure and less for pure diagnostic purposes.

After the previous achievements of Sven-Ivar Sel-dinger (1921–1999) and Charles T. Dotter (1920–1985), it was above all Eberhard Zeitler and Andreas R. Grüntzig (1939–1985) whose developments turned interventional radiology into a minimally invasive method for treating cardiovascular diseases throughout the world.

Today in interventional radiology, a great variety of often highly complex therapeutic interventions are carried out under image guidance (x-ray, ultrasound, computer tomography, magnetic resonance imaging), including interventions of the vascular system. An important method in the field of vascular intervention is digital subtraction angiography (DSA).

21.1 Definition of Digital Subtraction Angiography

Digital subtraction angiography is a type of angiography and is used for examining and visualizing blood vessels and blood flow (Figs. 21.1, 21.2).

In DSA, two consecutive images of the body part to be examined and the vessels to be diagnosed are acquired and postprocessed digitally. First, a mask

(empty) image is made. Then, contrast medium is injected and the fill image is acquired.

Visualization of the blood vessels, i.e., without surrounding tissue, is achieved by digitally subtracting the mask image from the fill image. Image parts differing in their x-ray absorption will remain – in this case the

Fig. 21.2 Image of hepatic vessels (courtesy of Siemens)

Fig. 21.3 Biplane angiography system (courtesy of Siemens)

Fig. 21.4 Monoplane angiography system (courtesy of Siemens)

inner volume of the vessels filled with contrast medium (Figs. 21.1, 21.2).

21.1.1 Components Required for DSA

An angiography room for DSA includes the angiographic x-ray system, the examination table with control elements, a display suspension system for image display, and different peripheral devices.

The angiography system (Figs. 21.3–21.5) for visualizing vessels filled with contrast medium has at least one x-ray tube and a receiver, which are mostly installed on one joint C-arm and can therefore be moved synchronously within one plane. Formerly used image intensifiers are nowadays frequently replaced by flat detectors.

Biplane systems (Fig. 21.3) – systems with two independent tube/detector units in two fluoroscopy planes

Fig. 21.5 Monoplanar angiography system with robotic technology (courtesy of Siemens)

– are mainly used in neuroradiology and pediatric cardiology.

Very important for optimal and convenient patient positioning and free access for physician and staff during the sometimes very time-consuming interventions is a radiolucent, tiltable table.

21.2 Application Range for Angiography

In interventional radiology there are several focus areas regarding vascular procedures and therapy. Depending on diagnosis and thus therapeutic requirements, the main differentiators are:

- Opening of a vessel (e.g., dilatation)
- Closing of a vessel (e.g., embolization).

The most important procedures are:

- Balloon angioplasty (PTA, percutaneous transluminal angioplasty): catheter procedure under x-ray guidance for reopening constricted or occluded vessel sections by means of unfoldable balloons
- Stent implantation (stent angioplasty): catheter procedure for inserting and unfolding metal grid vessel supports (stents) under x-ray guidance for treating recanalized vessel constrictions and occlusions
- Thrombolysis: x-ray-guided catheter procedure for eliminating blood clots through local administration of thrombolytic drugs
- Chemoembolization: x-ray-guided catheter procedure for local chemotherapy and atrophying tumor-supplying arteries, particularly in the liver and uterus

The angiography system and table are operated directly in the examination room via an operating panel and foot switch; like the tube and detector, both can be covered with a sterile cover.

Monitors for image viewing [live image, reference image, three-dimensional (3-D) visualization, etc.] are mostly installed in a common holder (display suspension system) and are available in various types and different numbers.

The contrast medium is mostly delivered through a semi- or fully automatic injector, which can be synchronized with the triggering of the acquisition.

Different catheters, sheaths, coils, stents, and balloons are used for catheter work. Sterile work procedures are very important in angiography.

In the control room, a reading workplace is required for postprocessing [e.g., pixel shift, transfer to a picture archiving and communication system (PACS), 3-D postprocessing] in addition to the control computer and image processor.

- Thermal ablation: image-guided needle procedure for thermal destruction of tumor tissue by radiofrequency or laser energy.

Thanks to cutting-edge catheter and imaging technologies, angiographic development is tending toward interventional procedures, away from merely diagnostic vascular visualization. A decisive advantage here is the minimally invasive character of these therapies, which can therefore be carried out in a much more convenient way for the patient. For the different, sometimes very complex examinations, high-resolution imaging is particularly important to ensure precise navigation and

Fig. 21.6 Three-dimensional spatial image of cervical vessels (courtesy of Siemens)

placement of substances in the potentially very narrow vessels.

Apart from diseases of the cardiovascular system, other vascular systems such as the biliary system can also be treated through such interventions.

Angiography systems are frequently used today. Applications include:

- Elimination of aneurysms using stents or coils
- Stenosis treatment (angioplasty) through balloons and/or stents
- Tumor treatment through embolization or injection directly into the tumor center

- Dialysis shunts through balloon dilatation
- Interventional technology combined with surgical intervention directly in the operating room (hybrid OR).

Today, thanks to digital technology and high-performance computers, 3-D spatial images (Fig. 21.6) can be created almost in real time. Images from computed tomography (CT), magnetic resonance imaging (MRI), or functional images from nuclear medicine can immediately be overlaid with the angiography images. This helps to increase diagnostic confidence, facilitate instrument guidance, and improve follow-up.

21.3 Advantages of Interventional Radiology Procedures

A minimally invasive intervention often saves the patient an open surgery and a long length of stay associated with it. Many interventions can be performed on an outpatient basis today. This is a convenient alternative for the patient and saves time and costs during his hospital stay.

Use of catheter techniques allows for drugs, instruments, and implants to be placed directly at the site of action. Advanced imaging techniques in the pre-, intra-, and postoperative phases enable safe, fast, and seamless documentation of intervention planning, performance, and follow-up.

21.4 Trends of Development

21.4.1 Enhanced Computer Performance

Due to the use of minimally invasive procedures, it has become increasingly important to ensure optimal, fast, and detailed imaging performance. All previous diagnostic images need to be available during an intervention and, if required, it must be possible to overlay them on the monitor to provide the maximum amount of information for the intervention. For this procedure, substantial amounts of data must be transferred and displayed, requiring the use of high-performance computer systems and networks.

enabling the user to implement the functions needed for his work.

21.4.3 Hybrid Applications

In radiology and surgery the tendency is toward hybrid ORs. These are operating rooms where multiple imaging modalities are used separately or simultaneously and where interventional radiologists work together with surgeons. Repositioning, which is time consuming and can jeopardize the patient, can thus be avoided, optimizing room and equipment utilization, as well. An example hybrid application is the combination of a cardiac catheter laboratory and OR.

General tendencies are for:

21.4.2 Special Visualizations

Special visualizations such as 3-D reconstructions (Fig. 21.6) or soft tissue visualization must be available for monitoring treatment success or to allow for fast reactions in case of critical incidents. This requires extension and specialization of the application range,

- Simplified system operation, e.g., through robot-assisted systems and case-specific protocols
- Comprehensive, customizable display of any required information in the angiography room/OR, for example, on large-format screens

- Reduction of radiation dose through radiographic procedures (e.g. DSA, CT angiography)
 - Increased use of 3-D imaging with shorter acquisition or processing times and higher resolution (Fig. 21.6)
 - Interdisciplinary use of imaging systems, e.g. in hybrid operating rooms.

Near-Infrared

22. Near-Infrared Spectroscopy (NIRS)

John McNulty, Michael Born, Robert S. Pozos

One of the greatest challenges facing medicine is to treat the patient using real-time data that accurately reflect oxygen concentration in the patient's tissue. Regulation of oxygen and its counterpart, carbon dioxide, is controlled by a large number of physiological control systems that are local, regional, and systemic. This key molecule is involved in oxidative metabolism and is an overall indicator of physiological well-being. Oxygen is attached to hemoglobin and released into cells, where it diffuses to mitochondria for utilization to produce adenosine triphosphate (ATP) that powers all cellular functions. The biomedical value of near-infrared spectroscopy (NIRS) is its ability to record oxygen levels, especially StO_2 , in a noninvasive manner. In clinical cases, peripheral StO_2 values recorded from the forearm and thenar regions are frequently used as surrogates for central oxygen levels. Thus, NIRS holds the promise of being a major tool in normal and pathological functioning. Applications of this technology are far reaching and range from monitoring patients suffering from septic shock, type 2 diabetes to schizophrenia. Use of NIRS has great promise but suffers from two major types of issues: technical and physiological. There are different types of NIRS devices which detect *oxygen concentrations* using different probing strategies and different algorithms. In addition to the dissimilar NIRS technologies is the fact that the NIRS signal has a number of anatomical, e.g., fat, and physiological barriers, e.g., skin blood flow,

before it reaches the muscle/organ vascular bed. Various regions of the body, e.g., thenar versus forearm, have dissimilar cardiovascular responses to physiology and pathophysiological conditions, making interpretation challenging. This chapter presents a brief overview of NIRS technology, its applicability, and promise.

22.1 NIRS – Technical

Near-infrared is part of the electromagnetic spectrum, which is described in terms of frequencies (Hz) or wavelengths (m). Some examples of such radiation include television (TV)/radio waves (10^8 Hz), microwaves (10^{10} Hz), infrared (10^{13} Hz), visible light (10^{15} Hz),

and ultraviolet (10^{16} Hz). This chapter will concern itself with the near-infrared (NIR), whose frequency is $10^{14.5}$ Hz and whose wavelength range is 780–2526 nm, its application to detection of oxygen levels in tissue, and its various medical applications [22.1].

Table 22.1 Comparison of various oxygen measurements

	SaO ₂	SpO ₂	SvO ₂	ScvO ₂	StO ₂
Measure	Arterial O ₂ saturation	Arterial O ₂ saturation	Mixed venous O ₂ saturation	Central venous O ₂ saturation	Tissue O ₂ saturation
Percent hemoglobin O ₂ saturation	Yes	Yes	Yes	Yes	Yes
Place of measurement	Arteries	Pulsing arteries	Pulmonary artery	Superior/inferior vena cava, right atrium	Peripheral circulation (veins, capillaries)
Method of measure	Arterial blood draw/ blood gas analyzer	Pulse oximeter	Pulmonary artery catheter	Central venous catheter	Placed on area in question: forearm, thumb, skull, etc.
Use of measure	O ₂ loading in lungs	O ₂ loading in lungs	Global tissue oxygenation	Surrogate for SvO ₂	Tissue perfusion
What it indicates during shock	Lung/heart function	Lung/heart function	Changes in O ₂ delivery and consumption	Changes in O ₂ delivery and consumption	Peripheral perfusion status
Requires pulsatile flow	Yes	Yes	Yes	Yes	No

Sir William Herschel (1738–1822) is credited with the discovery of near-infrared radiation (NIR) and designed a method to filter light from a telescope to demonstrate that there was light radiation outside of the visible range [22.2]. After Herschel's discovery, NIR was not pursued by the scientific community until nearly 150 years later, when *Kaye* [22.2] described a technique called NIR spectroscopy (NIRS) for analysis of biological specimens. Although *Kaye* was the first to describe NIRS, *Millikan* developed a dual-wavelength oximeter for muscle, and in 1977, *Jobsis* first described an in vivo application of near-infrared spectroscopy, a technique originally designed for clinical monitoring of tissue oxygenation [22.3, 4]. Today, NIRS is flourishing in the field of medicine, because of its noninvasive nature and ease of use for detection of oxygen levels.

The emphasis of this paper is on StO₂, since it is measured using NIRS. StO₂ values (saturation of tissue oxygen) are determined by different algorithms used by competing vendors and is expressed as a percentage of the ratio of oxygenated hemoglobin to total hemoglobin in veins and capillaries. This measurement is related to, although different from, SpO₂, SaO₂, SvO₂, and ScvO₂. SaO₂ and SpO₂ are measurements of arterial oxygen saturation, whereas SvO₂ and ScvO₂ are measurements of mixed venous oxygen saturation. StO₂ is a measure of tissue perfusion. During shock, StO₂ levels indicate tissue perfusion at the site, and those values are used in certain cases to infer the condition of the patient relative to oxygen saturation.

A key point is that oxygen measurements are tied to oxyhemoglobin measurements, which are dependent

on the factors that favor dissociation of oxygen. Oxygen is more easily released when pH is decreased, body temperature is increased, and when the arterial partial pressure of carbon dioxide is increased. Conversely, when pH is increased, temperature is decreased, and arterial partial pressure of carbon dioxide is decreased, oxygen is more tightly bound to hemoglobin. In addition, once oxygen reaches the mitochondria, its utilization or lack thereof is another indicator of cell integrity. The metabolic pathway for release of oxygen from hemoglobin and its diffusion to the mitochondria and subsequent oxidation must be kept in mind as one interprets StO₂ values.

To underscore the importance of the metabolic pathway of oxygen transfer by way of hemoglobin, the tissue hemoglobin index (THI) is another NIRS measurement that measures the hemoglobin signal strength and is useful for determining whether the StO₂ sensor is optimally positioned over muscle. THI levels are used to monitor the strength of the NIRS signal from tissue hemoglobin as compared with blood hemoglobin. Recently there has been interest in whether THI itself has value beyond simply verifying probe placement, and whether the correlation between THI and StO₂ could provide noninvasive data on blood hemoglobin concentration [22.5]:

THI has been studied during the clinical assessment of tissue oxygen perfusion status to convert a StO₂ downward slope during arterial occlusion to an index of local oxygen consumption and to assess microvascular reactivity when blood flow is reestablished after arterial occlusion. Since inva-

sive blood draws are not always feasible in patients, researchers have sought to establish a link between noninvasive continuous tissue hemoglobin measurements (THC) and blood hemoglobin concentration (Hbt).

To adequately understand the applications of NIRS, it is important to appreciate the interaction of the NIRS

signal with biological tissue from an engineering and well as from an anatomical, physiological point of view. The NIRS signal must penetrate skin and fat to get to the veins and capillaries. In addition, control of the blood flow to the skin may vary from one region to another depending on the condition, e.g., exercise, hemorrhage, shock, etc., which will also influence the accuracy of NIRS.

22.2 NIRS Technology: Engineering Aspects

22.2.1 Theory of NIRS Penetration

In the NIR spectrum of radiation, light photons are capable of penetrating deep into a tissue sample, even through bone. Hemoglobin absorbs NIR light better than other molecules in a biological media.

This region of NIR also detects the oxygen-dependent metalloproteins in hemoglobin. These metalloproteins act as chromophores, responsible for the color of the molecule. Hemoglobin (Hb) is a globular protein that has an iron(III) metal cofactor that binds oxygen. Myoglobin (Mb) is another metalloprotein that plays an important role in red muscle, and the saturation level is dependent on the workload of the muscle (Fig. 22.1). NIRS cannot distinguish the difference between hemoglobin and myoglobin, but studies using model calculations on general data for human muscle have been preformed. A group at the University of Nijmegen in The Netherlands found that both deoxygenated Hb and Mb as detected by NIRS varied between 0.04 and 0.13 mol/m³, while the variation in Mb saturation (53–86%) even exceeded that of Hb (63–84%) [22.6].

NIRS technology has advanced significantly over the last 30 years, and different instruments have been developed. Among these instruments, continuous-wave (CW) measuring instruments are the most common. These instruments are based on a modified Beer–Lambert law along with Doppler shift effect, vibrational spectroscopy, and the Frank–Condon principle [22.3]. The Beer–Lambert law provides the physical and mathematical basis for NIRS. It states that transmission of light passing through a solution of a colored compound, hemoglobin, is absorbed by the compound, resulting in a reduction in the intensity of the emerging light. Absorption and concentration of a chromophore are described by the Beer–Lambert law

$$A = \log \frac{I_0}{I} = \epsilon cd,$$

where A is the absorption of light expressed as optical density, c is the concentration of chromophore, ϵ is its extinction coefficient, and d is the thickness (optical path length) or depth of transmitted light in the tissue. The extinction coefficient describes the absorbance characteristics of a particular compound for a certain wavelength. As mentioned earlier, the extinction coefficients for different species of hemoglobin range from (carboxyhemoglobin) to 10.0 (methemoglobin). This enables the hemoglobin content to be measured. When NIR light illuminates a compound, some light passes through the compound. Knowing the wavelength, the extinction coefficient, and the thickness of the compound the Beer–Lambert law can be used to derive the concentration of the substance. Biological tissue poses a problem, because photons do not travel in a straight line as they do in other material. This is because living biological tissue is dynamic and constantly changing its makeup. Oftentimes, the light source and the light detector are in the same plane, and light does not com-

Fig. 22.1 Excitation coefficient of different hemoglobin molecules at different wavelengths

pletely traverse a tissue sample. If this is the case a correction factor is needed to compensate for the light path being greater than the probe separation. For NIRS probes, the wider the probes are separated, the deeper the light penetrates into a sample. A modification of the Beer–Lambert law is required to determine these differences in length

$$A = \sum \epsilon c d \text{DPF},$$

where DPF is the differential path length and d is the interpreted distance [22.4]. DPF is a scaling factor that expresses the actual path length for a given part of the sample, and the sum is over all the absorbing chromophores (hemoglobin) that contribute to the NIRS signal. A DPF is needed to conduct quantitative spectroscopic measurements. A typical range for DPF measurements is 4–6.5, which means that the path length of photons traveling through a sample is 4–6.5 times longer than the spacing between the optodes.

A similar technology to NIRS uses the principle of laser Doppler to measure the total velocity of the local blood and the concentration of moving blood cells within the measuring volume that is being studied. This technology works by emitting a laser beam that is carried by a fiber-optic cable and penetrates the sample. The light interacts with the tissue and is scattered and partly absorbed. Light hitting moving blood cells undergoes a change in wavelength (Doppler shift), while light hitting static objects is unchanged. The frequency and magnitude of these changes are related to the amount and velocity of hemoglobin in the sample. The returning light is collected by the returning fiber, converted into an electrical signal, and displayed on a monitor. The Peri-Flux System 5000 uses this laser Doppler principle and is mentioned later in this chapter in more detail.

The Frank–Condon principle describes the vibrational properties that are used for NIRS. When a molecule absorbs or emits a photon, its electronic and vibrational energy levels change. When a molecule vibrates, the probability of finding a given atom at a certain point is inversely proportional to its velocity. Atoms prefer a low kinetic energy level configuration when vibrating. This configuration is where the total energy and the potential energy of the molecule are nearly identical. When a NIR photon penetrates the sample, it is most likely to be absorbed when the nuclei of the hemoglobin molecules are stationary or moving very slowly. When the NIR photon hits the nuclei, it is not immediately excited. Thus, the excited nuclear configuration of the molecule tends to be close to the intersection of vi-

brational energy and potential energy because of the brief amount of time of an electrical transition. Therefore, transitions tend to take place between vibrational levels in which the nuclear configurations have minimal change, and they tend to occur when the nuclear kinetic energies are small. Hemoglobin molecules undergo this transition, and the energy of the molecules affects the returning light signal, thus providing information about the sample volume. These variations in vibrational and nuclear configuration give rise to anharmonicity, which is the deviation of a molecule's nature from a harmonic oscillator vibrating in simple harmonic motion. This causes the fundamental frequency of the molecule to be imprecise and causes combination and overtone bands. The NIR method gathers the measured spectral response caused by the fundamental vibration in the hemoglobin and correlates that to the structural information of the molecule. Depending on the quantity of NIR-absorbing molecule, absorbing type, and thickness of the sample, the harmonic vibrations occur at unique frequencies.

The molecular moieties that demonstrate the most overtones and combinations of fundamental vibrations when absorbing in the NIR region are $-\text{CH}$, $-\text{NH}$, $-\text{OH}$, (and $-\text{SH}$). The two key issues that determine the frequency and intensity of NIR absorption bands are anharmonicity and Fermi resonance [22.1]. Intramolecular interactions, such as nonsymmetrical vibrations, affect the energy curve of a molecule under NIR light. The spacing between energy levels that the molecule can attain is not identical. When the spacing of the molecule decreases, the energy level of the molecule increases. This energy increase is a quantum-mechanical model of an anharmonic oscillator. The origin of the NIR overtone bands is a result of these multilevel energy transitions that occur at multiples of the fundamental frequencies. With an anharmonicity constant χ of 0.01–0.05 the number of wave overtones can be estimated using the fundamental frequencies equation

$$v_x = \Delta v v_0 (1 - \Delta v \chi),$$

where v_x is the wavenumber of overtone x , v_0 is the wavenumber of the fundamental vibration, and χ is the anharmonicity constant [22.1]. Fermi resonance occurs when two vibrating molecules accidentally have exactly the same energy and interact with each other, producing a special type of configuration interaction between two NIR absorption bands of a polyatomic molecule. This causes the bands to split into two peaks of higher and lower frequencies that are different from the expected frequencies. In biological samples, dipole interactions

and hydrogen bonding must be considered, since they can alter the vibrational energy states. This can shift the absorption bands of certain molecules, such as hemoglobin, or possibly give rise to new ones. NIR absorption bands are typically broad, overlapping, and

10–100 times weaker than their corresponding mid-infrared bands. This makes near-infrared less sensitive than mid-infrared. As a result, data processing is needed to interpret and relate the spectral information to the sample properties.

22.3 Instrumentation and Equipment

There are numerous companies that manufacture NIRS devices, but they all share six basic components:

1. A filtered light source capable of generating multiple wavelengths in the NIR region
2. Fiber-optic bundles that link the probes to a computer for data collection
3. A tissue probe containing an emitting and collection region
4. Photon detection hardware such as a photocathode/photomultiplier and signal amplifiers
5. A processing computer for multivariate algorithm processing of light data
6. A data display system, usually a computer or TV monitor [22.4].

The light source is usually a tungsten halogen lamp, since it is small and rugged, but other sources can be used. Detector types include silicon, lead sulfide (PbS), and indium gallium arsenide (InGaAs). Silicon detectors have fast signal acquisition with high signal-to-noise ratio, small size, and high sensitivity from the visible region to 1100 nm, which is well within the NIR spectrum. PbS detectors are slower but are sensitive from 1100 to 2500 nm, making them very popular in biological settings because they provide good signal-to-noise properties. The most expensive of the three detectors is the InGaAs detector. It combines the speed and size of a silicon detector with the wavelength range of the PbS detector. Since the spectrum of NIR light is polychromatic, a filter is needed to produce a single, monochromatic beam of light.

As mentioned above, a computer processing algorithm is needed to compare the delivered light with the returning light. Each NIRS device uses its own, unique algorithm to analyze the collected data. The patents for these NIRS devices describe the algorithms they used. In a general sense, an algorithm is a method to solve a problem using a sequence of instructions. Computer data processing takes a process and uses a computer program to convert, analyze or summarize the data into usable information. To interpret the overlapping por-

tions of the NIR absorption spectra, a minimum of two NIR wavelengths are needed for the computer processor to apply its algorithm, although up to 12 NIR wavelengths can be used. A multiwavelength algorithm is needed because of the absorption peaks for the different molecules in the sample. Absorption coefficients are the basis of application of these multiwavelength algorithms, being nothing more than algebraic expressions. Each NIRS device has its own specially developed algorithm used to interpret the information collected. The basic criteria for the absorption coefficients are:

1. Each NIR spectrum should be measured independently without spectral contributions from other oxygen-dependent chromophores
2. The relative extinction coefficient should be measured for each chromophore at the same light scattering and path length conditions
3. Spectra should be acquired at optical geometries and scattering functions appropriate to the particular application used.

With the use of the principles stated above, a correct algorithm can convert the measured changes in light absorption at various NIR wavelengths into concentration or ratio data for the sample site of interest. A problem can arise if these multiwavelength algorithm principles are applied to a tissue sample where the hemoglobin content is rapidly changing. Human skin is a very complex medium and poses a great challenge to NIRS devices because the accuracy of data collected is an issue. Not only is human skin very dynamic, but the nonuniformity between person to person requires the NIRS device to be calibrated. Calibration of NIRS devices is necessary to quantify the information collected by these devices. Multivariate calibration is needed before a NIR spectrometer can be used for any quantitative analysis. That calibration process involves the following steps [22.1]:

1. Selection of a representative calibration sample set.
2. Spectra acquisition and determination of reference values.

3. Multivariate modeling to relate the *spectral variation* to the *reference values* of the analytical target property.
4. Validation of the model by cross-validation, set validation or external validation.

The two most frequently used multivariate regression methods in quantitative NIR analysis are principal component regression (PCR) and partial least-squares (PLS) regression. PCR uses the principal components to perform regression on a sample volume to be predicted. PCR is used when the variables are close to being collinear, which is problematic for quantifying a signal. Typically, only a subset of principle components in the regression are used, allowing for a normalized estimate. Oftentimes, the selection of the principle components is according to a standard protocol in NIR analysis. PLS finds a linear model between the signals by projecting the observed and predicted variables into a new space. PLS finds the directions of greatest variability by comparing both spectral and target property information. The main difference between the two methods is that the first principal component or factor in PCR represents the most relevant variations showing correlation with the target property values.

In qualitative analysis of an NIR signal, spectral variations acquire discrete values that represent the quality of the signal, which is related to the sample properties. As mentioned earlier, tissue is problematic for interpreting the returning NIRS signal. To solve this problem, multivariate classification methods are once again used, this time for grouping samples with similar characteristics such as deoxyhemoglobin and oxyhemoglobin in the microvasculature of human skin. Pattern recognition methods used in qualitative analysis are divided into two learning algorithm categories: *supervised* and *non-supervised*. Supervised methods use a machine learning technique to deduce a function from basic data. The basic data consist of inputs and desired outputs. The output can be a function similar to a regression used to predict the probable input. The task of the supervised method of analysis is to predict the value of the function for any input after experiencing the basic data examples. Supervised methods in essence are used to build classification rules for a number of prespecified subgroups. In most cases the group structure of the training set is known, such as average hemoglobin concentration. Nonsupervised methods are different than supervised methods in that they do not require any prior knowledge about the group structure in the data, but instead produce a grouping. The ultimate goal of qualitative analysis of a NIRS

signal is to develop mathematical criteria for applying parameters. This would allow similarity between samples to be expressed quantitatively.

NIRS signal quality must be determined before any data collection can occur. The noninvasive continuous nature of NIRS devices makes them very appealing, especially in a clinical setting where these devices are frequently used. Accurate data must be collected to understand what is happening in the sample volume being observed. Comparisons of NIRS signals between two different states for the sampling volume, for example, oxygen-bound hemoglobin and free hemoglobin, are required to determine whether changes are significant, commonly using a paired *t*-test. Paired *t*-tests are used for comparing means of NIRS signal changes between two states within a sampling volume. Autoregressive models are commonly used to analyze time-series data. An autoregressive model is a type of random process that tries to predict natural phenomena. It is very difficult to derive an autoregressive model for NIRS data because the signals are not constant during the dynamic processes of human skin regulation. Baseline corrections are oftentimes performed but could distort actual changes in the NIRS signal.

Recent NIRS technology is not without its problems. The major problem with NIRS is its inability to quantify concentration changes in hemoglobin using current CW-type instruments, although this has not stopped clinical use of these devices. Clinicians struggle with obtaining an accurate reading of oxygen delivery to vital organ beds. The state of organ perfusion could ideally be assessed by a tissue oxygenation device [22.7]. Quantification is the central issue surrounding use of NIRS data. NIRS technology is reliable when changes in hemoglobin are global, over the entire body, as quantification is possible and optical path length in the sample volume can be determined. Quantification of the NIRS signal becomes problematic when changes in hemoglobin are localized, such as localized skin cooling or heating. The reason for this inability to quantify localized changes is due to influencing factors that cause NIRS to become unreliable. Taking the example of localized skin cooling, some factors that influence the NIRS signal of concentration changes in hemoglobin include skin blood flow, adipose (fat) tissue, and muscle blood flow. With current CW-type instruments, deep muscle blood flow is difficult to quantify because the NIR light must pass through the skin and adipose tissue before reaching its target tissue. The skin has its own blood flow and the adipose tissue absorbs monochromatic NIR light, thus weakening its

Fig. 22.2 InSpectra StO₂ tissue oxygenation monitor by Hutchinson Technologies

signal. The complexity of this scenario creates a challenge for accurate measurement of localized muscle blood flow after localized skin cooling. This is just one example of the complicating factors that may influence NIRS measurements, yet the method is used in hospitals to assess patient status because studies have shown that these devices help doctors assess patient status.

Some of the modern NIRS devices include the InSpectra StO₂ Tissue Oxygenation Monitor by Hutchinson Technologies, PeriFlux System 5000 by Perimed Inc., Niro-500 Oxygenation Monitor by Hamamatsu, T.Ox Tissue Oximeter by Vioptix, and INVOS System by Somanetics, to name a few. This aspect of NIRS is rapidly changing, and the technology presented later gives an overview of the different approaches used in NIRS studies. Due to this rapid development, NIRS equipment may be completely different by the time this chapter is published. These systems may vary in a fundamental manner in that the number of wavelengths vary from 2 to 12. How effective these various systems are is difficult to ascertain.

The InSpectra StO₂ Tissue Oxygenation Monitor (Fig. 22.2) provides a noninvasive way to collect continuous, real-time information for the perfusion status of a patient by using StO₂, which is determined by the ratio of oxygenated hemoglobin to total hemoglobin in the microcirculation of the sampling volume. A strong linear correlation $r^2 > 0.93$ between StO₂ and microvascular %SO₂ was observed for isolated animal hind limb, kidney, and heart [22.6]. Observation of this parameter is used to assist clinicians in early detection of inadequate tissue perfusion (hypoperfusion) of a patient.

Fig. 22.3 PeriFlux system 5000 by Perimed Inc.

Fig. 22.4 The Niro-500 oxygenation monitor by Hamamatsu

The PeriFlux system 5000 (Fig. 22.3) is a modular system that enables simultaneous measurement of blood perfusion and transcutaneous pO_2/CO_2 using a laser Doppler method. One way in which the PeriFlux differs from the InSpectra device is its sampling depth. The PeriFlux system measures at a depth of 2 mm compared with 12 mm or greater depths in other systems. PeriFlux probes may also simultaneously collect temperature information from the site of interest, making this system very useful for shallow studies, e.g., skin.

The Niro-500 oxygenation monitor (Fig. 22.4) by Hamamatsu measures the tissue oxygenation index (TOI) of a sample volume. The TOI indicates the oxygen saturation level with respect to the normalized tissue hemoglobin index that reports the real-time concentration changes in oxygenated hemoglobin, deoxygenated hemoglobin, and total hemoglobin. This device allows for measurements at two sites simultaneously when monitoring patients' brain oxygenation in the intensive care unit (ICU), critical care unit (CCU), or neonatal intensive care unit (NICU).

Fig. 22.5 T.Ox (tissue oximeter) by Vioptix

The T.Ox (tissue oximeter) (Fig. 22.5) is a portable unit with a liquid crystal display (LCD) touchscreen monitor with the capability to operate two fiber-optic sensors. Along with instant data acquisition of the sampling volume, this device is equipped with adjustable audible and visual alarms for StO_2 concentrations and low battery.

The INVOS system by Somanetics (Fig. 22.6) uses in vivo optical spectroscopy. Like the other devices,

Fig. 22.6 The INVOS system by Somanetics

INVOS provides real-time information of regional oxygen levels in the sampling volume beneath the NIR-emitting probe. The newest model, the sixth generation INVOS, is the only commercially available four-channel system that reportedly monitors cerebral and peripheral blood circulation simultaneously. This is beneficial for detecting early indicators of shock or other cerebral perfusion abnormalities in patients.

22.4 New Developments: Multidepth Differential Approach

A new group of devices are being developed and evaluated to address the issue of skin blood flow influencing the NIRS signal and more broadly any situation in which the area of interest may be influenced by blood flow; for example, when monitoring StO_2 in the brain in adults, the NIRS signal may encounter blood flow from the sinuses. This new group of NIRS devices utilize a multidepth differential approach so that values from the skin can be subtracted from deeper tissues. Bezmer reports on the use of this system for measuring StO_2 values on forearm and thenar simultaneously. He utilized one multidepth probe on the thenar and another on the forearm. This device from Hutchinson Technology employs reflectance-mode probes that have one 1.5 mm optical fiber to illuminate the tissue and two optical fibers to detect the backscattered light from the tissue. Using space between the illumination fiber and the two detection fibers of 15 and 25 mm, respectively, he recorded StO_2 values at those depths. Subtracting those values from the 1.5 mm probe gives

a differential value that subtracts out the skin value and theoretically gives a value for the 15 and 25 mm depths. The optical data were subsequently analyzed using the second-derivative values of the ratio of 720 to 760 nm, which is related to StO_2 [22.1]. Other devices have been developed to utilize the multidepth

Fig. 22.7 O2C (oxygen to see) system developed by LEA Medizintechnik GmbH

differential approach [22.8]. The Lea is another example of such a system which measures blood flow and StO₂ levels simultaneously. Presently, many companies are addressing the need for multiple probes. Thus, this presentation will be outdated by the time it is published.

The O2C (oxygen to see) system developed by LEA Medizintechnik GmbH (Fig. 22.7) was designed to be a noninvasive diagnostic device for determination

of oxygen supply in the microvasculature of blood-perfused tissue. It uses a glass-fiber probe that serves as a measuring point for two separate channels. One channel measures the oxygen saturation of hemoglobin of the skin while the other channel records the oxygen saturation of deeper tissues such as skeletal muscle. Probes range from 2 mm depth up to 15 mm depth and can be used with a variety of probe heads for specific applications.

22.5 Clinical Application and Study of NIRS

22.5.1 Overview

The areas of the body where NIRS is used include the thenar or thumb region [22.5], the forearm [22.9], the cranial area [22.10], the legs [22.11], the breast [22.12], and others [22.13] where oxygen transfer to tissue takes place. This technology is also being used on neonates as well as in adults [22.13]. For peripheral measurements such as in the thenar and forearm, these values are sometimes used as surrogates for central cardiovascular measurements. Since the signal is thought to reflect what is occurring at the microvascular level, a vascular occlusion test (VOT) is used [22.14]. This consists of occluding the arterial flow to the upper limb and then releasing the pressure. The VOT-StO₂ values can be divided into baseline, ischemia, reperfusion, and hyperemia [22.15]. The rate of deoxygenation can be determined from the downslope during the ischemic phase, and the rate of reoxygenation can be measured from the upslope during reperfusion [22.16]. Although the VOT procedure has promise, since it may reflect pathological conditions such as sepsis, the procedure has not been standardized due to probe position and size as well as deflation thresholds [22.14]. The following are major factors that influence StO₂ values: gender (particularly with increasing age), position of the subject, which muscle is measured, adipose tissue thickness, skin blood flow, and edema.

22.5.2 Thenar

The thenar section of the hand is a popular testing site in current research [22.7] due to its convenience for clinical studies. The hand is easily accessible while the patient is in supine position and easily manipulated when the patient is unconscious. In a recent study, StO₂ values were reported to be a good predictor of

severe shock in trauma patients [22.7]. In this prospective, nonrandomized, observational, descriptive study in normal human volunteers ($n = 707$) and patients admitted to the trauma center ($n = 150$) StO₂ monitoring was performed continuously and noninvasively, with values recorded at 2 min intervals. The trauma team, blinded to StO₂ values, classified each patient into one of four groups (no shock, mild shock, moderate shock, and severe shock) using conventional clinical parameters. The mean \pm standard deviation (SD) thenar StO₂ values for each group were as follows: normal, $87 \pm 6\%$ ($n = 707$); no shock, $83 \pm 10\%$ ($n = 85$); mild shock, $83 \pm 10\%$ ($n = 19$); moderate shock, $80 \pm 12\%$ ($n = 14$); and severe shock, $45 \pm 26\%$ ($n = 14$). The thenar StO₂ values clearly discriminated the normal patients and those with severe shock ($p < 0.05$) [22.7]. The results indicated that NIRS of the thenar was a quick, noninvasive, and accurate predictor of tissue dysoxia.

22.5.3 Forearm

Another common site of interest for NIRS is the forearm. Studies such as [22.17] and [22.9] used the forearm as the site for their StO₂ measurements while studying skin blood flow. However, while this site is popular in research, questions arise regarding whether this site is suitable clinically, due to possible interference from adipose tissue above the muscular tissue on the NIRS readings [22.18]. This influence will be further discussed later on, as well as whether the forearm is more sensitive to cardiovascular changes than is the thenar.

22.5.4 Brain

NIRS is popular for use in neonates at intensive care units. Oxygen exchange in the brain is essential for

neonatal development, and noninvasive techniques are highly sought after when dealing with infants [22.19]. A recent study was conducted that compared NIRS technology and the intravenous ^{133}Xe clearance technique, which is the current clinical technique for measuring cerebral blood flow in newborn infants. Forty cerebral blood flow measurements using NIRS (CBF_{NIRS}) measurements were obtained during 19 ^{133}Xe measurements in 16 infants. The test–retest variation of repeated near-infrared measurements during each ^{133}Xe clearance was 17.5%. CBF_{NIRS} was closely related to CBF_{XE} ($r^2 = 0.84$, $p < 0.0001$), with a slope of 0.75 (standard error of the mean, $\text{SEM} = 0.064$) and an intercept of 1.58 ml/100 g/min ($\text{SEM} = 0.51$). The difference between the measurements obtained by the two methods ($\text{CBF}_{\text{NIRS}} - \text{CBF}_{\text{XE}}$) was negative in the high range of CBF, whereas the difference was close to zero in the low range. The conclusion was that CBF measured with near-infrared spectroscopy was in good agreement with CBF measured with the ^{133}Xe method. The near-infrared spectroscopy method has the advantage of being noninvasive, and it does not involve ionizing radiation. Because of methodological constraints, however, NIRS may underestimate CBF in the high flow range, and it may have limitations for application in clinical research [22.19]. Another question raised is the cranial placement of the NIRS probe, which may result in influence of the cranial bone on these particular StO_2 readings. The adult skull is much thicker and denser than that of an infant, which could possibly present an obstacle for use in adult patients. While it seems to be useful with babies, further studies need to be conducted before this application of NIRS is used in the adult ICU [22.20].

22.5.5 Lower Limb

NIRS probes have also been used in studies dealing with the lower extremities. A recently conducted study showed that StO_2 monitoring in patients with peripheral arterial disease was very beneficial for diagnosing those with this disease as well as for monitoring the disease once diagnosed. Thirty-five normal and 14 peripheral arterial disease (PAD) subjects from two clinical centers were evaluated in a prospective cross-sectional analysis comparing StO_2 by using the InSpectra tissue spectrometer at rest (baseline) and after treadmill exercise. Measurements were obtained at baseline and peak exercise for normal subjects and at baseline, initial claudication distance (ICD) and absolute claudication distance (ACD) in PAD subjects. Endpoint values were

the mean of 15 data points. Times to 50% StO_2 recovery to baseline (T50) and complete recovery to baseline (T100) were measured. Baseline StO_2 was 65% in both groups. The peak exercise StO_2 was significantly lower and the absolute change in StO_2 and the percentage change in StO_2 were significantly greater in PAD patients ($p < 0.45$). T50 and T100 were longer in PAD patients compared with normal subjects ($p = 0.0001$ and 0.002, respectively). T50 of > 70 s yielded a sensitivity of 89% and a specificity of 85% for PAD [22.21]. The noninvasive manner showed promise for identifying patients with PAD. However, a study performed on the same group but eliminating the exercise protocol and applying a more clinical protocol could provide further answers and insight on the use of NIRS for PAD.

22.5.6 Breast Tumors and Kidneys

Other areas of interest in NIRS monitoring that show promise of clinical benefits are in monitoring of the breast and the kidneys. A recent study conducted on breast tumor tissue showed that this particular tissue relayed different and unique StO_2 and THI readings as compared with normal breast tissue. THI values in tumorous breast tissue were shown to be 2–4 times higher compared with normal breast tissue, and StO_2 levels in the tumorous tissue tended to be 5–20% lower as compared with normal breast tissue [22.12]. If validated, this would not only make breast tumors easier to diagnose, but also make the female patient much more comfortable in the clinical setting. Another study conducted on infants monitored StO_2 levels in the deltoid and kidney of the baby. The kidney was chosen for these low-birth-weight babies because patent ductus arteriosus (PDA) in low-birth-weight infants would increase StO_2 in the pulmonary vasculature and parenchyma due to increased pulmonary blood flow, while the decrease in blood flow distal to the PDA would diminish StO_2 in distal organs such as the kidney and skeletal muscle, and these relative differences would be detectable by NIRS. The results from this study showed that, in those babies treated for PDA, StO_2 values were 34% in the kidney and 35% in the deltoid (average values, $n = 13$). The average StO_2 values in babies who ended up not being treated for PDA were 55% in the kidney and 53% in the deltoid. Data analysis showed that these differences in StO_2 values were significant ($p = 0.01$) [22.13]. Results suggested that portable NIRS technology showed great promise in predicting and diagnosing for babies with patent ductus arteriosus and low birth weight.

22.6 Does Skin Blood Flow Affect NIRS Measurements?

It is obvious that the portability, ease of use, convenience, and noninvasive characteristics of NIRS StO_2 monitoring make this technology very popular when thinking of future applications in the clinical setting. However, certain questions arise that must be answered before this technology can be completely embraced. To measure tissue oxygen saturation accurately at any given site, the NIRS signal must pass through other parts of the body that might not necessarily be of interest. Some of these areas include skin, peripheral blood, adipose tissue, and bone. Perhaps the most popular question of concern, and possibly the most influential, is whether skin blood flow influences StO_2 readings.

Skin blood flow in the human body serves many functions such as thermoregulation, oxygen transport, hormone transport, CO_2 transport, and hydrogen ion transport [22.22]. Skin blood flow can also be altered in various conditions such as exercise, extreme heat, extreme cold, and even shock. During exercise, extra oxygen must be delivered to the muscle and tissue cells so that they may perform their work. To address this extra need for oxygen, skin blood flow to the relevant area is increased [22.22]. In conditions of extreme heat, skin vasculature undergoes vasodilatation to divert the flow of heated blood to the skin, where heat can be more readily given off by the body in order to cool. The opposite of this process is called vasoconstriction and is seen in extreme cold conditions for the opposite effect on the

body. Both vasoconstriction and vasodilatation are controlled by the autonomic nervous system. Another state that alters skin blood flow is shock, resulting in deprivation of blood flow to the tissues. This serious medical condition can lead to serious conditions such as hypoxemia and even cardiac arrest. Shock slows and in some cases stops skin blood flow as compared with its normal rate of flow [22.23].

Limited studies have been carried out in a variety of ways, suggesting that skin blood flow has a significant influence on StO_2 readings. *Buono et al.* [22.11] reported that skin blood flow had a significant effect on NIRS measurements. Leg skin blood flow (SkBF) was increased and decreased following local heating and intradermal epinephrine injection using 30-gauge needle into the dermis and raising an intradermal wheal under direct visualization to avoid injection into the subcutaneous tissue. Epinephrine decreased muscle saturation (StO_2), and heating the leg increased StO_2 . Results are shown in Fig. 22.8a,b.

The results suggest that, with a significant decrease or increase in skin blood flow to the leg, a significant decrease or increase, respectively, in StO_2 was observed as well [22.11]. The major criticism of this research was that the authors had no way to determine how deep the epinephrine or warming affected deep layers. Supplemental study would be recommended to verify the influence of skin blood flow on StO_2 measurements. In addition, *Davis et al.* reported that skin blood flow of

Fig. 22.8 Effect of epinephrine and heat on muscle oxygen saturation (StO_2) (mean \pm SE). * Different from pretreatment measurements $p < 0.05$ (after [22.11])

Table 22.2 Effects of local cooling followed by capsaicin and occlusion on StO₂ values. * Significance at $p < 0.05$

the forearm influenced NIRS measurements. Using local heating as well as whole-body heating, they reported large increases in NIRS-derived tissue oxygenation correlated with increases in skin blood flow. They used the NIRO550 Hamamatsu Photonics unit that uses a different algorithm than the Hutchinson system used by *Buono et al.* [22.24].

22.6.1 Forearm Skin Blood Flow Study Versus StO₂

Recent studies in our laboratory suggest that skin blood flow had significant influence on NIRS StO₂ measurements taken on the forearm. Two different probes, 15 and 25 mm, were used on 11 male and female subjects who had their forearm skin blood flow al-

tered using a cooling pad to cause vasoconstriction followed by capsaicin (0.1%) to cause vasodilatation. Controls were run in both sets of experiments, where no capsaicin was used on the forearm. Results for the 15 mm probe showed that, prior to capsaicin application, subjects averaged a 75.4% StO₂ level, whereas after capsaicin application, an average of 90.4% was recorded, corresponding to a 15% increase. Results for the 25 mm probe showed a baseline of 77.9% and, after capsaicin, an average of 85.3%, a 7.4% increase. In addition, total hemoglobin index (THI) levels were recorded, and although the 15 mm probe recorded overall lower THI levels with an average of 5.64 before capsaicin and 6.8 after capsaicin, both the 15 and 25 mm probes recorded the same trends upon cooling and capsaicin application. The 25 mm probe recorded

Fig. 22.9 Effects of cooling, capsaicin, and occlusion of forearm on StO₂. Initial experiment was 1. To cool forearm followed by 2. Application of capsaicin and then 3. Occlusion while monitoring StO₂ and skin blood flow

an average THI of 12.48 before capsaicin and an average of 13.4 post application. These results suggest that, since the 15 mm probe showed twice the increase in StO₂ levels compared with the 25 mm probe, since THI trends were similar between the two probes, the 15 mm probe may be more influenced by skin blood flow in the forearm. A paired *T*-analysis test was run, which showed that the increase in skin blood flow due to capsaicin had a statistically significant effect on the StO₂ readings. The data are summarized in Table 22.2.

A representative graph of StO₂ values and blood flow values from the study is shown in Fig. 22.9. The gap in data is due to the removal of the probes for application of capsaicin.

Analysis of the data [with 95% confidence interval (CI)] shows that, with a significant increase in skin blood flow after capsaicin in both the 15 and 25 mm probes, a significant increase in StO₂ measurements was recorded for the 15 and 25 mm probes, respectively. These results suggest an influence of skin blood flow in the forearm on NIRS StO₂ measurements.

22.6.2 Thenar Skin Blood Flow Study Versus StO₂

A similar study was performed on the thenar eminence to investigate whether local vasoconstriction/vasodilation would influence StO₂ and THI values during body-wide vasoconstriction induced by drinking a cold drink followed by local vasodilation. Using the In-Spectra StO₂ tissue oxygenation monitor (15 mm depth probe) and the PeriFlux system 5000 noninvasive near-infrared spectrometer, the study monitored volunteers who ingested the cold beverage as quickly as they could followed by application of a topical vasodilator (capsaicin) to a local area of the thenar. Baseline readings of StO₂ and THI were 84.1 ± 4.8 and 15.1 ± 1.4 , respectively. After the consumption of the drink, the subjects' StO₂ readings dropped to 76.6 ± 5.01 and THI dropped to 14.8 ± 1.48 , suggesting a vasoconstriction effect. The blood flow data following the drink also demonstrated vasoconstriction, as the baseline value of 143.4 PU (perfusion units) dropped to 52.4 PU. The *capsaicin effect* reversed the vasoconstriction and leveled off the values

Table 22.3 Effect of ingestion of cold drink followed by capsaicin. Skin blood flow, THI, and StO₂ were measured. * Significance at $p < 0.05$

	StO ₂ (% O ₂)	THI	Skin flow (PU)
Baseline	84.1 ± 4.8	15.1 ± 1.4	143.4 ± 104.8
After drink	76.6 ± 5.01*	14.4 ± 1.23	52.4 ± 31.6*
After cap	78.3 ± 4.4	14.4 ± 1.2	56.3 ± 56.9
After cuff	80.7 ± 5.1	14.8 ± 1.3	81.5 ± 99

of StO₂ and THI to 78.3 ± 4.4 and 14.4 ± 1.2, respectively. After capsaicin application, blood flow was occluded by automatic blood pressure cuff occlusion. The purpose was to simulate an undeniable decrease in blood flow upon pressure release and study the StO₂ and THI values. Once the cuff was released, an increase in StO₂ and THI corresponded to the increase in superficial skin blood flow [22.25]. Results of this study are shown in Table 22.2.

These results, compared with those of the previous experiment in which the forearm was locally cooled, suggest that the forearm is more responsive to capsaicin than is the thenar, since the only significant changes were found after the subject drank the drink, and even then these changes were only significant for StO₂ and skin blood flow. In Table 22.2 these significant changes are indicated with an asterisk (95% CI). These different results between the thenar and forearm could be due to the location of the probe on the body, the thenar, or

possibly due to the different protocol of the experiment. However, the fact that these results agree with other similar studies that report that the forearm is more sensitive to cardiovascular changes than is the thenar may suggest that the thenar and forearm are physiologically different [22.1, 25].

Some additional questions raised about the previous studies concern the depth of the infrared probes and the correct depth for measurement of tissue oxygen saturation. Suggestions are that 15 and 25 mm probes do not penetrate deep enough to record a signal that is mostly oxygenated tissue hemoglobin. Criticisms suggest that skin thickness and tissue thickness must be taken into account [22.26]. Experimental design, different devices, NIRS device algorithms, and theory of the technology must be further reviewed and studied. Ince and Soller have expressed clearly opposing views on technology and by inference which technology may be superior [22.8].

22.7 Future of NIRS

Although NIRS signal derivation, accuracy, and qualitative ability are the center of controversy concerning this technology, NIRS still shows promise in monitoring oxygen balance and consumption in a sampling volume. The future of NIRS technology must address the current problems concerning transmission, reception, and quantification of the NIRS signal. Different technologies abound. Which is the best may depend on the application. In addition, the multidepth probe approach for NIRS is still in its infancy but might shed important light on the question of the influence of blood flow and oxygen concentration from interfering systems such as the skin or brain sinuses. Miniaturization of the NIRS system has been desired for quite some time. Fast signal spectroscopy offers an improvement over conventional NIRS instruments, which detect signals corresponding

to relatively slow hemodynamic responses. Producing a much faster signal is beneficial for detection by a CW-type NIRS system.

In addition, understanding the complex physiological responses that occur in physiological and pathophysiological states must also be pursued. The debate as to whether the forearm or thenar is a clinically important site for monitoring patients motivates the beginning of a new set of studies that need to combine use of multidepth differential probes with different physiological experiments that mimic various clinical conditions such as hemorrhage as well as normal physiological states such as exercise. Investigators in this exciting field should keep in mind the complex physiological control of skin blood flow. Joyner states the problem succinctly [22.27]:

We have another example (skin blood flow) (like the coronary and skeletal muscle circulations) of a highly redundant physiological system that is critical to whole body homeostasis.

Later he adds,

The control of skin blood flow defies simple reductionist explanations . . .

Muscle may also influence the NIRS signal. Although it is tempting to assume that the vasculature and tissue remain the same after some central hypoxic event, the researcher and clinician should be wary about making rapid decisions regarding an NIRS signal until they have considered the complications of the changing dynamics

of skin and muscle blood flow and its local and neural control. If possible, core and peripheral temperatures should be measured to possibly explain the StO₂ values.

Presently our laboratory is investigating use of a multidepth differential system in the forearm and thenar, utilizing capsaicin to promote local vasodilation. Further studies to elucidate the mechanisms associated with vasodilation and vasoconstriction are required to assist in the development of a robust, accurate NIRS technology based on new insights into physiological control in both normal and pathophysiological states. NIRS has become an important tool in clinical management of various types of hypoxic disorders, but before it is widely used, additional clinical and basic science research is required.

Magnetic Resonance Imaging

Wolfgang R. Nitz

Magnetic resonance imaging (MRI) represents an exciting technology not only from a technological perspective but also in view of its clinical potential. A brief introduction will be given with respect to the historical development of *nuclear magnetic resonance* (NMR) later to be called MRI. A MRI system can be considered primarily composed of a magnet, a magnetic field gradient system, *radio frequency* (RF) coils for signal processing. The introduction of those hardware components is followed by a description of basic MRI principles and applications. Although MRI is a noninvasive technology working without ionizing radiation, it has nevertheless a few safety aspects to be considered. The chapter will close with a speculative outlook to the future of MRI and combined modalities.

23.1 History of MRI

Wolfgang Pauli proposed the existence of a nuclear spin in 1924 [23.1]. His statement followed a year after the introduction of the spin of the electron by *George Eugene Uhlenbeck* and *Samuel A. Goudsmit*. In 1933, *Otto Stern* and *Walther Gerlach* were successful in demonstrating the existence of a nuclear spin in deviating a beam of hydrogen molecules in a magnetic

field [23.2–5]. Supported by the experience of *Gorter, Rabi* of Columbia University in New York was successful in measuring the *nuclear magnetic moment* [23.6] in 1937. Earlier, *Gorter* had performed similar experiments, but with negative result. *Gorter* was the first to use the term *nuclear magnetic resonance* (NMR) in his publications [23.7].

It is general perception that the experiments launching the development of NMR were performed by *Bloch* and *Purcell* in 1946, proving the existence of the nuclear spin and the phenomenon of (nuclear) magnetic resonance [(N)MR] [23.8, 9], work for which Bloch and Purcell shared the Nobel Prize in 1952.

The spin is characterized by an angular momentum combined with a magnetic moment. The spin is a quantum-mechanical entity. As a consequence, the magnetic moment of the proton (with spin quantum number $1/2$), exposed to an external magnetic field B_0 , can only have two possible positions: parallel or antiparallel to the direction of the field. Those positions are characterized by a difference in energy, with the parallel position being energetically preferred.

If the energy of an electromagnetic wave corresponds exactly to the energy difference between these two possible states, parallel aligned spins can be pushed into the antiparallel position. With the return of the antiparallel spins back to the original parallel position, the energy difference is released as an electromagnetic wave, also called the NMR signal. As the wavelength λ of the stimulating electromagnetic field has to be identical to the wavelength representing the difference between the two possible states

$$\Delta E = \gamma \hbar B_0 = h\nu = h \frac{c}{\lambda},$$

which is typical for a *resonance* condition, the phenomenon is also called *magnetic resonance*.

As more spins are aligned parallel to the external magnetic field, as compared with the antiparallel alignment, a longitudinal nuclear magnetization builds up. The longitudinal nuclear magnetization can be treated using the principles of classical physics. If the longitudinal nuclear magnetization is tilted away from the parallel direction of the external magnetic field, the angular momentum of the spins causes precession of the magnetization around the original alignment (the direction of the external magnetic field B_0). This precessional frequency is called the Larmor frequency and is identical to the frequency representing the energy difference between the two quantum-mechanical states. The projection of the precessing nuclear magnetization onto the transverse plane is called the transverse nuclear magnetization. If all the longitudinal nuclear magnetization is converted to transverse nuclear magnetization, the initiating radiofrequency (RF) pulse is called a 90° RF excitation pulse. Following excitation, the longitudinal nuclear magnetization within the tissue will recover within a tissue-specific timeframe. *Bloch* introduced

the term T_1 within his phenomenological Bloch equations [23.10] to characterize this *recovery time*. The mechanism of recovery is called *relaxation*, and the correlated time constant is termed the T_1 relaxation time. The precessing transverse nuclear magnetization will induce a voltage in any antenna system or coil in close vicinity to the object. The signal will decay within a tissue-specific time, which Bloch termed T_2 . The underlying mechanism is called T_2 relaxation, and the time constant the T_2 relaxation time. Experiments to measure tissue-specific relaxation times on living cells and animal tissues were performed as early as 1955 [23.11]. *Damadian* at the Downstate Medical Center in Brooklyn and *Hollis* at Johns Hopkins University in Baltimore evaluated the T_1 and T_2 relaxation times of normal and cancer tissue and observed that cancerous tissue demonstrated longer relaxation times as compared with normal tissue [23.12, 13]. It was *Damadian's* belief that he had found the ultimate technology for diagnosing cancer [23.14]. Unfortunately, he gave no practical hint regarding how to perform cancer screening on a human body.

It was the American chemist *Lauterbur* at the State University of New York who, in 1971, introduced the concept of using a magnetic field gradient superimposed on a static magnetic field to spatially encode the signal induced by the precessing nuclear magnetization [23.15]. The previously mentioned resonance frequency is a function of the strength of the magnetic field. If a magnetic field gradient is superimposed on the static magnetic field, the magnetic field strength becomes a function of location, and with this also the resonance frequency becomes a function of location. Fourier transformation (FT) can be applied to analyze the signal induced by the transverse nuclear magnetization in order to identify the frequency components indicating the location, and thereby assign a brightness to the pixel on the display representing that location, proportional to the detected amplitude.

Lauterbur used two test-tubes filled with water to demonstrate spatially encoded nuclear magnetic resonance (NMR) by superimposing a magnetic field gradient on a static magnetic field, producing a signal providing a projection of the objects. Repeating the experiment with rotated magnetic field gradients and applying the reconstruction algorithm recently established for x-ray computer tomography, he was able to produce an image of the water within the test-tubes.

In April 1974, *Lauterbur* gave a presentation at a scientific meeting in Raleigh, North Carolina, which was

also attended by Richard Ernst from the University of Zurich. Ernst recognized that the back-projection could be replaced by a combination of phase and frequency encoding of the MR signal [23.16]. This method is still the main reconstruction algorithm used in NMR. To avoid the fear associated with the word *nuclear*, NMR was more and more called magnetic resonance imaging (MRI) around 1981.

The British company EMI, which revolutionized medical imaging in 1973 with the introduction of the

first x-ray computer tomography system, announced in 1976 the development of a scanner based on radio waves, and in 1978 presented the first image of a human head using MRI. This announcement gave a significant boost to the medical imaging industry, as they were not to repeat their mistake of underestimating the potential of a new imaging modality as they did with x-ray computer tomography. In the early 1980s, the first MR installations based on commercial products and aiming for routine clinical applications were seen.

23.2 MRI – System Components

23.2.1 The Magnet – The Magnetic Field Strength B_0

The phenomenon of magnetic resonance is only observed in the presence of a strong magnetic field. The strength of the static magnetic field B_0 is described in units of Tesla (T), at least within the medical community [for physicists, T means the magnetic flux density in units of $V\ s/m^2$ and the magnetic field strength is measured in units of A/m or oersted (Oe)].

Early systems (1983) used resistive magnets with magnetic field strength in the range 0.1–0.2 T.

Within the same year it became obvious that superconductivity could be used to generate higher magnetic fields. Since then, the field strength used in clinical scanners has steadily increased. In 1985, the field strength of the majority of the systems was 0.5 T. Currently, in 2010, there is a strong tendency towards 3.0 T systems, whereas 1.5 T systems have the largest market share.

The primary reason for using a higher magnetic field strength is obvious: the ratio between signal and background noise (the signal-to-noise ratio, SNR) is, to a first approximation, proportional to the magnetic field strength [23.17].

The electromagnetic noise N , with its primary origin within the patient, is approximately linear in the magnetic field strength B_0

$$N \sim B_0 .$$

The induced MRI signal is a function of the rotating (transverse) nuclear magnetization, meaning proportional to the resonance frequency and the amplitude

$$S \sim \frac{dM_{xy}}{dt} \sim \nu M_{xy} ,$$

$$\nu \sim \gamma B_0 .$$

The transverse nuclear magnetization M_{xy} is generated by tilting the longitudinal nuclear magnetization M_z away from the direction of the main magnetic field. If a 90° RF excitation pulse is used, all of the available longitudinal nuclear magnetization M_z is converted to transverse nuclear magnetization M_{xy} .

The amplitude of the longitudinal nuclear magnetization is a function of the occupation probability of the different energy levels (of parallel and antiparallel alignment of the nuclear spins and their correlated magnetic moments). The amplitude of the longitudinal nuclear magnetization M_z scales with the magnetic field strength used

$$M_z \sim B_0 .$$

Considering amplitude and frequency, the induced signal is proportional to the square of the magnetic field strength used

$$S \sim B_0^2 ,$$

and the signal-to-noise ratio (SNR) is approximately linear in the magnetic field strength

$$\text{SNR} = \frac{S}{N} \sim B_0 f(T_1, T_2)$$

and is of course a function of the tissue-specific relaxation times T_1 and T_2 .

The increase of the SNR is only one aspect of *high-field* systems. There are a number of phenomena representing advantages and disadvantages correlated with utilization of higher magnetic field strength. T_1 relaxation times are prolonged with higher magnetic fields, and differences between tissues are often reduced, leading to a reduction of contrast in T_1 -weighted images. The sensitivity to gradients in magnetic susceptibility is increased with field strength, as magnet field inhomogeneities increase proportionally to the product

Fig. 23.1a,b A commercially available MR system using a permanent magnet with a magnetic field strength of 0.35 T (MAGNETOM C!). The T_1 -weighted sagittal image of a human brain demonstrates a slice thickness of 4 mm, acquired within 5 min (courtesy Air-force General Hospital, Beijing, PR China)

of magnetic field strength and magnetic susceptibility. With the improvement in SNR, motion artifacts are no longer masked by noise and are often pronounced due to the strong signal from fat-containing moving tissue. Safety-relevant aspects need special consideration [23.18] as some potentially hazardous interactions scale with the field strength. Last but not least, the costs for an MR system scale with field strength.

Around 1991 the major vendors decided to introduce low-cost *low-field* MR systems (field strength up to 0.4 T) parallel to the *high-field* systems, as 1.0 and 1.5 T systems were called at that time. This diversity has since been maintained, and *low-field* systems are still commercially available (Fig. 23.1). A magnetic field strength of up to 0.35 T can be achieved by assembling a number of permanent magnets. Only one vendor is known to be still working with resistive magnets (stand-up MRI, FONAR Corp.). All other vendors (Siemens, General Electric, Philips, Toshiba etc.) are working with either permanent magnets or superconductive magnets. Production and maintenance of permanent systems are relatively cost effective. A disadvantage is the limitation to low field strength and the corresponding limit in SNR. Another disadvantage is the change in magnetic field strength as a function of temperature of the magnet material. Approximately 14 t of permanent magnet material is needed to achieve a field strength of 0.35 T. Resistive magnets have relatively low production costs, but are expensive in operation, have in general an extreme weight (40 t), and share the disadvantage of a temperature-dependent field strength with the permanent magnets. The production costs of superconductive magnets are relatively high, and, if helium is to be refilled regularly, they are expensive in operation, but they have the advantages of a magnetic

field strength that does not change with temperature and that the generation of any reasonable magnetic field strength seems to be possible without limit and that the weight of the magnets is moderate (about 4 t for a 1.5 T system). The advantages and disadvantages of working with higher magnetic field strength will be further discussed in conjunction with safety-relevant aspects. Besides the magnetic field strength, the magnet design plays an important role that should not be underestimated. The size of the patient bore has been limited to 60 cm in the past, mainly for financial reasons, although since 2004 systems with larger patient bore openings have been available (e.g., 70 cm; Fig. 23.2). The larger opening of the patient bore is not only a comfort factor for the patient; it is also helpful in reducing the number of medical examinations refused due to claustrophobia and provides a possibility to study patients whose circumference would need more than a 60 cm bore.

23.2.2 The System for the Magnetic Field Gradient

To excite a specific slice or volume at a specific location, the MR resonance frequency, also called the Larmor frequency, has to be a function of location. For this reason, a magnetic field gradient is established in the direction of slice selection and for the duration of excitation. The slice is selected using a RF pulse whose frequency range covers the Larmor frequencies within the region to be excited. To cover all three dimensions, the magnetic field gradient coil (gradient coil) is a composition of three gradient coils arranged orthogonally to one other (x, y, z ; Fig. 23.3). Sending appropriate electric currents through these coils will generate magnetic field

Fig. 23.2a,b Commercially available MR system using a superconductive magnet with a magnetic field strength of 3.0 T and patient bore of 70 cm (MAGNETOM SKYRA). The T_1 -weighted sagittal image of a human brain demonstrates a slice thickness of 1.2 mm, acquired within 9 min

gradients that are linearly superimposed, providing the possibility of producing any arbitrary excitation plane without having to move any mechanical parts. A magnetic field gradient is also activated during the time of data acquisition. This encodes spatial information into the signal via frequency encoding, as the Larmor frequency of the emitted MR signal will be a function of location, depending on the established linear change in magnetic field strength in the direction of frequency encoding.

The electric currents I within the gradient coils will result in a Lorentz forces F in the presence of a strong magnetic field B_0

$$F \approx I \times B_0 .$$

These forces cause vibration of the gradient coil and are the primary source of noise during an MR examination.

The amplitude of the magnetic field gradient is important with respect to achieving a good spatial resolution. A strong magnetic field gradient is also essential for diffusion weighted imaging (DWI). Wherever the amplitude time integral is of relevance, the stronger the magnetic field gradient, the shorter the encoding action. The speed of a gradient system (coil plus amplifier) is characterized by the time needed to achieve a specified gradient amplitude (ramp time). The speed primarily determines the time needed between excitation and data acquisition and directly influences the resulting image quality. The ratio between the maximum gradient amplitude and the ramp time is introduced as the *slew rate*.

Fig. 23.3 Composition of a MR system

Air-cooled gradient coils were used in 1986 with gradient amplitudes of 3 mT/m and slew rate of 3 T/(m s). In 2003, generally available gradient amplitudes were 45 mT/m with slew rate of 200 T/(m s) using water cooling. Ramp times to establish a magnetic field gradient are between 100 and 800 μ s, during which several hundred Amperes have to be maintained. To drive these currents, \approx 2000 V are needed. The development of faster and stronger gradient systems is slightly limited by human physiology. Fast and rapid switching of magnetic field gradients induces electric potentials within the body that, with the current technology, can reach amplitudes usually used to control muscle contractions. The phenomenon is called *peripheral nerve stimulation* (PNS). As this can potentially be painful, it has to be avoided. All vendors providing strong and fast gradient systems have a *stimulation monitor* that changes imaging sequences prior to execution to avoid peripheral nerve stimulation.

Beginning with the development of MR imaging, methods have been developed and established with the aim of shortening measurement times by, e.g., under-sampling of the data, with correction of the artifacts resulting from the consequent signal ambiguity using fancy algorithms. Similar approaches are currently under investigation that may allow use of faster gradient systems [23.19].

23.2.3 The Radiofrequency System

The radiofrequency system consists of a transmitter, transmit antenna, receive antenna, and receiver. Depending on the magnetic field strength used, the fundamental frequency will be 8 MHz (0.2 T) up to 128 MHz (3.0 T). The RF power amplifier has to have a peak power of several kilowatts. Since the early days of MR, a transmit antenna, also called the body coil, is located immediately behind the cover within the patient bore. The body coil is usually also able to receive the MR signal. On the other hand, placement of a receive antenna as close as possible to the patient's body (surface coil) has some significant advantages. As the patient's body emits electromagnetic noise even in the absence of excitation, and as the signal amplitude scales inversely with distance from its origin, use of a surface coil improves the SNR. Current systems utilize an array of surface coils with independent preamplifiers and/or their own receive channels for SNR optimization and for other reasons to be mentioned later. For some regions it is of advantage to use the surface coil not only as a receive coil but also as a transmit coil.

In case of knee examination, an extremity coil is usually used for excitation and signal reception, exciting only the slice within the knee to be studied. The advantage is that, in transverse excitations, the adjacent knee is not excited, which otherwise would potentially lead to imaging artifacts. In case of imaging of the spine, large coil arrays, integrated into the patient table,

Fig. 23.4 Contrast-enhanced MR angiograph of the whole body measured within 1 min 17 s (courtesy Hong Kong Sanatorium & Hospital, Happy Valley, Hong Kong)

have been shown to be beneficial. Contrast-enhanced MR angiography studies demand an even larger surface coil coverage (Fig. 23.4) [23.20, 21]. Figure 23.5 shows a coil arrangement suitable to cover the whole vascular system from head to toe.

With the introduction of spatially distributed coil arrays, some methods evolved to utilize the spatial information provided by the coil distribution, reducing the measurement time by undersampling. As all coils receive the signal *in parallel*, the term *parallel acquisition techniques* (PAT) has been established, where the PAT factor indicates the degree of undersampling and the corresponding reduction in measurement time. The undersampling causes signal ambiguity leading to so-called *overfolding* artifacts. Prior to showing the final images to the user, a background task is to analyze the raw data or the final image of each coil to identify and remove such artifacts. The algorithm using image information for this purpose has been named *sensitivity encoding* (SENSE) [23.22]. Another algorithm applied to the signal data with the same aim of removing the above-mentioned artifacts is called *generalized autocalibrating partially parallel acquisitions* (GRAPPA) [23.23]. All these PAT techniques have one disadvantage in common: Any attempt to reduce the measurement time with the spatial resolution being held constant will result in a loss in SNR according to

$$\text{SNR} \sim \frac{1}{\sqrt{\text{PAT}}}.$$

The loss in SNR experienced when using parallel acquisition techniques can be compensated with the better SNR achievable with higher magnetic field strength. For this reason, parallel imaging techniques have shown their full potential in conjunction with high-field systems.

Besides the utilization of spatially distributed surface coils to improve the image quality or for the purpose of reducing measurement time with undersampling, it has been and still is discussed whether it would be of advantage to use spatially distributed coil arrays for transmission, so-called transmit arrays (TX arrays).

Following the term *parallel acquisition techniques* (PAT), the name *parallel transmit* (pTX) has been introduced. It seems that, with the increasing importance of high-field systems, pTX might provide some features to address some of the challenges faced when approaching higher magnetic fields. One of those challenges is the homogeneity of the excitation field, also called the B_1 field. The wavelength of the electromagnetic fields (EM) correlated with higher magnetic fields

Fig. 23.5 Possible coil arrangement for a whole-body MR angiography: head coil (1), neck coil (2), body array (3), and peripheral angiography coil (4) (spine coil integrated within patient table)

B_0 is approaching the spatial dimensions of the patient's body. This leads to potential interaction of the EM field with and within the patient's body, causing B_1 inhomogeneities. The latter results in different RF excitation and/or refocusing amplitudes, leading to signal intensity changes within the image that are unrelated to anatomy. This will lead to spatial inhomogeneity of an otherwise homogeneous signal distribution within the image, unrelated to the underlying anatomy. This is of course an unwanted phenomenon. Besides other possible alternatives to compensate this artificial appearance, spatially distributed transmit coils can be used to homogenize the B_1 field.

23.2.4 Measurement Control, Acquisition, and Image Reconstruction Systems

At the beginning of the development of MR imaging, documentation of patient data, image storage, and measurement protocols were handled by a PDP-11 computer, and measurement control as well as image reconstruction were performed using vendor-specific proprietary hardware and software. In the early 1990s, most MR vendors came to the conclusion that they could benefit from the vastly evolving market of personal computers (PCs).

Most (N)MR systems today use three computer systems:

- A *host*, handling the patient data including the generated images, providing the user interface to run

the measurements, and displaying the generated images.

- A *measurement control*, providing the gradient amplifier with data necessary to establish the magnetic gradient fields on time, supplying the RF power amplifier with the necessary information, and handling the synchronization with the image reconstruction system.
- An *image reconstruction system* with the primary task of performing fast Fourier transformation. The

spatial information is contained within the frequency and the phase information of the received MR signal. That information is retrieved using a Fourier transformation. Secondary tasks for the image reconstruction system are inline postprocessing algorithms that run prior to or during image reconstruction, or immediately afterwards.

In theory it is also conceivable to combine all of these tasks within one computer [23.24].

23.3 MRI – Basic Principles and Applications

MRI is a well-established modality for routine clinical imaging. In conjunction with healthcare reform, there are standards and guidelines describing as and when MRI is appropriate [23.25, 26]. To ensure the quality of diagnostic studies, these standards and guidelines are supported by matching billing codes for reimbursement [23.27]. Medicare and Medicaid service centers are constantly implementing cost-savings approaches in healthcare to ensure an affordable and adequate healthcare system [23.28]. Standards and guidelines include recommendations with respect to spatial resolution, weightings, slice orientations, and coverage. The nomenclature *weighting* is used to indicate the tissue-specific MR-related parameter that dominates the image contrast. The sources for MR signals are protons (primarily the nuclei of hydrogen atoms located within relatively freely moving water molecules). If the imaging protocol is selected such that the number of protons within a voxel dominates the signal amplitude and thereby the image contrast, the weighting is called proton density (PDw). If the factor dominating the image contrast is the speed of recovery of the longitudinal nuclear magnetization following excitation, the weighting is called T_1w . If the image contrast is dominated by the effect of the tissue-specific fading of the MR signal, the weighting is called T_2w . Based on experience acquired over decades, vendors provide programs consisting of a list of protocols for different regions (e.g., head, spine, shoulder, and knee), different weightings (e.g., PDw, T_1w , and T_2w), and different orientations (axial, transverse, coronal, tilted or any arbitrary orientation). An institution running an MR system can modify these programs based on current state-of-the-art imaging techniques, past experience, and current guidelines and recommendations, and can save these modified programs to become part of their routine clin-

ical imaging. The basis for a measurement protocol is the essential series of actions for excitation, refocusing, spatial encoding, and data acquisition, called a *sequence*.

23.3.1 Slice Selection and Spatial Encoding

The sequence starts with ramping up of the magnetic field gradient in the direction of slice selection, as shown in Fig. 23.6. As soon as the magnetic field gradient is stable, a RF pulse is applied with a frequency range matching the Larmor frequencies within the region to be excited. A user-defined field of view and matrix define the size of a single spatial volume, called a *voxel*. The sum of all signals coming out of a single voxel defines the brightness of the corresponding pixel on the screen. The only phenomenon utilized for spatial encoding is the fact that the precessional frequency of the rotating transverse nuclear magnetization is a function of the magnetic field strength at that location. If a brief period of different rotational frequencies is utilized, the phase position of the adjacent transverse nuclear magnetizations will be altered. This is called phase encoding. Such phase encoding is usually applied directly after excitation in a direction perpendicular to the direction of slice selection. At the same point in time the expected dephasing during frequency encoding is prospectively dephased in the opposite direction to get a rephasing point during data acquisition. When switching on the frequency-encoding gradient, an *echo* is formed, and the data are acquired in the presence of a magnetic field gradient that is perpendicular to the direction of slice selection and perpendicular to the direction of phase encoding. The acquired signal is digitized according to matrix size and frequency bandwidth and is stored in a raw data matrix. As each data point

Fig. 23.6 Sequence diagram. A RF excitation pulse is applied as soon as the slice selection gradient (GS) reaches the nominal value. Following the excitation pulse, the generated but (due to the differences in resonance frequencies in the direction of slice selection during excitation) dephased transverse nuclear magnetization is rephased. During the same time period the phase-encoding gradient can be applied (GP) and the rephasing in the direction of frequency encoding can be prepared (GA) – as the transverse nuclear magnetization will dephase due to the differences in resonance frequencies as a consequence of the frequency-encoding magnetic field gradient during the readout period. Finally, the data are acquired in the presence of a frequency-encoding magnetic field gradient (GA). The data are saved into a raw data matrix, also called *k-space*. A two-dimensional fast Fourier transformation (FFT) applied to those data will lead to the final image

within the raw data matrix has an index called *k*, the raw data matrix is also called *k-space*. Depending on the matrix size in the direction of phase encoding, multiple repetitions with different phase-encoding gradients are required to obtain enough information to reconstruct an image.

23.3.2 The Spin-Echo Sequence

The spin echo was found accidentally during an experiment to measure a tissue-specific T_1 relaxation time [23.29]. Combined with the spatial encoding scheme of an imaging sequence it is also termed the spin-echo sequence. Initially introduced for imaging in 1983, it is still used today for T_1w imaging. Besides the already discussed tissue-specific parameters PD, T_1 , and T_2 , there is another imaging-relevant parameter, the magnetic susceptibility χ , which indicates whether the external magnetic field is increased (paramagnetic or ferromagnetic behavior) or decreased (diamagnetic behavior).

With this, the protons within a given tissue experience an effective magnetic field according to

$$B_{0(\text{eff})} = (1 + \chi)B_0.$$

The Larmor frequency scales with this effective magnetic field. Biological tissue is diamagnetic in general, although differences on a scale of 10^{-6} [23.30] are considered small. For slice selection, these small differences are usually negligible. For spatial encoding, the

variations of the magnetic susceptibility within the spatial dimensions of a voxel will cause different resonance frequencies, resulting in faster fading of the MR signal. This faster fading is characterized by the time constant T_2^* , given by

$$\frac{1}{T_2^*} = \frac{1}{T_2} + \gamma \Delta B,$$

with γ being the gyromagnetic ratio of $2.675 \times 10^8 \text{ T}^{-1} \text{ s}^{-1}$ for the proton, and ΔB representing the magnetic field gradient caused by the difference in magnetic susceptibility. The resulting spatial distribution of different resonance frequencies is spatially fixed and constant in time. This allows the dephasing to be reversed using a so-called RF refocusing pulse. A spin-echo sequence has a 90° RF excitation pulse and also a 180° RF refocusing pulse. With this 180° RF refocusing pulse, the faster component of the transverse nuclear magnetization will be placed behind the slower component, and in the process of catching up, a spin echo is formed, which is acquired in the presence of a frequency-encoding magnetic field gradient.

Several repetitions with different phase-encoding steps are necessary to obtain enough information to reconstruct an image. The time between repetitions is called the repetition time (TR). The time between excitation and data acquisition is called the echo time (TE) (Fig. 23.7). A long repetition time (3–9 s) will suppress any influence of different T_1 relaxation times. If additionally a short echo time is selected (≤ 20 ms), dif-

Fig. 23.7 Sequence diagram for a spin-echo sequence, illustrating the repetition time (TR) and echo time (TE)

ferences in T_2 relaxation times will be suppressed as well. Such a protocol is called proton density weighting (PDw), as primarily the number of protons per voxel will be responsible for the amplitude of the MR signal. Selecting the same repetition time but using a longer echo time will lead to a T_2 -weighted (T_2w) protocol. With short echo times and relatively short repetition times (300–800 ms), T_1 -weighted (T_1w) images will be acquired. The above parameters are suggested in view

of the relaxation times within biological tissues (Table 23.1). The matrix size in the direction of phase encoding usually dictates the number of necessary repetitions and with this the overall measurement time. For a T_1 -weighted protocol, a measurement time shorter than 5 min should be possible. As mentioned above, the excitation is a result of introducing energy into the spin system. The T_1 relaxation time is a function of how fast the spin system can release this energy to the environ-

Table 23.1 MR relaxation times for different tissues

Region		T_1 relaxation time (ms)			T_2 relaxation time (ms)
		1.5 T	1.0 T	0.2 T	
Brain	Gray matter (GM)	921	813	495	101
	White matter (WM)	787	683	390	92
	Cerebrospinal fluid (CSF)	3000	2500	1200	1500
	Edema	1090	975	627	113
	Meningioma	979	871	549	103
	Glioma	957	931	832	111
Liver	Normal tissue	493	423	229	43
	Tumor tissue	905	857	692	84
Spleen	Normal tissue	782	683	400	62
Pancreas	Normal tissue	513	455	283	
	Tumor tissue	1448	1235	658	
Kidney	Normal tissue	652	589	395	58
	Tumor tissue	907	864	713	83
Muscle	Normal tissue	868	732	372	47
	Tumor tissue	1083	946	554	87

ment, the surrounding tissue. Aqueous solutions such as cerebrospinal fluid show long T_1 relaxation time and appear hypointense (dark) on T_1 -weighted images. Mass lesions such as tumors often not only show displacement of normal anatomy but usually involve edema, documented by hypointense (dark) appearance on T_1 -weighted images. With a few exceptions, tissues with long T_1 relaxation times usually also demonstrate long T_2 relaxation times, as a consequence of intramolecular dipole–dipole interactions within the rapidly tumbling water molecules. For this reason, pathologic tissue usually shows up as hyperintense (bright) on T_2 -weighted images. The signal amplitude that later defines the brightness of the according pixel is given by

$$S \sim \frac{dM_{x,y}}{dt} \sim M_0 \left(1 - e^{-T_R/T_1}\right) e^{-T_E/T_2},$$

where M_0 represents the maximum possible longitudinal nuclear magnetization M_z that can be achieved within the given voxel. M_z is converted to transverse nuclear magnetization $M_{x,y}$ using a 90° RF excitation pulse. $M_{x,y}$ rotates with the Larmor frequency, inducing a signal in an adjacent receiver coil.

Diagnostic confidence has been increased with the introduction of T_1 -shortening paramagnetic contrast agents [23.31–33]. Inflammatory lesions taking up contrast agents usually show up as very hyperintense (bright) on T_1 -weighted images.

23.3.3 The Multi-Echo Spin-Echo Sequence

Images with different echo times are needed to calculate the average T_2 relaxation time within a voxel. Those images can be acquired with a single sequence containing

multiple RF refocusing pulses. On viewing such images, it becomes obvious that image contrast is only slightly changing, especially for images acquired with late echoes. This observation led to the idea of acquiring another k -space line rather than producing another image. This concept will potentially significantly reduce the measurement time (Fig. 23.8).

Such a sequence has been introduced with the acronym *rapid acquisition with relaxation enhancement* (RARE) [23.34]. The image quality at the time of first introduction was rather moderate, and the method lacked attention. Seven years later, *Melki and Mulhern* were searching for a fast T_2 -localizer and *rediscovered* the multi-echo spin-echo approach [23.35]. Likely based on progress in technology, implementation of the *localizer* revealed images with impressive quality. The surviving acronyms for the sequences that evolved out of this approach are *fast spin echo* (FSE), and *turbo spin echo* (TSE).

The advantage of this method is a significant reduction in measurement time, where the reduction is proportional to the number of echoes utilized, the so-called *echo train length* (ETL). A disadvantage should be expected due to the fact that each Fourier line has a different *weighting*. Theoretically this could lead to imaging artifacts and image misinterpretation [23.36]. In practice, the potential shortening of measurement time is not fully exploited but rather used to improve the contrast by selecting longer repetition times and increasing the spatial resolution. Both measures would prolong the measurement time, where the prolongation is now compensated by using the multi-echo approach. This leads to a significant improvement for PD- and T_2 -weighted imaging and overcompensates the above-

Fig. 23.8 Sequence diagram for a multi-echo spin-echo sequence [turbo spin echo (TSE), fast spin echo (FSE)]

mentioned potential disadvantages of the multi-echo approach. Today PD- and T_2 -weighted imaging are solely done using FSE and TSE sequences.

23.3.4 The Gradient Echo Sequence

Omitting the 180° RF refocusing pulse leads to the generation of an *echo* by using bipolar gradient switching in conjunction with frequency encoding (Fig. 23.6). This suggested the acronym gradient-echo sequence (GRE). Different vendors use different acronyms for this generic approach, such as *fast low-angle shot* (FLASH) [23.37], *fast field echo* (FFE)-T1 or *spoiled gradient recalled acquired steady state* (SPGR). Without the use of a 180° RF refocusing pulse, the signal decay no longer follows solely the intramolecular spin-spin interaction characterized by the T_2 relaxation time, but is now also a function of local magnetic field inhomogeneities. The latter are partly introduced by the patient themselves due to differences in magnetic susceptibility of neighboring tissue. The *faster* signal decay as a consequence of all these dephasing mechanisms is characterized by the relaxation time T_2^* . It is customary in gradient-echo imaging to optimize the signal ampli-

tude by using a low-angle excitation instead of a 90° excitation pulse. The signal response in relation to the excitation angle α in any given tissue follows

$$S \sim M_{x,y} = M_0 \frac{(1 - e^{-T_R/T_1})}{1 - \cos \alpha e^{-T_R/T_1}} e^{-T_E/T_2^*} \sin \alpha .$$

GREs are used whenever short repetition times are desired. GREs are used for fast imaging and/or wherever T_2^* sensitivity is desired. As an example, GREs are applied for imaging of the beating heart (Fig. 23.9). Phase encoding is not limited to spatial encoding of the second dimension within an imaging plane, but can also be used to further *partition* a slice, in this case called a volume. This approach is called 3-D imaging. The only disadvantage is that, for every phase-encoding step in the direction of slice selection, all phase-encoding steps within the imaging plane have to be repeated. To stay within clinically practical measurement times (≤ 12 min), only gradient-echo approaches with short repetition times were suitable in the past. Gradient-echo sequences are the framework for all MR angiography methods (Fig. 23.10).

The T_2^* sensitivity is very helpful in identifying hemorrhagic lesions and is currently fully exploited

Fig. 23.9 Representation of a single timeframe of an image of a beating heart. Measurement time was 9.28 s with temporal resolution of 43 ms (four-chamber view, myocardial infarction; courtesy of the PLA 306 Hospital, Beijing, PR China)

Fig. 23.10 Axial view of the intracranial vasculature generated without use of a contrast agent. The contrast is solely based on unsaturated blood flowing into the imaging volume while acquiring the data [time-of-flight MR angiography (ToF-MRA)]. Measurement time was 5.5 min

in *susceptibility-weighted imaging* (SWI) [23.38]. The change in oxygen concentration within the blood vasculature of active brain regions is correlated with alteration of the magnetic susceptibility and is used in *blood oxygenation-dependent imaging* (BOLD) to visualize active brain regions. As this allows the function of the brain to be documented, it is also called *functional MRI* (fMRI) [23.39, 40]. In conjunction with intravenous injection of paramagnetic contrast agents, the correlated changes in magnetic susceptibility as a marker for the passage of the contrast agent can be used to trace and document perfusion deficits when using T_2^* -sensitive protocols [23.41, 42]. One further feature of gradient-echo sequences is worth mentioning. This feature is important for diagnosis of benign or malignant abdominal mass lesions. Protons of hydrogen atoms within lipids have a resonance frequency that is about 3.5 ppm lower than the resonance frequency of protons contained in hydrogen atoms within freely moving water molecules. This is due to the differences in the electronic environment (oxygen versus carbon). This will cause slower rotation of the transverse nuclear magnetization within lipids as compared with water, a phenomenon called *chemical shift*. In spin-

echo imaging, the 180° RF refocusing pulse places the faster component of the rotating transverse nuclear magnetization behind the slower component, and at the time the echo reaches its maximum, both transverse nuclear magnetizations are in phase again and only the image shift in the direction of spatial encoding will remain. In GRE imaging there is no RF refocusing pulse, and depending on the echo time, there will be a situation where the transverse nuclear magnetization within lipids will be in *opposed-phase* with the transverse nuclear magnetization within water, whereas at a later echo they will be *in-phase* again. In the *antiphase* case the net signal will be zero for a voxel, with fat and water showing approximately identical transverse nuclear magnetizations. The corresponding pixel will show up dark due to the signal void. As fat-containing mass lesions are usually benign, this can be used to differentiate benign adenomas from malignant metastases [23.43].

23.3.5 The Sequence Family

The subjective impression is that SE, GRE, and the multi-echo concepts of FSE or TSE are the most im-

portant imaging sequences for current routine clinical imaging. In any case, all existing imaging sequences can be characterized as belonging to either the SE or the GRE group [23.44], with different types of hybrids. Worth mentioning is the possibility of manipulating the longitudinal or transverse nuclear magnetization prior to or within an imaging sequence. A classic example is the inversion of the longitudinal nuclear magnetization prior to starting the imaging sequence. Such inversion allows the signal of a tissue with a specific T_1 relaxation time to be nulled. Tissue is only able to emit a signal if longitudinal nuclear magnetization is available at the time of excitation. The RF excitation pulse will convert the longitudinal nuclear magnetization to transverse nuclear magnetization which rotates with the Larmor frequency, inducing an MR signal in a coil adjacent to the object to be imaged. Following inversion, the inverted longitudinal nuclear magnetization will approach the parallel alignment with the main magnetic field within a time given by the T_1 relaxation time of the tissue. There is a point in time at which the longitudinal magnetization will be zero, occurring at the point of transition between antiparallel to parallel alignment. If the excitation pulse is placed at that point in time, that tissue with a specific T_1 relaxation time will not be excited. Lipids have a relatively short T_1 relaxation time. On selecting a short time period between inversion and excitation pulse, e.g., 150 ms, the signal from lipids will be suppressed. The time between inversion and excitation pulse is called the inversion time T_I . As a 150 ms inversion time was considered short at the time, the acronym short-tau inversion recovery (STIR) was established [23.45]. At the other end of the scale of relaxation times is the relative long time of freely moveable water molecules. If a long inversion time is selected (e.g., 2.5 s), the signal from fluid is suppressed, leading to the acronym *fluid-attenuated inversion recovery* (FLAIR) [23.46]. Such a protocol is helpful to identify benign cystic lesions and to identify periventricular lesions that might otherwise remain unnoticed in the presence of adjacent bright signal from cerebrospinal fluid. The recovery of longitudinal nuclear magnetization following inversion follows

$$M_z = M_0 \left(1 - 2e^{-T_I/T_1} + 2e^{-(T_R - T_E/2)/T_1} - e^{-T_R/T_1} \right).$$

A further important application is the preparation of the transverse nuclear magnetization in *diffusion-weighted imaging* (DWI). In the presence of diffusion, a bipolar

magnetic field gradient amplitude will lead to a dephasing, resulting in a signal void [23.47]. The effect on the signal can be characterized by the so-called b -value

$$b = \gamma^2 G_{DW}^2 \delta^2 \left(\Delta - \frac{\delta}{3} \right),$$

with G_{DW} being the amplitude of the diffusion-weighting magnetic field gradient, δ represents the duration of the magnetic field gradient, and Δ indicates the temporal distance between the two gradient lobes. In routine clinical imaging, b -values of up to 1000 s/mm² are customary.

The signal is as follows

$$S \sim e^{-bD},$$

with D being the *apparent diffusion coefficient* (ADC). As the diffusion is a tensor, *diffusion tensor imaging* (DTI) will enable the measurement of the preferred diffusional direction [23.48] with an according graphical representation [23.49]. The preferred diffusional direction of water molecules seems to be parallel to nerve sheets. The diffusional directivity of these water molecules indirectly allows the display of nerve fiber tracts.

23.3.6 MRI Spectroscopy

Different nuclei have different Larmor frequencies, and identical nuclei have different Larmor frequencies depending on their electronic environment. This phenomenon is exploited in MR spectroscopy (MRS) to measure the levels of different metabolites in body tissues. The shift in Larmor frequency as a function of the electronic environment is usually described in parts per million (ppm) with respect to a reference frequency (usually free water); for example, the resonance frequencies of hydrogen nuclei in amino acids such as *N*-acetyl-aspartate (NAA) found in neurons are shifted by 2 ppm relative to the spectral line of free water. Fourier transformation following data acquisition without a readout magnetic field gradient will lead immediately to a display of spectral lines, with the amplitudes of individual lines representing the concentration of the underlying metabolites. MRI spectroscopy enables chemical analysis of tissue without biopsy, although the number of detectable chemicals is rather limited. To achieve spatial resolution in MRI spectroscopy a dual echo can be applied, for example, a 90° RF excitation pulse and two 180° RF refocusing pulses applied in the presence of magnetic field gradients that

Fig. 23.11 (a) Proton MRI spectroscopy of a healthy prostate. (b) Proton MRI spectroscopy of a prostate carcinoma (courtesy of the University Hospital Mannheim)

are perpendicular to each other. The final signal will come out of the voxel represented by the intersection of the three orthogonal slices. The currently achievable voxel size is about 2–8 ml (for proton spectroscopy).

Besides proton spectroscopy, phosphorus spectroscopy should be mentioned. In this case, phosphorus is utilized as the signal-emitting nucleus.

Proton spectroscopy is mainly applied to the brain, whereas phosphorus spectroscopy is utilized to study muscles, as phosphorus allows detection of energy

metabolism. In confirming the diagnosis of a prostate carcinoma, proton spectroscopy demonstrates a lowering of the citrate peak and an increase of the choline peak as compared with a normal prostate. Citrate is produced by prostate tissue. Prostate carcinomas consume citrate, and the intracellular content of citrate will be lowered. Choline is part of the cell membrane and in malignant prostate lesions, in conjunction with cell proliferation, the choline level is increased (Fig. 23.11).

23.4 MRI – Safety-Relevant Aspects

For the time period 1995–2005, the Food and Drug Administration (FDA) database shows 389 entries where humans have been harmed in conjunction with MRI. Ten percent of these accidents were related to ferromagnetic objects attracted by the strong magnetic field. Seventy percentage were related to burns caused by RF interactions. The most important safety issues can be summarized as follows:

- Attractive forces by the strong magnetic field
- Significant torques within the strong magnetic field
- RF interaction with the patient's body
- RF interaction with active or passive implants
- Peripheral nerve stimulation (PNS) caused by the rapid switching of the large magnetic field gradient amplitudes
- Acoustic noise due to the Lorentz forces on conductors with electric currents flowing in the presence of a strong magnetic field

- Cold gases in case of loss of superconductivity (quenching)
- Nephrogenic systemic fibrosis (NSF), in conjunction with Gd-containing contrast agents.

23.4.1 Attraction and Torque Due to Strong Magnetic Fields

Attractive forces on ferromagnetic objects are a consequence of a change in energy as a function of location

$$F = \nabla U.$$

The potential energy is the product of the magnetic moment and the applied external magnetic field

$$U = \frac{1}{2} \mathbf{M} \mathbf{B}_0; \quad \mathbf{M} = \frac{\chi}{\mu_0} V \mathbf{B}_0.$$

The magnetic moment M of a ferromagnetic object is the product of its volume V , its magnetic susceptibility χ , and the magnetic field strength at the current

location B_0 . Simplified to the view of a single dimension, the attractive force on a ferromagnetic object is proportional to the magnetic field gradient at the current location and the magnetic field strength at that location

$$F_z = \frac{\chi V}{\mu_0} B_0 \frac{\partial B_0}{\partial z}.$$

For a pair of scissors with weight of 0.4 lb, the horizontal maximum pulling force for a 1.5 T system is approximately 20 times higher than the gravitational force, comparable to a weight of 8 lb. The critical aspect is the discontinuity of the force, which is rapidly changing as a function of location. The maximum attractive force is experienced in the vicinity of the patient bore, whereas the attractive force at the isocenter of the magnet is zero. A ferromagnetic geometrically asymmetric object will have a strong tendency to align its long axis parallel to the direction of the magnetic field. Ferromagnetic scissors will always fly into the magnet with their pointed tip entering first. The torque is proportional to the square of the magnetic field strength and is at its maximum at the isocenter of the magnet.

23.4.2 RF Interaction with the Patient's Body

The power spectrum of the electromagnetic radiation used in MRI is too weak to lead to ionization, molecular destruction, or generation of free-radical molecules. The applied energy will only lead to warming of the patient. The power W absorbed by the patient is proportional to the square of the resonance frequency of the system ω_0 (which is proportional to the magnetic field strength used) and proportional to the square of the magnetic component B_1 of the electromagnetic radiation used. The power W absorbed by the patient is proportional to the fifth power of the circumference b of the patient and inversely proportional to the internal conductivity ρ

$$W \approx \frac{\omega_0^2 B_1^2 b^5}{\rho}.$$

Acceptable levels of power deposition into a patient are documented in the international guideline on safety requirements in MR (IEC 60601-2-33). The metabolic rate of the average patient is about 90 W. This is the energy per unit time needed to maintain body temperature. IEC 60601-2-33 allows power deposition of up to 2 W/kg without medical supervision. With a body weight of 176 lb this means 160 W for the duration of the MR measurement. Doubling of the power deposition (4 W/kg) is allowed under medical supervision,

and this corresponds to the metabolic rate of a marathon runner. All vendors have to ensure that their systems will refuse to start a measurement where the patient will be exposed to an energy level beyond these guidelines.

Another known potential complication is examination of patients with permanent cosmetics and tattoos. Studies have reported transient, sometimes painful skin irritation, cutaneous swelling or heating sensations, in about 1.5% of these cases. If the patient communicates painful sensations, the MR measurement can and will be aborted by the technologist running the system. There are no reports that any of this damage is of permanent nature. Swelling, reddening or blistering have so far been temporary.

23.4.3 Interaction with Active and Passive Implants

In general, all active and passive implants are of concern [23.50]. The static magnetic field strength will dislodge ferromagnetic implants, if the torque and attraction exceed the holding force. This is reported to be the case for older pacemakers, older cochlear implants, and older aneurysm clips. Orthopedic implants are in general nonferromagnetic and do not present a contraindication to MRI study. The static magnetic field is also potentially harmful to the function of active implants such as older pacemakers. The industry involved in design and production of implants is, of course, aware of the importance of MR for today's diagnostic radiology, and is anxious to introduce MR-compatible products. There are already a number of publications dealing with the MR compatibility of some pacemaker designs and neurostimulators. Especially for active implants, the concern is not limited to the static magnetic field. The coupling of the applied RF should not be underestimated. The potential coupling of the RF with, e.g., pacemaker leads, remains a risk, even if this is considered a potentially low risk.

23.4.4 Interaction Based on Changes in Magnetic Field Gradients

Peripheral Nerve Stimulation (PNS)

The law of induction indicates that a temporal change in the magnetic field strength will induce a voltage

$$\oint_{\partial S} E dl = -\frac{\partial}{\partial t} \iint_S B dA.$$

The human body can present conductive loops, despite its poor conduction. Depending on the orientation

of the switched magnetic field gradients, the amplitudes and switching times of today's gradient systems are capable of inducing voltages and currents within the human body that mimic biochemical voltages usually applied to control muscle contraction. Vendors are obliged to provide measures to prevent painful patient experience during MR examination. Such a measure is called a *stimulation monitor*.

Noise Exposure During MR Examination

A conductor carrying a current in the presence of a magnetic field will experience a mechanical force, known as the Lorentz force after the Dutch physicist Hendrik Antoon Lorentz who described it. The current of up to 600 A flowing through a gradient coil located within a 1.5 T system will experience a force on a single wire on the order of 2.827 kN equivalent to a weight of 635 lb. That force will remain active for the duration of the magnetic field gradient being switched on and will vanish at the time the magnetic field gradient is switched off. The duration of a slice selection gradient is about 2.5 ms. The change from force to no force is 200 Hz, which generates a tone between a musical *a* (220 Hz) and a *g* (196 Hz). For a frequency bandwidth of 195 Hz/voxel, the duration of the frequency-encoding gradient will be 5.128 ms. The switching rate of the gradient would be 97.5 Hz, which is close to a *G* (98 Hz). Unfortunately the switching of magnetic field gradients is rarely sinusoidal, and different tasks require different switching frequencies, so the final noise is rarely considered harmonic. It is required that the noise level for a patient remain below 99 dB(A) with or without ear-protective devices. No vendor is allowed to introduce a scanner to the market capable of generating more than 140 dB(A).

23.4.5 Safety Issues in Conjunction with Loss of Superconductivity (Quenching)

The loss of superconductivity of the current-carrying coil of the main magnet is called a *quench*. Currently commercially available and relatively easy to handle superconducting wires are composed of niobium, NiTi, or Nb₃Sn and are placed in about 1800 l of liquid helium at a temperature of -269°C in order to be and remain superconductive. Loss of superconductivity is rarely sporadic (usually occurring during ramping up of the main magnetic field) but may be provoked by pressing the emergency button (the quench button). As the superconductive magnet becomes resistive, the energy stored

in the now decaying magnetic field will be transferred to the liquid-helium bath, resulting in vaporization of helium. After five seconds the pressure build-up in the cryostat will be high enough to activate the blowout disc, as planned in such circumstances. The evaporating coolant is directed out of the building through a *quench pipe*. Within 1 min the coil currents have reached a zero value and the magnetic field is zero. After 2 min, the vaporization of the helium is down to a negligible level. The temperature of the evaporating helium is close to -269°C , and the surrounding environment will be cooled accordingly. There remains the danger of burns when touching covers that were affected by the evaporating helium. In case of a blockage of the quench pipes, the helium gas will be forced into the scanner room and there will be the danger of displacement of oxygen. In that case, the scanner room is to be evacuated. Measures are to be planned and exercised to prepare for such an emergency. There are no known cases where humans have been harmed in case of a quench.

23.4.6 Gadolinium-Containing Contrast Agents and NSF

In contrast to iodine-containing contrast media, gadolinium-containing MR contrast agents were long considered non-nephrotoxic with very low risk of adverse reactions or other complications. The enthusiasm even triggered suggestions to use gadolinium-containing contrast agents in conjunction with x-ray imaging [23.51, 52]. In 2006, a group of scientists at AKH in Vienna published a study of nine end-stage renal disease patients who underwent MR angiography using a gadolinium chelate (gadolinium-diethylenetriaminepentaacetic acid bis-methylamide (Gd-DTPA-BMA)) over a period of approximately 2 years, of whom five patients developed nephrogenic fibrosing dermopathy (NFD), also called nephrogenic systemic fibrosis (NSF) [23.53, 54]. Nephrogenic systemic fibrosis involves fibrosis of skin, joints, eyes, and internal organs. The disease was first published in 2000 and has a mortality rate of 5%. Since 2006 it has been suspected and later confirmed that the disease is associated with exposure to gadolinium. Currently there are approximately 500 reported cases that can be linked to administration of Gd-containing contrast agents. Considering the approximate number of 21.5 million MR studies with MR contrast agents per year, the number of cases seems to be rather low. Nevertheless, the reported risk of Gd-containing contrast agents has to be acknowledged.

23.5 MRI – Pictures of the Future

For the past 20 years it has frequently been predicted that developments within the area of magnetic resonance and magnetic resonance imaging would reach maturity, and further progress would be slow and only incremental – similar to the development in x-ray computed tomography. So far we are still waiting for those times.

23.5.1 Magnetic Field Strength

About two-thirds of the market is currently working with magnetic field strength of 1.5 T. High-field systems with magnetic field strength of 3.0 T have a market share of about 20%, and the remaining devices are low-field (≤ 0.5 T) MR systems. Magnets with even higher magnetic field strength (7 T) are still limited to academic institutions, but there are already 37 installations known. It should also be mentioned that there are at least two 9.4 T installations and two 11.7 T systems, and of course this refers to magnets with a bore diameter suitable to study humans.

23.5.2 RF Technology

The signal gain when working with higher magnetic field strength (Fig. 23.12) is supplemental and supports measures to reduce measurement times in conjunction with the utilization of spatial information from distributed coil matrices. Otherwise, measurement of spatial information would involve time-consuming additional phase-encoding steps. The ability to use coil matrices for *parallel imaging* is a function of the number of coils and coil profiles. Modern commercial MR systems are currently prepared to serve coils of up to 128 independent receiver channels, and the first prototype coils are available. Direct digitization within the transmitter chain as well as the receiver chain has just been introduced into commercial systems and will enable future application developments.

23.5.3 Application Development

For development of new MR applications the following fields deserve special attention:

Fig. 23.12 Image of a T_2 -weighted axial cut of the brain of a patient with multiple sclerosis, performed on a 7.0 T system (courtesy of the University Hospitals of New York)

- Motion correction, registration, and mapping of anatomic structures
- Mapping and visualization of different (additional) information (parametric imaging)
- Perfusion measurements without contrast agents (arterial spin labeling (ASL))
- MR angiography without contrast agents (native)
- Time-resolved contrast-enhanced MR angiography (time-resolved imaging with interleaved stochastic trajectories (TWIST) and time-resolved imaging of contrast kinetics (TRICKS))
- MR data acquisition in the presence of a continuously moving patient table (TimCT – total imaging matrix with continuous table movement, MDS – move during scan).

In general it can be stated that the current standardization and automatization is streamlining the workflow, resulting in shorter times during which patient has to remain in the scanner, while simultaneously ensuring reproducible results; e.g., for brain studies, slice orientations and coverage are recommended in specific guidelines. In modern current systems a three-dimensional localizer is usually initiated automatically after the patient has been positioned. Current modern systems are immediately able to adjust the next imaging protocol with respect to angulation and requested coverage in automatically analyzing the 3-D-localizer for anatomical structures and landmarks. Similar approaches are currently already available to automatically position required slices and volumes for studying the knee of a patient. For imaging the heart, current modern systems utilize the localizer to select the recommended short-axis or long-axis views automatically. In imaging the spine, a single mouse click can indicate to the system which intervertebral disc space is to be evaluated, and the system will automatically adjust the imaging plane to have the same angulation as the disc.

The number of selected elements of a surface coil will affect the coverage as well as the image noise. If more coil elements are selected than needed, the image noise is unnecessarily increased. If the number of coil elements selected is too low, the coverage necessary for a diagnosis may be insufficient. Current modern systems automatically select or deselect required or unnecessary coil elements.

23.5.4 Hybrid Systems

Following the success of positron emission tomography–computed tomography (PET-CT), the idea of a MR-PET

system as a hybrid technology has also surfaced within the MR community. The introduction of an MR-PET system as a routine clinical modality is only a question of time. MR-PET combines complementary modalities. The superior ability of MR to display soft tissue contrast is combined with the unique feature of PET to provide biochemical information.

Potential scientific applications are:

- Simultaneous activation studies by PET and fMRI (real-time information correlation)
- PET combination with diffusion tensor imaging (DTI), three dimensional chemical shift imaging (3-D-CSI), and high-resolution structural MRI
- Dynamics of distribution of pharmaceutical products within anatomical structures
- Development and evaluation of cell therapy (stem-cell migration tracking and differentiation).

Potential clinical applications are:

- Differential diagnosis of recurrent tumors versus radiation necrosis
- Early diagnosis of Alzheimer’s disease – improved prognosis due to potentially earlier medication
- Staging, restaging, and therapy monitoring in pediatric oncology
- Whole-body tumor staging and therapy monitoring
- Myocardial infarction: differentiation between hibernation and stunning.

There are a few challenges to be mastered in integrating a PET system within a MR system, starting with the development of a MR-compatible PET detector

Fig. 23.13 Schematic sketch of a fully integrated MR-PET system

(Fig. 23.13). Beneficial for this development has been the early introduction of MR systems with a larger bore diameter.

23.5.5 Theranostics – Therapy Under Image Guidance

Another future possibility is the combination of an imaging modality such as MR with a therapy system such as radiation therapy. Patient position and immobilization in radiation therapy has been and still is a challenge. As of today there are no established solutions to treat cancer close to organs that permanently move due to breathing. The inherent and inevitable internal organ motion causes the tumor to be in different positions when treatment occurs, and it is impossible to determine where the dose is actually going. In the near future, continuous imaging – with MRI – will allow guidance of the focus of radiation therapy to ensure effective treatment.

As is obvious from the above, physicists and engineers as well as physicians and technologists will face an extremely exciting and interesting future in view of all these potential new and novel developments.

Magnetic Particle Imaging

24. Magnetic Particle Imaging

Jörn Borgert, Bernhard Gleich, Thorsten M. Buzug

Magnetic particle imaging (MPI) is a quantitative imaging method that uses the nonlinear re-magnetization behavior of ferromagnetic nanoparticles to determine their local concentration. Superparamagnetic iron oxide (SPIO) particles represent such suitable nanoparticles. SPIOs are readily available as clinically approved contrast agents for liver examinations in magnetic resonance imaging (MRI), and usually administered into the bloodstream via intravenous injection. Starting from a brief overview of the history of the discovery and ongoing research on MPI in Sect. 24.2, Sect. 24.3 introduces the technical concepts of MPI. Section 24.4 will explain how to get to actual images, once data has been acquired. Section 24.5 describes alternative system designs next to traditional, symmetric geometries commonly used for medical imaging devices, and other uses of magnetic particle imaging technology, like spectroscopy. A possible combination of MPI with magnetic resonance tomography (MRT) for hybrid MPI/MRT systems is introduced in Sect. 24.5.3. Finally, Sect. 24.6 discusses potential applications for MPI and how it can provide clinical benefits, covering cardiovascular applications in Sect. 24.6.1, oncology applications in Sect. 24.6.2, cell labeling/tracking in Sect. 24.6.3, and

concluding with applications that require new, modified tracer materials in Sect. 24.6.4.

In comparison to established methods for medical imaging, MPI is relatively new. It was invented in 2001 by *Gleich* and *Weizenecker*, who

first reported on the new method in 2005 [24.1]. The method provides a unique combination of features.

24.1 Introduction

MPI measurement is inherently quantitative; its signal, therefore, is a direct measure of how much material is

present at a certain location. The correlation of the image signal with material concentration is known from

methods in nuclear medicine, like PET and SPECT. This similarity is the reason why contrast agents are called *tracer materials* in the MPI context.

Furthermore, MPI promises to deliver high spatial and temporal resolution. In contrast to MRI, its sampling scheme exhibits a tenfold higher voxel rate. This advantage can be exploited to deliver true real-time imaging.

MPI realizes *direct imaging* of the particles by measuring their magnetic properties. In this way, the sensitivity of MPI in detecting iron oxide can exceed that of MRI by several orders of magnitude, since only

indirect particle imaging is realized in MRI, i. e. particles are detected by measuring their influence on the relaxation behavior of protons.

Since MPI uses various static and oscillating magnetic fields to perform its measurement, it is completely free of ionizing radiation, as used for computed tomography (CT) and x-ray based methods, and of sources of radioactivity, as used for positron emission tomography (PET) and single photon emission computed tomography (SPECT). As far as is known today, no adverse or long-term effects on patients are expected from magnetic fields like those applied for MRI or MPI.

24.2 A Brief History of Magnetic Particle Imaging

Magnetic particle imaging in its original form was invented in 2001. After a first publication as a patent in [24.2], results of static 2-D measurements of undiluted Resovist were presented in [24.1]. After extending the imaging of phantoms filled with magnetic material to dynamic two-dimensional image acquisition in [24.3], dynamic three-dimensional image acquisition in vivo with clinically approved tracer concentration was demonstrated [24.4]. Also in 2009, *Goodwill* et al. demonstrated an alternative approach, using so-called narrowband magnetic particle imaging [24.5–7], which bears potential for more sensitive imaging, while the former efforts by *Gleich* and *Weizenecker* et al. were aiming at demonstrating MPI's capabilities in real-time image acquisition.

Parallel to experimental work, important theoretical assessments have been published to determine the potential of magnetic particle imaging. Starting in 2007, *Weizenecker* et al. published a simulation study that allowed the assessment of the image quality of a virtual MPI scanner by taking into account different particle characteristics and concentrations [24.8]. In 2009, *Knopp* et al. extended this assessment to different trajectories of a field free point and their influence on the image [24.9]. To demonstrate that other system topologies can increase the performance of the method, *Weizenecker* et al. presented an approach using a field-free line instead of a field-free point in [24.10]. Additionally, *Knopp* et al. provided the proof that the realization of a field-free line in actually feasible in [24.11].

Exploiting the flexibility of magnetic particle imaging in terms of unconventional imaging system geometries, *Sattel* et al. published first results on the deployment of a single-sided MPI scanner design in [24.12].

Also in 2008, *Biederer* et al. presented the design of a magnetic particle spectrometer [24.13], and results of its use for the analysis and characterization of magnetic nanoparticles [24.14]. Details on the magnetic particle spectrometry, as well as on single-sided MPI will be presented in more detail in Sect. 24.5.

As an example of other applications of MPI, the group of *Weaver* et al. uses MPI for temperature measurements. They laid out the technical grounds and presented another approach for a magnetic particle spectrometer [24.15–19] already in 2007. They investigated an extension of MPI to improve temperature measurement by comparing the relative intensity of several individual harmonics. Independently, *Moreland* et al. presented a cantilever torque magnetometer based approach to realize a selection field gradient strength of more than 100 T/m for ultra high resolution MPI for very small samples in [24.20].

In 2008, *Bohnert* et al. started reporting on the physiological compatibility of MPI [24.21, 22].

In the important area of research on particle optimization for MPI, first efforts have been reported by *Lüdtke-Buzug* et al. [24.23, 24], *Krishnan* et al. [24.25], as well as *Markov* et al. [24.26, 27].

First results on the use of MPI for medical applications were published by *Bulte* et al. in [24.28]. They assessed the use of MPI for stem cell tracking, as detailed in Sect. 24.6.3.

24.3 How Magnetic Particle Imaging Works

In order to get MPI to work, two basic components are needed. First, one has to find a way to get the particles to emit some kind of characteristic signal. To end up at a quantitative method, this signal should contain information about the amount of magnetic material. How this is done by MPI will be explained in Sect. 24.3.1. As a second component, one needs a way to tell where the signal comes from in relation to the object that is examined. This usually is called spatial encoding, and will be explained in Sect. 24.3.2. In addition to these two basic components, Sect. 24.3.3 (drive field) and Sect. 24.3.4 (focus field) introduce means to increase the performance of MPI with respect to acquisition speed and size of the field-of-view (FOV), the volume-of-interest that can be examined.

24.3.1 Signal Generation and Acquisition

One possible magnetic material suitable for MPI is iron oxide, usually available in the form of iron oxide based nanoparticles. A basic theory for describing the magnetization curve of small mono-domain particles is the Langevin theory, which is defined under the assumption that the particles are always in thermal equilibrium. The relation between the external magnetic field and the magnetization of the particle is not linear, but exhibits nonlinear parts, as shown in Fig. 24.1. The magnetization shows a sharp increase, as the external field increases from zero, and quickly goes into *saturation*. In thermal equilibrium, hysteresis effects are not present.

In its very basic form, MPI applies a time-dependent external magnetic field to periodically change the magnetization of the magnetic material using *send coils*. It *simultaneously* detects this change in magnetization by the induced voltage in *receive coils*. Assuming for a moment that the relation between the external field and the magnetization of the particle would be linear, the induced voltage would indeed resemble the amplitude progression of the external field. In the frequency domain, the sent signal as well as the received signal would show up as a single peak at the frequency used, which is called the *fundamental frequency*. However, as the relationship is nonlinear, higher frequency components, named harmonics, are added to the spectrum of the received signal, showing up as multiples of the fundamental frequency. The presence of these harmonics is an indication of the presence of magnetic material, and the whole set of harmonics represents the *MPI signal*.

The time-dependent external field that periodically changes the magnetization of the magnetic material is called the *modulation field*. Its frequency is usually in the range of several tens to over hundreds of kilohertz, with the first results published using a frequency of 25 kHz [24.1]. These frequencies are normally not detectable to the human ear and scanner operation is thus scarcely audible. Using higher frequencies can be beneficial, as the noise in the receiver electronics is in many cases dominated by $1/f$ behavior. On the contrary, certain physiological limitations apply for the exposure of human bodies to electromagnetic waves, one of those being energy deposition. It is proportional to the square of the field amplitude and frequency, thus posing limitations to the use of higher modulation field frequencies.

To be effective, the amplitude of the modulation field should be high enough to ensure that the change in magnetization goes well into the nonlinear areas, preferably nearly into saturation. The higher the amplitude, the more pronounced the higher harmonics in the received spectrum, and thus the MPI signal, will be. Technically feasible amplitudes are in the range of several mT/μ_0 up to about $20 \text{ mT}/\mu_0$.

Fig. 24.1 The relation between the external magnetic field (usually measured in A/m or mT/μ_0) and the magnetization of the particle. If the external field is small, the particles are not yet in saturation, and the magnetization shows a sharp increase. For larger external fields, the particle goes into saturation, and the magnetization hardly changes with the external field

To gain information on the exact amount of magnetic material, i. e. to make a *quantitative measurement*, it is sufficient to read the amplitude of one selected harmonic from the spectrum. Given a suitable calibration measurement with a well known amount of magnetic material, the amplitude of the selected harmonic in relation to its value during the calibration measurement will be proportional to the amount of iron. It is, of course, mandatory to keep all parameters, for example the field strength of the modulation field, constant between measurements.

24.3.2 Spatial Coding: Selection Field

Using a setup as outlined above, i. e. a modulation field with sufficient amplitude that penetrates the volume-of-interest, one can easily tell whether or not magnetic material is present. However, it is not possible to determine *where exactly* the magnetic material is and how much material is present at a certain location. What has been missing up to now is a way to determine the spatial distribution of the magnetic material.

This is accomplished by introducing a local interaction field, which is constructed in such a way that it ensures signal confinement, i. e. the limitation of the origin of MPI signal to a very small region. Figure 24.2 depicts a magnetic field realized by a set of coils or permanent magnets in Maxwell configuration. In the

Fig. 24.2 The magnetic field generated by a Maxwell configuration of opposing magnets or coils. Mathematically, the field is zero in exactly one point, the FFP (FFP). It should be noted that for the use of coils to realize the field configuration, the current has to run in opposite directions

context of MPI, this field is named *selection field*. When realized with coils, the currents in the coils simply have to run in opposite directions. When using permanent magnets, equal poles have to face each other. In contrast to the modulation field, which exhibits approximately the same field vector everywhere, the selection field exhibits field vectors that depend on the position. More so, the field contains one special location, named *field free point* (FFP), which is simply characterized by the field magnitude or field vector being zero. While veering away from this FFP, the field strength quickly rises to nonzero values. By choosing either high enough currents or powerful enough permanent magnets, the selection field can be constructed such that the particles' magnetization quickly approaches saturation as the distance to the FFP increases. In this case, the modulation field acting on the particles does not result in a sufficient change in magnetization, as depicted in Fig. 24.3. Consequently, almost no MPI signal will be measurable, and the respective spectrum will only show the fundamental frequency of the modulation field.

By moving the sample in relation to the FFP, i. e. sampling the volume-of-interest, and measuring the amount of higher harmonics at each sample point, the complete volume-of-interest can be examined. In this most simple realization of an MPI system, it is assumed that a signal only originates from particles that are within or very near the FFP and thus are not in saturation and can, therefore, react to the modulation field with a measurable change in magnetization. All other particles are silenced, as they are in saturation.

This relative movement can easily be realized in 3-D, allowing for the construction of a simple MPI scanner device. The first publication on MPI [24.1] shows two-dimensional images acquired this way, while recent work of *Goodwill* et al. [24.5–7] shows first three-dimensional images. The largest disadvantage of this method is its slowness. The relative movement between the sample and the field has to be realized mechanically. Thus the entire measurement process bears a lot of latency, either resulting in measurement times of several minutes for samples of very limited size or in very coarse spatial sampling of the object. As a result, these acquisition protocols will never be sufficient to perform in vivo measurements with satisfactory spatial and temporal resolution. This is especially true for living specimens or structures of interest that move rather fast, like for example vessels in the cardiovascular system.

Estimation of the Spatial Resolution of MPI

By sticking to the simple picture outlined above, an estimation of the spatial resolution can be given by inspection of the magnetization curve of magnetic material as depicted in Fig. 24.3. As mentioned above, un-magnetized material, either being in or near the FFP, can easily react to the external field, whereas material that is already in saturation, will not. The size of the area that enables reaction to the external field is usually given by the full width at half maximum (FWHM) of the derivative of the magnetization curve of the magnetic material. The magnetization curve is given by the Langevin theory [24.29] to be

$$M = M_0 L \left(\frac{HVM_s \mu_0}{k_B T} \right)$$

with $L(\alpha) = \coth(\alpha) - \frac{1}{\alpha}$ (24.1)

with M_0 being the saturation magnetization of the sample, H being the external field, V being the volume of the particle, M_s being the saturation magnetization of the particles' material, μ_0 being the magnetic permeability of the vacuum, k_B the Boltzmann constant, and T being the absolute temperature.

The value of M at the FWHM nicely corresponds to the value of the external field $H_{1/2}$, at which the magnetization reaches half its saturation magnetization $M_{1/2} = 1/2 \cdot M_0$. The value of the selection field has to become high enough to render the particle sufficiently saturated, i.e. outside the FWHM. The main characteristic of the selection field is its gradient strength, which is given by the change of field per unit length. This information can be used to relate the field value to a length, which can be correlated to a resolution, since two structures, or two samples of magnetic material, have to be apart at least that distance to be separable by their signal. Thus, the resolution becomes

$$R = 2 \frac{H_{1/2}}{G} \quad (24.2)$$

assuming a constant gradient of the selection field G , which is justified for small distances.

By inspection of (24.1), it becomes apparent that the resolution of MPI depends on the volume V of the particles that constitute the magnetic material. The larger the volume, the steeper the magnetization curve and the better the resolution (Fig. 24.3). In particle analysis it is common to assume spherical particles and characterize them by their diameter. Using the relationship $V = 1/6\pi d^3$, the volume V can be translated into a diameter. Figure 24.4 shows isolines of the same resolution plotted over a two-dimensional parameter space

Fig. 24.3 Magnetization curves for particles with different core diameter sizes. The larger the diameter of the magnetic core, the steeper the magnetization curve

spanned by the core diameter of the particles and the selection field gradient strength. It can be seen that resolutions of the order of 1 mm, which are necessary for many medical applications, either require very high selection field gradients or very large particle core diameters. Taking a selection field gradient strength of $3 \text{ T}/(\text{m} \cdot \mu_0)$, which is feasible from the technical point of view, therefore, requires particles with a core diameter of 30 nm or more.

Estimation of the Detection Limit of MPI

In order to determine the detection limit of MPI, the signal that is being generated by a definite test sample of magnetic material must be compared to a noise signal. The lowest possible noise level is called *patient noise*, as it is assumed that the instrumentation itself no longer contributes to the total noise and all that is left is produced by the patient or the phantom alone (assuming a conductive object). Furthermore, from magnetic resonance imaging, it is known that a magnetization can be measured with equal sensitivity regardless of the frequency of the magnetization change [24.30]. When a magnetization oscillates faster, the induced voltage in a recording coil increases, so that the signal strength rises with the frequency. On the other hand, the thermal current fluctuations due to the conductivity of the patient are frequency-independent. For higher frequencies, these frequency-independent currents generate a higher noise voltage in the recording coil, as

Fig. 24.4 Isolines of the same spatial resolution plotted over the selection field gradient strength in $T/(m \cdot \mu_0)$ and core diameter of the magnetic nanoparticles in nm. The numbers in the small boxes give the resolution in mm for the denoted isoline

faster fluctuations induce more voltage. In total, the signal to noise ratio stays (almost) constant, independent of the chosen frequency of oscillation.

To determine the signal and the noise, a square-shaped single loop coil of 10 cm edge length is being used. Placing such a coil on the chest of an adult human yields an increase of the resistance of the coil of approximately 100 mΩ at 20 MHz, equating to a noise voltage of $40 \text{ pV}/\sqrt{\text{Hz}}$ root mean square, calculated from [24.31]

$$U_n = \sqrt{4k_B T R \Delta f} \tag{24.3}$$

To determine the signal strength, it is assumed that in a finite volume V , a given total magnetization oscillates with a given frequency, leading to

$$U_{\text{ind}}(t) = s\omega M V \cos(\omega t) \tag{24.4}$$

with ω being the angular frequency, M being the magnetization, V being the volume of the object, and $s = 10^{-6} \text{ T/A}$ being the sensitivity of the test coil. The product of the magnetization M and the volume V is a dipole moment, the value of which is 92 fA m^2 , assuming that the test sample consists of 1 pg of iron oxide

available in a finite volume. Using (24.4), this results in a signal strength of 12 pV peak and about 8 pV root mean square.

To ensure the detectability of the signal, the arbitrary choice is made that the signal must be five times higher than the noise, which would be 200 pV. This corresponds to 25 pg of iron in a given, finite volume. This derivation assumes a frequency bandwidth of 1 Hz, which corresponds to a measurement time of 1 s. Prolonging the measurement to, for example, 625 s – a little more than 10 min – leads to a frequency bandwidth of $1/625$ and, following (24.3), to a decrease in the noise by a factor of 25. This, in turn, would also lower the demand on the signal by a factor of 25 and thus lower the detection limit to 1 pg iron oxide.

To convert these amounts of material into concentrations, usually expressed by the number of iron atoms per liter of solvent/dispersion, the magnetic material contained in one voxel must be considered. As the molar mass of iron oxide (Fe_3O_4) is 231.5 g/mol, 1 g of iron oxide contains about 4.32 mmol iron oxide and thus about 13 mmol iron, and therefore, 1 pg of iron oxide contains about 13 fmol iron. Assuming that this number of iron atoms is contained in a voxel of 1 mm^3 , the

concentration in this voxel is about 13 fmol(Fe)/mm^3 , corresponding to a detectable concentration of about 13 nmol(Fe)/l .

Starting from 25 pg instead of 1 pg, implying a measurement time of 1 s instead of about 10 min, yields a detection limit of 324 nmol(Fe)/l for a voxel size of 1 mm^3 . Resovist has an undiluted concentration of 500 mmol(Fe)/l . Applied according to prescription, 1.4 ml of undiluted Resovist are administered for one examination during an MRI scan. Assuming an adult human's blood volume to be 6l, this results in a steady state concentration of $116 \text{ } \mu\text{mol(Fe)/l}$, about 360 times the detection limit for a voxel size of 1 mm^3 and a measurement time of 1 s.

All these estimations imply that MPI is being used as a single voxel method, i. e. the concentration of the magnetic material is measured one voxel at a time. Using more effective coding schemes, as exemplified in the next section, can also increase the detection limit.

24.3.3 Performance Upgrade I: Drive Field

The basic MPI setup described in Sect. 24.3.2 relies on the mechanical movement of the sample in relation to the FFP, while the MPI signal is generated by a modulation field. This results in a very slow image acquisition. In order to speed up the whole process, one can switch to electromagnetic fields in order to move the FFP instead of the sample. This was introduced first for two-dimensional imaging in [24.3] and finally for three-dimensional imaging in [24.4].

Taking into account the special shape of the selection field as depicted in Fig. 24.2, it becomes evident that the direction of the magnetization of a sample of magnetic material will change, once the FFP passes the sample. However, such a change also occurs when the FFP passes the material at some distance, and so the change of magnetization depends on the relative position and movement of the object with respect to the FFP. As this change in magnetization is picked up by a recording coil in the very same manner as a magnetization change induced by the modulation field, i. e. by the change in magnetization leading to the induction of a voltage in the recording coils, the explicit use of the modulation field can be omitted. This new, FFP-moving field is called a *drive field* and it replaces the modulation field. As a matter of fact, a modulation field of sufficient field strength already moves the FFP considerably and thus can be considered to act as a drive field. Already in the first publication about MPI, the use of a drive field was proposed as a means to improve the performance of

the imaging method. Later realizations of MPI, for example single-sided MPI as presented in [24.32], directly use a drive field for moving the FFP and changing the magnetization of the magnetic material, never even considering the slow and intricate mechanical movement of the sample.

By comparing the gradient field strength of the selection field at the FFP and the field strength limits of the drive fields as reported in [24.1], one can conclude that the spatial range that is being covered by this electromagnetic FFP movement cannot exceed more than some tens of millimeters

$$\begin{aligned} 2 \frac{20 \text{ mT}/\mu_0}{3 \text{ T}/(\text{m} \cdot \mu_0)} &= 13.3 \text{ mm} \\ \text{and } 2 \frac{20 \text{ mT}/\mu_0}{1.5 \text{ T}/(\text{m} \cdot \mu_0)} &= 26.7 \text{ mm} . \end{aligned} \quad (24.5)$$

This kind of limitation for the volume-of-interest is clearly not acceptable for medical applications in general diagnostics, where it is expected to have systems cover a complete crosssection of a human body, like for example, magnetic resonance imaging (MRI) or computed tomography (CT). Due to the very nature of the Maxwell equations it is not possible to realize a gradient field with an FFP that has the same field gradient in all three spatial directions. In accordance with Fig. 24.2, a gradient field imposed by a Maxwell configuration of coils or by permanent magnets will have a high gradient in the lateral direction, e.g. $3 \text{ T}/(\text{m} \cdot \mu_0)$, to go with the example given above, and henceforward a gradient of $1.5 \text{ T}/(\text{m} \cdot \mu_0)$ in the axial directions. As a result, the volume-of-interest in the high gradient direction is only half of that in the other two directions, leading to non-cubic voxels and MPI being intrinsically nonisotropic. In other words, based on the Maxwell configuration, the spatial resolution, which depends on the gradient strength of the selection field, is twice as high in the high gradient direction compared to the two low gradient directions.

24.3.4 Performance Upgrade II: Focus Field

In order to overcome the limitation to small volumes-of-interest, one could simply increase the field strength of the drive field. While this is technically challenging to begin with, applying fields of several hundred mT at frequencies of 25 kHz or even more might lead to energy deposition values (specific absorption rate – SAR) exceeding regulatory limits, and to peripheral nerve stimulation (PNS). For the time being it is sufficient to realize that an increase in amplitude has to be compen-

sated by a decrease in frequency. So, in addition to the drive field, which is limited to about $20 \text{ mT}/\mu_0$, another set of orthogonal, homogeneous fields, called *focus fields*, is added. For a focus field strength in the area of $300 \text{ mT}/\mu_0$, the coverage of the field of view would be 20 cm for the high gradient direction of a selection field of $3 \text{ T}/(\text{m} \cdot \mu_0)$ and 40 cm for the low gradient direction. The frequency of the focus field, however, is low compared to the drive field, i. e. in the area of a few hertz, such that the field will not be used to move the FFP over the whole field of view for imaging, which thus would result in a rather poor performance. In fact, the movement of the FFP will be produced by a combination of the focus and the drive field. This can be done in *multistation mode*, where the focus field is used to move the whole volume that is covered by the drive field, named *cuboid*, to a certain position within the field-of-view and keep it there, while the drive field does its job. This results in covering the volume-of-interest

by cuboids, which constitute small 3-D images in their own right, which are then combined into a complete 3-D data set. Another option is to combine a simultaneous variation of both, the focus and the drive field, to produce a continuous movement of the FFP, called *continuous mode*. In contrast to the multistation mode, the resulting image is rather one complete image that covers the volume-of-interest than a combination of small cuboids.

In addition to just covering the complete volume-of-interest, the focus field can also be used to realize a different, but very effective imaging mode. If, for example, the area of interest consists of only a sub-volume of the complete field-of-view, and, moreover, this subvolume is not rectangular, but rather a part of an irregular 3-D shape, then the focus field can be used to image only those cuboids containing the respective subvolume. As a result, much less space needs to be scanned, leading to an effective image acquisition.

24.4 From Data to Images – Reconstruction

The role of reconstruction is to turn abstract data that are acquired during a scan into something meaningful to the user. Most often, the result is an ordered set of gray values, triplets or even multiplets, that describe color and other features of the object or phantom. These values are mapped to a rectangular grid and constitute a volume in the case of a 3-D scan or an image in the case of a 2-D scan.

When MPI is performed in its simplest form as described in Sect. 24.3, reconstruction is a simple task. The location of each single voxel is recorded together with information about the concentration, which can easily be transferred into a volume or image, depending whether the trajectory of the FFP is two-dimensional or three-dimensional in space.

If MPI is realized with performance and effectiveness in mind, i. e. by deploying a drive field to move the FFP over the object or phantom, then a dedicated reconstruction algorithm becomes a necessity. The main reason is that while moving the FFP over a distribution of magnetic material, the receiving coils do not only receive signal from the material that is directly located at the FFP, but also from material that is located within a certain distance to the FFP.

To understand this, a close examination of the two-dimensional case is sufficient. Recapitulating the geometry of the selection field from Fig. 24.2, one can easily observe that the field direction of the selection

field changes, depending on whether the observed position is above or below a horizontal line through the FFP. Furthermore, limiting the observation to the z -component of the field suggests that this z -component switches from a negative value (aligned against the axis) to a positive value (aligned along the axis). So, changing position from above to below is in effect the same as having an FFP that moves from below to above. The result of the FFP passing by is that the z -component of the magnetization aligns itself along the external field, given that this field is strong enough, and the magnetization itself changes, as depicted in Fig. 24.5. This change in magnetization is, of course, detected by the z -recording coil and constitutes an MPI signal. It is obvious that such a signal can result from every piece of magnetic material that is located on a line perpendicular to the path of the FFP, albeit the signal will be lower the further away the material is from the path. Effectively, the signal recorded while the FFP is moving originates from all magnetic material on that line.

To incorporate this into the reconstruction, one must rely on the fact that MPI imaging can be described by an approximate linear imaging model. This implies that the impact of an amount of magnetic material on the resulting MPI signal is proportional to its concentration, e.g. twice the amount leads to twice the signal. This is justified, as long as the fields generated by the magnetization change in the sample can be considered small in

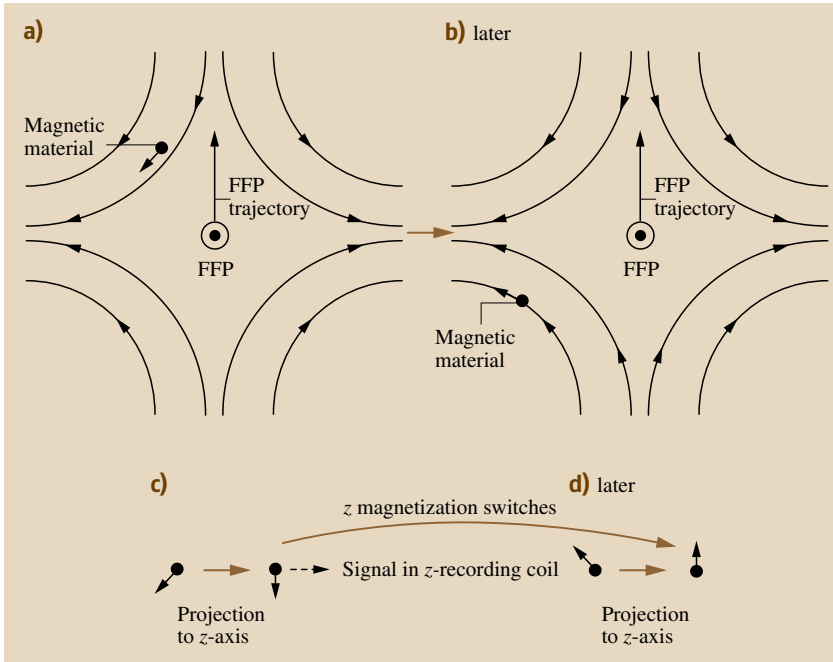

Fig. 24.5 Signal generation by magnetic material that is not directly on the path of the FFP. As the FFP passes the magnetic material, its direction of magnetization changes (a to b). Hence, limiting the observation to the z -component of the magnetization, one can conclude that the magnetization switches (c to d), even for particles that are not directly on the trajectory of the FFP

comparison to the external fields. In that sense, knowing the impact of a single deposit of magnetic material on the signal and taking into account that this impact is proportional to the concentration, the total signal is a superposition of all signals from small deposits of magnetic material located along the line, weighted with the respective local concentration.

Taking this one step further, the knowledge about the signal caused by small deposits of magnetic material everywhere within the volume-of-interest, or at least at points on a suitable grid covering the volume, can be used to calculate the concentration values on this grid for an unknown object. The reason is that the signal caused by the object must be the same as that of the small deposits weighted with the local concentration of the unknown object. This information is collected during a calibration step using a small *delta-like* probe that is positioned at suitable locations within the whole volume-of-interest. The data that is collected during one individual measurement n of N total measurements results in a time series of K samples over time, recorded during the motion of the FFP along a certain trajectory. Recording at all N positions leads to $K \times N$ values that constitute a matrix \mathbf{G}_{kn} with dimensions $K \times N$, which is usually named the *system function* or *system matrix*.

An object can be represented by the unknown concentrations C_n at all N positions, and the measurement

of that unknown object, which is a time series U_k of K values, can be expressed as an expansion in terms of the entries of the system function G_{kn} as

$$U_k^{\text{meas}} = \sum_n G_{kn} \cdot C_n. \quad (24.6)$$

If C_n can be determined in such a way that the right-hand side of (24.3) resembles the measured values, then the unknown distribution of concentrations C_n has been reconstructed. Technically, this is done by minimizing the following terms with respect to C_n in a least squares sense:

$$\left\| U_k^{\text{meas}} - \sum_n G_{kn} \cdot C_n \right\|^2 = \min \quad (24.7)$$

which is equivalent to solving the set of linear equations $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ by inversion of \mathbf{A} to $\mathbf{x} = \mathbf{A}^{-1} \cdot \mathbf{b}$.

Depending on the number of reconstructed voxels, the mathematical problem described by (24.6) and (24.7) can be over-determined, as G_{kn} bears more information than necessary due to the large amount of measurements gathered during the acquisition of the system function. Usually, G_{kn} is not a square matrix, thus inversion is not straightforward. Being over-determined, this kind of problem has more than one solution, and it is not ensured that a numerical procedure converges towards the one solution that resembles the distribution of C_n , as G_{kn} contains systematical

errors and noise. To ensure convergence towards the desired solution, i. e. to stabilize the numerical problem, Tikhonov regularization can be applied by adding an additional term [24.33]

$$\left\| U_k^{\text{meas}} - \sum_n G_{kn} \cdot C_n \right\|^2 \pm \lambda^2 \left\| \sum_n \Gamma_{kn} \cdot C_n \right\|^2 = \min . \quad (24.8)$$

The usual choice for Γ is the identity matrix, which leads to a solution that is minimal in the sense of the

sum norm of C_n , and thus, in this case corresponds to a solution with the smallest possible overall concentration. Tikhonov regularization and especially the choice of the identity matrix for Γ is sometimes interpreted in a *Bayesian* sense, arguing that it ensures convergence towards the most probable solution, given that the errors contained in G_{kn} and the actual measurement process obey certain statistics. To actually perform the minimization of (24.8), and thus the reconstruction, several algorithms such as the conjugate gradient and algebraic reconstruction techniques have been proposed and analyzed, for example in [24.4, 9].

24.5 Beyond General Purpose Systems – Special Geometry

Strictly speaking, MPI relies only on the existence and controlled movement of an FFP or line, generated by a suitable selection field. How the other fields, i. e. drive and focus fields, are generated and applied, does not depend on the selection field geometry. Due to this flexibility, it is possible to build and deploy MPI systems that differ from the traditional geometry of medical imaging devices, which is a kind of tube, ring, or bore that surrounds the patient. One such realization, a single-sided MPI scanner, is described in Sect. 24.5.1.

For special purposes, e.g. tracer material research, it can be efficient to realize systems that only measure the signal from a bulk probe, without any spatial resolution. Section 24.5.2 introduces such a system for the concept of magnetic particle spectroscopy, using special devices

that do not bear any means for spatial encoding, but only record the spectrum of a tracer, i. e. its MPI signal. Finally, Sect. 24.5.3 explains that MPI systems can also be built in ways that allow for magnetic resonance imaging, thus representing intrinsic or hybrid combinations of MPI and MRI.

24.5.1 Unlimited Access – Single Sided Magnetic Particle Imaging

If one of the coils that generate the selection field is considerably smaller than the other, it fits concentrically into the other one. As a consequence, an FFP is generated on both sides of the assembly on the coil axis, as depicted in Fig. 24.6, and currents in the two transmit coils run in opposite directions. If all other components of the system can be assembled on one side of the plane defined by the selection field coils, a single-sided MPI scanner can be realized, which allows for improved patient access. No interfering structure elements are present on one side of the scanner, and the volume-of-interest is defined by the region around one of the FFPs. As the other field free point is located within the device itself, i. e. at the other side of the coil assembly, it must be assured that no magnetic material resides within the respective vicinity of its location.

Sattel et al. demonstrated first experimental results of such a single-sided MPI device using various phantoms in [24.12]. The performance with respect to resolution and contrast is lower than that of a symmetric geometry. However, the results of this new concept are promising, as the key benefit of this design lies in the flexibility. There is no limitation to patient size,

Fig. 24.6 A concept for a single-sided MPI scanner [24.12]. The setup generates two FFPs, one in front of the device, which will reside within the patient, and one within the device, which cannot be used for imaging

because the coil assembly can be applied similarly to an ultrasound transducer. However, due to limitations in penetration depth of several centimeters for practical scanner dimensions and selection field gradient strength, only tissues and structures near the patient surface are within reach for high resolution imaging.

24.5.2 Zero-Dimensional Imaging – Magnetic Particle Spectroscopy

As introduced in Sect. 24.2, *Biederer et al.* and *Weaver et al.* in [24.14, 16, 17], reported on a magnetic particle spectrometer (MPS) that can be used to measure the nonlinear magnetization of particles and can thus be of use for tracer research. As an example, characteristics of the particles such as the size of the iron core and magnetization behavior can be calculated from spectrometer measurements. Results like these enable more realistic simulations of the imaging performance in magnetic particle imaging and can lead to an improvement in the process chain of the development of new magnetic nanoparticles [24.25].

Essentially, an MPS consists of a magnetic particle imaging device without facilities for FFP movement (zero-dimensional movement). In a shielded chamber, the probe to be measured is subjected to an oscillating magnetic field. A measurement of the decay of the harmonics in the magnetization response can be correlated to the nonlinearity of the magnetization curve given by (24.1). This, to stay within the above example, can be used to estimate the particle core size [24.23].

24.5.3 MPI/MRI Hybrid Systems

By design, MPI measures the spatial distribution of a magnetic material. In order to interpret this information in a medical/diagnostic context, it is required to provide an image of the underlying anatomy for reference. A simple solution would be the subsequent acquisition of the anatomical information with a suitable other modality, e.g. CT or MRI, and a retrospective fusion of that information with the MPI data. However, it seems theoretically feasible to realize an intrinsic combination of MPI with MRI, constituting a hybrid MPI/MRI system, that would provide both the distribution of the magnetic material and the anatomical reference information.

Both MPI and MRI use strong magnetic fields for spatial encoding and transmission and both are equipped to receive and record weak signals. The field geometries and frequencies are not identical, but with

moderate technical effort, components for hybrid use of MPI and MRI can be realized. One example would be an MPI selection field generated by electromagnets. Reversing the current in one of the coils turns the selection field into a homogeneous field suitable for polarizing protons, with a possible field strength of up to 0.5 T for resistive coils and 1 T or more for superconducting coils.

However, the realization of hybrid MPI/MRI systems bears a lot of challenges, e.g. sufficient homogeneity for MRI (B_0), the lack of a transmit system for the RF-field (B_1), and a receive system for frequencies as high as several 10 MHz. One potential solution, or rather a work-around, would be the deployment of field cycling or prepolarized MRI systems [24.34].

In such a system, a strong, but not necessarily highly homogeneous field is applied for several hundred milliseconds in order to polarize the protons. After this polarizing pulse, the field is reduced to a much lower value to apply the RF pulses. In MRI, the field homogeneity needs to be roughly $10 \mu\text{T}/\mu_0$, which would be 10 ppm for 1 T, but a moderate 1% for 1 mT, which seems feasible for realization by a selection field coil pair. For such a low field, the drive field coils can be used to apply the RF pulse. The Larmor frequency of protons at 0.6 mT is 25 kHz, which is the drive field frequency of current experimental MPI demonstrators [24.1]. The drive field amplitudes possible in an MPI scanner do exceed the necessary amplitudes for MRI by far. To ensure that the MRI signals are above a certain frequency, e.g. 1 MHz, the drive field strength is ramped up to several tens of mT/ μ_0 . Higher frequencies result in a higher signal to noise ratio (SNR).

Such a prepolarized MRI approach may be sufficient to create an anatomical reference for many applications of MPI. For some applications, it may even be superior to conventional MRI. For patients with implants, for example, prepolarized MRI would allow near implant imaging as long as the implant is not ferromagnetic [24.35]. The MPI/MRI combination would be able to operate at even lower frequencies than the 2 MHz used in [24.35]. Therefore, it would be possible to image inside metallic stents for the assessment of re-stenosis. Furthermore, field cycling allows for contrasts that are not accessible to conventional MRI. *Conolly et al.* demonstrated that the protein content of tissue can be imaged using field dependent T_1 relaxation times [24.36]. Other favorable applications exist in the area of tissue conductivity and multinuclei imaging.

24.6 Putting MPI to Use – Applications

As MPI is a relatively new imaging technique, the proof of clinical benefit for virtually all medical applications is still pending. In the following sections, some of those applications in medical diagnostics will be exemplified. In addition to applications in diagnostics, MPI can also offer advantages in image-guided treatment and in the field of hyperthermia.

24.6.1 Cardiovascular

As commercially available tracer materials like Resovist are formulated for intravenous injection, MPI is well suited for applications that can use tracer materials flowing in the blood stream for a certain amount of time. One important application falling into this category is the diagnosis and assessment of cardiovascular disease (CVD). One of the most important aspects of CVD is coronary artery disease (CAD), which is responsible for conditions that are known as myocardial infarction, with unstable or stable angina, commonly referred to as a *heart attack*. All of these conditions are caused by either a partial closure (stenosis) or a complete obstruction (occlusion) of vessels that supply the heart muscle with blood. If the blood supply is not restored in time, the result is necrosis of heart muscle tissue.

In acute cases, a direct referral to the catheter laboratory (cathlab) for catheterization and angiography, with the option of immediate treatment by angioplasty and stenting, is still the most common course of action. However, in subacute cases, a clear trend to replace this invasive step with noninvasive methods can be noticed, using, for example, contrast enhanced computed tomography or CT-angiography (CTA) [24.37]. Consequently, only those patients showing a treatable stenosis or obstruction in the CT exam will be subjected to an intervention.

In certain cases, these diagnostic steps are preceded by electrocardiography (ECG) to investigate heart function and determine the levels of certain enzymes released during heart muscle cell death. These can include creatine phosphokinase (CPK) and, more recently, troponin [24.38]. In some countries, the diagnostic process is combined with a cardiac stress test using single photon emission computed tomography (SPECT [24.39]) and sometimes positron emission tomography (PET [24.40, 41]) to determine myocardial perfusion. Areas of decreased perfusion can indicate the presence of a stenosis or occlusion as its cause, increas-

ing the diagnostic evidence and indicating the need for intervention.

This whole set of information, from in vitro tests and imaging, can be used to develop a comprehensive picture of the state of the heart of the patient. It might be presumed that MPI is able to provide a large part of this information, thus simplifying the use of different modalities and the need for a complex workflow to the use of one modality.

As shown for a preclinical setting in [24.4], tracer materials in clinically approved concentrations can provide functional information while flowing through various parts of the heart and the cardiovascular system of a mouse. In a next step, it has to be proven that these results can be translated to the clinical case. During a potential examination, the tracer material would be followed while entering the right atrium via the vena cava. Subsequently, it would be possible to assess the wall motion of the right ventricle and the dynamics of the ejection into the pulmonary vessel system. In a similar manner, left ventricle wall motion and ejection dynamics would complete the collection of functional information. Additionally, the coronary blood supply would be imaged, while the tracer material passes through the coronary arteries, providing information similar to an angiography performed in the cathlab or in CT. In contrast to the traditional two-dimensional cathlab, the information delivered by MPI would be three-dimensional, preventing foreshortening and overlapping. Additionally, MPI works without using any harmful ionizing radiation, which would be beneficial in those cases that require long examination times. Immediately after imaging the coronary blood supply, the myocardial vitality can be assessed by measuring myocardial perfusion. Similarly to cardiac stress tests using SPECT or PET, this information will be correlated to potential stenosis or occlusions in the coronaries.

As a result, most of the information used today to form a comprehensive overview of the state of the cardiovascular system might be acquired with MPI in a single session while following the flow of a tracer material through the cardiovascular system. Consequently, MPI has the potential to reduce required hospital resources, to simplify workflow, and to add to the benefit of the patient, who has to undergo fewer and shorter examinations.

It still has to be analyzed whether MPI can also be used to determine the atherosclerotic plaque burden. If suitable amounts of iron oxide would accumulate in

the plaque, it could be quantified by MPI. Widespread research effort is being put into the understanding of such accumulation processes already [24.42]. The coatings of the tracer materials determine the physiological properties and the pharmacokinetics of the tracer. It may be possible that improved tracer materials with custom-made coatings to support the accumulation process will lead to vast improvements in the detectability of atherosclerotic plaque by MPI.

24.6.2 Oncology, Sentinel Lymph Node Imaging and Hyperthermia

New studies suggest the importance of measuring microvascularization for tumor staging [24.43]. Particularly during therapy, monitoring of the blood supply can indicate the success of the therapy by showing a decrease in the blood supply. After intravenous injection, MPI might be used to image this local blood supply with high spatial accuracy by measuring the amount of blood per tissue. Additionally, it is investigated whether iron oxide based tracer materials can migrate into tumor tissue or lymph nodes after systemic injection [24.44]. Given that sufficient amounts of iron oxide can be accumulated in these tissues, MPI could be used to perform quantitative measurements.

One specific application is the quantitative measurement of magnetic materials accumulated in sentinel lymph nodes. These are lymph nodes near a tumor, which collect the interstitial fluid of the tumor. If a tumor forms metastases, it is likely that malign cells migrate via the lymph nodes and show up first in the sentinel lymph nodes. During surgery, usually all lymph nodes in the vicinity of the tumor are resected. However, if only the sentinel lymph nodes are resected and those present themselves as negative, i. e. no trace of metastases can be found, it is an option to refrain from further lymph node resections. As a consequence, the extent of the surgery is greatly reduced, and the trauma for the patient would be limited, leading to increased quality of life. Today, this procedure is most common in the treatment of mamma carcinoma. To locate the sentinel lymph nodes, tracer materials containing blue dye and radioactive colloids are injected into the mamma carcinoma and its circumference. The distribution of the fluid is imaged by a gamma camera prior to surgery in order to identify the sentinel lymph nodes. During surgery, a Geiger counter and visual identification of the blue dye are used to find the marked lymph nodes.

It might be assumed that an MPI scanner can image the distribution of magnetic material used instead of the

radioactive colloids in the current procedure. Instead of using a whole body scanner, however, it would be more appealing to have smaller, more versatile devices, like the single-sided MPI devices presented in Sect. 24.5.1. Such small and mobile devices may also be suitable for other applications during surgery.

The use of magnetic materials and oscillating electromagnetic fields for hyperthermia is currently under investigation as an experimental therapy for certain tumor types, especially those that are inaccessible to surgery [24.45]. To perform the therapy, the magnetic material is injected into the tumor and expected to stay within the tumor or near the tumor during heating, thus minimizing the damage to surrounding tissue. In hyperthermia, MPI can provide an additional benefit by locally confining the heat generation. If a selection field is present, the heat generation will be focused on the area that is covered by the field free point. This can be helpful in those cases where the magnetic material has leaked out of the tumor or if important tissue is very near the area that should be heated. In those cases, MPI might also monitor the distribution of the magnetic material and the power dissipation to optimize the treatment and outcome.

24.6.3 Cell Labeling and Tracking

To date, cell labeling is a very exciting and broad field of research. Although many different cell types can be labeled, only two examples, red blood cells and stem cells, will be treated in detail.

Red Blood Cell Labeling

Blood is composed of almost 50% red blood cells (RBCs). Similar to labeling them with radioactive tracer materials for SPECT imaging, RBCs can also be labeled with nanoparticles made from iron oxide. *Magnani et al.* [24.26, 46] described techniques of cell loading for murine and human RBCs. These cells, as with the radioactive case, might be used as a blood pool agent with ultra long blood retention time to highlight vessel structures and blood filled compartments. This might support certain interesting applications that rely on the determination of the local blood volume, e.g. hemangiomas [24.47] and monitoring and detection of bleeding, for example in the intestine [24.48, 49].

Due to the high abundance of RBCs, it seems possible to realize a sufficient tracer concentration of 1 mmol/l in the blood, enabling fast MPI applications like those described for cardiovascular applications. In oncology, monitoring the tumor blood volume by

repeated measurements might lead to interesting opportunities for therapy monitoring during radiation- and chemotherapy.

In cardiovascular applications, blood pool agents might allow for therapy response monitoring with MPI, e.g. after angioplasty as a treatment of a stenoses it could be used to monitor the restoration of the blood supply. In neurovascular applications, loaded RBCs might be used for monitoring stroke patients for bleeding in intensive care and during therapy. Bleeding can be a life-threatening condition, especially during lyses therapy. MPI could be used to detect small amounts of labeled blood, which flows into regions that have previously been free from blood, thus indicating unwanted bleeding.

Stem Cell Labeling

Among cell labeling applications, stem cell labeling is the most challenging, as it is most desirable to localize only a few cells, or ultimately single cells. Given that stem cells can be loaded with up to 10 pg of iron and taking into account a detection limit of 1 pg for MPI, as previously stated, a single stem cell should be detectable with MPI. First explorative studies to use currently available, experimental MPI systems to detect loaded stem cells have been published in [24.28]. To date, the successful detection of very small quantities is limited by the sensitivity of current experimental devices. *Goodwill* et al. report on efforts to maximize sensitivity [24.5–7]. Additionally, available tracer materials only perform at about 1 to 3% of the theoretical optimum [24.1]. An improved tracer material would also improve sensitivity and promote various applications, including the area of stem cell tracking.

24.6.4 Gastrointestinal and Lung Imaging

In contrast to the applications in the previous sections, which use tracer materials administered into the blood stream, some applications, that would make use of other pharmaceutical forms of magnetic material, seem possible and interesting. In the area of gastrointestinal imaging, it might be an option to provide the magnetic material as ready to swallow. This would facilitate the imaging of the colon, an area where patient discomfort (need for bowel cleansing) hinders widespread adoption of colonoscopy for cancer detection, and diagnosis of small bowel diseases, like Crohn's disease or ileus and bowel obstructions. In the latter area, MPI would compete with contrast enhanced x-ray or CT, but would allow for extended acquisition times and potentially better diagnosis, due to its lack of harmful radiation and insensitivity to motion.

Another area for the application of new pharmaceutical forms of magnetic material would be the assessment of lung ventilation. Combining ventilation and perfusion exams to provide comprehensive information about the status of the lung might provide new and improved diagnostic information similar to the correlation of coronary to myocardial perfusion for cardiovascular diagnosis, as presented in Sect. 24.6.1. It can be estimated that the inhalation of the iron content of 1 ml of Resovist, which is equivalent to an iron amount of 28 mg, as an aerosol would be sufficient to perform imaging with acquisition times in the area of a few seconds. This would be considerably faster than today's method of choice, SPECT imaging, which takes several minutes to produce an image.

25. MR-Guided Interventions and Surgery

Andreas Melzer, Erwin Immel, Rachel Toomey, Fabiola Fernandez-Gutierrez

This chapter covers the use of magnetic resonance imaging (MRI) for guidance of interventional and operative procedures, including the basics on MRI systems design, integration, workflow principles, device visualization, and instrument positioning and tracking. MRI provides soft tissue contrast superior to x-ray technology and ultrasound. The contrast can be weighted towards water or fat, and images acquired in arbitrary, multiplanar orientations and three-dimensional (3-D) volumes. MRI's flow and temperature sensitivity alongside its lack of ionizing radiation and nephrotoxic iodinated contrast agents renders it a suitable imaging technique for vascular and percutaneous interventions. Intraoperative MR imaging allows detection of hidden structures of the tissue volume in the surgical field. Although MRI has been applied since the beginning of the 1990s during operation and intervention, the lack of approved MRI-compatible tools and the technical hurdles in integrating MRI systems into clinical applications have hampered its wider distribution. These problems can be overcome through appropriate technical solutions and the use of suitable nonmagnetic and nonconductive materials.

Image-guided interventional procedures can be divided into *percutaneous interventions* performed by rigid cannulae or probes, i.e., for core biopsy, drainage, and local drug injection, and *vascular interventions* performed by flexible guide wires and catheters inserted through access ports into the arterial or venous system. Ultrasound, x-ray fluoroscopy, and computed tomography (CT) are the main imaging modalities

for percutaneous interventions. Vascular interventional radiology is usually performed in the catheterization laboratory (cathlab). Apart from the occasional use of ultrasound for initial vascular access, conventional x-ray angiography and fluoroscopy systems are applied for guiding catheters and guide wires, and monitoring delivery of implants such as stents, filters or valves. The obtained pictures are a projection

of all the objects in the x-ray beam path and provide only limited spatial orientation. Soft tissue and vascular structures become indirectly visible only after administration of allergenic and nephrotoxic iodine contrast agents or carbon dioxide gas. The increasing cooperation between interventional cardiologists and cardiac surgeons has led to the integration of angiographic equipment into operating rooms. Intraoperative imaging generates novel hybrid procedures of interventional, catheter-based methods combined with conventional or minimally invasive techniques. As the depiction of bony structures and bleeding is the domain of computer tomography (CT), it is successfully used in trauma surgery [25.1]. MRI provides soft tissue contrast superior to x-ray technology and ultrasound (US). The contrast can be weighted towards water

or fat, and images acquired in arbitrary, multiplanar orientations and 3-D volumes. MRI's high flow and temperature sensitivity alongside the lack of ionizing radiation and nephrotoxic iodinated contrast agents renders MRI a suitable imaging technique for vascular and percutaneous interventions and surgical techniques. Although MRI has been applied since the beginning of the 1990s during operation and intervention, the lack of approved MRI-compatible tools and the technical hurdles in integrating MRI systems into clinical applications have hampered its wider distribution. These problems can be overcome through appropriate technical solutions. In the following sections a selection of interventional MR techniques and examples of instruments, devices, and MR systems are described and discussed.

25.1 MRI Basics

Magnetic resonance imaging is based on a strong static magnetic field (0.2–7 T), alternating magnetic fields (gradients), and a high-frequency (HF) system with transmitting and receiving coils (antennae). The image acquisition uses resonance effects with the magnetic moment of hydrogen nuclei (proton spins) bound in water, lipid, and protein molecules [25.2]. The spins can have two energy states (parallel and antiparallel). Due to the interaction of the magnetic moment of the nuclei with the static magnetic field B_0 , the spins precess to the B_0 orientation at a certain frequency. This precession frequency of protons is described by the Larmor equation (25.1) and is about 42 MHz in 1 T, about 64 MHz in 1.5 T, and about 128 MHz in 3 T.

$$\omega_0 = \gamma \cdot B_0, \quad (25.1)$$

where ω_0 is the Larmor frequency and γ is the gyromagnetic ratio.

The state of the parallel and antiparallel protons in a magnetic field B_0 is excited by the absorption of electromagnetic pulse energy from the transmitting coil (high-frequency/radio-frequency (HF/RF) system), resulting in alignment of the spins at a certain angle (90°). This excitation can only be achieved if, before the excitation, the total magnetization is in the B_0 direction and the frequency of excitation is equal to the Larmor frequency (25.1).

The flip angle (FA) describes the deflection of the spins caused by a RF pulse in a simplified mechanistic model. Following the RF pulse, the protons return back to the original state (relaxation) and send a signal

at the same frequency, which is detected by the receiving coil. The gradient coils change the static magnetic field to generate spatial information due to the resulting differences in the resonance frequencies. Specific sequences of RF pulses and switching of the gradients in the millisecond range in combination with certain times of echo (TE) and times of repetition (TR) of the pulses yield the optimum signal strength for reception. Spin-echo (SE) and fast gradient echo (GRE) sequences can be distinguished. The image contrast can be weighted towards a water (T_2) or lipid (T_1) signal or with the options of suppressing either the water or the fat signal. As change of temperature changes the MR signals, this can be monitored during interventional procedures. There are numerous methods of MR thermometry applied, based on the temperature-sensitive processes of MR imaging, e.g., proton resonance frequency (PRF), the diffusion coefficient (D), T_1 and T_2 relaxation times, magnetization transfer, proton density, and experimental temperature-sensitive contrast agents [25.3]. After image processing, the MR signals are defined for each volume element, and the signal intensity is calculated. The MR signal is a mathematically complex quantity. A distinction is made between amplitude (magnitude of the signal = gray level) and the phase of the complex signal. Temperature deviations are calculated using the phase change for each voxel at different times. Temperature changes can be represented in milliseconds, for example, during thermal ablation by percutaneous laser probes (LITT) [25.4] or MRI-guided focused ultrasound (MRgFUS) [25.5].

25.2 MRI Image Guidance for Interventions and Surgery in Comparison with CT and Ultrasound

MRI provides reproducible cross-sectional images in variable orientation with variable soft tissue contrast. The high flow sensitivity, as well as the representation of static fluids and the visualization of pathological tissue alteration, answer a variety of diagnostic questions during interventional or surgical procedures. Although CT guidance is similar to the approach of intervention under MR guidance, comparison with ultrasound guidance is also considered. Ultrasound (US) and MRI provide for multiplanar display, whereas CT only enables axial and para-axial views. In contrast to MRI, ultrasound, however, requires direct acoustic coupling with the tissue via liquids or gels. In addition, a needle during puncture

is barely shown at full length. MR visualization of instruments in comparison with CT and ultrasound is of a different kind, since the signal originates from excited protons in the tissue itself, and not from attenuation, scattering or reflection of sound or ionizing radiation. An important requirement during interventional procedures is the need to map thermal destruction of tissue, which is only provided by MRI but not by CT or US. Disadvantages of MR guidance are the lack of space for access to the patient inside the magnet, the relatively low contrast and low spatial resolution of fast sequences, the high sensitivity to motion and material artifacts, and the difficult visualisation of instruments (Table 25.1).

Table 25.1 Comparison of imaging modalities for interventional guidance: x-ray fluoroscopy (FL), ultrasound (US), computed tomography (CT) und magnetic resonance imaging (MRI)

Characteristics	FL	US	CT	MRI
Ionizing radiation	–	++	--	+
Soft tissue contrast	--	o	+ KM	+++
Temporal resolution	+	(+)	++	(+)
Spatial resolution	–	o (+++) ¹	+	+++ ²
Instruments visualization	+	–	++	o
Usability, intraoperative	o	++	+	–
Interactive control, tracking automated image plane localization	–	–	–	++
Acquisition time	+	++	++	++
Artefacts	++	–	+	--
Real time imaging	(++) Radiation!	++	+	+
Reproducibility	–	--	+	+
Flow sensitivity	-- KM	++	-- KM	++
Temperature mapping	--	o	--	++
3-D data set	-- ³	+ ⁴	++	+++

¹ Depending on frequency: high resolution at high frequency at low penetration depth.

² High field strength and longer acquisition time increase spatial resolution.

³ CT analogue 3-D reconstruction of x-ray fluoroscopy can be achieved through rotation during imaging and reconstruction.

⁴ 3-D ultrasound requires spatially defined movements with reconstruction or 2-D arrays.

25.3 MR Systems Design and Setup for Interventions and Surgery

The geometry and field strength of MR systems are important to determine access to the patient and relevant for the achievable image quality. The implementation of operational processes and interventional MRI is limited due to the strong electromagnetic fields and physical limitations of access to the patient.

The following technical solutions are currently being promoted.

1. MRI installed in the operating room.
2. MRI movable on a rail system connecting two operating rooms.

Fig. 25.1a,b Open MRI. (a) 0.5 T General Electric (GE) Signa SP MRI and (b) 0.2 T Siemens Magnetom OPEN provided the first options for intraoperative and interventional MR imaging

Fig. 25.2a,b State-of-the-art intraoperative MRI. (a) BrainSuite, Brainlab, Munich, Germany; (b) MR surgical Suite General Electric and Maquet, Milwaukee

3. MRI adjacent to one or more operating rooms, installed and accessible for surgical control, interventional or diagnostic techniques. The patient table is moved via a floor-mounted rail system or via wheeled cradles.

MRI systems were first applied for operations and interventions in the mid 1990s, for example,

0.5 T vertical open-configuration MR (Fig. 25.1) [25.6]. Due to the high costs, technical problems, and the limited diagnostic capabilities, this system has been discontinued. Horizontal open MRI equipment with field of 0.2–0.6 T was evaluated for interventional percutaneous techniques and for development of tools and systems for experimental procedures.

Fig. 25.3 (a) nitinol guide wire in MRI. The MRI image shows only a minor artifact, but the conductivity can lead to heating, and electric arcing in the worse case (b) (after [25.7])

Fig. 25.4a,b Ceiling-mounted MR can be translocated between the surgical room (a) and cathlab (b) and can be used for diagnostic procedures while parked in the center

For applications in neurosurgery, the development of pivoting and linear movable operating tables successfully enabled transfer of the patient between operating room (OR) and MR [25.8]. Despite their relatively low field strength (0.2–0.6 T), open MRIs have acceptable image quality, however they are inferior in terms of spatial temporal resolution, signal-to-noise ratio, and contrast compared with closed-bore high-field MRI at 1.5 and 3 T. Therefore, operations and interventional procedures are increasingly carried out in high-field MRI systems with patient transfer cradles (Fig. 25.2).

The resonance frequency of 64 MHz at 1.5 T and 128 MHz at 3 T can produce inductive heating effects in electrically conductive instruments or implants [25.9]. In experimental studies with guide wires, temperatures above 60 °C [25.10, 11] were measured, and the formation of an electric arc from a guide wire to the skin could be documented in an animal study (Fig. 25.3) [25.12].

Standard closed-bore high-field MR systems provide bore diameter of 60 cm and length of 165–180 cm, which compromises the positioning of instruments, the conduct of the procedure on the patient within the bore,

and administration of general anesthesia. Direct manual access and instrument guidance is almost impossible. To solve this problem, 1.5 T MR scanners with 70 cm bores such as the Siemens Magnetom Espree in 2005 and GE Optima MR450w in 2009, which have 125 and 145 cm bore lengths respectively, were introduced. At the same time, ceiling-mounted, moveable MR(I) system/scanner was commercialized to allow intraoperative MR imaging without moving the patient and use of conventional neurosurgical instrument systems, while the MR scanner is parked in the adjacent room

(Fig. 25.4). In 2009 the combination of mobile MRI system between a catheter laboratory and the operating room was presented. In this case, the MR scanner is transferred from a central room into either the operating room or the cathlab. The angiography system must be powered off and rebooted for subsequent use. For all free-moving equipment and systems in the MR space, a consistent MR-safe structure made from predominantly nonmagnetic materials is required. Electrically conductive components in contact with the patient must be avoided [25.7].

25.4 Instruments for Interventional and Intraoperative MRI

Tools and techniques for MR-guided biopsies were published as early as 1986 [25.13]. MRI-controlled tumor ablation was described in 1996 [25.14], and the first clinical experience with MR-guided stent implantation [25.15] in 2001. The further spread of interventional MRI has been hindered by the lack of other suitable CE-marked or Food and Drug Administration (FDA)-approved instruments. The most important material for conventional interventional probes and instruments is surgical steel. Its ferromagnetic properties, however, prohibit its application in a magnetic field. Even conventional metal-based implants and instruments (for example, stents, needles or guide wires) lead to significant imaging artifacts due to their electromagnetic properties [25.16]. The following metals and alloys are suitable for MR because of their material properties such as biocompatibility, mechanical properties, ease of processing, and magnetic characteristics: tantalum, titanium and titanium alloys, nitinol (nickel-titanium shape-memory metal), nonmagnetic steel-like alloys with chromium/cobalt/molybdenum, and to a limited extent precious metal alloys (gold and platinum). Puncture needles made from the mentioned alloys are commercially available from various manufacturers.

Cannulae with diameter of 0.8–3 mm are represented at 3–5 times size magnification in the MR image (Chap. 26). From personal experience, an artifact size of 3–5 mm is required for reliable detection of the cannula in the MRI image. Therefore, metals that produce

a susceptibility artifact have been preferred for cannulae and puncture needles with diameter up to about 1.5 mm. The strong electromagnetic fields used in MR imaging can induce heat in electrically conductive instruments [25.16]. The critical length of the instruments is determined by the wavelength of the RF pulse. A cannula can form a dipole antenna for the electric field of the RF pulse transmitting coil. The induced alternating current (AC) reaches a maximum when the length (L) of the instrument is a multiple of half the wavelength ($L = k\lambda/2$). According to (25.2), critical tool lengths are calculated to be about 1.88 m in 0.2 T, about 0.23 m in 1.5 T, and about 0.11 m in 3 T, for example.

$$L = \frac{\lambda_{\text{tissue}}}{2} = \frac{c}{2f\sqrt{\epsilon}} \quad (25.2)$$

Because of these findings, preferably diamagnetic materials such as ceramics and plastics should be used to avoid inductive heating. MR visibility can be improved using metal rings or paramagnetic coatings. Ceramics and plastics, although MR compatible, were previously not suitable for thin-wall tubes with small diameters in view of the required stiffness and hardness. Adequate sharpening combined with sufficient elasticity is difficult to achieve. First experience with the use of glass-fiber-reinforced plastics has been positive [25.17], and corresponding puncture needles and guide wires are commercially available. MR visibility of polymer wires and cannula can be enhanced by dotting with paramagnetic nanoparticles.

25.5 MR-Applicable Endoscopic Instrument Systems

Intraoperative application of MRI in endoscopic surgery has advantages due to the reduced operative trauma.

Limitations of endoscopic surgical procedures are, among others, the indirect visualization of the operative

Fig. 25.5 (a) Experimental MRI-guided laparoscopic surgery in a human cadaver in 1.5 T MR; (b) rigid MR compatible rod lens endoscopes (Olympus Winter & Ibe, Hamburg)

field and the absence of tactile and haptic feedback. The endoscope enables a high-quality display of tissue surfaces in the surgical field, but the extent of a tumor and its vascular supply is beyond optical intraoperative visualization. Intraoperative MR imaging allows detection of hidden structures of the tissue volume in the surgical field. Diagnosis of areas behind or under the surfaces of the respective organs and anatomical compartments enables assessment of tumor spread and important adjacent structures such as nerves and vasculature. MR visualization of the operative tissue volume allows rigorous planning of access, sparing of surrounding tissue, and control of the surgical resection and thermal or cryogenic tissue ablation (freezing technique). Different optics for endoscopic procedures have been developed based on nonmagnetic nonferrous metals, titanium, and plastics (Fig. 25.5), and evaluated [25.18]. Metal-free optical cable of up to 4 m in length has been designed to enable removal of the light source from the MR room to eliminate disturbing influences from the light generator.

The same approach has been applied for the camera control unit to ensure the largest possible distance to the magnet outside the RF cabin for interference-free imaging. Battery-powered camera equipment showed the least interference with MRI. For observation of the endoscopic image, liquid-crystal display (LCD) or thin-film technology (TFT) with radiofrequency (RF) shielding, without significant disturbance of MR imaging, can be used in proximity to a magnetic field. Brightness and contrast are, however, reduced by the use of fine metal mesh screen for RF shielding. Modern screens and projection systems based on light-emitting diodes (LEDs) and organic LEDs are relatively brighter and offer improved usability. The first animal experiments assessing MR-guided endoscopic surgery were performed in 1998, and in the same year MR-guided neuroendoscopy was carried out on human cadavers [25.19, 20]. The open MRI working group at the Charité, Berlin, is currently developing MR-guided endoscopic surgery and MR-compatible instruments [25.21].

25.6 Instrument Representation and Tracking in MRI

Since invasive procedures entail a significantly greater risk than diagnostic methods, the appropriate technical conditions for visualization of critical structures and instruments have to be established. To obtain optimized images during the intervention, continuous adaptation of the picture settings and minimization of the acquisition time are required. Modern MR systems allow such adjustments to be made while a sequence is running. However, currently no correlation between sectional position of the MR image and the instrument is provided

by MR manufacturers. Third-party products were established in the late 1990s to provide correlation of instrument position and slice orientation using optical navigation systems. These localization techniques are based on two principles: optical tracking of LEDs or light-reflecting spheres, and tracking of resonant antenna coils.

Optical tracking is based on the principle of monitoring either infrared LEDs or light-reflecting spheres (Fig. 25.6).

Fig. 25.6a,b Opto-electronic tracking of instruments in horizontal open MRI: (a) active LEDs and (b) light-reflecting spheres (Northern Digital, Waterloo, Canada; Siemens, Erlangen, Germany)

Fig. 25.7 Electromagnetic tracking in MRI enabled by a 3-D magnetic field sensor made from three orthogonal pick-up coils for a handheld guided tool and a microsensor with about 1.5 mm diameter for catheters (Robin Medical, Baltimore)

The position of the patient, the MRI, and the interventional device have to be monitored and registered into a world coordinate system. The coordinates of the device detected by the optical navigation system are provided to the MRI scanner so that the slice orientation and position of the image acquisition are set accordingly. Thereby, the MR follows the instrument position. Unfortunately, approaches realized for both the 0.5 T GE Signa open and 0.2 T Siemens horizontal open magnet have been discontinued.

Electromagnetic coils, another option for tracking of devices in MR, have been established at the same time and are commercialized by Robin Medical of Baltimore, MD (Fig. 25.7). These coils are detected based on the signal acquired by the MRI.

These two techniques are only suitable for rigid instruments such as surgical tools and cannulae and can-

not be applied for guidance of flexible guide wires and catheters. Elastic bending of cannulae during insertion is also not detected. The difficulty with the mentioned tracking tools is the restriction to only one set of spatially defined layers per sequence. Unexpected patient movement or respiratory movement results in instrument displacement from the given layer. In addition, anatomy with different resilient tissues in the insertion path often leads to elastic bending of the needle. The beveled end-cut of cannulae creates a moment at the tip of the cannulae while penetrating collagenous fiber-containing layers, triggering further deterioration. When the instrument can no longer be clearly identified on the monitor, the sequence must be restarted with modified orientation. During this maneuver, lasting several minutes, there is no visual control of the instrument. The instrument tip may be in a painful

Fig. 25.8 (a) Resonant markers proximal and distal to a balloon catheter for stent implantation. The markers are tuned to the resonance (Larmor) frequency of ca. 64 MHz of a 1.5 T MRI and lead to signal enhancement (b)

Fig. 25.9 The resonant marker requires a medium that provides an MR signal, such as water or oil. For instruments or devices such as endoscopes positioned in air, a small container with the microcoil embedded can be used for tracking (Siemens Magnetom OPEN 0.2 T at CWRU, Cleveland, OH, USA)

or critical position for the patient and must be withdrawn [25.22].

Therefore, intracorporeal tip-tracking techniques are required to adjust the MR slice position according to the instrument's position.

The visibility of instruments and implants made from nonconductive polymer composites can be improved using resonant circuits tuned to the Larmor frequency of the MR system (25.3) [25.22]

$$\omega_0 = \frac{1}{\sqrt{LC}}, \quad (25.3)$$

where L is the inductance and C is the capacitance.

The resonant circuit consists of a coil and capacitor and undergoes inductive coupling (like an antenna) with the electromagnetic energy of the RF pulses and the energy emitted by the proton relaxation. On MR images of gradient-echo sequences (GRE) with low flip angles ($FA < 60^\circ$), a local increase in signal intensity in and around the resonant circuit is shown (Fig. 25.8). Localization and imaging of catheters and implants are improved with this feature. This improved visualization may provide significant advantages – for example, a resonant circuit may allow detection of thrombosis or stenosis in a stent, and resonant markers may allow tracking of devices (Fig. 25.9) and automatic slice selection.

25.7 MR-Guided Robotics and Navigation

Although three-dimensional MR imaging provides a defined spatial orientation, compared with other imaging techniques (US and CT) it is difficult to determine the position of an image slice relative to the position of the instrument and locate this position within the scanner at the patient's skin surface. The problem of localization of instruments by MRI can be reduced with navigation and robotics systems. These systems capture the spatial position of the instrument and pass this data to

the computer of the MR system. Based on these data, correlation between the layer orientation and the axis of the instrument becomes possible. Optoelectronic or electromagnetic tracking navigation systems are helpful; however, positioning of the instrument is performed manually. There is no feedback from the position of the MR image to the hand–arm system of the operator, or vice versa. This shortcoming can be overcome by the use of mechatronic systems.

Fig. 25.10 Innomotion (Innomedic, Herxheim and KIT, Karlsruhe, Germany) MR-compatible robotic system (1.5 T GE HDX, Dundee (left), 1.5 T Philips Intera at Praxis Dr. Gert Lorenz, Gelsenkirchen, Germany)

Robotic systems have sensors to determine the position of the movable elements to enable a controller to drive the robotic arm to certain points in space. The sensorial position data can be transmitted by means of a coordinate transformation to the MR imaging system for corresponding imaging orientation. It is also possible to send the coordinates of the MR image position and orientation to the robotic system to move the arm to the corresponding point in space. The robotic system bridges the gap between positioning an instrument according to the image data and hands-free navigation [25.23, 24]. The deviation of the instrument during introduction into the body is not influenced, as this is determined by the structural and mechanical properties of the pierced tissue together with the material, diameter, and beveled end of the needle tip. The robotic system can, however, indicate this deviation after insertion and provide a visual indicator to correct the insertion angle (Fig. 25.10).

Conventional robotic and manipulator systems for surgical applications are usually based on the kinematics of the human hand–arm system [25.25]. These designs are not suitable due to the limited space inside the magnet and typically used ferromagnetic metals, electric sensors, and electric motors. In the last 10 years, special robotic systems for x-rays and ultrasound techniques, and in some cases also for MR imaging, have been developed [25.26]. The technologically sophisticated requirements to realize MR-compatible robotic systems with respect to nonmagnetic, nonconducting materials, sensors, and drive systems make it difficult to develop a medical device and are associated with considerable financial cost. The published systems have not been developed as medical devices, except for one [25.27], and therefore do not have the appropriate approval from the FDA or CE mark. The Innomotion system has had CE marking since 2005 and is enabled by pneumatic cylinder drives and

metal-free sensors to position a nonmetallic kinematic arm with accuracy of ± 0.1 mm and $\pm 0.1^\circ$. Use of precision-engineered plastics, composites, and ceramics eliminates interaction with the MR system [25.28]. The system is suitable for various indications, for example, MR-guided biopsies [25.27, 29], MR-guided treatment of pain, and MR-guided tumor ablation. The system can also be applied in computed tomography, for example, for CT-based positioning of osteosynthesis in pelvic fracture treatment and infiltration of joints [25.30]. At the National Institutes of Health (Bethesda, Virginia) two Innomotion systems are currently being developed for MR-guided robotic-assisted heart surgery. First experiences have been described for implantation of heart valve prostheses by minimally invasive approach through the apex of the heart in both ex vivo and in vivo porcine animal models [25.31].

25.7.1 Technology of MR-Compatible Robotic Instrument Guiding Systems

Innomotion (Innomedic and Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany), the first MR-compatible assistance system, has been developed to provide precise and reproducible instrument positioning inside the magnet. MRI compatibility is achieved by testing all components and the complete system at different field strengths for MRI units including the 1.5 T Siemens Magnetom Symphony/Espreo, Philips 1.0 T Gyroscan, 1.5 T Intera, and GE 1.5 T HDx. Targeting precision under MRI guidance has been determined in ex vivo organ models embedded in agarose gel. In vivo targeting precision has also been evaluated during MRI-guided percutaneous interventions in a porcine animal model.

The pneumatic robotic assistance system (Fig. 25.11) consists of a MR-safe robot arm which can be maneuvered in six degrees of freedom. The robot

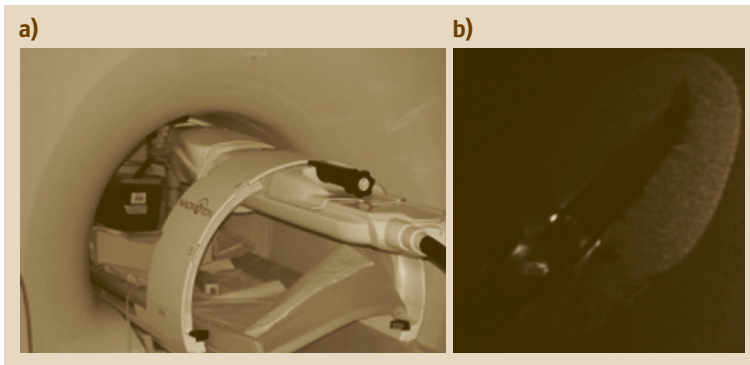

Fig. 25.11 (a) MRI-guided robotic-assisted transapical implantation of an MR-enhancing self-expanding heart valve prosthesis in an ex vivo porcine heart (b) MR image of the heart valve (Philips 1.5 T, Intera FFE, TR = 140 ms, TE = 4.25 ms, FA = 30°)

arm is attached to a 260° arch that is mounted onto the patient table of the scanner and that can be passively prepositioned on either side of the arch at 0, 30, and 60° according to the region of interest (e.g., spine, liver, kidney, breast). The arch is movable along the x -axis (longitudinal) of the scanner and can be firmly attached to the patient table of the MR system. Due to its exchangeable fittings, the robot can be easily attached to other MRI platforms or bore sizes. Active position detection is achieved via fiber-optically coupled limit switches, along with rotational and linear incremental sensors. The kinematics of the device has been carefully optimized for use in closed-bore MRI scanners and the CT gantry. Piezoelectric drives were tested, but due to the RF noise during MRI scanning and the risk of inductive heating of the electric power lines, they were discarded and pneumatic cylinders with slow motion control have been developed instead to drive all six degrees of freedom (DOFs).

At the front end of the arm, a module for application and insertion of coaxial probes (e.g., cannulae for

biopsies, RF, cryo- or laser probes, endoscopes, etc.) provides two degrees of freedom along the x - and z -axes and is attached to a robotic arm with four degrees of freedom. This design ensures stable positioning of the instrument within a tool center point while maintaining an *invariant point of insertion* at the skin entry point. In conjunction with the two axes for movement about the tool center point ($\pm 30^\circ$), the instrument trajectory can be changed to other targets without moving the robot arm or repositioning the arm on the arch. The application module for clinical use provides manual translation and rotation of the cannula. A pneumatic drive has been developed to insert the cannula in incremental steps of 1–20 mm. Such automated cannula insertion is considered in the same product class as the interventional probe 2B or 3 (for applications near the cardiovascular or central nervous system). A graphical user interface provides trajectory planning directly on the MRI images (Fig. 25.12). MR digital imaging and communications in medicine (DICOM) images are sent via the picture archiving and communication system (PACS) to the robot personal computer (PC) and used for intervention planning and registration of the robot. A set of transverse and coronal 20 mm-thick slices are acquired, covering the contrast-agent-filled markers. Through graphical analysis of the marker alongside the coordinates of the slices listed in the DICOM header of the exported images, registration of the robot is performed.

Fig. 25.12 MR images are sent as DICOM files via PACS and can be used on the graphical user interface (GUI) of the robot for planning and registration (Prostate Biopsy, Zangos et al., University Frankfurt)

25.7.2 Technique for Robotic-Assisted MR-Guided Interventions

The patient is placed in a predetermined position suitable for the intervention (supine, prone or lateral). The system is prepositioned and firmly attached to the table with clamps. Based on the pre-interventional im-

Fig. 25.13 (a) MRI target precision of a 20 gauge cannula insertion into a porcine kidney embedded in agarose. (b) Overlay images for graphical evaluation of target precision in an in vivo porcine model (Michael Bock et al. DKFZ, Heidelberg Germany)

ages and the anatomical region of interest, the table is moved using the projection of laser beams from the MRI gantry. In the first version the robot is referenced to the coordinate system of the MR scanner using the same laser line. The arm moves back and forth and returns so that the light detectors at the upper part of the application module are aligned with the laser (within ± 0.5 mm). The laser light is switched off, and the table is automatically moved into the MRI bore until the position of the laser line matches with the zero position of the z-axis of the MRI scanner. The latest release just requires approximate manual positioning of the markers in the laser light. For planning of the intervention, MR imaging is performed by using fast gradient echo sequences in transverse, sagittal or coronal orientation. Suitable slices are selected and sent via the network in DICOM format to the computer of the robotic assistance system. The insertion site and a target point are selected using the graphical user interface, and the corresponding coordinates are sent to the control unit. The drives are activated, and the application module is moved with the tool center point to the insertion site on the skin. The cannula can then be inserted through a guiding sleeve or along an open angle.

25.7.3 Evaluation of Targeting Precision

Mechanical targeting precision has been determined with a FARO arm under dry-lab conditions. The MRI procedures were performed using a 1.5 T Siemens Magnetom Symphony, a Philips 1.0 T Gyroscan, and 1.5 T Intera. The test was done on ex vivo organ models consisting of fresh porcine kidney embedded in agarose and gelatine (Fig. 25.13).

Targeting precision was also evaluated during MRI-guided percutaneous interventions in a porcine animal model under general anesthesia (isoflurane). The animals (four 3 month-old domestic pigs, 30–40 kg) were placed in prone position on the patient table, and a surface coil was fixed around the planned insertion site lateral to the spine. Using T_1 - and T_2 -weighted planning images, the appropriate region of interest was defined using the graphical user interface of the Innomotion control computer. The robot arm then moved and oriented the needle holder to the insertion point automatically. Manual insertion of 20 and 22 gauge MR-compatible titanium grade 4 cannulae (MRI Devices-Daum, Schwerin, Germany) was carried out under real-time MRI guidance. The accuracy of the insertion point and the insertion angle were determined by overlaying the pre-interventional images with the new MRI image.

The intervention was completed within the magnet from the rear opening, where an MR-compatible in-room monitor was placed. During the insertion of the needle, real-time MR images were acquired to control the route of the cannula. To visualize the advancement of the cannula through the tissue, fast gradient echo sequences ($TR = 4.4$ ms, $TE = 2.2$ ms, $FA = 70^\circ$, $TA = 0.7$ s) were used. At the desired region of interest (nerve root, plexus coeliacus), spin echo images were acquired for verification of the cannula position. A test injection of contrast agent solution (gadolinium diethylenetriamine penta-acetic acid 1 : 100 ml of 0.8% saline solution) was carried out under real-time MRI control ($TR = 1.8$ ms, $TE = 4.3$ ms, $TA = 0.5$ – 0.8 s, $FA = 20^\circ$) to visualize the drug distribution. Final therapeutic injection of 10–25 ml with

Fig. 25.14 MR guided facet joint pain treatment. Targeting precision can be evaluated by image overlay of planning line and needle artefact (1.5 T Philips Intera at Praxis Dr. Gert Lorenz, Gelsenkirchen, Germany)

contrast doped mepivacainhydrochloride (Scandicain 1%, Astra-Zeneca, Germany) was performed.

All procedures were completed successfully, including injections at the sympathetic chain, sciatic nerve, and coeliac plexus. The direct MRI control and new sequence techniques allowed correction of the insertion path in case of misdirection due to anatomical structures. The insertion site and the insertion angle were evaluated by manual measurements on overlays of the planning Innomotion image and the subsequent MR control image (Fig. 25.14).

The position and orientation of all cannula insertions were appropriately visualized on axial MRI images. The precision of the insertion site in the ax-

Fig. 25.15 Johns Hopkins MR-compatible robot in an animal procedure for prostate interventions (after [25.32])

ial plane was ± 1 mm (minimum 0.5 mm, maximum 3 mm). The angular deviation in the transverse plane of the cannulae was $\pm 1^\circ$ with a minimum of 0.5° and maximum of 3° .

For MRI-guided cannula interventions, as the cannula is currently advanced manually, access is difficult if the insertion is done inside the magnet. Therefore, direct control of the insertion under real-time MRI is recommended to allow correction of the insertion in case of misdirection of the cannula and for precise positioning of the tip of the cannula in the volume of interest. To facilitate the procedure, tip-tracking techniques have been evaluated to provide automated correlation of the robot position with the image slice orientation [25.24].

25.7.4 MRI-Compatible Robot MrBot for Prostate Biopsy

MrBot [25.33] has been developed at Johns Hopkins for image-guided access to the prostate gland. The robot is designed for transperineal cannula insertion for closed-bore tunnel-shaped scanners. The system accommodates various end-effectors for percutaneous interventions such as biopsy, serum injection, or brachytherapy with low-dose radiation seed implantation. For MRI safety the robot is constructed exclusively of nonmagnetic, dielectric materials such as plastics, ceramics, and elastomers and is free of electrical conducting wires. The system is driven by novel pneumatic step motors (PneuStep) [25.32]. This unique motor provides easily controllable, precise, safe pneumatic actuation comparable to electric step motors. Fiber-optic encoding is used for position detection, so that all electric components are located outside the MR room (Fig. 25.15).

The precision of repeated motion has been evaluated in a 1.5 T MRI scanner, showing mean errors of 0.076 mm. The robot has been tested as MR safe in all MR systems available at the time of development [25.32]. Clinical use and regulatory approval remain to be conducted. The robot has been evaluated for cannula insertion accuracy with in vitro and ex vivo experiments and in vivo animal experimental studies [25.34,35].

25.7.5 Technical Issues of MR Robotics

The following main technical issues require careful consideration

- MR imaging safety and procedures compatibility (Chap. 26),

- coregistration of robot and image position,
- compensation of patient movement and respiration,
- options for haptic (force) feedback,
- mode of operation and level of robotic control.

MR Imaging Safety and Procedures Compatibility

MRI safety can only be achieved by using nonmagnetic and nonconductive materials. For use in computed tomography, radiolucency of the robot arm can be accomplished by the same materials so that the robot end-effector holding the instrument in the scan plane does not cause undesired artifacts. The robot system must also provide safe interfacing with the imaging system and allow rapid displacement for immediate access to the patient in emergency situations. When the robot system is actuated, it should not interfere with the imaging system and should allow passive displacement at all times.

Coregistration of Robot and Image Position

Intervention planning is based on images in certain planes and orientations. The coordinate system of the robot must therefore be registered to the coordinate system of the imaging system. If the robot is permanently attached to the patient table of the imaging device, this registration can be done through an imaging procedure or through microcoil-based tracking. Microcoil tracking has the benefits of being very fast and accurate and providing continuous registration, and immediate reregistration in case the device is moved from one imaging unit to another or shifted between two rooms.

Compensation of Patient Movement and Respiration

A limiting factor of robotic assistance during image-guided interventional procedures is inadvertent patient movement and organ displacement due to respiration motion. Compensation of these effects would first require real-time tracking of target movement due to respiration motion and accurate transformation to motion of the robot. Making such a robot clinically viable, robust, and safe would result in very high cost.

Industrial robotic systems react faster than a human and are able to compensate respiratory motion, such as the CyberKnife (Accuracy, Sunnyvale) and linear accelerator held by an industrial robot arm [25.36]. This massive, metal robot driven by powerful electric motors is not suitable for MRI-guided procedures. Therefore, other safety means need to be realized that avoid risk of instrument displacement caused by patient motion. The

safest approach is to provide for mechanical release of the instrument from the holder.

Options for Haptic (Force) Feedback

Robotic systems with master–slave functionality that include active needle-driving mechanisms and force feedback may need to be provided to the operator. The importance of this feedback is a subject of ongoing debate, but there are some clinical applications where it seems desirable, e.g., if the cannula touches bone. The technical hurdle is, however, to measure the force at the tip of the instrument accurately and to transmit this to a master control unit. Existing force feedback devices are too bulky and not approved for the clinical environment. In addition, friction between the cannula and tissue during insertion is high, which compromises the accuracy of force feedback measurements [25.37]. Therefore, assessment of the need for force feedback remains at the clinical research level.

Mode of Operation and Level of Robotic Control

The adequate user interface for an interventional robot has not yet been determined. Joystick control should be designed for master–slave systems to mimic the classic handling position of a probe during conventional interventions. Scaling of motion and applied force would be helpful only if fine manipulation of tissues is required, which is not the case in interventions. During procedures such as biopsy with a straight-line trajectory through predictable soft tissue, some degree of autonomy seems appropriate if sufficient robustness can be achieved. During percutaneous radiotherapy procedures, radioactive seeds or probes are implanted into the patient, which could be performed by the robot. The main element of autonomous control is tracking of position and coregistration of MR slice orientation and robot front-end, and vice versa. The robot should also move automatically to the skin insertion point.

Undoubtedly, MR robotics carries the potential to facilitate MR-guided interventions and provide the required access to the patient while lying in the scanner bore. Successful clinical application of MR robotics, however, requires intuitive systems operation and minimal user training. The robot must be quick and easy to setup and not significantly increase the length of procedures, and preferably shorten it. The robot must also be cost effective.

At the University of Dundee, Innomotion in combination with a MR-guided focused ultrasound system (MRgFUS, Fig. 25.16) is being applied and further developed (Sect. 25.8).

Fig. 25.16 MR-compatible robotic system in combination with a MR-guided focused ultrasound system (ExAblate 2001, InSightec, Tirat Carmel, Israel)

25.8 Hybrid Multimodal Imaging for MR-Guided Diagnosis and Therapy

Despite the excellent diagnostic imaging capabilities of MRI, which does not expose patients and physicians to ionizing radiation, it is difficult to use during intervention and surgery due to spatial constraints and the strong electromagnetic fields. Ultrasound and optical imaging are harmless compared with ionizing radiation-based imaging and easier to apply compared with MRI. Ultrasound and the emerging field of biophotonic imaging are usually not MRI compatible and not designed to be used in conjunction with MRI. As a consequence, surgeons and interventionists continue to use traditional imaging and operating techniques, which are based on visual inspection of the pathological anatomy structure either by traditional open or endoscopic surgery. Radiologists still have to expose themselves and their patients to long radiation times to perform complex cardiac interventional procedures. The frequent inadequacy of fluoroscopy as a navigation guide and failure to visualize the pathological target results in long procedure times and the use of nephrotoxic and allergenic iodine contrast agents. In Germany, 1.5% of the cumulative risk of cancer has been attributed to diagnostic x-rays [25.38].

MR provides superior soft tissue contrast in different weightings and functional imaging for visualization of pathological lesions. Positron emission tomography (PET), however, visualizes biochemistry, e.g., lactate

concentration or detection of specific molecular targets. Combining MR with PET/CT information and biophotonics for local imaging in combination with ultrasound for instrument guidance could therefore improve image-guided diagnosis and treatment precision. With this functional and operational integration, both time to diagnosis and time to operation or intervention could be significantly reduced, and some of the technical hurdles of MRI safety and access limitations could be avoided. Various efforts have been undertaken to make instruments and devices available for procedures performed by surgeons and interventionists, but only a few sites worldwide have so far introduced MRI/PET/CT to ORs despite the very promising outlook.

Because of the needs for intraoperative imaging at different stages of a procedure, the concepts of intra-, inter-, and perioperative MR imaging have developed [25.39]. The objective is to apply imaging immediately after or during an operation for economic and safety reasons and to improve the necessary techniques and tools. For this purpose a teaching and research operation system for integration of imaging procedures was established in 2001 at the Fachhochschule Gelsenkirchen, Germany [25.40]. The complex requirements for the integration of imaging procedures should include computer-based numerical simulation [25.41]. A first implementation of this ap-

Fig. 25.17 Integrated multimodality image-guided diagnosis and therapy setup (MITOS) at the Clinical Research Center of University Dundee & NHS, Tayside, Scotland

Fig. 25.18 Advanced multimodality image-guided OR (AMIGO) 1st GE concept by Jolesz and Hynynen (after [25.5]) (BWH, Harvard Med School, Boston)

proach in the clinical setting is currently underway at the University of Dundee, Scotland, by combining 3 T MRI and PET/CT with a multifunctional intervention/surgical suite (MITOS) (Fig. 25.17). The focus

is on development of multimodal image-guided diagnostic and therapeutic procedures for early detection and treatment of cardiovascular and oncological diseases [25.38]. The work is closely linked to clinical

requirements, supported by ISO-certified processes, and continuously assessed in view of product capability and marketing.

Jolesz and Hynynen [25.5] have developed a similar concept named AMIGO with GE for integration of MRI and PET/CT with surgery (to be installed at BWH, Harvard Medical School, Boston, MA) (Fig. 25.18), and Philips has announced the first XMRO suite in Japan, combining MR, Angioblab, and CT.

Installation of multimodality interventional imaging systems is difficult in the current clinical setting, and thus the potential benefit to patient care and the healthcare system is not being realized. One (and perhaps the major) reason for this is that the imple-

mentation and safety of intraoperative imaging require an interdisciplinary (*interclinical* and *inter-technical-science*) and cross-sectorial approach (academia and industry), which is difficult to establish. It is therefore the intention of the Integration of Interventional Imaging in the Future Operating System (IIIOS) consortium (www.IIIOS.eu) and the National Center for Image Guided Therapy (NCIGT) (www.NCIGT.org) to undertake research and training to develop dedicated technology, processes, and skills for safe, efficient, effective, and economic implementation of magnetic resonance (MR) with ultrasound and biophotonics in combination with imaging from computed tomography (CT) and positron emission tomography (PET).

25.9 Therapeutic MR-Guided Imaging

MRI-guided focused ultrasound (MRgFUS) is a method that combines thermal ablation with MRI. The ExAblate (InSightec, Tirat Carmel, Israel) delivers high-intensity focused ultrasound energy precisely directed from an extracorporeal (phased-array) transducer towards the target tissue through the intact skin, resulting in irreversible coagulative necrosis and apoptosis when temperature above 56 °C is maintained for at least 1 s (Fig. 25.19).

Real-time MR thermometry allows continuous temperature monitoring and precise case-dependent customization of the therapeutic energy at the focus. Due to the sharp drop in energy density outside the treatment focus, the resulting lesion is highly discrete, sparing tissues adjacent to the focus, and enabling an outstandingly high safety profile compared with other ablative

therapies. The main advantages of this combination are the good delineation of the tumor for target definition, the exact three-dimensional treatment planning, and continuous temperature measurement for control of local warming. MRgFUS, which allows access to noninvasive thermal ablation, is likely to represent an alternative to interventional ablation, surgical resection, and radiation therapy [25.42]. The method is approved in Europe, Japan, and the USA for treatment of uterine fibroids and is being evaluated in clinical trials for treatment of breast, liver, prostate, and brain cancers as well as for relief of pain associated with bone metastases. Its use for bone metastases has already received CE approval [25.43].

A promising development is MR-guided, ultrasound-induced targeted drug delivery (UITDD) [25.44] in

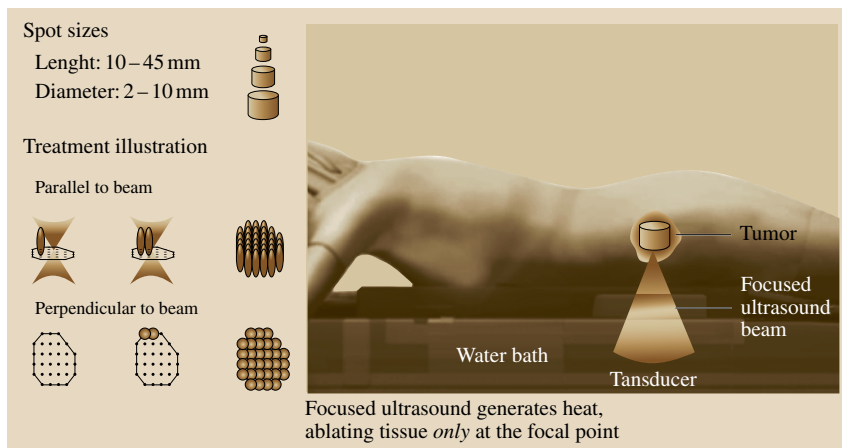

Fig. 25.19 Principle of non-invasive and no-access MR-guided focused ultrasound (MRgFUS) ablation of tumors (ExAblate 2001, InSightec, Tirat Carmel, Israel)

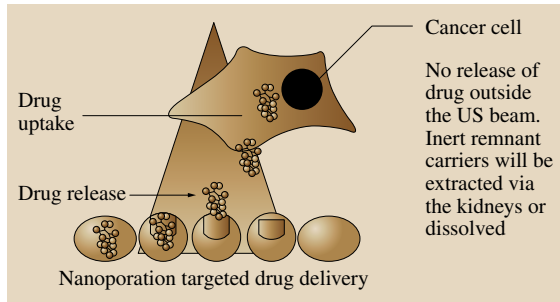

Fig. 25.20 Concept of MR-guided focused ultrasound-mediated targeted drug delivery of chemotherapy agents (www.nanoporation.eu)

which focused ultrasound induces a temporary change in vascular and cell membrane permeability. This principle is described as sonoporation [25.45] and can lead to release of drugs from drug carriers; for example, liposomes [25.46] or polymers [25.47] are used (Fig. 25.20). The aim of current research in this area is combination of MRgFUS tumor ablation with subsequent drug release. This can result in a higher concentration of active drug in the treatment zone while maintaining a low systemic concentration and fewer side-effects.

From a clinical perspective, the combination of PET and MRI is desirable to allow better correlation of PET signals to the morphology and anatomy of the patient. A PET scan may give direct evidence of remaining ac-

Fig. 25.21 Innomotion robot test setting on the ExAblate 2000 MRgFUS system (InSightec, Tirat Carmel, Israel), positioning the conformable bone system mobile FUS transducer ExAblate 2001 (IMSaT, Dundee, UK)

tive tumor tissue following ultrasound-guided ablation. Remnant tumor tissue can either be ablated or, if this is not possible due to adjacent important anatomical structures, MR-guided focused ultrasound-mediated drug delivery can be applied to provide high focal concentration of potent chemotherapy agents. The Innomotion robotic arm is being investigated as a positioning aid for the MRgFUS system (Fig. 25.21), which may be useful in ultrasound-mediated drug delivery and in tumor ablation.

25.10 MR-Guided Delivery of Implants

Implant delivery under image guidance is mainly used for endovascular implants such as stents, filter, valves, or occluders. Tumor markers are implanted via image guidance in breast and lung tumors to provide the surgeon with guidance during subsequent surgical excision of the marked lesion. Non-magnetic stainless-steel medical alloys (e.g. 316L) cause major MR image artifacts due to the material (susceptibility artifact) and/or its electromagnetic characteristics (RF artifacts) which are undesirable in instruments for MR-guided interventional procedures. These artifacts are caused by distortion of the magnetic field and interference with the radiofrequency (RF) waves of the MR imaging process. Complete signal loss occurs in close proximity to or inside such implants (Chap. 26). The unconventional electromagnetic characteristics of nitinol (50 : 50 nickel and titanium) render it suitable for endovascular implants for MR imaging and guidance. Although nickel is

a ferromagnetic metal, when combined as an intermetallic compound with a cubic-centered crystal structure of titanium and nickel atoms, it loses its magnetic moment. nitinol shows similar magnetic susceptibility to other medical-grade titanium alloys [25.48].

Although nitinol was considered the perfect choice for MRI, research into its MRI safety in recent years has revealed the problem of conductive heating of metallic implants, which occurs at about 10 cm length in 3 T MRI imaging and at about 20 cm length in 1.5 T MR systems. Most implants are below the critical length, but care has to be taken if stents are implanted with overlap and for very long stents designed for abdominal aortic aneurysm (AAA) and superficial femoral artery (15–20 cm length). Heating of more than 4 °C has been measured in phantom models according to American Society for Testing and Materials (ASTM) standards [25.16].

A secondary risk for the patient is the problem of missing MR signals in the lumen of the implants leading to lack of diagnosis. The signal void is caused by the closed-cell design of the implant structure, which functions like a Faraday cage. The MR signal cannot be received from the substrate in the lumen, thus making MRI detection of instant thrombosis and restenosis or other intra-stent complications impossible. By integrating a MRI antenna (electric resonator tuned to the resonance frequency of the MRI, i. e., 64 MHz for 1.5 T) into the stent and other vascular implants, i. e., heart valve prosthesis, improved imaging is possible, as has been proven in various animal trials.

25.10.1 MR-Guided Delivery of Stents and Stent Grafts

A variety of reports on MR imaging behavior of stents have been published in recent years. MRI in the presence of stents has been examined in terms of contrast enhancement [25.51, 52], influence of different materials and structures [25.53], and stent grafts [25.49, 50] under particular MRI settings. The effects of 0.2, 1.0, and 1.5 T sequences and imaging parameters, the orientation of the stent axis in the static magnetic field, and the orientation of the recorded slice have been systematically assessed [25.22, 54].

Preclinical evaluation of an artifact-free copper alloy based balloon expandable stent, invented by *Bücker* and *Rübber*, has been carried out. The concept of their stent is a design that avoids the RF shielding effect [25.55]. Although the stent has not shown any image interference, its complete lack of visualization does not allow guidance during delivery and makes later diagnostic MR difficult. In addition, the copper alloy is not biocompatible. MRI-guided implantation of coronary stents has been demonstrated in a porcine animal model [25.56].

The first clinical report of MR-guided stent delivery was published in 2000 [25.57]. The group used nitinol self-expanding stents, implanted under MR guidance in a 1.5 T system. MRI-guided implantation of AAA grafts (for AAA repair) has been performed in an animal trial on pigs with success [25.58, 59].

All self-expanding nitinol stents and stents for grafts show an artificial diameter increase in MRI imaging, and shielding of the stent lumen. To overcome the RF artifacts, stents have been enabled to function as electric resonators to interact with the MR imaging process [25.60]. The balloon expandable version of the resonant stents has been evaluated in a chronic animal trial, and the MR enhancing function was still present up to 7 months after implantation [25.61]. Current research and development (R&D) effort includes the design of a nitinol stent comprising a resonant circuit as a discrete component, comparable to an x-ray marker (Fig. 25.22). This stent will provide MR-guided delivery with control of the implantation process. As described by (25.3), the resonance frequency is a function of the inductivity (L) and the capacity (C). The inductivity is dependent on the surface and the length of the windings of the coil in and around the stent. The smaller the surface encapsulated by the coil, the lower the resonance frequency. The stent's resonance frequency is tuned at the expanded stage to its optimum, i. e., 64 MHz for 1.5 T. For implantation, the stent is either crimped onto a balloon or constrained within a delivery system. At this stage, the resonance frequency is below the MR Larmor frequency (25.1). During expansion, the inductor achieves its preset shape and at the same time the resonance frequency tunes to the preset value, i. e., 64 MHz for 1.5 T. As a result, the stent starts enhancing the MR signal (Fig. 25.23). This technique carries the greatest potential for adequate visualization of stents in MRI.

Fig. 25.22 MRI imaging of self-expanding nitinol stent. To overcome RF artifacts, the stent has been equipped with an electric resonator (fine wire coil on the right side) tuned to 64 MHz to couple inductively with the MR imaging process of a 1.5 T scanner (after [25.49, 50]) (www.vueklar.com)

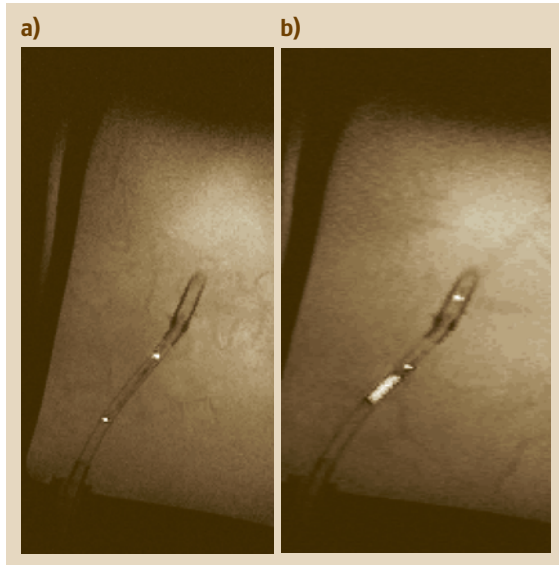

Fig. 25.23 (a) The crimped stent is invisible, but after balloon expansion the resonance frequency tunes to the preset value, i. e., 64 MHz for 1.5 T. (b) As a result the stent starts enhancing the MR signal (Siemens 1.5 T, University Frankfurt) ◀

Artifacts can be minimized by using nitinol with suitable magnetic susceptibility (Chap. 26) and a design of the holding structural element which avoids electrical conductive loops. Due to the mechanical design cannot be made loop-free and nonconductive. A resonant circuit tuned to the Larmor frequency of the MR tomography can overcome the RF artifacts and thus improve visualization of the resonant prosthetic heart valve, similar to the stents described above. We have developed a first set of prototypes using a nitinol stent and freshly excised porcine aortic valve (Fig. 25.24) [25.62]. The valves have been successfully implanted under MRI guidance (1.5 T) in an acute porcine animal model [25.31].

25.10.2 MR-Guided Heart Valve Prosthesis

Artifact-free visualization of heart valve prosthesis is one of the main conditions for safe and reliable examination with MRI and a prerequisite for MRI-guided valve repair.

25.10.3 MR-Guided Delivery of Vena Cava Filter

MRI artifacts of a vena cava filter (VCF) are dependent on both the susceptibility and the RF characteristics of the design. Closed loops of the metal struts are

Fig. 25.24 (a) MR-visible self-expanding heart valve prototype using a nitinol $22 \times 60 \text{ mm}^2$ stent and a freshly excised porcine aortic valve (after [25.27]). The nonresonant section is shielding the lumen (b). The section with the bright signal contains the resonant circuit (c, d) and shows the valve leaflets in detail. Panel (d) shows the enhanced MR image of a resonant heart valve compared to the non resonant MR image of a native human valve. (e) The MRI-signal intensity can be measured along the profile lines shown in (b–d)

Fig. 25.25 (a) Basket-type nitinol vena cava filter demonstrates a sectional MR signal void because of a blood clot. (b) Integration of a resonant circuit provides improved imaging and depiction of clotted blood in the filter. Panel (c) shows a photo of the blood clot visualized in MRI (b) (1.5 T at RWTH, Aachen, after [25.65])

subjected to eddy-current induction and local magnetization. The TrapEase and OptEase VCFs are cut from nitinol tube in a structure of interconnected closed cells, leading to RF shielding [25.63, 64]. Two types of active MRI VCFs with integrated resonant circuits have been produced: wire based and laser cut from nitinol tube (Fig. 25.25). The active VCFs have been successfully tested in an acute porcine animal model for evaluation of MRI-guided implantation, blood clot imaging, and retrieval of the filter [25.65].

25.10.4 MR-Guided Delivery of Closure Devices for Cardiac Septal Defects

MR imaging of cardioseptal defects is an option to avoid ionizing radiation, invasive catheterization, and transesophageal ultrasound specifically for pediatric patients, although the adult patient who has received a patent foramen ovale (PFO) closure also benefits from

MRI during follow-up [25.66]. MRI-guided delivery of closure devices has been successfully evaluated in an animal model [25.67] using a custom-made passive nitinol occluder.

Closure devices have been examined by MRI, e.g., the Amplatzer from AGA medical [25.22] and Starflex from NMT. The Starflex is made of stainless-steel wire, causing major artifacts, while the nitinol mesh of the Amplatzer also contributes to RF shielding with low artifacts, although the proximal threaded tube and the distal tube that are used for clamping both ends of the mesh lead to large artifacts (Fig. 25.26). Novel intratunnel devices for PFO closure such as SeptRx (NDC, Fremont, CA, USA) and Coherex feature smaller artifacts, mainly because less material is present and no stainless-steel components are applied as structural components. PFO compression via two rings connected through the PFO tunnel should provide safe sealing, and the integration of resonant circuits is equally helpful to overcome shielding artifacts and facilitates cardiac MR imaging for PFO leakage detection. During delivery the two rings are constrained, which detunes the resonance frequency; during expansion the frequency reaches 64 MHz, leading to signal enhancement.

Fig. 25.26 (a) The cardioseptal occluder of AGA Medical (Amplatzer) is made of nitinol mesh connected at both ends by stainless-steel tubes which generate significant MR artifact. (b) Novel nitinol dual-ring occluder functions as a resonant circuit to overcome shielding artifacts and to facilitate cardiac MR imaging and assessment of PFO occlusion (c). Profile line was positioned on the occluder in the MR image to measure the MR signal intensity

25.11 Conclusions

Safe and efficient MR-guided interventions can be realized if important criteria of MRI safety and imaging compatibility are applied to the development of appropriate instrument systems. Today's potential indications for interventional MRI are in the field of the classic radiologic procedures, i. e., organ puncture for biopsy, interstitial tumor treatment, and vascular procedures. Intraoperative MRI has been proven beneficial in neurosurgery, leading to improved tumor resection, and cardiovascular surgery under MRI guidance is currently being explored. The advantages of MR application lie in the variable soft tissue contrast with flow and temperature sensitivity, the arbitrary slice orientation, and the lack of ionizing radiation and nephrotoxic contrast media. The majority of interventional and intraoperative MRI hardware and software components, devices, and systems are technically suitable and clinically feasible, providing an interesting key technology for the medical industry. Although thousands of MR-guided interventions and surgical procedures have been performed within the last 15 years, the ongoing lack of approved medical devices for MRI-guided interventions,

particular in the vascular field, hinders widespread introduction. As soon as clinical feasibility has been proven and positive results of the evaluation of clinical procedures become public knowledge, patients' attending physicians will certainly ask for the MRI option, mainly because of the lack of radiation exposure. This can create a situation in which the patient drives the medical market (a so-called patient-driven market). The same was observed for laparoscopic cholecystectomy. Here, with the introduction of video endoscopy 20 years ago and especially with the publication of the first 100 laparoscopic cholecystectomies by *Périssat* [25.68], rapid spread occurred. Today, hardly any patient would choose surgery by conventional open approach. This possibility runs the risk of too rapid an introduction of new MRI-guided treatments and technologies. However, on the other hand, conservative structural hurdles may be overcome faster. It is therefore necessary to answer questions about the safety, efficiency, effectiveness, and economy of MR-guided interventions within multidisciplinary teams and prove these aspects in valid clinical studies.

26. Devices and Materials in MRI

Devices and

Gregor Schaefer, Andreas Melzer

Magnetic resonance imaging (MRI) provides superior visualization of morphology, biochemistry, and physiology through differently weighted soft tissue contrasts (T_1 , T_2 , fat or water suppression, etc.). In addition, its high flow sensitivity depicts functional aspects such as blood flow, perfusion, and diffusion of tissue and organs. The physical nature of MRI provides three-dimensional, spatially defined image volumes which allow image guidance and automatic slice orientation as well as device localization (tip tracking). Therefore, magnetic resonance (MR) safety and compatibility are important issues for all items, including implants, surgical tools, and electronic or mechatronic equipment, to be used within an MR environment. MR testing of medical devices is required for device approval by regulatory agencies, e.g., the Food and Drug Administration (FDA) and the European Union (EU) Notified Bodies.

The intention of this chapter is to provide established scientific data and information, but also to cover the developing character of the field. It is useful for the growing reader community in the field of MR safety/compatibility to understand the historical path of developed methods and the complexity of this subject, especially MR labeling information derived from testing performed from approx. 1995 to 2005 and even before, which is already obsolete but has to be understood by the clinical MR operator to avoid risk to patients. The change in 2005 of the labeling "MR compatible" to the new ASTM labeling of medical devices into the categories of "MR safe", "MR conditional", and "MR unsafe" and the related revision of MR testing reflect the ongoing research in this field. chapter provides a comprehensive overview of MR safety and compatibility interactions, issues on existing MR testing methods, and published standards [26.1–4], as well as updating the discussion on physical interactions that will be relevant in the future.

Use of items and devices in MR applications such as clinical diagnosis and interventional procedures is increasing with the increasing number of MR scans car-

ried out each year. Products have to comply with MR safety and compatibility requirements. The intention of the basic testing methods issued as ASTM stan-

dards [26.5–8] is testing of passive devices or implants for MR safety and MR image artifacts. New test methods are currently under development for active implantable medical devices and will be published in 2011 as an ISO/IEC technical specification [26.9]. After improvement of these new methods within the MR technical community, these test methods will be probably also related back to passive devices to test certain interac-

tions such as radiofrequency (RF)- and gradient-induced voltages and heating as well as gradient-induced vibration as sources of unintended stimulation of devices. Device operation safety is mostly impacted by the electromagnetic and pulsed as well as static magnetic field described under electromagnetic interference (EMI) to a device or electromagnetic compatibility (EMC) within the upcoming ISO/IEC technical specification [26.10].

26.1 MR Safety

Although the general opinion is that there are no permanent negative health effects related to MR scanning, MR manufacturers have to take the necessary precautions to achieve and maintain this situation. Apart from the general safety aspects related to electricity, temperatures, mechanical precautions, etc., also the specific safety aspects of MR scanning must be controlled and have to fulfill the requirements formulated in safety standards. For MR, these specific safety requirements are stated in IEC 60601-2-33. Recently the third edition of this standard has been published [26.11]. It includes the specific requirements and limits formulated for electromagnetic fields applied during MR scanning of patients. The third edition now also introduces safety limits for these parameters specifically for the MR worker (the operator in the hospital, the MR engineer at the MR manufacturer, MR researcher, MR tester, etc.). The limits for patients are all based on temporary effects, i. e., dizziness, light flashes or metal taste related to the static magnetic field, heating related mainly to the RF fields, and peripheral nerve stimulation (PNS) generated by gradient application. Since these limits are set conservatively, they also apply for the MR worker as set for the patient. The fact that MR workers may be exposed more frequently does not change the limit values for short-term effects, since it is generally believed that no long-term effects are to be expected. Negative long-term effects

related to exposure to electromagnetic fields generated by MR scanners have not yet been proven. Initial studies have been started recently to try to demonstrate that such effects will indeed not be observed.

It is important to realize that the third edition of IEC 60601-2-33 does not include safety requirements specifically addressing interventional applications of MR scanners. Consequently, no requirements are formulated in this standard related to the type testing needed to demonstrate the safety of accessories applied during interventional scanning or additional safety requirements formulated for MR scanners used for interventional scanning. Also, safety requirements for other equipment used in combination with MR scanning, such as medical implants, surgical tools, and electronic or mechatronic equipment, are not specified in this standard, although warnings are included. However, a number of other standards do partly address these situations, and more work is underway in the international MR community to improve this situation. IEC 60601-2-33, however, requires that:

When the implant device is labelled as MR safe or MR conditional, the instructions for use shall explain that further information is described in the accompanying documents of the implant manufacturer.

26.2 Interactions in the MR Environment

The various parameters for the most important MR interactions are given in Sects. 26.2.1–26.2.7 (the list being limited due to current developments). For further details, other literature is available, where the physics of the MR interactions is explicitly described [26.12], therefore an overview level is the intention of this section.

In MRI, the expression “magnetic field” is used for the main static magnetic field. Because of the fact that the working volume of this homogeneous static magnetic field is air, the relative permeability μ_r is considered to be 1. Electromagnetic theory shows that the magnetic field strength H (magnetizing field) in units of

A/m is given by

$$B_0 = \mu_r \mu_0 H, \quad (26.1)$$

where the magnetic flux density B (the magnetic field) in units of T equals H if we ignore μ_0 . The static field is denoted by B_0 , the electromagnetic alternating field component by B_1 , whereas $dB_{x,y,z}/dx, y, z$ denotes the magnetic field gradient.

26.2.1 Magnetically Induced Displacement Force (Static, Dynamic)

Note, for diamagnetic, paramagnetic, and ferromagnetic materials in devices below their magnetic saturation when exposed to a magnetic field, the maximum deflection (angle) occurs at the point where the gradient product $|\mathbf{B}| \cdot |\nabla \mathbf{B}|$ is maximal. For ferromagnetic materials in devices that are magnetically saturated, the maximum deflection is measured where $|\nabla \mathbf{B}|$ is maximal [26.13]. Thus, especially for devices or parts within the magnet bore entrance, the maximum magnetically induced displacement force is dependent on the extent of the static magnetic field and is influenced by the active shielding of the magnet and the field decay as well as the magnetic saturation of the test object material and the magnetic properties of the material itself.

In summary, for ferro- and paramagnetic materials (all metals) and diamagnetic materials, the magnetically induced displacement force depends on:

- The static magnetic field B_0 (saturation)
- The static field gradient of the fringe field
- The magnetic saturation of the device material.

26.2.2 Magnetically Induced Torque (Static, Dynamic)

The magnitude of the torque induced by the static magnetic field depends on the device dimensions and geometry, and on the magnetic saturation of the material if the device is not completely saturated. The maximum static torque experienced by the device is at the isocenter of the magnet, where the static magnetic field is homogeneous and maximum.

In summary the torque depends on:

- The static magnetic field B_0 (below saturation)
- The device dimensions and geometry
- The magnetic saturation of the material.

Dynamic forces and torques are possible for electrically conductive devices and structures which are translated in the magnetic field. In addition to the static, magnetically induced force, a dynamic magnetically induced force based on Lenz's law can be detected for electrically conductive device parts of large size that are translated through the spatial gradient of the static field. This effect is potentially important for moving components. The interaction is dependent upon the speed of the movement, the magnitude of the spatial gradient of the magnetic field, and the effective area of induction, as well as on the conductivity of the device material.

Dynamic torque, which can occur in the static magnetic field, becomes detectable if electrically conductive parts are rotated within the static magnetic field. Device parts with high conductivity and a significant area of induction for eddy currents will especially exhibit a counter-torque that influences the handling of the device.

This interaction depends on:

- The speed of movement
- The magnitude of the spatial gradient of the magnetic field
- The effective area of induction
- The conductivity of the device material.

26.2.3 Radiofrequency-Induced Heating

Radiofrequency (RF)-induced heating and induced voltages are a complex issue, dependent on various parameters. RF pulses are in the MHz range and are the main source of energy amongst the interactions responsible for heating [26.14]. Not only device properties such as electrical conductivity, dimensions, shape, etc. have to be considered, but also the geometric arrangement relative to the specific MR environment of a given MR scanner. This includes also the geometric arrangement relative to the specific MR coil and the parameter settings of the MR sequence. It is necessary to know exactly, for each MR system, which coil and pulse sequence produces which RF output (spatially localized power deposition) and how the specific absorption rate (SAR) (see IEC 60601-2-33 for limits [26.11]) is calculated, measured, adjusted, and displayed by the system software [26.14]. In the area of RF fields, computer simulation of electromagnetic fields, SAR, and temperature distribution is currently being developed to assist in heating testing, at least for implants or instruments [26.15, 16]. Loop-closing contacts or the insertion of an instrument can be dangerous for the patient due to induction

from and coupling with the RF field. Electrically conductive structures as well as the patient's body can suffer from induced voltages and thus currents through the patient tissue. These currents, as well as sparking due to high voltage, may cause skin burns or even fire [26.17] and harm the patient or the MR interventionist.

This interaction depends on:

- The electric conductivity and permittivity of the device materials (and the impedance of connected device parts if electronic)
- The geometric dimensions of the device
- The relative configuration of the device or its components
- The conductivity and permittivity of surrounding tissue
- The power of the RF pulses (SAR)
- The geometric arrangement relative to the RF transmit coils (or to the tangential electric field)
- The position and architecture of the patient's body relative to the RF transmit coil
- The specific MR coil used (i.e., its electromagnetic field characteristics)
- The center frequency of the specific MR system.

26.2.4 Gradient-Induced Interaction

Switched gradient magnetic fields of currently, for instance, 40 mT/m gradient strength and 200 (mT/m)/ms gradient slew rate (see IEC 60601-2-33 for limits [26.11]) are used in MRI to provide spatial encoding of MR signals. Voltages induced by these switched gradient fields interfere with medical devices and may also, via the device, indirectly impact on the patient (through stimulation). If specific coupling criteria are met for interaction with the switched gradient magnetic fields, heating may also take place in electrically conductive structures.

Voltages induced due to this switched gradient field environment can interfere with medical devices in terms of their operation or by stimulating pulses in the patient.

In addition, dynamic forces and torques can be generated by switched gradient magnetic fields, resulting in vibration of the device or manipulator arms due to eddy currents in electrically conductive device parts, thus causing interaction also with the static magnetic field. The magnitude of such vibration (amplitude and frequency) is a function of the geometric position and arrangement of the device relative to the gradient coils (x , y , z) and depends on the gradient parameters (gradient pulse frequency, gradient strength, and slew rate) as well as on the size and weight of the device itself. The

source of this vibration is inside the device materials acting on the outside and considering each components source vibration.

Interactions induced by switched gradients include:

- Gradient-induced voltages (stimulation, activation)
- Gradient-induced heating
- Gradient-induced vibration.

This interaction depends on:

- The gradient amplitude (x , y , z) expressed in units of mT/m
- The effective stimulation time of the gradient pulses
- The combination of these two parameters resulting in the gradient slew rate expressed in (mT/m)/ms
- The gradient pulse shape
- The device position within the gradient coil
- The device orientation within the gradient coil
- The effective area of induction
- The conductivity of the device materials
- The static magnetic field B (providing the counter-part field).

26.2.5 Safe Operation of Devices Within the MR Environment (Dependent on Individual Demands)

Some examples of how an MR system can affect safe device function are inhibition of electrical circuits or mechanical components such as springs or levers of devices. For cases where specific parts, actuators or sensors cannot be designed to be suitable for high-field application, MR testing has to determine specific conditions under which a device can operate safely in the MR environment.

The maximum peak acoustic noise level of the MR system during scanning is not allowed to exceed 140 dB relative to 20 μ Pa in the accessible area of the MR equipment [26.11]. Thus, acoustic noise could also be an issue for certain sensors. Finally, it is important to examine the interaction among different devices or systems before MR safety labeling. The aforementioned examples show the importance of a specific and comprehensive functional testing protocol.

For evaluation of safe operation, the following interactions have to be considered:

- Static magnetic field
- Switched gradient magnetic field
- RF electromagnetic field

including parameters such as:

- Device configuration
- Device orientation
- Possible or intended device operational status (on, off, standby or other function modes).

26.2.6 Image Quality

Image quality issues, such as signal-to-noise ratio (SNR) and B_0 homogeneity, are important for safe diagnostic operation of MR systems.

The effect on image quality is a major consideration. RF emission by actuators or other active parts of a device can significantly decrease the image quality of the MR system (e.g., by decreasing the SNR) and can therefore affect the clinical diagnosis. Interference can be visible in the MR image, appearing as, for example (but not limited to), noisy images due to spikes, dots or stripes and spurious proton signals [26.19]. Other degradations, disturbances or inaccuracies of the MR image are likely (decrease in SNR or B_0 field homogeneity, etc.).

26.2.7 MR Image Artifacts Due to the Medical Device

In most cases, MR image artifacts do not primarily affect patient safety but rather have high clinical relevance for adequate diagnosis, e.g., stent patency. If exact positions are needed, e.g., for needle insertion or implantation of x-ray markers or radioactive seeds, safety becomes critical for the whole diagnostic procedure. Susceptibility [26.20] and RF artifacts depend on various parameters such as the magnitude and orientation of B_0 , the alignment of the medical device relative to B_0 , and the MR pulse sequence parameter settings (Fig. 26.1).

MRI susceptibility artifacts are caused by field inhomogeneity around an object (Fig. 26.1c,d) and show a particular pattern due to the magnetic field lines [26.18, 21]. Comprehensive artifact testing is necessary to provide artifact information for all relevant configurations. With respect to MR imaging compatibility, artifacts influencing image quality can hide information or result in incorrect depiction of the position of a device, e.g., a needle, in the MR image [26.19, 22]. Thus, artifacts can lead to diagnostic misinterpretation due to missing information resulting from susceptibility artifacts due to the device materials. Furthermore, RF artifacts [26.23] are likely, due to coupling of electrically conductive structures with the electromagnetic field, e.g., for an instrument introduced into the patient. Such coupling can result in signal shielding

(Faraday cage effect), distortion or even intended amplification of the signal (mainly by designed structures, e.g., coils), which can be used for active device visualization such as tip tracking. For external devices placed close to the patient, image distortion in different dimensions can occur. The image distortion can extend into the patient tissue even if there is no physical contact of the device with the patient.

Application of low-susceptibility materials such as polymers and ceramics minimizes such artifacts. However, plastic parts can contain hydrogen protons that disturb the image due to MR signals generated inside the imaging volume. On the other hand, signals from plastic parts outside the imaging volume can degrade image quality if folded into the field of view. Therefore, MR artifact testing should be implemented at an early stage of the development process of devices to check the materials used within or close to the imaging volume of the MR system. Polymers can also contain dotting with

ferromagnetic debris from manufacturing, causing significant artifacts. The presence of an oxide layer can play a role for the artifact size, but only if the oxide has certain paramagnetic characteristics different from the core metal or alloy. On Nitinol samples, increasing thickness of oxide layers have been determined in MRI. Figure 26.2a–d shows 1 mm × 40 mm Nitinol wire samples which were placed in 0.9% NaCl doped with 2 mmol/l

gadolinium MR contrast agent, (Multihance, Schering AG, Berlin) parallel to the main field of a scanner with 1.0 and 1.5 T, and perpendicular to it at 0.3 T. Coronal (TE) and transversal (TR) orientated spin echo (SE: TR/TE = 300/30 ms) and gradient echo (GE: TR/TE = 100/10 ms, FA = 40°) images were obtained with a Hitachi (0.3 T)/Philips Gyroscan NT (1.0 T/1.5 T) using a quadrature head coil with 27 cm inner diameter.

26.3 Examples of MR Artifacts Caused by Medical Devices

Instruments as well as implants can cause significant image artifacts. The problem of imaging artifacts will be illustrated using the example of stents. These are tube-like, expandable devices which are placed via catheters, mainly in narrowed or occluded arteries to reestablish or maintain blood flow. The metallic material and the stent shape can lead to severe changes of the image information, leading to artifacts [26.10, 12, 24, 25].

Conventional imaging sequences are often compromised and signals complete vanish inside the stent lumen and in close proximity. A variety of reports on experimental [26.26–28] and clinical studies [26.29, 30] of postinterventional MR imaging of stents have been published in recent years, plus safety aspects and the influence of different materials and structures for MRI in the presence of stents [26.31] and stent grafts [26.32, 33] for particular MRI settings. Evaluation of imaging parameters and the effects of different field strengths, sequence types, parameters, and stent orientations have been reported. We have utilized field strengths of 0.2, 1.0, and 1.5 T and a variety of different material processing techniques with a particular focus on nitinol and implementation of resonant stent structures. MR image quality of the material (tissue) outside and inside eight different common vascular stents with nominal diameter of 8 mm and length of up to 80 mm after expansion was examined. Experiments were performed with unchanged sequence parameters at static magnetic field strengths B_0 of 0.2, 1.0, and 1.5 T. Effects of the type of sequence and imaging parameters, the orientation of the stent axis in the static magnetic field, and the orientation of the recorded slice were systematically assessed [26.34]. Suitable strategies for recording diagnostic MR images during interventional procedures and in follow-up examinations were derived from the experiments. The results should help to choose the optimal imaging modality and, in the case of MRI, suitable sequence types and imaging parameters in examinations of patients during and after stent implantation. As a result

of these experiments, specific strategies have been developed to reduce susceptibility artifacts by selecting other materials such as niobium and tantalum for expanding balloon stents and to improve the behavior of nitinol for self-expanding stents. To overcome RF artifacts, stents that work as electric resonators to interact with the MR imaging process have been developed. This RF antenna effect of stents provides enhanced signal intensity of the stent lumen. By inductive coupling, improved imaging of the stented area has become possible [26.35, 36].

MR systems have field strengths that vary from 0.2 up to 3 T. Basically the same sequence types are used, such as spin echo and gradient echo [26.37]. The sequence choice has an important influence on the size of the artifacts in MRI. Another important factor is the field strength of the MR system. The field strength has a significant influence on the generation of artifacts from devices and implants such as stents. The higher the field strength, the greater the influence on the MR image. Changes of the susceptibility also become more relevant. Thus, devices that show only minimal artifacts in low-field (0.2–0.5 T) MRI demonstrate significantly increased artifact size for higher fields. Susceptibility artifacts are well understood and have been examined extensively [26.34, 38, 39].

Flow artifacts [26.40–42] depend on the field strength, and the basic material characterization and the electromagnetic behavior are more relevant to the MR imaging of stents. Although 1 and 1.5 T differ by 50%, the artifact size does not increase by 50%. As 1.5 T is the current state of the art in coronary MR angiography as well as cardiac imaging, stent samples have been examined in 1.5 as well as 1 T. RF artifacts are more relevant in this context, because the resonant frequencies are different, leading to different imaging behavior [26.23, 43]. All stents that consist of interconnected segments are subjected to eddy current induction as well as parasitic resonant frequencies, both of which lead to shielding of the lumen (Fig. 26.3).

Fig. 26.3 Palmaz 3 mm stainless-steel stent (316L) in MRI

As described above, susceptibility artifacts and RF artifacts prevent lumen visualization.

The MRI Larmor resonance frequency is defined as

$$\omega_L = \gamma_H * B_0 ,$$

where $\gamma_H = 42.58 \text{ MHz/T}$, i.e., 63.87 MHz at 1.5 T (Fig. 26.5).

In addition to the pulse sequence (gradient or spin echo) and the *susceptibility* of the material, the geometric shape of an implant, e.g., a stent, has a significant influence on the distortions of the static magnetic B_0 field. As a result, a nonuniform pixel intensity is generated in areas which should have a uniform pixel intensity.

Copper has magnetic susceptibility close to those of tissue and water. Thus, susceptibility artifacts can be neglected when using copper wire rings. To prove this concept, an experiment has been performed using four copper rings: a noninsulated and insulated ring closed by soldering, an open ring, and a ring tuned using a capacitor to the resonant frequency (42.58 MHz) of a 1.0 T magnet (Figs. 26.6, 26.7).

26.3.1 Stent Artifacts Summary

The following simplified description for stent artifacts can be defined:

- The material causes a local inhomogeneity of the stent lumen, whereby the spatial encoding of the MR signal is altered.
- Eddy currents cause magnetization of the stent. These local magnetic fields lead to additional local

Fig. 26.4 Stent sample with schematic pathways for eddy currents depending on the direction of gradient fields and RF fields. Eddy currents are also induced in the circumference of the stent, because all segments are interconnected

Fig. 26.5 In MRI, biological tissue is exposed to strong static, permanent magnetic field and switched gradient magnetic fields (schematic view with MRI cut open)

inhomogeneity of the magnetic field, causing spatial miscoding of the spin frequency similar to the effect of susceptibility.

- RF pulses from the MRI device do not enter the stent lumen because of the Faraday cage shielding effect and the induction of eddy currents.

Fig. 26.6 Schematic representation of the principle of a susceptibility artifact. Alteration of the magnetic field homogeneity by a metallic rod causes a change of the local resonance frequency and thus a mismatch of the spatial encoding, leading to the artifact on the right

Fig. 26.7 Copper rings in MRI. The first and second closed Cu rings on the *left* demonstrate the phenomenon of local magnetization with induction of eddy currents. The field inhomogeneity shields the inner section of the ring. Whereas the open ring is neutral and does not alter the MRI signal, the resonant ring (*right*) shows significant signal enhancement depending on the flip angle of the gradient echo (GRE). This proves that the resonant structure can enhance the MR signal intensity within the lumen of a stent. Most stents can be characterized as a set of interconnected rings

- If excitation RF pulses enter the stent, escape of the signals emitted due to proton relaxation inside the stent is hindered.

To evaluate the capability of a resonant circuit to overcome stent artifacts, we selected the stent with the small-

Fig. 26.8 Dependence of the signal-to-noise ratio on the flip angle for a vena cava filter (*open circles*), a thrombus clot (*open squares*), and a tube filled with 1 mol/l gadolinium-doped water (*solid circles*) (after Bartels et al. [26.23])

est visible MR artifacts. The stent was equipped with a wire coil tightly wound around the stent, and the wire was soldered to a surface-mount device (SMD) capacitor and thus tuned close to the resonance Larmor frequency: 42.58 MHz at 1 T and 63.87 MHz at 1.5 T. In addition to the resonant circuit, the technique described by Bartels [26.23] has been used, i.e., using the flip angle to increase the pulse energy within the stent to overcome the shielding (Figs. 26.8, 26.9).

Fig. 26.9a,b Setup schematic and photograph of MRI testing of stent samples. Measurements took place in a Petri dish as a test container in 1 T and 1.5 T Philips and Siemens MR using the standard head coil. The test medium was water and 2 mmol/l Magnevist (Schering, Berlin), equivalent to 1 mmol/l Gd-diethylenetriamine penta-acetic acid (DTPA)

26.5 MR Safety Labeling

In medical practice, the question arises of whether a patient with a specific implant can be safely MR-scanned or whether a specific device can be used close to or on the patient during MR scanning. This information is often not available, and the clinical staff have to make the decision. It is very important to base such clinical decisions for MR safety or conditional scanning on original information from the instructions for use from the MR implant manufacturer. Some information can be found on the Internet, for example, at www.mrisafety.com; however, often the reader is pointed to advices of e.g. or similar *consult the manufacturer of the particular device for the latest safety information* (e.g. Conditional 5,

whereas only *MR Conditional* is the official term according to ASTM F2305). Information from the Internet only may not be complete, can be outdated or may not cover the responsibility of the device manufacturer or the MRI operator. MR safety labeling provided by the device manufacturer is mandatory to ensure patient safety.

www.magresource.com for example is listing original MR labeling information from the device manufacturer. Information based on old MR standards as well as new MR standards is clearly marked. The database is however restricted to registered users.

Currently, ASTM F2503 [26.9], which defines marking practice for items brought into the MR environ-

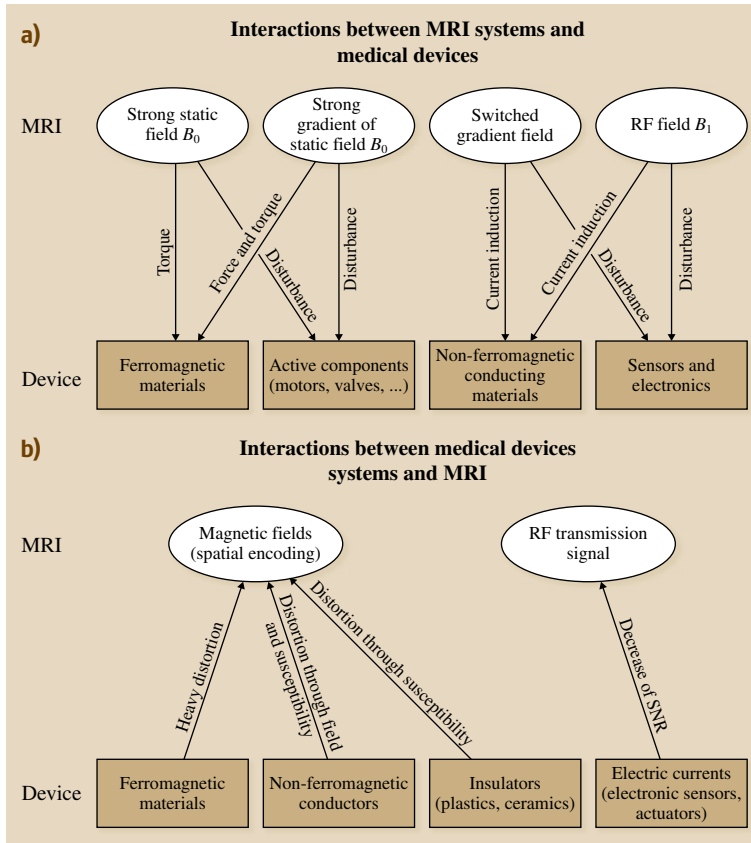

Fig. 26.12 (a) Interactions of MRI with devices and (b) interaction of a device with MRI (after Gutmann)

ment, requires MR safety labeling using the following categories and icons: MR Safe, MR Conditional, and MR Unsafe. Besides implants and interventional instruments commonly used with diagnostic imaging modalities, other devices, e.g., surgical setup, frames or robots, are being used with MRI as well, and enter the MR environment. Considering complex systems, basic and specific tests are needed for evaluation of the MR interaction between device components and the MR environment. Thus, medical device manufacturing requires not only standard technical and clinical knowledge but also MR safety-specific knowhow for device use in combination with a specific MR environment (Fig. 26.12)

In the early 1990s, standards were established for safety testing of passive devices brought into the MR scanner during scanning.

ASTM F2052 [26.5], ASTM 2213 [26.6], and ASTM F2182 [26.7] are regularly updated and therefore are still of value, although the limits proposed in these standards are still based on practical experiences

rather than scientific data. Also, ASTM F2119 [26.8] has been updated very recently.

26.5.1 Terms, Definitions, Icons, and Marking

ASTM F2503 [26.9], which describes terms, definitions, and icons for marking items (including medical devices) for use in MR environments, superseded the *historical* definitions of MR safe and MR compatible [26.44], which are listed here for clarity but no longer in use:

MR safe: The device, when used in the MR environment, has been demonstrated to present no additional risk to the patient or other individuals, but may affect the quality of the diagnostic information.

MR compatible: The device, when used in the MR environment, is MR safe and has been

demonstrated to neither significantly affect the quality of the diagnostic information nor have its operations affected by the MR device.

The MR conditions under which the device was tested should be specified in conjunction with the terms MR safe and MR compatible, since a device which is safe or compatible under one set of conditions may not be found to be so under more extreme MR conditions. The definitions were extracted, with permission, from [26.44].

In addition to several MR safety issues that apply to items and components such as magnetically induced displacement forces and torques, RF-induced heating, induced voltages, acoustic noise, interactions among devices, as well as a considered safe device, the term MR compatible covers image quality and safe operation of the device according to the definition above. MR image artifacts are not considered a direct safety issue but, on the other hand, safe operation of the device is a direct safety issue. MR compatible was often misinterpreted and used incorrectly for device labeling. Thus, the ASTM subcommittee F04.15.11 for MR standards decided to withdraw the term in 2005 based on the marking practice defined in ASTM F2503 [26.9]. MR compatible was not redefined and

is no longer used in current standards or for MR labeling.

The current *active* terms (MR safe, MR conditional, and MR unsafe) are defined in ASTM standard F2503 and cover MR safety-related interactions in the MR environment as discussed earlier in this chapter. As mentioned, MR image artifacts are not considered as a direct safety issue. However, information regarding image artifacts and degradation of image quality is requested in order to inform the MR operator.

Figure 26.13 shows the three current icons of MR safety, which should be used for direct marking on items if applicable and/or together with more detailed information in their instructions for use. The definitions of the terms are as follows:

MR conditional: an item that has been demonstrated to pose no known hazards in a specified MR environment with specified conditions of use. Field conditions that define the specified MR environment include field strength, spatial gradient, dB/dt (time rate of change of the magnetic field), radiofrequency (RF) fields, and specific absorption rate (SAR). Additional conditions, including specific configurations of the item, may be required.

MR safe: an item that poses no known hazards in all MR environments. NOTE 1 – MR safe items include nonconducting, nonmagnetic items such as a plastic Petri dish. An item may be determined to be MR safe by providing a scientifically based rationale rather than test data.

MR unsafe: an item that is known to pose hazards in all MR environments. NOTE 2 – MR unsafe items include magnetic items such as ferromagnetic scissors. The definitions were extracted with permission from [26.9].

Fig. 26.13 Current icons for MR marking of devices and items used within the MR environment (extracted with permission from ASTM F2503-08 [26.9])

All devices including interventional tools that cannot be marked MR safe or MR conditional are marked as MR unsafe. MR unsafe devices may not enter the controlled access area, which can be larger than, but is often identical to, the RF shielded room or the MR room. Considering the definitions of the terms above, most items (and devices) will be subject to the MR conditional label, due to the fact that more or less specific conditions – result from MR testing that determine un-

der which conditions the device's use is safe inside the MR environment. Basically, these devices contain metal components that can exhibit a certain level of force and torque, but also have the possibility of induced voltages and induced heating because of the materials' conductivity. The latter issues can be encountered for other conductive materials, e.g., carbon fiber. Other safety issues may exist that affect the safe operation of the device (e.g., electrical drives and circuits) or the MR system (degradation of image quality by, e.g., RF emission). Devices that consist of metal or other electrically conductive materials cannot be marked MR safe unless testing has shown no known hazards in all MR environments. This rigorous requirement is mainly satisfied by devices that consist solely of nonmetallic and non-conductive materials such as plastic, wood, and glass. The historical definition of MR safe could be used only in conjunction with the MR conditions under which the device was tested. Therefore, a device considered MR safe under at least one condition according to this historical term was (and still is today) in reality an MR conditional device, and should be labeled as MR conditional instead of MR safe using the F2503 terminology. Replacement of old device MR labeling is considered important by responsible agencies to ensure clear understanding of safety by the MR operator.

The content of MR labeling is based on the interactions mentioned above as include in ASTM F2503 [26.9] and in the FDA guidance on *Safety and Compatibility of Passive Implants* [26.45]. The following provides an extended example of such labeling.

Through nonclinical testing it has been demonstrated that the DEVICE is MR Conditional:

Force and Torque. *By testing of magnetically induced displacement force and torque the DEVICE showed a magnetically induced force of 3% (equal to 2° deflection) of the limit and a magnetically induced torque of < 1% of the limit; static magnetic field of 3 T with a spatial gradient magnetic field of 8.4 T/m and a spatial gradient field product of 18.0 T²/m. According to these test results, entering the MR magnet can be con-*

sidered safe directly after implantation without safety discussion only for static magnetic fields of 3 T and less with a spatial gradient magnetic field of < 100 T/m and a spatial gradient magnetic field product < 100 T²/m (values extrapolated and cut off; extrapolation exceeds 100 by far). Nonclinical testing has not been performed to rule out the possibility of implant migration at static gradient magnetic fields stronger than mentioned above.

RF Heating. *In nonclinical testing with a 3 T MR SYSTEM NAME and MODEL and implant in worst-case phantom position, the DEVICE produced a maximum temperature rise of 4.5 °C in a static human torso-shaped phantom with a background temperature increase of 3.4 °C at a whole body averaged specific absorption rate (WBA-SAR) software display of 3.8 W/kg (3.4 W/kg in a phantom calorimetric test) for 20 min of MR scanning with transmit/receive body coil. The local body SAR shall be limited to 5.0 W/kg for using the MR body coil (theoretical estimated WBA-SAR < 1.5 W/kg). Note that the WBA-SAR is inappropriate to scale exact local temperature increases. Local SAR can deviate and result in much higher values than the WBA-SAR software display. Measurement inaccuracies and additional safety margins should be taken into account. Before each individual MR procedure, it might be necessary to discuss the situation with regard to patient benefit by consulting medical experts and MR physicists.*

Gradient Interactions. *(to be considered for induced voltages/heating/vibrations (standardization work in progress))*

MR Image Artifacts can affect the surroundings of the implant with a distorted DEVICE length of +20% in a standard spin echo sequence and +50% in a standard gradient echo sequence. The image artifact of the DEVICE diameter can be +300% in a standard spin echo sequence and +540% in a standard gradient echo sequence.

26.6 Interpretation of MR Labeling

Old and obsolete MR labeling information exists for several medical devices from the past. Therefore, the MR user should be aware of risks and pitfalls when MR scanning a patient with an implanted or exter-

nally attached medical device. It should also be verified whether there is a contraindication to MR scanning of patients with devices expressed in the instructions for use from the MR system manufacturer. Import-

tant information that is needed for interpretation is as follows:

- Exact and secure data about the medical device
- Written original MR labeling information from the instructions for use (from the device manufacturer or cooperating reliable MR safety online database) according to the example above
- Compatibility datasheet of the MR system used
- Exact and secure data about the RF coils of the MR system.

The MR labeling should have a section about magnetic forces and torques. Important parameters to be controlled based on the compatibility datasheet of the MR system are the static magnetic field with its spatial gradient magnetic field in T/m and the spatial gradient magnetic field product in T²/m. Note that static magnetic fields of less (1 T) than that displayed in the labeling (e.g., 3 T) exist, but with higher spatial gradients, which is not covered by the static magnetic field only. Also it might be possible that the MR labeling only displays the maximum technically accessible spatial gradient magnetic field used for MR testing. Usually, the MR manufacturer presents the global maximum spatial gradient magnetic field. Comparing these values, two options for the decision that entering the MR magnet is safe are technically meaningful (but very different from liability point of view):

1. The MR labeling reports also the extrapolated spatial gradient magnetic field (e.g., < 100 T/m in the example above) which is directly comparable with the compatibility datasheet of the used MR system, or
2. MR labeling only reports the maximum technically accessible spatial gradient magnetic field used for MR testing, but in addition the corresponding deflection angle, which allows the experienced MR user to carry out the extrapolation for comparison with the compatibility datasheet. Note: A lot of MR labeling information are providing 700 or 720 G/cm. This value is low compared to the spatial gradient magnetic field inside the magnet bore of most modern MR systems. Furthermore, this value is technically meaningless if not a deflection angle is provided to make the user aware of how far the

item might be away from the limit of 45° deflection and which safety margin is still remaining under the given value of 720 G/cm obviously used for testing.

The RF heating section of the MR labeling should provide sufficient data [MR system, field strength, temperature increases, scan duration, local and average SAR (software displayed, calorimetric, background), location, configuration, orientation, MR coil, pulse sequence, etc.] from MR testing of the sensitivity of heating of a device under so-called worst-case considerations in a specific test phantom.

This information provides an experimental example. Such data for safe MR scanning are difficult to transfer to a specific patient, especially if high sensitivity for RF heating is shown in the MR labeling. The specific absorption rate (SAR) and related B1/RF mode selections on the MR system are today the only parameters to limit the RF power and tissue heating of the patient. Note that the WBA-SAR is inappropriate to scale to exact local temperature increases at implanted devices. Only under the specific assumptions stated in the MR labeling is MR scanning intended to be safe. Therefore the device manufacturer should have considered the whole product matrix to be covered by the worst-case(s). Additionally; a transfer of test results from the phantom test to human is necessary to apply, using for example computer simulation.

Before each individual MR procedure, it might be necessary to discuss the situation with regard to patient benefit by consulting medical experts and MR physicists.

Future test methods currently under development will increase the reliability of data, resulting in less uncertainty for the patient population.

Data considered for the interaction with switched magnetic gradients should include both, parameters about software and hardware (device location and orientation).

Information from MR labeling about MR image artifacts should show dimensional data to inform the MR user about the extent of artifacts created by the device when using standard spin and gradient echo sequences. Optimization to decrease artifacts is feasible by adjusting the individual MR pulse sequence.

26.7 Discussion

Overall patient safety during an MR scan is obviously very important. Formulation of safety-related require-

ments in international standards enables this safety to be obtained and maintained. The risks related to MR

scanning are therefore minimal. Nevertheless, careful attention by the operator is required before each scan, because interaction between the MR environment and materials or devices brought into the MR scanner with the patient may introduce additional risks to the patient. When these devices are accessories, labeling on the devices should provide enough information regarding allowable MR scan parameters, but the label cannot cover all potential circumstances.

Interviewing the patient prior to each scan remains very important, whereby it must be realized that sometimes the patient himself does not know the relevant information about the materials or devices which he brings into the scanner, because they are implanted. Therefore, patients should be subject to further clinical examination or imaging by other modalities if the situation remains unclear.

Currently, many studies are ongoing and results have sometimes been published on the MR safety of specific devices, although such results must always be interpreted with care. Often, these studies apply a limited set of MR parameters, defining in fact the con-

ditions for safe scanning. Also, the number of patients studied is usually very limited, therefore the conclusions cannot be extrapolated to form general safety statements. Careful testing of MR safety for devices by the manufacturer or testing laboratory working according to ISO 17025, GLP or other quality standard therefore remains essential.

It is good to realize that, for reasons mentioned in this chapter, MR manufacturers in general still do not approve scanning of patients with implants, and formulate warnings in their instructions for use regarding the significant risks associated with scanning of patients with active or passive implants containing conductive materials.

When the implanted device is labeled as MR safe or MR conditional, the operator is informed via the instructions for use of the implant regarding the safety and possible conditions to be taken into account during scanning. The instructions for use from the MR manufacturer should explain according to IEC 60601-2-33 that further information is described in the documents from the implant manufacturer.

27. Long-Term Ventilators for Intensive Therapy

Thomas Peyn

Long-term ventilators are life-sustaining devices. Depending on patient conditions, intensive care ventilators must support or replace spontaneous breathing. In this context, optimizing mechanical ventilation and weaning the patient off the ventilator are typical challenges that caregivers face on the intensive care unit every day. To meet all clinical requirements, current ventilators provide many different ventilation and weaning modes, some of which are explained in this chapter.

27.1 Tasks of the Ventilator

In order to supply the body with air containing oxygen, the volume of the lungs increases when breathing in. When breathing in, the pressure in the lungs drops, and in this way atmospheric air is sucked into the lungs. The reverse applies when breathing out: thoracic and respiratory muscles return to their idle state, and the lung volume reduces. The resulting intrapulmonary increase in pressure results in the expiratory gas, which contains carbon dioxide, being expired. In an idle state, this procedure is repeated about 10–20 times per minute, in the case of an adult. For bodyweight of 75 kg, the

volume moved with each breath varies between about 350 and 850 ml. Taking into account additional physical activities, which can result in a significant increase in respiration, it is more than possible that our respiratory musculature shifts a total volume of 10 000–15 000 l of air over the course of a day. These figures underline the fundamental importance of our respiratory system for the entire organism. If the interplay of the organs and muscles involved in respiration is interrupted, ventilators can completely take over breathing or, if the patient is simply breathing too flatly, a share of the breathing

Table 27.1 Reasons for using ventilators

Reason for ventilation	Examples of possible causes
Functional limitations of the respiratory musculature	Due to a muscular injury or paralysis
Pathophysiological changes to the respiratory system and/or pulmonary tissue	Due to increased airway resistances or to a reduced lung compliance
Disruptions to respiratory mechanism	In case of thorax injuries
Disruptions to gas exchange/diffusion	Through the accumulation of pulmonary liquid or changes to the alveolar membrane
Disorders of the respiratory drive	Due to neurological disruption, cranial illness or injury

work. The many reasons that may require the use of a ventilator can, in principle, be allocated to five different issues (Table 27.1).

As well as the examples named here, use of a ventilator can also be required due to undesired respiratory depression caused by strong pain relievers or use of muscle relaxants. The examples listed make clear that patients can be dependent on breathing gas being supplied to them via special gas dosage equipment for many different reasons. A differentiation must be made here between a patient who is still breathing spontaneously and only needs to be offered an increased concentration of oxygen from a ventilation therapy device and a patient who is no longer able to perform the necessary breathing work and must be ventilated by a ventilator. Regardless of the breathing disruption, a long-term ventilator performs a life-saving function in all cases. Against this background, the ventilator must fulfill three different tasks:

1. Oxygenation of the patient: Provide and supply the patient with a mixture of oxygen and air.
2. Partial or total assumption of respiratory work: Generate and dose defined gas flow and respiratory pressure.
3. Monitoring of the device and patient: Generate alarms and visualize changes.

Ventilation therapy is primarily aimed at supporting or replacing the patient's breathing, thus guaranteeing efficient gas exchange. For this reason, the user of a ventilator must ensure that the selected device configuration

Fig. 27.1 Intensive care ventilator (Evita XL, Dräger Medical)

supplies the patient with adequate oxygen and that the ventilation sufficiently reduces the amount of carbon dioxide in the body. The required efficiency control is performed using arterial blood-gas analysis (Chap. 41). With a long-term respiratory device (Fig. 27.1) the therapist is given a tool with the help of which he can simultaneously train and strengthen the respiratory musculature of the patient, so that the patient gradually becomes used to breathing independently. This weaning process can last hours, days or even weeks. One reason for this wide range is the different duration of ventilation, during which atrophy of the respiratory musculature can occur. Furthermore, the duration of the weaning phase is influenced by the clinical picture of the patient, the recovery process, and the overall clinical situation.

27.2 Function and Components of a Long-Term Ventilator

If the patient's own respiratory activity is insufficient, some form of external substitution or complementary

intervention is required to ensure that the breathing gas is transported to the lungs. Artificial respiration can

be achieved by the delivery of defined gas flows and by the creation of positive pressures. There is a significant difference from spontaneous breathing: When the patient breathes spontaneously, the intrapulmonary pressure stays roughly at the baseline of atmospheric pressure. During artificial respiration, in contrast, the breathing gas is supplied to the lungs with a positive pressure. A hose or breathing circuit forms the interface between the ventilator and the patient. It is generally designed as a dual-hose circuit (consisting of an inspiratory and expiratory hose) in the case of clinical intensive care ventilators. In principle, the patient can be connected with the ventilation system either via a face mask or via a tube inserted into the trachea. The user will decide which method to use based on the respective circumstances such as the expected ventilation period and take the appropriate medical measures to prepare the patient.

Different system components are required for the technical implementation of a long-term ventilator. Their systematic arrangement is shown in Fig. 27.2.

27.2.1 Power Supply

Ventilators require electric power, oxygen, and compressed air to operate properly. The devices are usually supplied via an external power source as well as via the hospital's central gas supply (with a supply pressure of approximately 3–6 bar or 39–87 psi). In functional areas without a central gas supply or during transportation of patients within the hospital, it is necessary to ensure the functioning of the device by other means. Potential solutions include the use of separate compressors, compressed gas cylinder packs, and accumulators. Increasingly, ventilators not dependent on compressed air, which provide ventilation by filtering and using ambient air, are also being used. Only an oxygen source and a power supply are needed to operate such types of ventilators.

27.2.2 Gas Mixer

The gas mixer allows the user to vary the oxygen concentration of the inspiratory gas between 21% and 100% by volume. While ventilators often used to be supplied by external mechanical gas mixers, technological developments have resulted in an electronically controlled gas mixer integrated in the ventilator becoming standard. Gas mixers usually have a dual function in that they are also responsible for ensuring that the

breathing gas to be supplied is prepared and delivered in the required quantity and at the correct rate. It is often the threshold ranges which pose the greatest challenges to these metering systems. If, for example, a volume of 20 ml with an oxygen concentration of 30% by volume is required for ventilation, 17.7 ml of gas must be delivered via the compressed air valve and 2.3 ml via the oxygen valve.

27.2.3 Pressure Generator

The pressure or flow generator is responsible for delivering the mixed gas prepared by the gas mixer according to the ventilation parameters set in the operating unit. At the simplest level, the gas flow or pressure can be created manually using a manual ventilation bag. Technically comparable methods are to be found in older

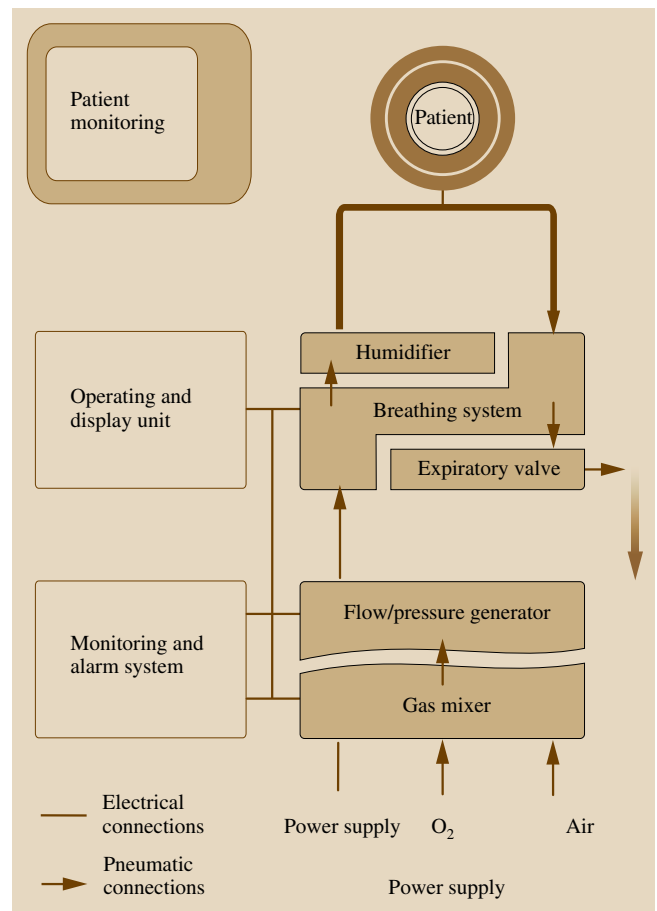

Fig. 27.2 Components of an intensive care ventilator

ventilators and anesthesia workstations. These devices generate the inspiratory gas flow using mechanically moving parts, for example, bellows or piston pumps. Modern intensive ventilators, on the other hand, feature combined gas mixture and metering devices which provide the required gas quantities directly from the gas supply systems. From a technical point of view, these components can be designed as a flow or a pressure generator. A flow generator is a controlled valve whose output provides a defined gas flow; the output pressure is not specified. A pressure generator, on the other hand, behaves similarly to a compressor, whose output provides a defined pressure with an unspecified gas flow. Pressure generators are often used to drive ventilators which are not dependent on compressed air and that use suctioned ambient air for patient ventilation.

27.2.4 Breathing System

The breathing system forms the interface between the patient and the ventilator. Clinical long-term ventilators are usually connected with the patient via an inspiratory and an expiratory hose (dual-hose circuit). The expiratory valve is closed during the inspiratory phase. The gas flow delivered through the inspiratory port passes through a breathing gas humidifier before entering the patient's lungs, so that it is adapted to the climatic conditions in the patient's lungs (see later). After the inspiratory phase, the patient exhales when the expiratory valve is opened. Thus, the expiratory gas passes through the ventilator again, but is not reused for the following inspiration as with anesthesia workstations. Based on this characteristic, the breathing systems of long-term ventilators are also referred to as *non-rebreathing circuits*.

For the sake of completeness, it should be mentioned that ventilators with *one-tube circuits* are used in individual clinical function areas. These circuits are also non-rebreathing circuits; however, in this case the expiratory valve is not positioned on the side of the device but near the patient. The improved handling provided by the single hose is thus in conflict with an expiratory valve that is arranged in the field of vision of the patient. Ventilators with single-hose circuits have become the standard in the areas of emergency care and intermediate care based on individual product requirements. In intensive care units, on the other hand, ventilators with two-hose circuits are more common due to the required expiratory volume monitoring.

27.2.5 Gas Humidifier

Breathing gas humidifiers are used to warm and humidify the inspiratory gas. Since the dry and relatively cool supply gas would dry out the patient's airways, it is absolutely vital to humidify and warm the breathing gas to avoid the risk of causing irreversible damage to the ciliated epithelium. Active or passive breathing gas humidifiers are available for this purpose. Active breathing gas humidifiers are located in the inspiratory limb and use electrical energy to heat a water bath. When the cold, dry gas passes over the water surface it absorbs water molecules and is thus warmed and humidified. Passive breathing gas humidifiers, termed heat and moisture exchangers (HMEs), in contrast, are placed close to the patient, between the tube and the Y-piece. These products are designed to buffer a significant fraction of the moisture and heat expired by the patient. This retained moisture is then used to condition the inspired gas passing through the HME during the next inspiration. Using a HME together with an active breathing gas humidifier in a single breathing circuit is not permitted as it would significantly impair the resistance of the HME. HMEs are also unofficially referred to as *filters*, which is a misnomer as they have nothing in common with each other, unless they also fulfill a hygienic function (for example, HMEs with an integrated microbial filter).

27.2.6 Expiratory Valve

Besides the above-mentioned switchover function, the expiratory valve is also responsible for two additional important tasks. If the valve is not opened completely during expiration, a positive end-expiratory pressure (PEEP) is created in the lungs. This PEEP pressure is therapeutically important because it increases the gas exchange surface of the lungs. An adequate PEEP can also prevent the collapse of individual alveolar areas. The expiratory valve can also fulfill another function providing that the ventilator also controls the valve during the inspiratory phase. In this case, the expiratory valve can compensate for undesired pressure rises in the breathing system caused, for example, by the patient coughing.

27.2.7 Operating and Display Unit

The operating and display unit forms the interface between the ventilator and the user. These units are often touchscreens designed to display pressure and flow curves as well as multiple menus for setting different ventilation modes, adjusting alarm limits or measured

value overviews, etc. The parameter settings entered in the operating unit control the other device components and therefore significantly influence the ventilation pattern applied to the patient.

27.2.8 Alarm System

The monitoring and alarm system ensures that the ventilation parameters set in the operating and display unit are actually applied. It also issues audible and visual alarms to alert staff to critical changes in the patient's condition or technical malfunctions. The following is measured: the inspiratory oxygen concentration (controlled by the gas mixer), and the ventilation pressure and ventilation volume (to monitor the pressure/flow generator). In addition, the use of an active breathing gas humidifier makes inspiratory breathing gas temperature measurement with an alarm system obligatory (to con-

trol the breathing gas temperature). Please note that this chapter does not provide a detailed explanation of the sensor technology or the different measurement principles as this information can be found in Chap. 47.

27.2.9 Patient Monitoring

Patient monitoring is used to monitor the patient's vital functions. This includes, for example, electrocardiogram (ECG), blood pressure (noninvasive and/or invasive), oxygen saturation, and often also the measurement of the carbon dioxide concentration in the breathing gas. Although patient monitors do sometimes display ventilation data, these devices are to be seen as an independent display unit with an alarm facility. This makes patient monitoring a significant component of the intensive care workstation, but it is not part of the ventilator. For more information on this topic please refer to Chap. 48.

27.3 Technical Implementation

Ventilators differ according to their gas flow behavior. Devices which provide ventilation by generating a continuous gas flow (continuous flow systems) are used as well as demand flow devices which only provide a gas flow during the inspiratory phase.

27.3.1 Continuous Flow Systems

A continuous flow of oxygen and compressed air is supplied from the pressurized gas sources via meter-

ing valves. This gas flow is guided via an inspiratory hose to the patient and from there via an expiratory hose to an expiratory valve. Thus, a patient who is breathing spontaneously can always cover his air requirements from the gas flow. If the patient needs to be ventilated, the expiratory valve is closed for a defined period. This leads to a pressure rise in the breathing system and the gas flow is supplied to the patient's lungs. The inspiratory ventilation pressure is limited by an adjustable pressure control valve. With

Fig. 27.3 Continuous flow system

Fig. 27.4 Demand flow system

the switchover to expiration, the expiratory valve is opened and the pressure in the breathing system returns to the ambient or the PEEP pressure. The breathing gas exits the lungs through the existing decrease of pressure, is mixed with the constant flow, and flows through the expiratory valve. In practice, continuous flow systems are preferably used in neonatal respiration and in respiration therapy. Respiration therapy or also continuous positive airway pressure (CPAP) devices differ from ventilators in that their expiratory valve can only generate a constant, positive pressure. The use of a respiration therapy device is thus reserved for spontaneously breathing patients, who are, for example, dependent on an increased oxygen concentration (Fig. 27.3).

27.3.2 Demand Flow Systems

In contrast to the above-mentioned continuous flow systems, demand flow systems only supply a gas flow during the inspiratory phase. In the case of controlled ventilation, the gas flow is generally synchronized in accordance with the user-defined time pattern (time-

cycled ventilation). This can be defined with controllers, for example, for the inspiratory and expiratory time according to the operating philosophy of the device. Demand flow systems respond to spontaneous breathing activities by the implementation of a trigger criterion (Sects. 27.4, 27.5). Demand flow systems reduce the gas consumption considerably and are therefore also used in inhalators which promote the breathing depth of the patient and/or apply aerosols synchronized with inspiration (Fig. 27.4).

27.3.3 Combined Flow Systems

Some ventilators use combined flow systems for technical reasons or due to special operational requirements. These deliver a low constant or base flow on the order of some liters per minute, compared with the patient's gas requirement. These systems then increase the gas flow to meet the respective requirement when inspiration is triggered. Combined flow systems are used, for example, in ventilators which need to cover the entire spectrum of patients ranging from premature babies through to adults.

27.4 Controlling the Ventilator

27.4.1 Start of Inspiration

The start of an inspiratory phase is mandatory in controlled ventilation modes after the expiratory time has

elapsed. In ventilation modes during which the ventilator merely supports the patient's work of breathing, on the other hand, the ventilator must recognize the patient's breathing activities and provide an adequate gas

flow. The trigger of the ventilator acts as a detector for the spontaneous breathing efforts. This is a device function with a user-adjustable threshold (known as the trigger threshold). Although the patient's spontaneous breathing activity is reflected in pressure and flow changes in the breathing system and both signals could in principle be used as a trigger criterion, flow trigger systems are mainly used in current ventilators because the tendency for artifacts is low. In this case, the ventilator responds to the flow signal generated by the patient and the trigger threshold can be adjusted in units of l/min.

27.4.2 Switchover Behavior

The ventilator's switchover behavior from inspiration to expiration or vice versa is influenced significantly by the long-term ventilator control. In this regard, a distinction can be made between four different types of control:

- Time-cycled (occasionally also referred to as time-time-cycled) mode. The duration of the inspiratory and expiratory phase and thus also the switchover time is defined by user-adjustable time parameters. Controlled (mandatory) ventilation modes are often implemented with this control type, as it enables patient ventilation with a defined ventilation ratio (inspiratory to expiratory time).
- Pressure-cycled mode. In pressure-cycled modes, the switchover from inspiration to expiration takes place when an adjustable ventilation pressure has been reached. Inspiration takes place after a time phase has elapsed (pressure-time-cycled mode) or by a patient activity and on reaching a trigger criterion. Nowadays, pressure-cycled mode is mainly used with impermissibly high pressure rises in connection with an audible alarm as a safety element.
- Volume-cycled mode. The switchover from inspiration to expiration occurs in this case after the delivery of a ventilation volume (tidal volume) to be defined by the user. As with the pressure-cycled mode, the next inspiration takes place after a time phase has elapsed (volume-time-cycled mode) or by a patient activity. The volume-cycled mode is sporadically used in supporting ventilation modes. Moreover, in US and American-influenced markets it is used in mandatory ventilation modes, too.
- Flow-cycled mode. This control is primarily used for supporting ventilation modes and initiates the expiratory phase when the gas flow decreases to a defined value (e.g., 25% of inspiratory peak flow). In flow-cycled modes, the start of inspiration is mostly initiated by a patient activity and on reaching a trigger criterion.

27.5 Ventilation Procedures

Basically, ventilators can only follow two different behavior patterns despite the virtually endless number of ventilation modes. These are controlled and supported ventilation methods. The main difference between these techniques is as follows: During controlled (mandatory) ventilation, the behavior of the ventilator is defined by the user-configured ventilation parameters. In supported ventilation modes, on the other hand, the ventilator follows the patient's breathing activities and only provides support by increasing the pressure in the breathing system. Variations of these two ventilation methods are pure spontaneous breathing without any support pressure and mixed ventilation modes with alternating mandatory and supporting phases. Figure 27.5 provides an overview of the different respiration/mechanical ventilation methods and illustrates the medical necessity of having an individual ventilation therapy.

27.5.1 Controlled Ventilation (Total Respiratory Substitution)

The ventilation modes belonging to this category are characterized by the fact that the patients do not breathe spontaneously (SPN) and that the ventilator performs the total work of breathing. The different modes can be divided into volume-controlled (VC) modes and pressure-controlled (PC) modes. Volume-controlled modes are characterized by the fact that the patient is ventilated by a user-defined volume. In volume-controlled modes the airway pressure is a resulting parameter and provides information on lung expansibility (compliance) and airway resistances (resistance). In contrast to this, the user specifies an inspiratory ventilation pressure in pressure-controlled modes. Conversely, in these modes it is not the ventilation pressure but

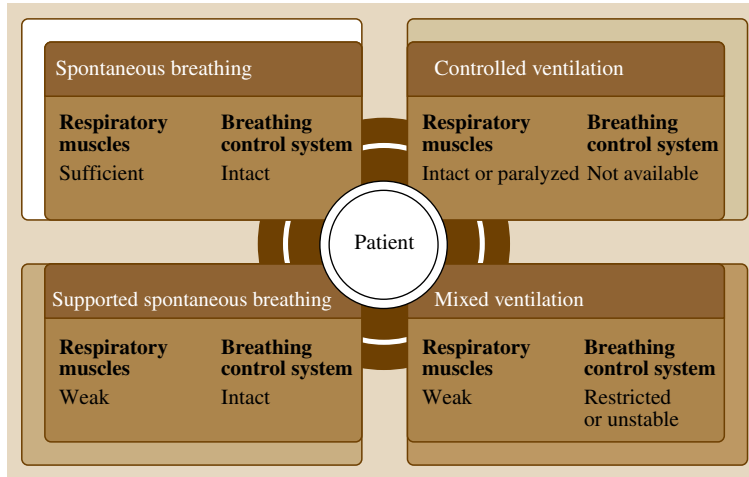

Fig. 27.5 Forms of respiration and mechanical ventilation

the tidal volume which provides information on the condition of the patient's lungs. In some cases ventilation modes are manufacturer specific but naming also varies in international linguistic usage. To enhance usability, particular operating philosophies or a prefix to the ventilation mode have been implemented by the manufacturers.

Volume-Controlled Ventilation

This mode is suitable, for example, for patients with healthy lungs but without spontaneous breathing. It is

Fig. 27.6 Volume control, continuous mandatory ventilation

important to note that in this mode the device does not respond to any spontaneous breathing activities by the patient.

The chronological sequence of inspiration and expiration (Fig. 27.6) is as follows: At the beginning of inspiration the ventilator closes the expiratory valve and delivers the (constant) inspiratory flow according to the *flow setting*. This leads to an increase in pressure in the breathing system and in the lungs. If the inspiratory flow setting is so high that the set tidal volume (V_T) is reached before the inspiratory time T_{insp} elapses, the inspiratory valve closes and the delivery of breathing gas stops. Owing to pressure compensation between the breathing system and the patient's lungs, the ventilation pressure decreases from the peak pressure p_{Peak} to the plateau pressure value p_{Platt} . The expiratory valve remains closed until the inspiratory time T_{insp} has elapsed. This inspiratory pause (insp. pause) can be recognized as a plateau pressure phase p_{Platt} in the pressure curve. The expiratory valve opens when the inspiratory time T_{insp} has elapsed. The pressure in the breathing system therefore falls to the PEEP pressure level generated by the expiratory valve. The expiration gas leaves the lungs and is transported via the expiratory branch of the ventilator into the atmosphere. The next inspiration follows after the expiratory phase, whose length is determined by the respiratory rate setting (RR or f), has elapsed. To avoid pressure peaks, the maximum inspiratory working pressure of the ventilator can be limited via the p_{max} controller. If provided by the device, pressure limitation is available in all volume-controlled ventilation modes. The term pressure-limited ventilation (PLV) used in this context does not therefore

provide any information on the ventilation mode that is currently being applied. The abbreviation PAW used in the graphic stands for *airway pressure*.

The user should keep in mind that the sudden resumption of spontaneous breathing in this ventilation mode can lead to serious dyssynchronies between the patient and the ventilator. In such an event, the patient would literally fight with his spontaneous breathing against the mandatory ventilation pattern. The activation of the trigger function (VC-AC = volume control-assist control or IPPVA_{Assist}) can compensate for this deficiency to an extent. However, in this operating mode, the device will respond to every inhalation effort by the patient by applying the set ventilation stroke. The increase of the respiratory rate and the minute volume then lead inevitably to a decrease of the arterial carbon dioxide concentration. The breathing drive is thus reduced and may lead to respiratory standstill (apnea). Volume-controlled ventilation (VC-CMV) or intermittent positive pressure ventilation (IPPV) is becoming less important, as the VC-SIMV ventilation mode (mixed ventilation) provides an identical ventilation and, moreover, also features a weaning mode (Sect. 27.5.4).

Independent Lung Ventilation. Independent lung ventilation (ILV) is the independent ventilation of each lung using a special double-lumen tube whose ends are each connected to a separate ventilator. To chronologically synchronize the actions of both ventilators, Evita ventilators, for example, can be electrically connected with each other using a special connection cable. One of the ventilators assumes the *master* function, determining the breathing rhythm. Depending on the selected presetting, the second ventilator, also referred to as the *slave*, performs ventilation in parallel, delayed or inversely to the actions of the master. ILV is only available as volume-controlled ventilation.

Pressure-Controlled Ventilation

During classic pressure-controlled ventilation, user-defined pressure alteration intervals are used for patient ventilation. Pressure-controlled ventilation dominates in neonatology intensive care units and is extremely important for treating adults with pulmonary damage, but is not only reserved for this group. There are major differences between the conventional pressure-controlled ventilation (PCV) and pressure control-biphasic positive airway pressure (PC-BIPAP)/pressure control-continuous mandatory ventilation (PC-CMV) as regards the spontaneous breathing characteristics. While the pa-

Fig. 27.7 Pressure control, biphasic positive airway pressure (PC-BIPAP)

tient's activities in PCV can create undesired pressure rises and lead to corresponding alarms, the PC-BIPAP and PC-CMV ventilation modes give patients the complete freedom to inhale or exhale at any time. For more information on this topic please refer to Sect. 27.5.4.

The chronological sequence of inspiration and expiration (Fig. 27.7) is as follows: At the beginning of inspiration the ventilator closes the expiratory valve and delivers an initial flow, which causes a rise in pressure in the breathing system. Although the user-defined inspiratory pressure P_{insp} is built up very rapidly in the breathing system, the time required until the prevalent pressure in the breathing system can be built up in the lungs is much longer because of the resistance of the tube and the expansion of the lungs. The continuously decreasing pressure difference between the pressure in the breathing system and the pressure in the lungs in this phase is reflected in a decelerating gas flow delivery. The ventilator stops the gas flow delivery as soon as a total pressure balance has been achieved. The expiratory valve opens when the inspiratory time T_{insp} has elapsed. The pressure in the breathing system therefore falls to the PEEP pressure level generated by the expiratory valve. The expiration gas leaves the lungs and is transported via the expiratory branch of the ventilator to the atmosphere. The next inspiration follows after the expiratory phase, whose length is determined by the respiratory rate setting (RR or f), has elapsed. The time in which the ventilator changes the pressure from PEEP pressure to the inspiratory pressure level can be adjusted by the *ramp* controller.

In pressure-controlled ventilation it is also possible to activate the trigger function and to synchronize the rise of pressure to spontaneous breathing efforts of the patient. The PC-CMV mode then changes to pressure control-assist control (PC-AC). The result of this is that the ventilator responds to every inspiration effort by the patient with a mandatory inspiratory phase. The PC-AC mode is referred to as BIPAP_{Assist} on some ventilators but behaves as described above.

27.5.2 Supported Spontaneous Breathing

In principle, the modes belonging to this group have several similarities, including, for example, that the spontaneously breathing patient triggers the start of inspiration and that the ventilator responds by producing a positive pressure in the breathing system. For this reason, supported spontaneous breathing is often known as *pressure-supported spontaneous breathing*. Internationally, the use of the abbreviations for pressure support (PS) and assisted spontaneous breathing (ASB) differs, but generally users are familiar with both names. Switchover from inspiration to expiration takes place when mode-specific criteria such as flow or volume target values have been met. Supported spontaneous breathing is suitable for patients with weakened respiratory muscles and an intact respiratory drive.

Conventional Pressure Support

The chronological sequence of inspiration and expiration (Fig. 27.8) is as follows: As soon as the ventilator is triggered by an inhalation effort, the ventilator delivers a gas flow and generates the inspiratory pressure defined by the adjuster Δp_{Supp} . The speed at which the ventilator achieves the set pressure support level can be influenced by the *ramp* controller. A rapid rise time results in a high initial flow and reduces the patient's work of breathing. The switchover to expiration takes place when the level of pressure support has been reached *and* after the inspiratory gas flow has decreased to a defined inspiratory flow (e.g., 25% of inspiratory peak flow). Although in this method the patient is always provided with the same pressure support irrespective of the intensity of his breathing efforts, the spontaneously breathed volumes can vary depending on patient activity.

Proportional Pressure Support

The proportional pressure support (PPS) and proportional assist ventilation (PAV) modes are further

Fig. 27.8 Pressure support (PS)

developments of the pressure support mode described in the last section. While in conventional pressure support the ventilator provides the support pressure itself when the patient no longer actively breathes, in PPS (PAV) mode the ventilator supports the patient in proportion to the work of breathing performed by the patient himself. This also results in the markedly high variability of tidal volumes which follow the natural course of spontaneous breathing. The main idea and objective of proportional pressure support is that the ventilator should only take over that part of the work of breathing which the patient is not capable of performing himself. Since the work of breathing to be performed is determined by the airway resistance and the elastic recoil force of the lungs, PPS can be individually adjusted to the patient's respective disease by means of two different adjustment parameters ($\text{Vol}_{\text{Assist}}$ and $\text{Flow}_{\text{Assist}}$). This differentiation is necessary because a patient with increased airway resistance has to cope with a fundamentally different problem than a patient with a pathologically changed elasticity. In the first case the flow is impaired, whereas in the second case the volume of spontaneous breathing is insufficient. A different pressure curve profile is therefore allocated to the controllers. When the resistive work of

breathing increases, support is provided by means of a flow proportional pressure characteristic (FlowAssist). If, on the other hand, the disease is characterized by a marked elastic work of breathing, the pressure curve is proportional to the tidal volume (Vol.Assist). For better understanding, the different pressure curve profiles are shown separately in the lower part of Fig. 27.9. The pressure support which is actually effective for the patient results from the overlap of the two curve functions. Support that has been calculated too generously can result in the patient receiving a greater volume than intended (*runaway*) because of the reinforcing characteristics of the system. For this reason, the pressure and tidal volume alarm limits are extremely important here.

Variable Pressure Support

By observing one's own breathing activities it can be noticed that breathing volumes are not constant but vary within a certain range. Variable pressure support is available in the spontaneous breathing mode SPN-CPAP and tries to mimic the physiologic course of respiration. For this purpose in this mode the level of pressure support changes from breath to breath (Fig. 27.10). Variations in pressure result from the settings Δp_{supp} and Press. var. (pressure variation from 0% to 100%). Preliminary findings indicate that this mode might have beneficial effects on oxygenation.

Volume Support

This method varies the level of pressure support as well. However, the main objective and the circumstances

Fig. 27.9 Spontaneous proportional pressure support (SPN-PPS)

differ from the modes described above. Activating volume support ensures that the patient receives the

Fig. 27.10 Variable pressure support

user-preselected tidal volume. The tidal volume will be delivered even if the lung compliance changes or spontaneous efforts decrease.

27.5.3 Spontaneous Breathing (Without Respiratory Support)

In these modes the patient receives neither pressure support nor mandatory ventilation strokes. In fact, the modes allocated to this group are not ventilation modes but rather spontaneous breathing (SB) modes. Spontaneous-continuous positive airway pressure (SPN-CPAP) facilitates spontaneous breathing at a certain pressure level which the user can set by adjusting the PEEP controller. If the patient inhales, causing the pressure in the breathing system to fall slightly, additional gas is immediately delivered in order to ensure the pressure level remains constant at all times. This method requires that the patient's spontaneous breathing and breathing drive are sufficiently stable and the patient himself can be responsible for the respiratory rate and the tidal volume. The task of the ventilator is limited to providing the required breathing gas, creating the PEEP pressure, and monitoring the patient's spontaneous breathing activities. Spontaneous breathing on a ventilator is always useful when the patient's physical condition requires the breathing activities to be closely monitored. This also means it is possible:

- to prevent the collapse of individual alveolar areas
- to increase the gas exchange surface of the lungs by a positive airway pressure and
- to provide the patient with an increased oxygen concentration.

To increase efficiency, CPAP can be combined with a support method. This turns a purely spontaneous breathing mode into a supported spontaneous breathing mode. Figure 27.11 shows spontaneous breathing in combination with pressure support.

27.5.4 Mixed Ventilation

As already described, different ventilation modes allow adaptation of ventilators to meet individual patient requirements. In a figurative sense, the different ventilation modes also represent the patient's transition from controlled ventilation to spontaneous breathing. Reducing respiratory or ventilatory support (the weaning process) should be started as early as possible to allow the patient to breathe on his own. Not

Fig. 27.11 Spontaneous continuous positive airway pressure/pressure support (SPN-CPAP/PS)

only is this in the patient's own interest, it is also important from an economic point of view. The ventilation modes (VC-SIMV, PC-BIPAP, etc.) belonging to mixed ventilation combine elements from controlled ventilation and supported spontaneous breathing. The mandatory phases take place in either pressure- or volume-controlled form, as already known from controlled ventilation, and ensure a certain minimum ventilation. The user will determine the weaning strategy based on the type of controlled ventilation (volume or pressure controlled) and gradually reduce the work of breathing performed by the ventilator. In practice, this reduction is achieved by reducing the mandatory frequency or alternatively by reducing the inspiratory pressure. The ventilation modes belonging to this category are especially suitable for patients whose breathing drive is not stable and whose respiratory muscles are weak. These modes also require that the user pays close attention to the fact that the ventilator settings correspond to the physical working capacity of the patient.

Volume-Controlled Mixed Ventilation

The volume control-synchronized intermittent mandatory ventilation, with or without pressure support (VC-SIMV) mode ensures a defined, constant, mandatory, volume-controlled ventilation irrespective of any spontaneous breathing activities by the patient. VC-SIMV can therefore replace the VC-CMV mode and already be used in the controlled ventilation phase. In addition, in VC-SIMV mode the ventilator is responsible for ensuring that mandatory ventilation is as

Fig. 27.12 Volume control synchronized intermittent mandatory ventilation (VC-SIMV)

comfortable as possible for the patient. For this reason in VC-SIMV mode the ventilator is free to vary the time between the mandatory ventilation strokes, while maintaining the number of ventilation strokes per minute. As with VC-CMV, the mandatory minute volume (MV) results from the respiratory rate and the set tidal volume. The patient is supplied with additional breathing gas at the start of spontaneous breathing so that the total minute volume consists of mandatory and spontaneous minute volume (Fig. 27.12).

The chronological sequence of mandatory and supported phases is as follows: In VC-SIMV mode, a trigger window is present before the mandatory ventilation stroke. If the patient inhales during this phase, the ventilator will already start the ventilation stroke, which was about due anyway. The time difference between the regular default cycle time (IMV time) and the actual cycle time is added to the next spontaneous breathing phase so as not to exceed the user-defined number of ventilation strokes per minute. The ventilator supports spontaneous breathing with pressure support from the end of a mandatory phase until the trigger window is activated again. This produces a series of alternating *mandatory phases* in which the ventilator delivers a set ventilation pattern and *supported phases* in which the patient is allowed maximum freedom. Although, in principle, there is nothing wrong with this method, unfortunately overlaps frequently occur between mandatory and spontaneous activities in clinical practice. This results in unpleasant dyssynchronies and an increase in the number of alarms for the medical staff because the ventilator does not respond to the patient's requirements in the mandatory

phase. This type of situation is therefore equally undesirable for the patient and medical staff and should thus be avoided by all means, also in view of the weaning duration. In this context, ventilation modes [e.g., pressure control-synchronized intermittent mandatory ventilation plus (PC-SIMV+) or PC-BIPAP] or additional functions (e.g., AutoFlow), which also tolerate spontaneous breathing during the mandatory phase, can provide a remedy.

If the patient is not breathing spontaneously, the volume control-mandatory minute volume (VC-MMV) ventilation mode (Fig. 27.13) behaves in the same way as a volume-controlled ventilation mode and, under these conditions, is apparently not different from the previously described VC-SIMV mode. The only crucial difference between the two modes is that the mandatory part of ventilation in VC-MMV can vary depending on the spontaneous breathing activities. If the patient is breathing a sufficiently large volume independently, the controlled ventilation stroke is not applied. VC-MMV thus provides the patient with *unlimited* freedom to switch from pure controlled ventilation to total spontaneous breathing. The mode has proven itself, for example, during postoperative ventilation, but is not a substitute for individual breathing training. As during other volume-controlled ventilation modes, unpleasant overlapping of spontaneous and mandatory phases can also occur during VC-MMV. The implementation of an additional function (e.g., AutoFlow), if available, may improve tolerance of these interferences, like in VC-SIMV.

The chronological sequence of mandatory and supported phases is as follows: The mandatory minute

Fig. 27.13 Volume control mandatory minute volume (VC-MMV)

volume is determined by setting the respiratory rate and tidal volume controller. Controlled ventilation takes place according to the known pattern. At the start of spontaneous breathing, the ventilator continuously calculates and forecasts which spontaneous volume the patient will reach in a minute. If the calculation is positive (the portion breathed spontaneously by the patient is greater than the mandatory portion which the device would deliver), the ventilator automatically stops mandatory ventilation. If the calculation is negative, the ventilator delivers a corresponding number of synchronized mandatory strokes in order to reach the user-defined minute volume. In case of apnea, ventilation takes place according to the predefined adjustment parameters. Pressure support can be used to support spontaneous breathing. Furthermore, adequate adjustment of the spontaneous breathing rate alarm limit RR_{spont} is especially important in VC-MMV to detect abnormally fast respiration (tachypnea).

Pressure-Controlled Mixed Ventilation

PC-BIPAP is equally suitable for use in patients with pulmonary function disorders and those with healthy lungs. The PC-BIPAP ventilation mode can be described as a time-cycled and pressure-controlled form of ventilation that allows the patient to inhale or exhale at any time. PC-BIPAP is therefore also often compared to the time-controlled switchover between two different SPN-CPAP levels. The mandatory and spontaneous activities do not therefore alternate in chronological succession as in VC-SIMV, but take place simultaneously. This device behavior, also referred to as a *free breathing system*, significantly improves patient comfort and facilitates the smooth transition from controlled ventilation through to complete spontaneous breathing. The technical basis of the mode is the dynamic interplay of the inspiratory gas metering device and an active expiratory valve. In the case of a pressure loss, the gas delivery unit supplies the additionally required gas flow.

A sudden pressure rise (for example, caused by the patient coughing), on the other hand, is compensated by limited controlled opening of the expiratory valve. This special form of pressure-controlled ventilation offers different benefits to both patient and user.

- The ventilator responds to the patient's requirements at all times; eliminating the struggle against closed valves; ensuring patient ventilation is less stressful.
- The harmonized interaction between the device and the patient enables shallower sedation; the reduction of medication might reduce costs and increases the patient's breathing drive.
- An awake and responsive patient can be activated and motivated, both positively influencing the healing process.
- Communication with the patient allows pain medication or ventilator settings to be optimized.
- The patient's spontaneous breathing allows the reduction of mandatory ventilation and improves the pulmonary gas distribution and the gas exchange.
- Spontaneous breathing decreases intrathoracic pressure forces, relieves the heart, and has a positive effect on the venous return flow to the heart.
- The patient contributing to the work of breathing as early as possible can reduce the ventilation period and thus the risk of infection.
- The *free breathing system* reduces the number of alarms triggered by dyssynchronization, making ventilation less stressful not only for the patient but also for medical staff.

These benefits are also available to the user in volume-controlled ventilation when using the AutoFlow function (Sect. 27.6).

The chronological sequence of mandatory and supported phases in PC-BIPAP is as follows: As with VC-SIMV, a trigger window is present before the

Fig. 27.14 Pressure control-biphasic positive airway pressure combined with spontaneous breathing (PC-BIPAP)

mandatory ventilation stroke. If the patient inhales during this phase, the ventilator will already deliver the pressure change, which was about due anyway. The time difference between the regular default cycle time and the actual cycle time is added to the next spontaneous breathing phase. This offset ensures that the user-defined respiratory rate remains constant. The ventilator supports spontaneous breathing with pressure support from the end of a mandatory phase until the trigger window is activated again. The pressure rise time defined by the user with the *ramp* setting influences both the supported and mandatory pressure rise. Thus, the patient always receives the breathing gas with a uniform flow characteristic, whose decelerating course is generally perceived to be significantly more pleasant than a constant flow. As a further feature, PC-BIPAP is provided with an additional trigger window which is used to synchronize the pressure change from inspiratory pressure to the PEEP level with spontaneous breathing. This may mean that the length of the inspiratory period can also vary to a certain extent. Like for the ventilation frequency, the intervals are also corrected and compensated accordingly here by the inspiratory period adjustment in the next mandatory ventilation phase (Fig. 27.14).

Pressure Control-Synchronized Intermittent Mandatory Ventilation

This ventilation mode behaves like the volume-controlled pressure control-synchronized intermittent mandatory ventilation (VC-SIMV) variant as regards the chronological switchover between mandatory and spontaneous ventilation phases. The only difference from volume-controlled VC-SIMV is that the mandatory ventilation strokes are pressure con-

trolled in this case. The *free breathing system* described under PC-BIPAP is not obligatory here or has only limited availability depending on the manufacturer.

Pressure Control-Airway Pressure Release Ventilation (PC-APRV)

Although the main characteristics of PC-APRV (Fig. 27.15) are very similar to the PC-BIPAP ventilation mode, this mode is based on a completely different ventilation philosophy. As an interesting contrast to all the other modes in which the mandatory inspiration produces a pulmonary pressure rise, the volume change in PC-APRV occurs by a brief pressure relief. This *release phase* enables an extremely short and incomplete expiration. To better understand this situation, it may be useful to imagine a patient who breathes spontaneously at an increased pressure level (SPN-CPAP). If spontaneous breathing subsequently deteriorates, resulting in an increase of arterial carbon dioxide, it will be necessary to increase ventilation. Until recently the

Fig. 27.15 Pressure control airway pressure release ventilation (PC-APRV)

pressure in the breathing system, and thus the volume transported to the lungs, was increased. PC-APRV, on the other hand, utilizes the fact that the patient's lungs are already filled by the positive pressure and causes a brief expiration by reducing the pressure in the breathing system. The pressure relief phase in PC-APRV is extremely brief, typically 0.5 s. Since this time does not allow for a complete expiration in adult ventilation, only the lung compartments which can be quickly emptied and filled are ventilated in the release phase. The regions to which the gas only reaches slowly due to increased airway resistance are hardly influenced by the brief pressure change. However, often it is precisely these lung regions which can only be ventilated with difficulty using conventional ventilation and/or are susceptible to collapse. By stabilizing the pressure conditions in these critical parts of the lungs, PC-APRV can usually provide for gentler ventilation and improved gas exchange. The PC-APRV adjustment parameters differ slightly from the usual designations and parameters due

to the specific features of the ventilation mode. In PC-APRV, for example, the expiratory time T_{low} can be set instead of the respiratory rate. This makes it easier for users to set the brief release phases. Accordingly, the inspiratory time is referred to as T_{high} and the inspiratory pressure as p_{high} . The term "PEEP" would also be absurd here and is therefore replaced by the designation p_{low} .

PC-APRV does not provide pressure support as it would be in conflict with the philosophy of the ventilation mode. Otherwise PC-APRV has the same spontaneous breathing characteristics as PC-BIPAP, i. e., the patient can inhale or exhale at any time. PC-APRV has been used in the past very successfully in the treatment of patients with severe gas exchange disorders and is gaining in importance, at least in this application. PC-APRV can, in principle, be used for patients with healthy lungs, but is only seldom observed due to the described deviations from physiological respiratory patterns.

27.6 Ventilation Extras and Special Functions

27.6.1 Inverse Ratio Ventilation

Normally, the inspiratory period is shorter than the expiratory phase. However, the inspiratory time may need to be increased at the expense of the expiratory phase when treating diseases with serious oxygenation disorders. The term inverse ratio ventilation (IRV) merely states that ventilation takes place with an inverse inspiration-to-expiration ratio, in other words, the inspiratory time is longer than the expiratory time. The designation IRV alone does not provide any information on whether the ventilation is volume or pressure controlled.

27.6.2 Sigh

By observing one's own spontaneous breathing you will have noticed that breathing is not always even. Occasionally we inhale a larger quantity of air than usual, i. e., we sigh. Originally, the sigh function was introduced in ventilation with the aim of reproducing the typical variations in volume that occur during spontaneous breathing, thereby breaking up the monotonous and unphysiological ventilation pattern of controlled ventilation. The sigh function, which is also referred to as intermittent PEEP, is accomplished by temporar-

ily increasing the PEEP pressure to a higher value. In the Evita ventilator the PEEP pressure is increased, for example, every 3 min for two breathing cycles. The term *sigh* results from the deep drawn inspiration whose discharge creates a noticeable flow murmur similar to that of a spontaneous sigh. The use of a sigh could not become established as originally conceived. However, today the sigh function has become important as a therapeutic tool to reopen collapsed alveoli (recruitment).

27.6.3 AutoFlow

The AutoFlow function is an optional addition which is available in all volume-controlled ventilation modes on Dräger ventilators (with the exception of ILV). The ventilation mode is set using the ventilation parameters which are valid for the respective mode. When AutoFlow is activated, the ventilator replaces the constant flow typical of volume-controlled ventilation modes with the decelerating flow pattern known from pressure-controlled ventilation modes. This combines the benefits of pressure-controlled ventilation with the strengths of volume-controlled ventilation. The modified volume-controlled ventilation can be characterized as follows:

- AutoFlow ensures that the user-defined tidal volume is applied at the lowest possible ventilation pressure.
- AutoFlow automatically adjusts the ventilation pressure to pulmonary compliance changes, eliminating the need to manually correct the inspiratory pressure in pressure-controlled ventilation.
- AutoFlow tolerates spontaneous breathing activities by the patient at any time, thus adding the benefits of a *free breathing system* listed under PC-BIPAP to volume-controlled ventilation.
- AutoFlow eliminates the peak pressure usually occurring during volume-controlled ventilation, which might cause partial overinflation of individual lung areas.
- AutoFlow takes over the responsibility for setting the “Flow” and p_{max} controllers. The reduction of parameters makes it easier to set volume-controlled ventilation.

The sequence of inspiration and expiration and control characteristic is as follows: The chronological sequence of inspiration and expiration remains unaffected by the AutoFlow function and corresponds to the behavior of the respective ventilation mode. After activation of AutoFlow, the ventilator applies the next mandatory ventilation stroke with a minimum constant flow. The ventilation pressure measured at the end of this

inspiration is used as the inspiratory pressure in the following inspiratory phase. The flow is then delivered with a decelerating flow profile. After the switchover to expiration, the ventilator compares the applied tidal volume with the user-defined set value. The inspiratory pressure of the following mandatory phase is slightly increased or decreased to offset the differences. The adjustment mechanism is limited to a fluctuation margin of ± 3 mbar from breath to breath. The pressure increase is stopped as soon as the inspiratory pressure approaches the upper airway pressure alarm limit of up to 5 mbar. If this pressure is not sufficient to apply the set tidal volume completely, the device generates the alarm *volume inconstant*. Although spontaneous breathing activities can lead to fluctuations in the expiratory volume, AutoFlow ensures that a constant tidal volume is applied on average over time. Using AutoFlow is always possible and useful provided that there are no special pulmonary restrictions and the patient is receiving volume-controlled ventilation anyway. Irrespective of the current ventilation situation, the upper airway pressure alarm limit is very important because of the above-mentioned dual function. Figure 27.16 shows a screenshot of EvitaXL. From left to right, you can recognize a conventional, volume-controlled ventilation stroke, the stroke applied with a minimum constant flow after activation of AutoFlow, as well as the first of the subsequent AutoFlow ventilation strokes.

Fig. 27.16 AutoFlow

Volume guarantee (VG) is an adjunct in pressure-controlled ventilation modes and is comparable to the above-mentioned AutoFlow function. Depending on the manufacturer, such specific control algorithms are available in separate ventilation modes only (e.g., PRVC = pressure regulated volume controlled).

27.6.4 Automatic Tube Compensation

Intubated patients have to perform considerably more work to breathe due to the artificial narrowing of their airways. This additional work of breathing (WOB) results from the pressure difference arising along the tube, which also has to be counteracted by the respiratory muscles. The tube type (endotracheal tube or tracheal cannula), the tube diameter, and the gas flow currently delivered through the tube are major determining factors. To better understand the importance and the effect of the gas flow, simply try to breathe for several minutes through a 0.2" straw while holding your nose closed. You will notice that considerably greater breathing efforts are required to create larger gas flows. Consequently, this means that the patient should be supported in relation to the flow. Based on this idea, automatic tube compensation (ATC) increases the pressure in the breathing system during inspiration by the pressure drop induced by the flow between the tube connector and tube tip. During expiration, compensation takes place by a brief reduction of the PEEP level. This gives the patient the impression that he is not actually intubated. However, the dynamic pressure changes in the breathing system lead to significant changes in the pressure–time curve. These curve progressions, which are initially unusual for the user, merely reflect the variations in pressure before the tube and do not thus correspond with the pulmonary pressure curve. More detailed information on the pressure

at the tube tip can be provided by devices which calculate this pressure and display it as a separate pressure curve. Tube compensation is available in all ventilation modes and can be adjusted to the current ventilation situation by entering the tube type, the tube diameter, and the desired compensation as a percentage. Since ATC greatly simplifies the patient's work of breathing, the user should significantly reduce the pressure support, or even switch it off temporarily, before activating the ATC function. Tube compensation (TC) is, in principle, suitable for all intubated patients, but can be configured to be limited to the inspiratory phase, for example, for patients with obstructive respiratory diseases (Fig. 27.17).

27.6.5 Noninvasive Ventilation

Noninvasive respiratory therapy is gaining in importance as a means of avoiding intubation or as a supporting respiration therapy after extubation, not to mention the tremendous drive to cut costs in the health-care sector. However, mask ventilation presents the user, patient, and ventilator with special challenges. These include, for example, the availability and acceptance of suitable face masks and the communication and cooperation between the user and the patient. There are also special technical challenges concerning the performance of the ventilator, since leaks and disconnections occur frequently during mask ventilation. Noninvasive ventilation (NIV) is an optional addition and should be available as an adjunct to all standard ventilation modes. Due to the wide range of manufacturer-specific features, only a few basic aspects of mask ventilation are considered here. The quality of mask ventilation is primarily determined by whether the ventilator is prone to self-trigger due to leaks at the breathing mask. Depending on the ventilator, the trigger sensitivity either is adjusted automatically or has to be manually adapted by the user. In this context, it must be mentioned that not all ventilators provide volume-controlled ventilation in NIV. However, even if this feature is available, applied volumes might vary significantly based on the respective device performance. In any case, high-performance leak compensation is essential in such applications. Leak compensation continuously compares the set tidal volume with the expiratory measured volume and increases the inspiratory gas delivery in the event of leaks. Last but not least, monitoring and alarm limits must meet special demands during noninvasive ventilation. For example, if the position of the mask needs to be corrected and this involves temporarily removing and

Fig. 27.17 Automatic tube compensation (ATC)

refitting the mask, it would usually result in a near-immediate disconnect alarm under normal conditions. Such an alarm can be avoided by an adjustable alarm delay time $T_{\text{Disconnect}}$, which usually is only available in the NIV operating mode.

27.6.6 Apnea Ventilation

During the weaning process, the ventilator and patient share the responsibility for the total minute volume. If apnea occurs in this phase because the patient cannot

cope, the remaining mandatory volume applied may not be able to ensure sufficient ventilation anymore. For this reason, to avoid hypoventilation, the apnea alarm can be combined with apnea ventilation in modes which allow or support spontaneous breathing. In this case, the ventilator ensures the defined controlled ventilation of the patient, until the user can attend to the current patient situation. In adult ventilation, apnea ventilation is generally implemented as volume-controlled ventilation, whereas in neonatology pressure-controlled ventilation is used.

27.7 Patient Monitoring and Alarm Limits

Although the ventilator automatically monitors many device functions, the user has to set alarm limits manually for other different measured values. The importance of patient monitoring has already been shown using the example of apnea ventilation. Despite this, many users often view alarms as an unpleasant side-effect of ventilation. A more positive picture emerges when you compare the adequate adjustment of the alarm limits to a *protective fence* surrounding the patient. As long as patient activities remain within the limits of the *fenced-off* area, there is no cause for worry or reason for an alarm. However, as soon as the patient tries to leave the *protective zone* which has been created for him, the device will report this *breakout attempt* by generating a corresponding alarm. Inevitably, this raises the issue of what importance should be given to the different alarm limits and how they should be set. Basically, the following can be stated:

- There are no unimportant alarm limits. It must be noted that the patient's situation may change at any time. The alarm limits which do not currently appear relevant should therefore also be adjusted according to the patient's needs.
 - Alarm limits should always be set based on the current respective measured values with the aim

of allowing as much freedom as possible while giving priority to safety.

- All alarm limits must always be checked and adjusted to meet the patient's current needs whenever a ventilation mode is set or changed. These steps can avoid predictable alarms and unnecessary stress.
- There are no useless alarms. Each alarm is generated as a result of a change in the patient's condition, a misjudgment by the user or a technical fault requiring the user's immediate attention.

The task of the monitoring and alarm system changes as the work of breathing is transferred to the patient in the weaning process. During controlled ventilation the monitoring and alarm system is mainly used to monitor the functioning of the device and its effect on the patient. However, it also assumes responsibility for monitoring respiratory sufficiency in the weaning phase. Obviously, the physiological fluctuations of the respiratory rate and the tidal volume require that the alarm limits, based on the current measured value, are set much more tightly in controlled ventilation than during mixed ventilation or (supported) spontaneous breathing.

27.8 Weaning Strategy and SmartCare/PS

The total time during which a patient is ventilated and the length of the weaning process can vary greatly. While some postoperative patients may only still need to be ventilated for a few hours and can be weaned almost immediately, this process may prove to be ex-

remely problematic and protracted for other patients. Particularly in the latter case, the user is required to assess the patient's situation and strength intensively to achieve the correct balance. While the patient should not be overexerted, the weaning phase should not be al-

lowed to continue for an unnecessary length of time. For this reason, assessing the patient and adjusting the ventilation parameters accordingly has the highest priority, requiring immediate attention. In clinical practice, this demand cannot always be met or only partially met by the medical personnel. Furthermore, assessing the patient and making the corresponding ventilator adjustments used to be based just on the personal experience of the responsible physician. The wide range of different ventilation modes available also meant that a consistent weaning strategy was not necessarily recognizable in all cases. Despite that, there are signs that potential for optimization has already been identified, and it can be expected that the situation will develop positively. Nowadays, users can apply ventilation modes which, for example, allow spontaneous breathing from the start of ventilation. Since it is possible to ventilate and wean the patient in one mode, ventilation can be adapted more effectively to the patient's needs and it is no longer necessary to switch back and forth between different modes. Furthermore, protocols or guidelines have been developed within the framework of quality control procedures describing and regulating the gradual weaning process. Many users are therefore instructed to conduct weaning adhering to a defined procedure. If any deviations are necessary, they are documented and integrated into the further development of these protocols as part of a continuous improvement process. Despite that, this does not seem to have helped clinical personnel to a significant degree, so that the time intervals between the individual weaning steps are still often longer than actually necessary.

A highly promising approach to weaning therapy is provided by the optional SmartCare/PS function available on some Dräger ventilators. SmartCare/PS can be used for weaning intubated or tracheotomized patients and is only accessible in the SPN-CPAP/PS ventilation mode. This knowledge-based system automates the weaning process on the basis of an implemented therapeutic strategy. SmartCare/PS compares the current measured values for the respiratory rate, the tidal volume, and the expiratory carbon dioxide with the different threshold values defined in the weaning protocol. In this way, SmartCare/PS can independently assess the ventilation situation and can even recognize *normal* ventilation (normoventilation). The measured values are interpreted every 2 or 5 min, and the pressure support is increased or reduced as a result. If the support pressure reaches a minimum value which is dependent on the setup of the breathing system, the

system carries out a spontaneous breathing trial with the patient. During this phase, the system observes and assesses the patient's activities as well as potential instabilities. An instability exists when the patient is no longer normoventilated, and SmartCare/PS responds by increasing the pressure support. If the observation phase is completed successfully, SmartCare/PS will suggest that the patient should be disconnected from the ventilator. If extubation can or should only occur at a later time, SmartCare/PS will continue to respond to changes in the three input values and adjust the pressure support accordingly. At this stage, SmartCare/PS can still revise or uphold its recommendation that the patient should be disconnected from the ventilator. This decision is based on the number and relative duration of instabilities registered by the device. The duration of the previous stable normoventilation is used to assess the time of an instability.

This brief description of SmartCare/PS clearly shows that the system is based on medical knowledge and not mathematical algorithms. The classifications performed at intervals of several minutes and automatic changes to the support pressure release intensive care medical staff from routine tasks, thus enabling the weaning phase to be reduced. Besides these reasons, other factors such as increasing cost-cutting pressure, numerous attempts at standardization, and efforts to improve the quality of patient care indicate that the symbiosis of clinical knowledge and innovative technology is soon set to capture other day-to-day clinic operations.

28. Defibrillators and ICD Systems

Defibrillators

Rüdiger Kramme

Part D | 28

Defibrillation is the definitive treatment for the life-threatening cardiac arrhythmias, ventricular fibrillation, and pulseless ventricular tachycardia. Defibrillation consists of delivering a therapeutic dose of electrical energy to the affected heart with a device called a defibrillator. Defibrillators can be external, transvenous, or implanted, depending on the type of device used or needed. Some external units, known as automated external defibrillators (AEDs), automate the diagnosis of treatable rhythms, meaning that lay responders or bystanders are able to use them successfully with little, or in some cases no, training at all except safety precautions also covered in this chapter (Sects. 28.1–28.5). An implantable cardioverter-defibrillator (ICD), described in Sect. 28.6, is a small, battery-powered electrical impulse generator which is implanted in patients who are at risk of sudden cardiac death due to ventricular fibrillation and ventricular tachycardia. The device is programmed to detect cardiac arrhythmia and correct it by delivering a jolt of electricity.

Variable impulse generation or conduction can cause arrhythmias, with the result that the coordination of the myocardial fibers is impaired, suspended or even plunged into chaos (fibrillation). Ventricular fibrillation is uncoordinated myocardial fibrillation with no ejection from the ventricles, being characterized on an electrocardiogram (ECG) by irregular and disorganized depolarizations with high frequency. Pulseless ventricular tachycardia is characterized by a regular and rapid sequence of broad QRS complexes, and as with ventricular fibrillation, there is no ejection. Both types of rhythm are life-threatening conditions of the cardiovascular system and are thus indications for defibrillation. Defibrillation is understood as meaning a brief, phasic pulse of energy which is intended to bring about si-

multaneous depolarization of all the myocardial fibers, which means that, after approximately 5 s of administering an electrical pulse, no ventricular fibrillation or ventricular tachycardia can be detected any longer in the ECG. The objective of this measure is to terminate tachycardic ventricular and supraventricular arrhythmias so that, following a refractory period (no excitation is possible in this phase) which generally lasts between 200 and 500 ms, the sinus nodes once more assume the pacemaker function as the primary center of excitation.

Defibrillators are electrotherapeutic high-voltage devices which are used within the course of resuscitation and to terminate tachycardic ventricular and supraventricular arrhythmias (Fig. 28.1).

Fig. 28.1 ECG documentation of a defibrillation

28.1 Defibrillator Technology

28.1.1 Physical Principles

The portable defibrillator is a direct-current (DC) voltage system which is usually not dependent on mains electricity (Fig. 28.2) and which is essentially composed of the following system components:

- The energy supply via mains connection or rechargeable batteries
- A capacitor as an energy store (capacity = n pulses at 360 J)
- A charging circuit for the capacitor (duration of charging, i.e., when the maximum energy is reached, is on average 10^{-8} s, considerably less in some manufacturers' models), and a discharge circuit which delivers the current pulse at different, preselectable energy levels (e.g., 2–360 J).

The DC pulse stimulation ranges between 3 and 8 ms at current of 10–27 A (internally) and 22–60 A (externally).

Automatic safety discharge should occur when no shock is triggered (after ≈ 10 s), when the defibrillator shock is triggered, and when a new energy level is preselected, as well as in the event of technical malfunction.

The energy (E) which can be stored in the capacitor can be determined from the capacity (C) and the available voltage (U) as

$$E = \left(\frac{1}{2}\right) CU^2, \quad (\text{VA} = \text{W}).$$

Waveform of the Energy Shock

The terms waveform and curve technology are understood as referring to the time-based sequence of energy output. The shape of the wave dictates firstly how much energy is supplied to the patient and secondly

over what period this energy is administered. The optimum amount of energy for the defibrillator pulse is the amount of energy which causes least myocardial damage. A distinction is made between mono-, bi-, and triphasic defibrillation shock configurations (Fig. 28.3). Whereas, in the case of the monophasic waveform, the current only flows in one direction and the polarity does not change, with the biphasic waveform the current is delivered in one direction, interrupted, and continued in the opposite direction. Here, the polarity changes with every phase. The main forms of the biphasic discharge characteristic are the truncated exponential curve and the square pulse. Today, particularly in the case of implantable and automatic external defibrillators, biphasic shock forms are preferably used, which differ as a result of varied adaptation to the thoracic impedance of the patient (e.g., different pulse output, peak-to-peak voltage, and pulse duration) and are more effective on the first shock administered than monophasic shocks. Biphasic defibrillations are generally more effective and gentler on the heart than monophasic ones and have the advantage that the shock-induced dysfunction of the myocardial cells is less and that defibrillation success can be achieved with lower energy and voltage. The device-dependent amount of energy is 150–200 J for the first defibrillation and 200–360 J for all others, whereas it is always 360 J in the first monophasic defibrillation. In addition, biphasic pulse forms allow devices to be further miniaturized.

Whereas the optimum energy flow in monophasic defibrillation is somewhere in the range from 30 to 40 A s, with biphasic shock it is believed to be in the range from 15 to 20 A s. Defibrillators whose administered shock corresponded to the real transthoracic flow would be preferable. Some of the biphasic defibrillators which are available on the market use very different

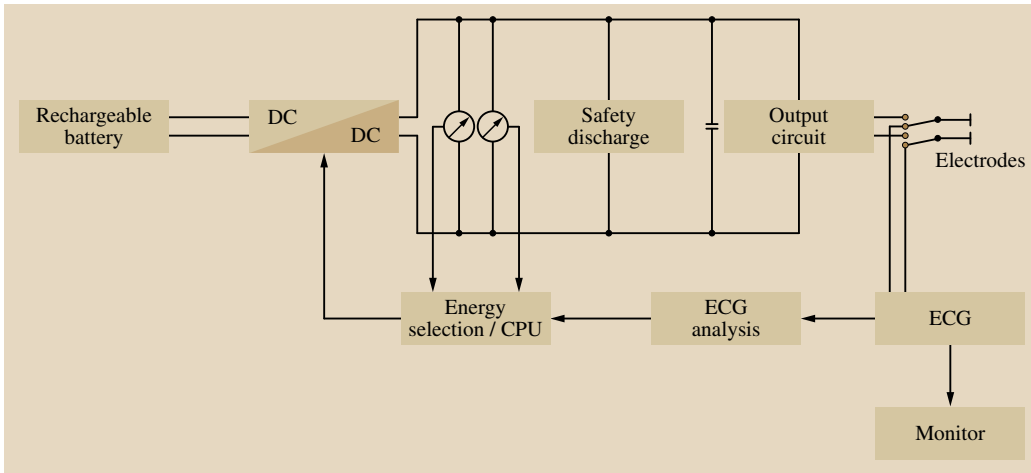

Fig. 28.2 Block diagram of a semiautomated DC defibrillator (after [28.1])

manufacturer-specific pulse forms. There is currently no general consensus about the effectiveness and potential negative effects of the various pulse forms on offer. The operating modes are divided into asynchronous and synchronous operation: whereas the heart's own pulses are taken into account in the synchronous operating mode (so-called sync pulse or QRS triggering), this is not done in the asynchronous operating mode. The latter operating mode should be reserved for *strictly emergency defibrillations*. Only the synchronized operating mode is suitable for cardioversion.

Thoracic Impedance

Thoracic impedance is the resistance in the body which opposes the energy pulse or flow from the defibrillator.

It ranges between 15 and 150 Ω ; usually it is 70–80 Ω . The impedance should therefore be taken into consideration when the necessary energy is administered, as the patient's thoracic impedance is crucial to the amount of energy required. Because the impedance varies to a large degree in humans, dynamic adaptation of the waveform of the energy pulse is an important feature. In modern devices, the thoracic impedance is automatically measured and taken into account before defibrillation, meaning that energy can be delivered more accurately. Larger electrodes incidentally reduce the impedance.

Defibrillators can be divided into manual defibrillators, semiautomated and automated external defibrillators (AED), fully automated defibrillators, and defibrillator implants (Fig. 28.4). The criterion for

Fig. 28.3 Monophasic and biphasic pulse forms

Fig. 28.4
Overview of
types of defib-
rillator devices

distinguishing between semi- and fully automated defibrillators is that, with the semiautomated defibrillator, the user is shown a defibrillation recommendation and the administration of the pulse is triggered by the user, whereas this is done automatically with a fully automated defibrillator. The electrodes used are so-called paddles, adhesive electrodes or internal paddles.

28.1.2 System Properties

In addition to the conventional manual defibrillators, there are also semiautomated and automated systems (AED), which perform an automatic ECG analysis via attached electrodes and have an integrated display. Defibrillation without a monitor or display and without rhythm analysis is known as *blind defibrillation*. Modern defibrillators have a *quick look* monitoring device in the paddles. When ventricular fibrillation is detected, in a semiautomated device (Fig. 28.5) the user is given a recommendation to defibrillate.

The expandable functionality, which is usually achieved using pluggable modules, makes the real system properties possible in semiautomated defibrillators and modules: integrated external pacer (transthoracic pacemaker), noninvasive blood pressure, S_pO_2 , capnography, arrhythmia detection, and recording component for documentation. Within the scope of quality assurance for a defibrillation which has been performed, complete recording by the device is of particular interest, including ECG recording and 12-channel ECG reports as well as recording of all other relevant data for later evaluation and documentation. The possibility of remote transmission of data, for example, from the

ambulance to the hospital's emergency department, will also play a relatively large role in the future.

Form Analysis of Ventricular Fibrillation

To determine the optimum time to deliver the defibrillation pulse when fibrillation characteristics are definitely present, computer-aided form analysis of ECG signals is a promising and innovative new development which is currently still being researched. It involves evaluating the frequency and amplitude characteristics of the surface ECG using so-called fibrillation scoring algorithms. This algorithm is based on linear (e.g., Fourier analysis, wavelet theory) and nonlinear methods (such

Fig. 28.5 Semiautomated defibrillator with paddles (courtesy Schiller)

as an $N(\alpha)$ histogram, which can be used to investigate the degree of randomness in a signal). Further advantages of this technology may be that ineffective energy pulses are avoided and damage to the myocardium is thereby limited, and that information is provided about the quality of the resuscitation performed.

Automated External Defibrillator

AED systems – predominantly using two-phase curve technology – only deliver a defibrillation pulse if there

is a life-threatening cardiac arrhythmia present which is recognized as such by the device. The user (or also semiskilled lay helper in the case of *public access defibrillation*) is also guided by means of a control menu. Modern systems additionally offer a voice-controlled user interface. The American Heart Association (AHA) takes the view that up to a third of all deaths resulting from sudden cardiac death could be prevented by widespread AED use. The use of AED systems is classified as an integral part of basic resuscitation measures.

28.2 Therapeutic Intervention

Synchronized defibrillation (Fig. 28.6) is referred to as electrical cardioversion, i. e., the pulse of energy is triggered by the R wave in the ECG.

28.2.1 Defibrillation/Cardioversion

This synchronization is carried out to prevent the pulse being delivered in the vulnerable phase (T wave) and to prevent the risk of ventricular fibrillation being triggered. In contrast, asynchronous cardioversion, which

takes place independently of the R wave, is what is known as defibrillation (Fig. 28.7). From a hemodynamic point of view, blood is no longer or is hardly pumped into the circulatory system during ventricular flutter and fibrillation, as the individual muscle fibers do not contract in a coordinated fashion. In the case of atrial flutter and fibrillation, approximately 20–30% less blood is ejected since the filling capacity of the ventricles is not optimized as a result of atrial contraction being stopped. Indications for electrical cardioversion are:

- Atrial flutter and fibrillation
- AV junctional reentrant tachycardia
- WPW (Wolff–Parkinson–White-syndrome) and ventricular tachycardia.

Fig. 28.6 Synchronized defibrillation at the point $R + x$

With ventricular fibrillation, defibrillation is the only therapy which can be used that has any prospect of success. Electrical cardioversion is contraindicated in digitalis overdose, hypokalemia, and atrial fibrillation (if there is deficient anticoagulation for at least 2–3 weeks and arrhythmia for longer than 48 h).

Fig. 28.7 Method overview for defibrillation/cardioversion

28.2.2 External and Internal Defibrillation

External, transthoracic defibrillation is performed by means of electrodes and pulses of energy from $\approx 2\text{J}$ up to 360J . As a guide value which is dependent on the body weight, a pulse strength of 3J/kg is recommended for adults and 2J/kg for children. In terms of electrode application, a distinction is made between the anterior–anterior method and the anterior–posterior method: whereas in the anterior–anterior method, which is mainly used in emergency situations, both electrodes are placed on the thorax (at the base and apex of the heart), in the anterior–posterior method a large-area electrode is placed below the back. The anterior–posterior method is preferred for electrotherapy in the case of arrhythmias, since the largest proportion of the administered pulse of energy flows directly through the myocardium. For internal, that is to say intracorporeal, defibrillation, sterile internal paddles are used which in

the case of an open thorax cover the exposed heart (in this case the pericardium), i. e., the surfaces of the electrodes must be in contact with the myocardium over its entire area. For internal defibrillation the energy pulse is a maximum of 50J .

Special Applications

Esophagus. An esophageal pulse electrode (cylindrical electrode at the end of a catheter) is placed at the level of the left atrium. The counterelectrode is attached to the thorax. An additional electrode to the cylindrical electrode enables bipolar stimulation and recording of an esophageal ECG signal which is used to synchronize the energy pulse.

Intracardiac. This application is likewise carried out using a catheter. One electrode lies at the apex of the right ventricle, while the second electrode is placed in the superior vena cava.

28.3 Methodological Notes

In principle, all commercially available defibrillators are operated in the same way and are suitable for both internal and external defibrillation. As a rule, a visual and/or acoustic signal is generated when the defibrillator is operational, i. e., when the capacitor is charged. The electrodes, which are provided with gel, are placed firmly on the thorax and pressed on, and the preselected energy dose is triggered. This is usually done directly via a trigger on the handles. Owing to the ERC Guidelines of 2005, the practice of performing defibrillation three times within the space of a minute using mono- and biphasic defibrillators is obsolete. This application model has been replaced by delivery of a single shock at full energy (so-called one-shock strategy); i. e., with a monophasic shock, 360J is recommended for delivery of the shock. For the first biphasic shock, at least $150\text{--}200\text{J}$ is advised for all discharge characteristics. Following each shock, cardiopulmonary resuscitation should be performed for 2 min before administering the next shock. If further shocks are necessary, with monophasic defibrillators the energy level is kept at 360J and with biphasic defibrillators the energy level is in contrast successively increased.

The energy pulse delivered and its amplitude, the form and polarity of the shock, the electrode size and position, and also the homogeneity of the current den-

sity in the cardiac muscle (myocardium) are all crucial for efficient defibrillation or cardioversion.

28.3.1 Electrodes and Contact Agents

Correct application of the adhesive electrodes is necessary to achieve faultless ECG recording and ultimately to prevent equipment-related interpretation errors. Despite being more expensive, self-adhesive defibrillation electrodes (so-called pads) are safe and effective and should therefore be preferred over normal plate electrodes (so-called paddles). Another advantage of adhesive electrodes from the viewpoint of the operator is that it is possible to defibrillate from a *safe distance*, without having to lean over the patient. It is also quicker to administer the first pulse of energy using self-adhesive electrodes than it is with paddles. Whereas with paddles a contact gel is needed between the skin surface and the metal plate in order to reduce the skin impedance – and thus improve the electrical contact – and also to prevent burns, this is not necessary with adhesive electrodes. Compared with electrode paste and gels, gel pads are favorable for safe operation because they avoid the risk of arcing and of a short circuit and thus prevent ineffective defibrillation. The Association for the Advancement of Medical Instrumentation (AAMI) recommends a minimum electrode

area of 150 cm^2 , since larger electrodes have a lower impedance or even lead to a decrease in the transmural flow. The diameter of customary electrodes is

in the region of 8–12 cm for adults and children with body weight $> 10\text{ kg}$ and 4.5 cm for children with body weight $< 10\text{ kg}$.

28.4 Complications

Cardioversion and defibrillation can result in the following serious and minor complications:

- Induced ventricular fibrillation, e.g., as a result of incorrect triggering, which can ultimately lead to asystole (cardiac arrest) (currents $> 10\text{ mA}$ flowing through the heart can cause fibrillation in the ventricles).
- Postdefibrillation arrhythmias such as ventricular and supraventricular extrasystoles and ventricular flutter.
- Arterial embolisms.
- Burns and irritation of the skin, for example, due to an insufficient amount of electrode contact paste being used on the electrode surface.

28.5 Technical Safety Aspects

28.5.1 Use

- Avoid direct contact with the electrodes (life-threatening), conductive contact with the patients or other people (safe distance).
- There should be no moisture on the patient's skin (electrical bridge), and the patient should also be positioned such that he is electrically isolated.
- Only perform cardioversion if the ECG is free from artifacts and if reliable ECG monitoring is possible. When too much electrode contact paste is used on the paddles there is the possibility of an electrical bridge forming (risk of short circuit).
- All additional devices which are connected to the patient must be defibrillation proof; otherwise, they must be disconnected from the patient during cardioversion/defibrillation.
- Caution should be exercised with patients with energized implants: the functioning of the implant may be restricted or suspended, and the implant itself may be damaged or may even become unusable.

28.5.2 Device

- Defibrillators belong to class IIb of the German Medical Devices Act (MPG, Medizinprodukte Gesetz).
- Defibrillators must only be used in an explosion-proof atmosphere.
- Devices which are not defibrillator proof must be disconnected from the patient, otherwise
- Equipment should be labeled according to DIN-IEC 601 as defibrillator proof.
- Maximum energy 360 J.
- Trigger buttons only on both paddles (connected in series).
- Protective circuits, which ensure a reduced power setting when the defibrillator is switched off and ensure energy recovery no later than 1 min after defibrillator charging.
- Because of their unforeseeable and frequently changing use, defibrillators should always be connected to mains electricity at their device base locations so that they are operational and ready for use on an ad hoc basis.

28.6 Implantable Cardioverter-Defibrillators

Implantable cardioverter-defibrillators (ICD) are primarily used for reliable detection and treatment of life-threatening cardiac arrhythmias (ventricular tachycardia and fibrillation) which originate in the ventricles and which cannot be treated with medication (Fig. 28.8). The American and European Societies of Cardiology

(American College of Cardiology (ACC)/AHA and ESC) also recommend ICD implantation in patients who have survived sudden cardiac death which did not occur as a result of myocardial infarction and also for primary prophylaxis in patients with restricted cardiac pumping function ($\text{EF} < 30\%$). When necessary,

Fig. 28.8

Chest x-ray with implanted ICD system (courtesy Medtronic)

ICD systems can also administer pacemaker pulses in bradycardic phases. ICD systems can also provide antitachycardic stimulation, cardioversion, and defibrillation.

ICD implantations have increased significantly in numbers. The following reasons are vital to this development:

- A simplified implantation technique reduces the rates of mortality resulting from surgery.
- Very low morbidity.
- High level of patient acceptance.
- ICD therapy has considerable advantages over medicinal therapy for prevention of sudden cardiac death – within the scope of secondary prophylaxis, for example, following hemodynamic ventricular tachycardia.
- For idiopathic ventricular fibrillation there is currently no alternative to ICD therapy.
- A further indication is primary prophylaxis for high-risk patients with no symptoms.
- The costs of ICD therapy have decreased considerably as a result of a reduction in product prices alongside increasing product life.

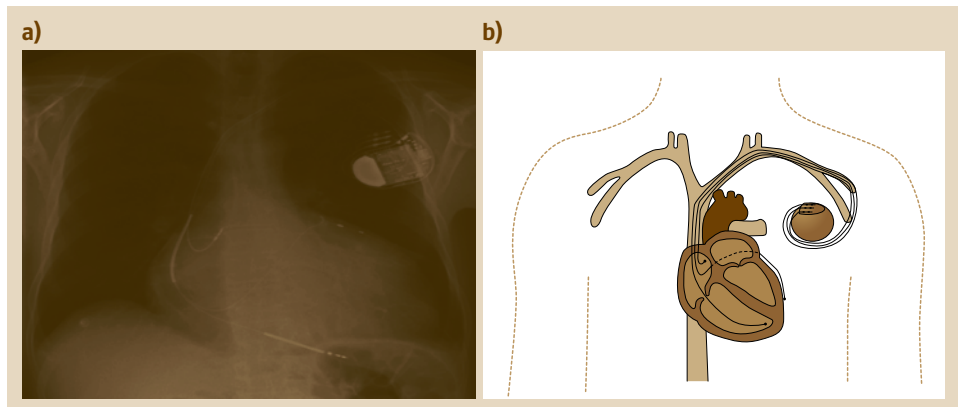

28.6.1 ICD Development

The following chronological events are of particular significance in ICD development. The first transthoracic defibrillation with direct current was carried out by Lown in 1962. The first model of an implantable automated defibrillator (*automated implantable cardioverter-defibrillator*, AICD) was presented by Mirowski as early as 1969 and was implanted in a human for the first time in 1980. This system was used to detect ventricular flutter and fibrillation using the criteria of heart rate and/or absence of isoelectric ECG portions. Detection of arrhythmias was done using myocardial screw-type electrodes. A programmable ICD system was used in clinical practice in 1988 and a multiprogrammable ICD system in 1989. The first dual-chamber ICD came onto the market in 1997, while an atrial defibrillator was implanted as early as 1996. ICD electrodes placed intra-atrially are a safe and effective method for terminating atrial fibrillation. The advantages of this are firstly the low energy output and secondly that the patient does not require short anesthesia.

A combined atrioventricular defibrillator was first implanted in 1997. More sophisticated atrioventricular defibrillators have the advantage that, besides providing fully automated detection of atrial and ventricular signals, they also deliver electrical pulses to both ventricles in order to terminate arrhythmias which occur. So-called implantable CRT defibrillators (CRT-ICD for short) for cardiac resynchronization therapy (CRT) have been available since 2001. These devices deliver a shock to interrupt and therefore stop tachycardia. The right and left ventricles are also stimulated simultaneously so that the cardiac beats are coordinated (resynchronized, in the true meaning of the word) (Fig. 28.9).

Fig. 28.9a,b

Implantable biventricular or CRT-ICD system. (a) Position checking in the x-ray image. (b) Schematic electrode positioning (courtesy of Biotronik)

28.6.2 System Technology

Miniaturized construction, more effective defibrillation as a result of low-energy pulses, and improved and updated software enable subpectoral implantation with transvenous electrode insertion under local anesthetic to be standard practice today (Fig. 28.10).

Conventional products have volume < 40 cm³ and weight < 80 g, with average device lifespan of 4–6 years. Today, ICD technology provides fine-tuned, integrated systems:

- Single-chamber ICD (ventricular rate adaptive/rate modulation (VR) system) with the therapeutic possibility of antitachycardic stimulation, cardioversion, and defibrillation. The defibrillator electrode is placed in the right ventricle.
- Dual-chamber ICD (dual rate adaptive/rate modulation (DR) system) with an additional atrial electrode or *single-lead ventricular pacing with atrial tracking-ICD (VDD-ICD)*.
- Triple-chamber ICD (biventricular defibrillator system, CRT-ICD) with the additional possibility of cardiac resynchronization therapy (CRT). The electrode fixed in the right ventricle is supplemented by a further electrode (a so-called coronary sinus electrode) which selectively stimulates the left ventricle (Fig. 28.9a,b).

Just as there is the international pacemaker code (North American Society of Pacing and Electrophys-

Fig. 28.10 Implantable ICD system (schematic) (courtesy Medtronic)

iology/British Pacing and Electrophysiology Group generic Pacemaker Code (NBG), Chap. 38), there is also a code for ICDs (Table 28.1).

An ICD system consists of a generating unit (or pulse generator) and an electrode. The generating unit includes the housing, the battery (lithium iodide), capacitors, microprocessor, amplifier, magnetic switch, audio transducer for signals, antenna for telemetry, and a connection head for electrodes. The electrode (or probe) consists of an isolated electrode body with a multilumen construction. The conductors for detection, stimulation, and defibrillation are arranged inside the electrode, isolated from one another.

Table 28.1 The NASPE/BPEG defibrillator (NBD) code (after [28.2])

I Shock chamber	II Antitachycardia stimulation chamber	III Tachycardia detection	IV Antibradycardia stimulation chamber
0 = none	0 = none	E = intracardiac EG	0 = none
A = atrium	A = atrium	H = hemodynamics (H includes E)	A = atrium
V = ventricle	V = ventricle		V = ventricle
D = dual (A + V)	D = dual (A + V)		D = dual (A + V)
Short-form code			
ICD-S	ICD with shock capability only		
ICD-B	ICD with bradycardia pacemaker as well as shock		
ICD-T	ICD with tachycardia and bradycardia pacemaker as well as shock		
Additional note:			
Site of detection and stimulation: Single-chamber system = atrium <i>or</i> ventricle, dual-chamber system = atrium <i>and</i> ventricle.			
Reaction to detection:			
1. Triggered: synchronous stimulation at available and nonadjustable frequency when there is no cardiac activity.			
2. Inhibited: when cardiac activity is present, delivery of a pulse is suppressed.			
3. Frequency adaptation: stimulation frequency is adapted to the physical strain at the time.			
The coding is listed on the ICD housing and in the ICD documentation.			

Depending on the ICD model, the therapy possibilities are:

1. Pacing (pacemaker function in the case of bradycardic cardiac arrhythmias)
2. Antitachycardic pacing (ATP, the intention is to terminate ventricular tachycardias with overstimulation – a so-called burst with every n -th stimulus)
3. Cardioversion (when ATP is unsuccessful, a shock of energy of 15–20 J is automatically administered, and up to 35 J for further shocks)
4. Defibrillation (in the case of ventricular fibrillation, a shock of energy is initiated immediately with an upper limit, depending on the device, of 35–40 J).

Integrated ventricular demand rate-responsive pacing (VVIR) or dual chamber rate-responsive pacing (DDDR) pacemaker circuits (Chap. 38) are standard in modern ICD technology. The operational lifespan of dual-chamber systems is somewhat shorter than that of single-chamber systems. New shock forms, improved electrode systems, and optimized shock delivery are leading to a considerable reduction in the defibrillation threshold (DFT), which today is generally below 15 J. There is also the fact that short and constant charge times prevent the DFT from increasing. Biphasic or sequential defibrillator pulses are currently preferred in clinical use. Studies have confirmed that the pulse of energy required increases with the duration of ventricular fibrillation and with the increase in conduction fronts, and conversely that the sooner the ventricular fibrillation is terminated after it arises, the lower the energy. Comprehensive diagnostic program memories, which in the context of patient aftercare enable validation of the therapeutic intervention, are part of today's standard equipment. Some ICD devices provide the option of telemetry transmission of recorded intracardiac electrograms via an antenna in the head of the ICD implant. The periodic or event-triggered reports are transmitted via mobile telephony to an Internet-based database by means of a mobile patient unit. The attending doctor can then access the transmitted data via the Internet.

28.6.3 Algorithms

Internal ECG signal detection algorithms analyze the amplitude, frequency, and slew rate of the ECG. Errors in the interpretation of tachycardic arrhythmias can lead both to false ICD discharges and to erroneous failure to detect ventricular arrhythmias (so-called undersensing). Detecting ventricular arrhythmias and differentiating them from supraventricular arrhythmias is based on dif-

ferent algorithms for detection and differentiation. The cardiac rhythm frequencies which emerge are classified and assigned to up to six detection zones: a bradycardia zone, a sinus rhythm zone, a fibrillation zone, and one to three tachycardia zones.

ICD algorithms distinguish between supraventricular and ventricular tachycardias on the basis of criteria such as frequency stability, QRS width criterion (if, for example, six out of eight QRS complexes are wider than in the sinus rhythm), sudden-onset rapid heartbeat, the relationship between atrial and ventricular signals, the site of acceleration and AV association, or distinguishes between different variants in the AV relationships by means of detection of a pattern over a period between two RR intervals. Detection criteria can be programmed in the sensing system responsible for detection and re-detection. Furthermore, it is also possible to include atrial events in the detection algorithms. The mode switch algorithm induces an automatic change of operating mode from the DDDR to the dual chamber demand rate-responsive pacing (DDIR) mode to ensure that, after high atrial frequencies have been detected, the triggered mode for ventricular stimulation is actuated in aid of inhibited operation. To increase the sensitivity and specificity of the detection of ventricular tachycardias in ICD therapy, in addition to the electrical criteria it is also a good idea to take into consideration information about the hemodynamic situation, such as the contractility of the left ventricle.

28.6.4 Electrodes

If ICD implantation was still a complex surgical procedure at the beginning of the 1990s, then the development of a transvenous electrode was a considerable simplification. The combination of transvenous electrodes with subcutaneous defibrillation electrodes is a vital step forwards.

The electrically active generating unit housing (*active can*) and/or proximal section of the defibrillation probe is used as the anode, while the section of the electrode in the right ventricle functions as the cathode. A distinction is drawn between two configurations: the single-coil probe from the right ventricle to the ICD housing, and the dual-coil probe with a defibrillation surface between the right ventricle, the superior vena cava, and the ICD housing (triad configuration), which is the most favorable in terms of energy. If the section of the electrode in the right ventricle functions as an anode due to programming, this reversal in polarity likewise results in a reduced energy requirement during defibrillation.

This measure is particularly suitable for patients with a very high defibrillation threshold. The signal detection function and antibradycardic stimulation are performed via the tip of the probe, which is constructed in true bipolar fashion (between the electrode tip and a proximally positioned ring) or in integrated bipolar fashion (between the electrode tip and the distal shock coil).

Modern ICD electrode bodies have a multilumen construction, and a few are coaxial. Silicone is predominantly used (or less often polyurethane) as the insulation for the external layer of the probe and offers a high level of biocompatibility and flexibility but is very sensitive to mechanical stress. Other distinguishing features of transvenous probes are the number of defibrillation probes (one or two) and the number of coils (single or dual). Active or passive fixing of ICD electrodes can be done using fixed screws or extensible screws and using anchors.

Atrial and epimyocardial electrodes and coronary sinus electrodes (CS or superior vena cava (SVC) electrodes) are used as additional pacing/sensing electrodes. The CS electrode has at its distal end an acceleration sensor, which is used to record and differentiate acceleration values in at least two different directions.

A special shock probe is the array electrode (also known as a finger electrode or SQ array), which is implanted subcutaneously. This electrode has up to three shock coils and is used additionally when there is an insufficient defibrillation threshold. The individual coils of the finger electrode are connected in parallel with the right-ventricular shock coil via a Y-connector.

The single-lead VDD-ICD is an electrode system for a dual-chamber ICD. The atrial signals are recorded at this electrode, which is fixed in the apex of the right ventricle, by means of two electrode rings. This electrode thus replaces the otherwise additional atrial electrode. Bipolar and tripolar ECG leads in ICD systems enable reliable ischemia detection, which has considerable advantages over the conventional surface ECG owing to the early detection of ischemias and also their severity and duration.

28.6.5 Complications

The spectrum of ICD complications ranges from harmless complications, such as skin irritations and minor burns on the areas where the electrodes have been applied, to serious complications, such as the emergence of extrasystoles following defibrillation, ventricular tachycardia, ventricular fibrillation (in the case of incorrect triggering) or the occurrence of asystole following

electric cardioversion in the case of sick sinus syndrome. ICD-specific complications can be caused on the one hand by the generating unit:

- Pressure-related necroses
- Risk of infection
- Technical errors and malfunctions as a result, for example, of strong external magnetic fields or battery depletion
- Perforation of the generating unit

and on the other hand by the electrodes:

- Electrode dislocation can cause stimulation of muscles
- Inadequate administration of shocks as a result of detection of muscle potential or external sources of interference
- Fractures in the electrodes, defects in the insulation or a rise in the sensitivity threshold can cause electrode malfunction.

One malfunction in the detection function (sensing) is undersensing or oversensing. In the case of undersensing, life-threatening arrhythmias are not detected or are detected too late, whereas with oversensing the shocks administered are inadequate.

28.6.6 Function Checking

Whereas in the early days of ICD device technology it was still necessary for technical reasons to test the functioning of an ICD patient's implant every 2 months, this check is now carried out independently by the device itself. Function checking of the system (ICD query, analysis of stored ECGs, battery status, detection test, etc.) every 3–6 months is sufficient. If there is an indication of incorrect detection (*so-called* over- or undersensing), a chest x-ray is generally performed to identify insulation defects in the probe. Because of the improvement in battery technology, the shelf-life of single-chamber systems should be ≈ 9 years, dual-chamber systems should last ≈ 7 years, and triple-chamber systems ≈ 5 years. The lifespan of the device will therefore be considerably longer than that of previous ICD systems. Replacement of the generating unit is also only necessary at a later point in time. Stored data, such as treatment episodes, electrograms, battery state, and electrode resistance, can be queried via telemetry. For the purpose of function checking, various device parameters are measured intraoperatively during pacemaker and ICD implantations and, if necessary, adjusted (Table 28.2).

Table 28.2 Limit values for intraoperative measurements during implantation of pacemakers and ICD systems (after 28.3)

	Ventricle	Atrium
Signal amplitude	> 5 mV, optimally > 8 mV	> 2 mV, optimally > 3 mV
Impedance (electrode-dependent)	300–1200 Ω	300–1200 Ω
Slew rate	> 0.5 V/s	> 0.3 V/s

Laser System

29. Laser Systems

Frank Zgoda

This chapter gives a short introduction to the laser and its history providing an insight into the physics and technology of laser systems. For the use of lasers in medicine, not only knowledge of the application methods and biophysical effects of the laser radiation on tissue is essential but also detailed information about the specific characteristics of the various laser systems. The fields of use are manifold and can be classified according to parts of the body and special treatment modalities. The chapter concludes with a section on safety aspects and future prospects with relating to technological developments in endoscopy and smart systems.

The laser has been linked to medical applications from the very start. Light has been used in healing processes for some time, for example, for treating diseases of the

skin, supporting the production of vitamin D by UV light and for treating eye diseases (Meyer-Schwickerath 1948). The defining feature of laser radiation is that it

is an easy to control energy source that can be used not only to heat specific tissues and to destroy autolo-

gous stones but also to selectively excite photochemical processes [29.1, 2].

29.1 History of the Laser

The word LASER is an acronym for light amplification by stimulated emission of radiation. This process was postulated by Einstein as early as 1917 [29.3] and forms the basis for the production of monochromatic, coherent and collimated light with a higher power density and a greater spectral purity than can be attained with any other light source [29.4, 5].

Working according to the same principle, in 1954 Townes built the first maser, an amplifier for microwaves. The principle of the laser for optical radiation was published for the first time four years later by Schawlow and Townes (USA) and Basov and Prokhorov (USSR). Maiman made an important breakthrough in 1961 with the first working laser emitting visible light (ruby laser), and Javan followed in the same year with the first infrared gas laser (HeNe).

The medical use of lasers began when Campbell (1961) introduced the use of the ruby laser into ophthalmology, who was soon followed by Goldman in dermatology. Although the laser quickly became established in ophthalmology (initially the argon-ion laser,

L'Esperance 1968), its use in other areas of medicine was more gradual. Polanyi first pioneered the use of the carbon dioxide laser (CO₂ laser) in 1965, to be followed by Kaplan in 1967. Since then the CO₂ laser has become established in all surgical disciplines.

The argon-ion laser and the Nd:YAG laser became interesting for a wider range of medical applications when it became possible to couple the lasers to glass fibers. From this point on, further developments progressed very rapidly. Hematoporphyrin derivatives (HpD) were discovered in 1960 but they were not used for photodynamic therapy until 1972 by Diamond. Q-switching and mode-locking were introduced into pulsed systems in ophthalmology in 1977 by Fankhauser and Aron-Rosa, and it was in this field that Trokel used the excimer laser for the first time in 1983.

Today, physicians have a wide variety of lasers to choose from for a multitude of uses. The advantages offered by the laser have led to it being used as a standard procedure in many medical fields, which are constantly being added to.

29.2 Physics and Technology

A laser is a device for the conversion of electrical energy into *ordered* light energy. Conventional light sources such as light bulbs or fluorescent lamps have as much in common with lasers as a spark gap has with a radio transmitter. Lasers are ideal light emitters in the terahertz region and are analogous to radio transmitters in the megahertz region. Einstein postulated that induced emission is rudimentarily apparent in every luminescent effect of matter; however, it can only be brought to dominance in selected materials [29.6].

Different medical lasers are employed according to the tissue to be treated and the specific therapy required much in the same way as special instruments are used in medicine for different operations (Fig. 29.1). Lasers differ from one another by their emission wavelength, beginning in the UV region at a wavelength of 0.2 μm and extending to 10 μm in the infrared. As most lasers are based on a narrow spectral transition

of electrons, in general they cannot be tuned in the same way as a radio transmitter. The only exceptions to this are dye lasers, vibronic solid-state lasers and the free-electron laser. Some gas lasers have several fixed wavelengths according to the type of selected gaseous medium.

Laser systems vary in their technical and physical configuration, more specifically in their constructional design and the temporal characteristics of the emission. On its own, the laser is just a light source. However, what is required is a complete system made up of a beam transmission system and an end device to direct the radiation to the tissue to be treated, together with a means of controlling the effect. According to the wavelength, a quartz glass fiber, a fiber bundle, a hollow waveguide, or an articulated arm is used for transmission of the radiation. The end device can be, for example, a surgical microscope

with a micromanipulator, an endoscope, or a slit lamp (Fig. 29.2).

Monitoring of the effect is dependent on the laser-induced processes and is, in many cases, based on the visual control of an experienced therapist. Imaging systems, such as ultrasound or magnetic resonance tomography, are used for highly differentiated procedures where precise dosage control is required e.g. interstitial thermotherapy of tumors or metastases.

29.2.1 Laser Medium

In order to be able to understand the need for the wide variety of appliances available, some principles of physics that form the basis for the different *light amplifiers by induced emission* are explained here.

Spontaneous emission of light results when energy is fed into a gaseous, liquid, or solid body so that *luminous electrons* are raised from the ground state energy level n_1 to an excited state n_2 . After a characteristic time interval, the electron spontaneously reverts to the ground state, thereby emitting a photon. The distribution of the electrons between the ground state and the excited state (ratio of the occupation numbers) is dependent on the temperature (Fig. 29.3) i.e. the higher the temperature, the more electrons find themselves in an excited state.

In a thermal light source, such as an electric light bulb, energy is continually fed by heat in order to transfer the electrons to higher levels. The life span of the excited states is short; in order for the electron to be able to return to the ground state this cannot be completely filled. The excitation of an electron can also be effected by irradiation of light. In this case, the higher level is populated by absorbing the corresponding energy difference ΔE .

In addition to the direct transition from a higher level directly to the ground state, a return to the ground

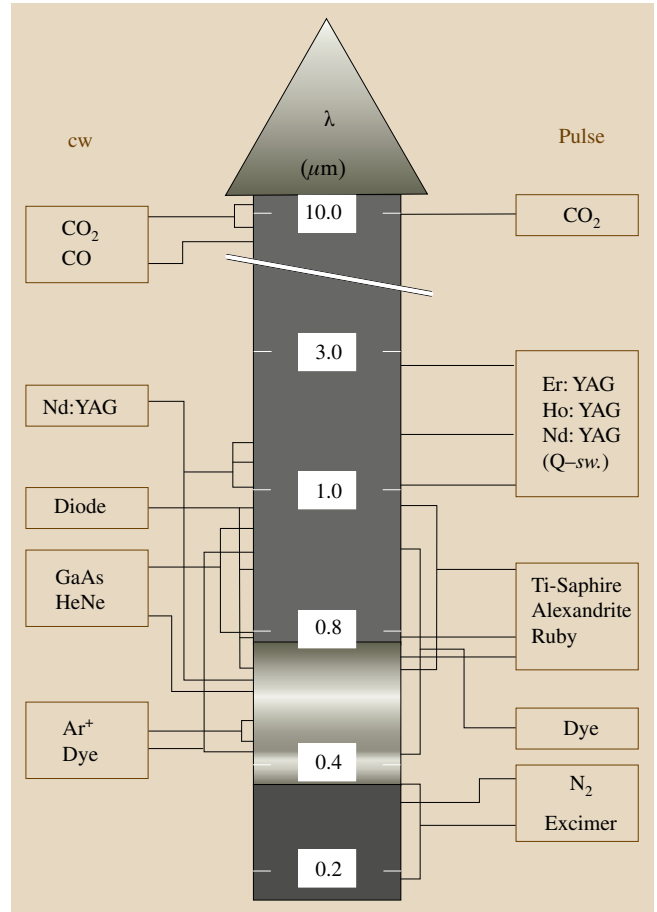

Fig. 29.1 Medical laser systems and their wavelengths

state can also occur stepwise through several intermediate levels. As the lifetimes of the levels are different, i.e. the levels empty at different rates, the electrons can collect at higher levels.

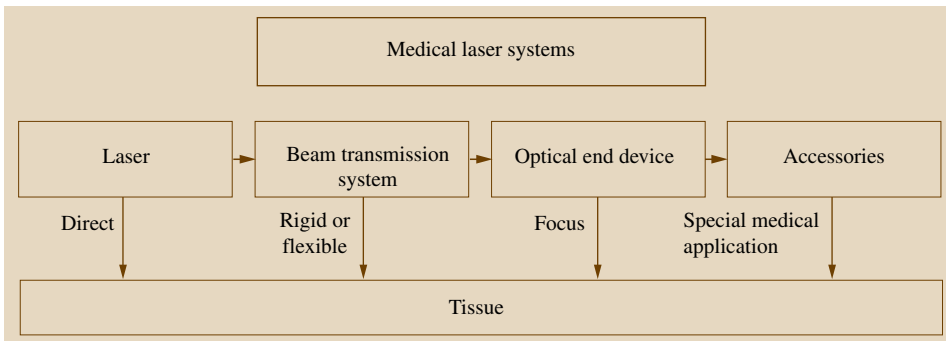

Fig. 29.2 Components of a medical laser system

Fig. 29.3 According to Planck's law the ratio n_2/n_1 of the occupation numbers shifts toward 1 during thermal heating. It is impossible to reach population inversion

Induced emission is a process by which irradiation of a photon of a matching energy triggers the premature transition of an electron from an occupied higher level to a partially empty lower level. A special feature of this is that the emitted photon has the same wavelength, direction and phase as the incident photon, which is not absorbed in the process. The incident photon is duplicated i.e. amplified. Most lasers make use of several levels, which vary both in lifetime and in occupation number. Figure 29.4 shows schemes for a three-level or a four-level laser.

With regard to the laser process, the number of atoms with occupied upper laser levels must always be larger than the number of atoms in the ground state. All substances in which this so-called occupation inversion is possible can be used as a laser medium e.g. free atoms, molecules and ions in gases or vapors, dye molecules dissolved in solution, atoms and ions incorporated into a solid (crystals and glass), doped semiconductors, and free electrons harnessed in external magnetic fields.

The relevant excitation mechanism for the production of an occupation inversion is specific for the particular type of laser. The most important processes are optical pumping and electrical gas discharge. Excitation of a semiconductor is achieved directly by an electric current (charge injection). Chemical reactions can also be used as a means of excitation.

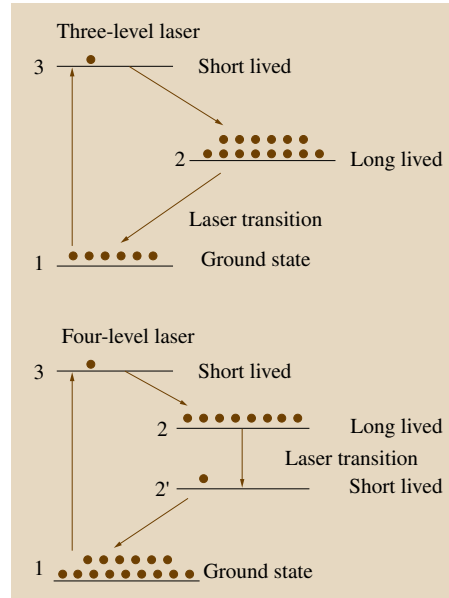

Fig. 29.4 Energy levels in laser systems

In the case of continuous-wave lasers, the occupation inversion must be constantly maintained i.e. pumping energy must be fed into the system continually.

In the laser medium excited atoms already emit spontaneous photons in all directions. These can produce more photons in the laser medium by induced emission, which in turn leads to more induced photons being set free etc. This process continues like an avalanche until the photons leave the laser medium. If the laser medium is allowed to expand in one direction, the random photon avalanches that are produced in this direction have a significantly higher amplification than in any other direction because they run through the laser medium longer.

Using two mirrors placed at each end, the photon avalanche is reflected back into the medium and effects a further amplification. If the mirrors are optimally adjusted, the photon avalanche can run back and forth in this *resonator* up to several hundred times. One of the resonator mirrors must be semitransparent in order for a fraction of the photons to leave the resonator as a laser beam.

Figure 29.5 shows a comparison of a high-frequency transmitter with the components amplifier and feedback circuit with a laser, where the laser medium and the resonator have the corresponding functions.

Fig. 29.5 Comparison of the functional principles of a high-frequency transmitter and a laser using the laser medium as an amplifier

29.2.2 Laser Radiation

In contrast to the radiation of a thermal light source, laser radiation has three important characteristics (Fig. 29.6).

1. **Coherence:** The laser radiation has a defined spatial and temporal order (set phase relation).
2. **Collimation:** The laser radiation is well collimated (low divergence).
3. **Monochromaticity:** The laser emits a high intensity, narrow (monochromatic) spectral band.

These three characteristics determine the good focusing ability necessary to attain high energy densities enabling precision work with a beam of very small cross sectional area.

In addition to the basic physical characteristics of laser light, the optical characteristics of biological tissue i.e. absorption, fluorescence, and scattering also play a crucial role in medical laser applications and in the use of laser radiation for diagnostics. These characteristics can be evaluated both photometrically and spectroscopically.

For therapy it is the collimation of the radiation and the absorption characteristics of the irradiated tissue that are the properties that are used the most. The interaction of the radiation with different tissue types is influenced by two main parameters: the exposure time on the tissue and the effective power density (Fig. 29.7). The power density can be varied over a wide range by selecting the appropriate focal length. A smaller focus is achieved with a shorter focal length rather than a longer one; however in this case, the irradiation area is more affected by small deviations in the optimal distance. The exposure time can be regulated using either continuous-wave mode (CW), switched mode (with variable duty cycle), or short pulses.

Fig. 29.6a–c Properties of laser light: (a) coherence, (b) collimation, (c) monochromaticity

Fig. 29.7 Relationship of focal size and power density for different focal lengths and working distances

Fig. 29.8 Some examples of the ratio between pumping energy and laser energy; the losses in heat must be removed by cooling

This allows the ratio of therapeutic effects to side effects to be controlled according to the tissue interactions required.

29.2.3 Laser Systems

Laser systems are not only made up of a laser medium, a resonator and a pump source. Only a small amount of the energy used is converted into laser radiation, leaving a major part to be dissipated as heat. Figure 29.8 shows examples of the ratio of pump energy to laser energy produced for lasers in common use. It can be seen that the efficiency of an argon-ion laser is less than 0.1%, whereas that of a Nd:YAG laser is about 1–3%, and for a CO₂ laser it is 5–20%. Diode lasers have the highest efficiency with 30–40%, which is on a par with light-emitting diodes (LED). For comparison, the light yield of a common light bulb is only 3%.

The most important components making up medical laser systems are shown in Fig. 29.9. The schematic representation shows the laser resonator with the pumping source, the electrical power supply and cooling system together with a detector for the power measurement, a safety shutter for the release of the laser radiation, and the in-coupling point of a pilot or aiming beam for those lasers operating in the invisible UV or infrared range.

29.2.4 Beam Delivery Systems

The distance between the laser device output and the patient must be bridged in order to deliver the laser radiation to the tissue (Fig. 29.2). Flexible quartz glass fibers, specially doped if necessary, can be used for the transmission of visible laser radiation and the adjacent spectral range of approx. 0.3–2 μm. Beyond this spectral range articulated mirror arms are used to cover the range 0.19–0.3 μm (excimer lasers) and 3–10 μm (erbium and CO₂ laser, Fig. 29.10). CO₂ laser radiation can be transmitted over short distances by waveguides but the beam quality is not comparable with that achieved using articulated arms. The transmission of short pulsed energy-rich laser radiation such as that required for laser lithotripsy and laser angioplasty, makes special demands on the optical fibers.

The current development of photonic bandgap fibers has met with considerable interest for devices with wavelengths and power densities that cannot be transmitted with normal fibers or, if at all, with only poor quality. These special fibers have a hollow core surrounded with a periodically microstructured cladding. The two-dimensional periodic structure creates a pho-

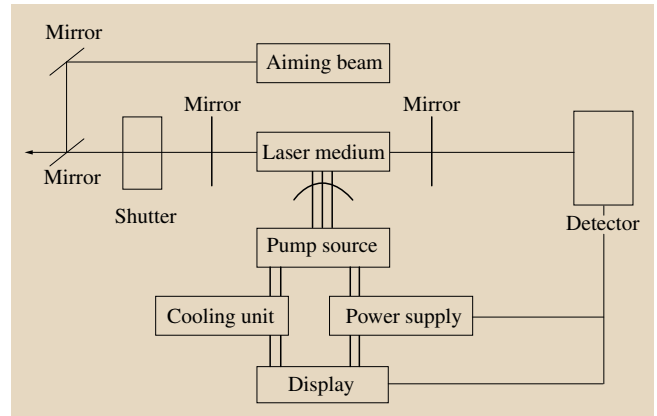

Fig. 29.9 Technical components making up a laser device. The laser beam is apparent by a visible aiming beam if it emits at a wavelength outside the visible region. The detector measures the power or energy at the laser head

tonic bandgap in the fiber material, preventing the radiation of a particular wavelength from propagation in the material. As a result the radiation is confined to the hollow core and guided with very low attenuation and is practically dispersion free.

29.3 Application Methods

29.3.1 Noncontact Mode

For the noncontact mode, laser radiation is delivered to the tissue via a beam guidance system without contact with the tissue. Articulated arms and quartz glass fibers can be used for this, whereby handling of the fibers is easier because they are more flexible. With the possible exception of the bare fiber (glass fibers with a cleanly broken or polished end) from which the radiation is emitted divergently, optical end devices such as focusing handpieces, micromanipulators (for use with surgical microscopes or ophthalmic slit lamps), or endoscope coupling devices (for rigid endoscopes) are fitted to the end of beam delivery systems.

29.3.2 Contact Mode

The tissue to be cut is brought into direct contact with the end of the fiber. The tissue is vaporized with the hot fiber end and a homogenous carbonization zone remains as a sharply demarcated cut edge. The blackening of the fiber end by adherent carbonization is important for effective cutting. A quick change to noncontact mode e.g. coagulation, is possible by *burning off* the tip. The small diameter of commercially available fibers allows endoscopic use in the contact mode.

29.3.3 Gas or Liquid Flushing During Laser Cutting

In order to protect the optics of end devices at the patient end or the distal end of the fiber, the applicator or

the fiber tip can be flushed with inert gas. Both Nd:YAG and diode lasers can also be used with liquid flushing. In this case, the laser beam is guided away by total reflection in the stream of water making it possible to effect coagulation of the tissue *around the corner* as it were. Flushing enlarges the depth of the cut in soft tissue because vaporization and ablation products are removed from the cutting channel, allowing unhindered penetration of the laser radiation. Photoablation, in the contact mode, can increase the photohydraulic effect and result in the formation of ablation channels that allow the fiber to pass through without any resistance.

29.3.4 Special Applicators

In addition to standard applicators, other delivery systems have been developed for special purposes. The scattering applicator ensures homogenous and isotropic irradiation and is used for the interstitial coagulation of tumors and metastases. For intracardial and urological coagulation and ablation of tissue special catheters that allow laser radiation to irradiate sideways are available. A multifiber catheter composed of a number of thin quartz fibers is used for laser angioplasty with the excimer laser (308 nm). This construction includes a flushing channel and facilitates the transmission of the laser radiation over a large cross section whilst maintaining a high level of flexibility. The light guides for photodynamic therapy are fitted with micro optics at the distal end, allowing homogenous irradiation of a sharply defined area.

29.4 Biophysical Effects on Tissue

For therapeutical purposes, the effect of the radiation on the different types of tissue is mainly determined by two parameters: the exposure duration of the radiation and the effective power density, taking account of the tissue's specific absorption and scattering [29.1, 2].

29.4.1 Absorption and Penetration Depth

Tissue specific chromophores such as hemoglobin and melanin, which both absorb in the visible region of the spectrum, limit the penetration depth of the laser radiation in the tissue. In contrast, radiation in the near infrared region is distributed homogeneously in the tis-

sue, leading to penetration depths of more than 5 mm, depending on the wavelength.

Light energy is mainly absorbed in water in the mid to far infrared (3.0–10.6 μm). As the coupling is 10–100 times more effective compared to laser absorption in the visible range, the penetration depth and the distribution volume is very small. The fact that tissue is vaporized in this wavelength range, even at low power densities, means that tissue can be cut and/or removed without causing significant thermal damage to the surrounding area.

Figure 29.11 shows the spectral profile of the absorption coefficient for water and soft tissue. In the

Fig. 29.11 Absorption coefficient as function of wavelength for water and tissue

visible region, soft tissue exhibits a clearly higher absorption due to autologous chromophores such as hemoglobin, melanin and coenzymes etc., whereas in the infrared region the spectral profile of water exhibits a good approximation.

It should be taken into consideration that during irradiation of body tissue with progressive exposure, photothermal effects have a considerable impact on optical characteristics such as absorption and scattering [29.1].

Fig. 29.12 Energy density regions as a function of the application time for different laser radiation effects on tissue

Table 29.1 Laser–tissue interaction

Photochemical effects	
Photoinduction	Biostimulation
Photoactivation of drugs (POD)	
Photochemotherapy	Photodynamic therapy (PDT) Black light therapy (PUVA)
Photothermal effects	
Photohyperthermia	37–43 °C: Damage of normal tissue is reversible 43–65 °C: Edema forms in cells, tissue welding, protein precipitation
Photothermolysis	Thermal dynamic effects Microscopical slight overheating
Photocoagulation	65–100 °C: Coagulation, necrosis
Photocarbonization	100–300 °C: Drying out, vaporization of water, carbonization
Photovaporization	> 300 °C: Pyrolysis, vaporization of tissue
Photodecomposition effects	
Photoablation	Rapid thermal explosion
Photodisruption	Optical breakdown, mechanical shockwaves
Photofragmentation	Lithotripsy

For medical treatment methods, depending on the exposure duration and power density, the effects can be divided into three main classes (Table 29.1, Fig. 29.12) [29.1, 2].

- Photochemical effects (10–1000 s; 10^{-3} – 1 W/cm²),
- Photothermal effects (1 ms–100 s; 1 – 10^6 W/cm²),
- Photodecomposition effects (10 ps–100 ns; 10^8 – 10^{12} W/cm²).

29.4.2 Photochemical Effects

The main effects are photoinduction or photoactivation, also known as biostimulation, and photodynamic therapy (PDT) including photosensitization. Laser energy is used to bring about photochemical reactions by absorption either in the body's own, or in extraneous, chromophores.

There are four basic types of photochemical reaction mechanisms

- Photo-induced isomerization e.g. bilirubin decomposition
- Photo-induced charge generation e.g. in visual processes

- Photo-induced synthesis e.g. photosynthesis in plants
- Photo-induced dissociation e.g. in photodynamic therapy (PDT).

29.4.3 Photothermal Effects

Here the incident radiation is converted into heat and causes coagulation, vaporization, or carbonization of the tissue, depending on the temperature reached.

At temperatures of 43–65 °C the membrane disintegrates, followed by enzymatic induction and edema formation. Thermodynamic inflammatory response occurs in this transition zone. The irradiated tissue reacts to the treatment after several weeks by sealing off the smallest vessels. This reaction is exploited for the treatment of naevi flammei. Tissue welding also occurs in this temperature range but it is based on another vaguely defined tissue reaction, which is as yet not fully understood.

Coagulation of the tissue (protein precipitation) is effected at a temperature of 65–100 °C; hemostasis and tumor denaturation are examples of processes using coagulation. Here, the tissue is damaged but is retained as a tissue composite to be decomposed at a later stage by the body and subsequently replaced by new tissue growth.

Fig. 29.13 Depending on wavelength and laser pulse length, it is possible to recognize two regions separated by the critical time. The thermally altered border zones of the regions are determined either directly by laser radiation or by thermal conduction (α : absorption coefficient in cm^{-1} ; κ : temperature conduction $1.2 \times 10^{-7} \text{ m}^2/\text{s}$)

Carbonization of the tissue in the temperature range 100–300 °C is the result of vaporization of water and desiccation of the tissue. The vaporization of tissues occurs at temperatures over and above 300 °C (Fig. 29.1). Bone material *melts* at temperatures above 700 °C.

29.4.4 Photodecomposition Effects

Nonthermal effects such as photoablation and photodisruption can be summarized as the photodecomposition of material. This third class of interaction is based on nonlinear optical effects because of the higher order components of the absorption coefficient becoming effective at the high peak intensities of energy-rich laser pulses. Pulsed lasers can produce peak powers from megawatts to terawatts (10^6 – 10^{12} W) in the nanosecond to femtosecond range. This principle is currently used in ophthalmology for the destruction of turbid posterior lens capsules and uses the same method as the destruction of calculi in laser lithotripsy.

If tissue is exposed to pulsed UV-laser radiation, it is absorbed by a very thin layer on the surface. The tissue layer absorbs so much energy that it is separated with force from the lower surface layers. This effect, known as photoablation, uses light induction

to separate material fragments from a surface without causing a secondary heating effect in the surrounding tissue. However, a specific repetition rate of the laser pulses should not be exceeded in order to avoid subjecting the surrounding tissue layers to thermal damage. Photoablation is used in the laser recanalization of arteriosclerotic vessels and in refractive corneal surgery.

Depending on the optical penetration depth of the radiation, the energy from each laser pulse must have a tissue specific intensity in order to exceed the threshold for photoablation and to ablate tissue. As the damage threshold of the delivery system limits the transmitted energy density, the energy per pulse can be raised accordingly by increasing the pulse length. On the other hand, a greater pulse length means a longer continuous exposure time, allowing heat to be conducted from the heated volume to the neighboring tissue, ending with the explosive ejection of tissue particles.

Figure 29.13 can be used to calculate at which wavelength and laser pulse duration the damage zone Δd is either mainly determined by the optical penetration depth or by heat conduction [29.1]. This knowledge can be used to optimize the parameters of a photoablation laser and, as a result, limit the degree of thermal damage to an absolute minimum.

29.5 Laser Types in Medicine

The specific characteristics of different laser systems are used according to the tissue interaction required (Fig. 29.14, Table 29.2). Laser systems are usually classified by the aggregate state of the laser medium into solid-state lasers (e.g. ruby, Nd:YAG, Er:YAG,

Ho:YAG, alexandrite lasers), diode lasers, gas lasers (e.g. CO₂, argon- and krypton-ion, excimer and HeNe lasers), and liquid lasers (dye lasers). The free-electron laser (FEL) is not classifiable according to this pattern.

Table 29.2 Medical application fields for different lasers

Lasers	Mode	Medical application field
Ar+, (Kr+)	CW	Dermatology, ophthalmology, ENT
KTP	Pulsed	Plastic surgery, dermatology
FDL	Pulsed	Dermatology (585 nm), urology (504 nm)
Nd:YAG	CW	Surgery, urology, gynecology, neurosurgery, gastroenterology, pulmology
Nd:YAG	Pulsed	Ophthalmology, lithotripsy
CO ₂	CW	Surgery, dermatology, ENT, gynecology, neurosurgery, plastic surgery
Er:YAG	Pulsed	Dermatology, plastic surgery, dentistry
Diode	CW	Surgery, dermatology (810, 940, 980 nm); PDT (630 nm); dermatology (800 nm)
Excimer	Pulsed	Angiology, ophthalmology
Ruby	Pulsed	Dermatology
Alexandrite	Pulsed	Dermatology

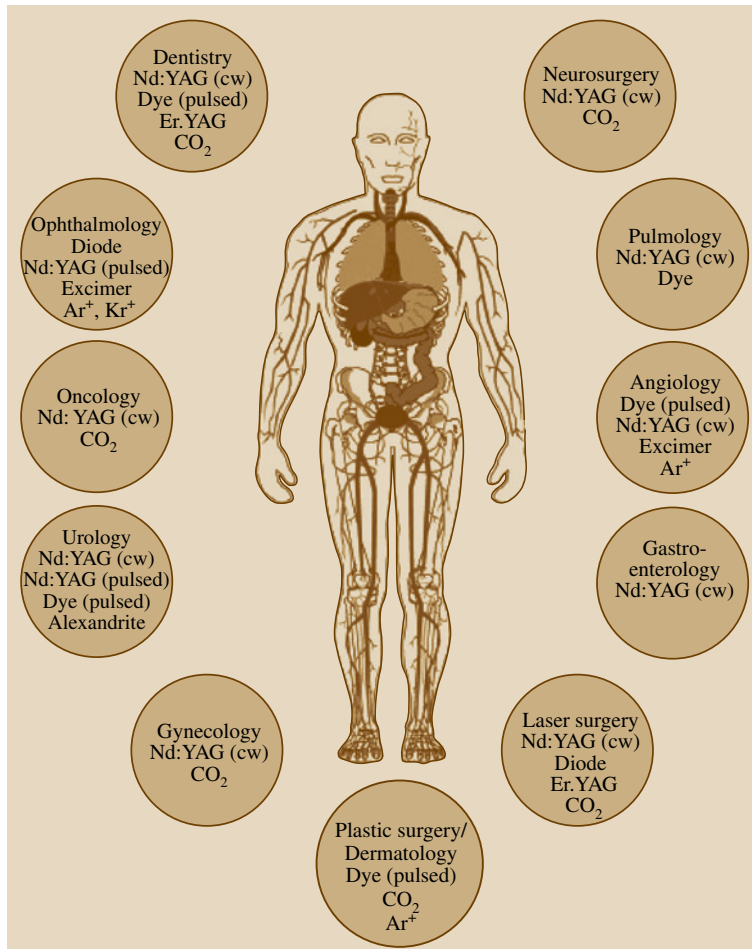

Fig. 29.14 Medical application fields of the laser

29.5.1 The Ruby Laser

The ruby laser, operating at a wavelength of 694 nm, was the first laser to be built. In the early stages of their development ruby lasers had a number of technical weaknesses, such as low efficiency or local intensity spikes, which led to destruction of the delivery fibers. However, this has now changed and modern medical ruby lasers are compact and reliable systems. Designed as Q-switched lasers (Q-switched ruby laser, QSRL) these lasers deliver high-energy pulses with durations of 20–40 ns. The QSRL is currently used both for the treatment of superficial pigmented skin lesions and for the removal of tattoos. Ruby lasers with a longer pulse length (0.3–5 ms) have recently become available and these devices are the preferred laser for epilation treatment (hair removal).

29.5.2 The Neodymium:YAG Laser

The continuous-wave Nd:YAG laser is currently the most important representative of solid-state lasers. At a wavelength of 1064 nm (less frequently at 1320 nm) it is a typical volume coagulator. It is possible to effect a deep unspecific coagulation, vaporization, or to cut tissue, according to the power density used. Transmission using glass fibers allows ubiquitous application of the radiation. For example, it can be used via a flexible or rigid endoscope for the coagulation of hemorrhages, minor malformations or tumors, and at higher power densities for the recanalization of tumor stenoses. Using a focusing handpiece and correspondingly higher power densities, resection of parenchymatous organs such as liver, spleen, pancreas and kidney is possible with simultaneous hemostasis. The wavelength 1320 nm is used particularly for lung parenchymal tumor resection. The Nd:YAG laser is also used very frequently in the contact mode (Sect. 29.3.2).

Pulsed Nd:YAG laser systems (Q-switched Nd:YAG) in the nanosecond and picosecond region are used to effect photodisruption and have established themselves in ophthalmology for the treatment of posterior capsular opacification and for peripheral iridotomy in cases of acute angle-closure glaucoma. The laser can also be employed in lithotripsy.

29.5.3 The Frequency-Doubled Nd:YAG Laser (KTP Laser)

By positioning certain crystals in the optical path of a laser, the nonlinear optical effects can be utilized

to generate the harmonics of the basic wavelength. The frequency doubling of Nd:YAG laser radiation is usually effected with the help of a potassium titanyl phosphate crystal (KTP, KTiOPO_4). The resulting wavelength, 532 nm, is absorbed well by hemoglobin and its clinical use corresponds to that of the argon-ion laser. Devices with a high output power (> 15 W) have the advantage of allowing the use of shorter pulse durations, thereby reducing discomfort during the treatment. A partial frequency doubling of short-pulsed Nd:YAG laser radiation is utilized in lithotripsy laser systems. In this case, the higher absorption of the shorter wavelength facilitates ignition of the plasma necessary to produce the laser-induced shockwaves (FREDDY principle).

29.5.4 The Erbium:YAG Laser

The Er:YAG laser is a flashlamp pumped solid-state laser emitting infrared light at 2940 nm, which corresponds to the local absorption maximum of water. Articulated arms are usually used as laser beam delivery system, and less frequently zirconium fluoride or sapphire fibers. If short pulse durations (approximately 1 ms) are used, it is possible to ablate extremely thin skin layers (depending on the energy density, up to 10 μm) almost athermally. This property makes the Er:YAG laser highly suitable for use in dermatology and plastic surgery. The laser is also used as a dental drill, usually in combination with a water spray to cool the enamel.

29.5.5 The Holmium:YAG Laser

The Ho:YAG laser emits infrared light at a wavelength of 2100 nm. These lasers are usually flashlamp pumped pulsed systems, although more recently, diode pumped continuous-wave low-power Ho:YAG lasers have also been developed. Ho:YAG lasers are used for the treatment of hard substances such as cartilage and bone, and because the radiation can be transmitted via glass fibers, they can also be used endoscopically (arthroscopy, lithotripsy).

29.5.6 The Alexandrite Laser

The alexandrite laser emits light at 755 nm and operates by virtue of its Q-switching properties at pulse durations in the nanosecond region. Both the clinical fields of use and application techniques are similar to those of the Q-switched ruby laser. A long pulsed version of the

alexandrite laser, with pulse lengths in the millisecond region, has been developed for use in laser epilation.

29.5.7 The Diode Laser

Diode lasers in the near-infrared region have been employed in ophthalmology since the end of the 1980s. Further development of the spectral emission range (630–980 nm) and the output power (medical lasers up to 100 W), has led to a wider use of the diode laser in medicine. Its advantages over other laser systems are not only its compact design, but also its mobility, water-free cooling system, easy installation and low-key maintenance.

Diode lasers with output powers of up to 1 W are used diagnostically in a variety of ways, ranging from optical imaging in laser Doppler sensors to determine blood flow, to use in fluorescence diagnostics.

Applications such as laser-induced coagulation using the Nd:YAG laser can be carried out equally well by the diode laser operating at an emission wavelength of 980 nm. The lower penetration depth at 980 nm can be compensated for in most tissues by making relevant changes to the application parameters, i. e. higher output power and longer exposure times. The depth of the coagulation is identical for both 1064 and 980 nm because the regions beyond the optical penetration depth are only influenced by wavelength independent heat conduction.

Urology is currently the main indication field for new high-power diode lasers although they are gradually also becoming established in other disciplines, such as ENT. Diode lasers that operate at 630 nm are used as the light source for photodynamic therapy.

29.5.8 The CO₂ Laser

The continuous-wave CO₂ laser (10 600 nm), by virtue of its high absorption in water, is a very precise cutting instrument with a very low penetration depth. It has found use in microsurgical procedures and areal removal because it does not cause significant thermal damage to the surrounding area. However, its hemostatic properties are very limited and it can only be used to stop minor bleeding from small vessels such as capillaries.

As it is not possible to transmit the radiation by fibers, the laser beam is transmitted using the articulated mirror arm, which is currently this laser's biggest disadvantage. Hollow waveguides are sporadically used, which allow flexible beam guidance; however their

beam quality and focusability are poor. Further progress is expected along the lines of photonic fibers, but as yet, no products are commercially available (Sect. 29.2.4).

Pulsed CO₂ lasers emit a very quick series of short impulses with a high energy density instead of a continuous beam. As less heat is transferred to the surrounding tissue, cutting or vaporization can be performed with considerably less thermal side effects to the surrounding tissue (the so-called *super-pulse* mode). Pulsed or continuous-wave CO₂ lasers fitted with special scanner systems are used in dermatology and plastic surgery for the superficial removal of thin layers of skin [29.1, 7].

29.5.9 Argon-Ion and Krypton-Ion Lasers

Argon-ion lasers are continuous-wave lasers that can principally emit at several wavelengths in the range of 250–530 nm, whereby the systems usually used in medicine emit blue/green mixed light (488 and 514 nm, *all-lines* mode) or green light (514 nm alone). The argon laser's high selectivity for the body's own chromophores (hemoglobin, melanin) makes it suitable for use in ophthalmology and dermatology. The radiation is guided via an optical fiber with a focusing handpiece or a slit lamp fitted to the distal end. Special scanners are available to facilitate the automated and uniform treatment of larger areas. The krypton-ion laser can also emit at several wavelengths within the range 350–800 nm, whereby the most intensive emission lines are 531, 568 and 676 nm, and the main area of use is in dermatology and photodynamic therapy (PDT).

Gas ion lasers have the disadvantage of not only being sensitive to vibration, but also of being bulky and relatively expensive to maintain. Moreover, the laser tubes have an average lifetime of between 1000 and 10 000 operating hours, which is relatively short for a laser. As a result, in many applications gas ion lasers have now mostly been replaced by frequency multiplied solid-state lasers or diode lasers. However, there are situations where their excellent beam quality is required and for these special cases they remain indispensable.

29.5.10 The Excimer Laser

Excimer lasers are gas lasers with a laser medium that is a mixture of a noble gas (argon, krypton, xenon), a halogen (chlorine or fluorine) and a buffer gas (helium or neon). According to the gas mixture the exclusively pulsed laser radiation lies in the ultraviolet range between 157 and 351 nm. The most common appliances are those with the mixtures ArF (193 nm), KrF

(249 nm), or XeCl (308 nm). Using these wavelengths with short pulse lengths (10 ns) and very high peak power densities (10^8 W/cm²), the threshold for the process of photoablation can be exceeded. These lasers are not only used in corneal surgery for the operative correction of defective vision but also in laser angioplasty.

29.5.11 The HeNe Laser

The red helium-neon laser (632 nm) is used therapeutically for low-level laser therapy (LLLT, soft laser, biostimulation) but its main use in the past was as a pilot laser for invisible radiation of surgical laser appliances such as CO₂ and Nd:YAG laser in noncontact mode. However, more recently this function has been taken over by the smaller and much less expensive diode laser.

29.5.12 The Dye Laser

The functional principle of the dye laser is based on the excitation of an organic dye solution to fluorescence by energy-rich flashes of a flashlamp (for pulsed systems; FDL, flashlamp pumped dye laser) or by a pumping laser (continuous-wave systems). In contrast to other lasers, dye lasers emit over a relatively broad spectrum. However, by using a wavelength selective filter, only a selected wavelength, fixed or variable, according to the laser device, is amplified and transmitted through

a fiber optic system. Rhodamine 6G is a typical representative of the dyes used and, with the appropriate tuning, emits wavelengths in the visible range from 570–630 nm. These specialized lasers are used clinically in dermatology [29.7] and lithotripsy.

29.5.13 The Free-Electron Laser

The laser medium of the free-electron laser (FEL) is a high-energy electron beam that reaches relativistic velocities (i. e. near the speed of light). Compared to the materials that make up conventional laser media in which the electrons are bound to atoms or molecules, these free electrons oscillate in a spatially periodic magnetic field. This very complex technology allows the tunable production of radiation ranging in wavelength from microwaves, through the visible and ultra violet spectral range to x-rays, whereby the emission duration can extend from quasi continuous to femtosecond. However, with the systems that have as yet been technically realized, it has only been possible to use a fraction of the possibilities this technology promises. A medical FEL system emitting in the mid-infrared range has already been employed as a surgical tool in ophthalmology, otorhinolaryngology and neurosurgery. Other research is investigating the use of FEL for the spectroscopy of biological molecules, as a tool to kill pathogenic microorganisms and as a radiation source for optical coherence tomography (OCT) [29.8].

29.6 Fields of Use

29.6.1 The Eye

Due to the optical transparency of the cornea, lens and vitreous body, the laser was predestined for use in ophthalmology. Laser radiation over a broad wavelength range can pass through the transparent media to reach the back of the eye. Photocoagulation of the detached retina was the first application to be used on the eye and is still one of the most frequently used laser procedures in ophthalmology. There are various other standard procedures such as laser trabeculoplasty (LTP) and laser iridotomy (LI), both of which are used to effect a lowering of intraocular pressure for the treatment of glaucoma.

Short pulsed excimer lasers that utilize photoablation are widely used for refractive corneal surgery. One example of photodisruption is the opening of the after-cataract membrane using the Q-switched Nd:YAG laser

(laser capsulotomy), which utilizes of the optical breakdown effect.

29.6.2 The Body Surface

The body surface was one of the first application fields to use the medical laser. The indications can be divided into the two main tasks

- removal or coagulation of skin and skin appendages, and
- therapy of intracutaneous vessel lesions and malformations.

Coagulation with the Nd:YAG laser or removal with the CO₂ laser are currently the methods of choice for skin tumors such as basaliomas, spinaliomas and metastases of malignant melanomas. Pigment anomalies are

treated with the ruby or alexandrite laser although the argon laser can also be used. The argon, Nd:YAG, and CO₂ laser are used to remove virally induced tumors such as condyloma, molluscum lesions and verrucae. Due to its low penetration depth, treatment with the CO₂ laser leads to a vaporization of these structures, whereas the argon and Nd:YAG lasers, with their high penetration depth, coagulate the tissue and this is subsequently rejected by the body.

Use of the CO₂ laser leads to immediate vaporization of the skin, and is therefore the laser of choice for the treatment of epithelial dysplasia (leukoplakia, morbus Bowen), for the therapy of chronic ulcers and for cleaning wounds. The ruby, alexandrite, pulsed Nd:YAG and CO₂ lasers are used for the removal of tattoos.

29.6.3 The Vascular System

Argon-ion, dye and Nd:YAG lasers have proved to be very successful for the therapy of spider nevus, nevus flammeus and cutaneous planotuberous hemangiomas. The argon-ion laser is particularly successful because of its low penetration depth and high absorption in hemoglobin. A thermal dynamic reaction is induced in the laser treated vessels in the form of an angiitis, which results in an occlusion of the teleangiectasia. The occluded vessels are then left to the natural resorption processes of the body.

The dye laser is used in the treatment of port-wine stains and particularly good results are achieved in the treatment of homogenous port-wine stains in children.

Hemangiomas belong to the most common pediatric vascular tumors. The majority of hemangiomas heal spontaneously before the age of eight, which is why a *wait-and-see* approach is advisable. If however, an unfavorable localization leads to considerable functional disturbance or disfigurement of the patient, then there is a case for an earlier therapy indication, even if the patient is very young i.e. a baby or a small child. The Nd:YAG laser is used for the treatment because of its larger penetration depth. Superficial burns to the skin are avoided by using special ice cubes to cool the skin during the laser procedure [29.1].

A further application of the Nd:YAG laser is the percutaneous interstitial irradiation of voluminous cavernous angiomas using a bare fiber. The lesion to be treated is punctured and the fiber positioned in the tissue. The laser output of 4–5 W and an exposure time of 1 to 5 s culminate in an intraluminal thrombosis and

damage to the vessel wall is followed by sclerotization [29.9]. If a higher laser output (8–10 W) is used, the end of the fiber should be flushed during the laser operation to prevent damage to the fiber tip.

29.6.4 Open Surgery

Even with the best preoperative planning, surgical interventions are never free from possible intraoperative or postoperative complications. Bleeding can be a cause for concern both during an operation and postoperatively, as can also bile leaks or bilio-cutaneous fistula after liver resection or complications after operations on the pancreas, spleen, kidneys, mammary tissue, and the brain in particular. A loss of 100 ml of blood in pediatric surgery can already lead to a life-threatening condition, which then urgently requires blood transfusion.

Under these circumstances, the advantages of lasers in surgical disciplines can be summed up in five points.

1. Inherent hemostasis
2. Precision work
3. A decrease in the number of instruments used in the operation area
4. Noncontact tissue removal (i.e. aseptic application)
5. Minimal traumatization of the surrounding tissue due to zero-force application.

Neurosurgeons use the Nd:YAG laser and CO₂ laser in the cranial cavity to resect tumors, for angioma sclerotization in stereotactical operations and for plexus coagulation.

In surgery of the thorax, the laser is used for parenchyma resection, for treatment of fistulas and for decortications. The Nd:YAG laser is an established tool in open surgery for the resection of parenchymatous organs in the abdominal cavity. Small veins, with a diameter of 3–5 mm, and arteries up to 1.5 mm are sealed when they are cut by the laser beam, but larger vessels must be ligated beforehand.

The laser has also established itself in gynecological abdominal surgery. The CO₂ laser is used in a number of operative refertilization methods such as intrapelvic adhesiotomy or tube implantation, as well as for the operative removal of myomas. CO₂ lasers and Nd:YAG lasers are also used for mammary amputation and subcutaneous mastectomies.

A further indication for the CO₂ laser is for the treatment of mechanically irritating malformations or deformities. Some examples of these are interdigital

neuromas, ganglion cysts, heel neuromas, bony heel spurs, bone and hip joint operations for hemophiliacs, and the tarsal tunnel syndrome. The use of the CO₂ laser makes it possible to completely remove the structure by vaporization and thereby help prevent it from growing again.

29.6.5 Endoscopy

The introduction of endoscopic procedures has marked a major change in surgery. Not only does the risk of infection decrease when a body cavity is not opened, but also the danger of postoperative adhesions is considerably less and the operation stress for the patient is much reduced.

Laser light can be transmitted via a quartz glass fiber to the application site through the working channel of an endoscope under visual control. This technical development has led to further miniaturization and increased flexibility of the minimal invasive operation method. The use of this technique makes it possible to access and open malignant stenoses of the esophagus and the alimentary canal.

The Nd:YAG laser can be used in contact with a bare fiber for the treatment of congenital scarred nonmalignant changes. CO₂ laser radiation can currently only be delivered to the site of treatment using an articulated arm, which restricts application to the use of rigid endoscopes with endoscope couplers.

29.6.6 Photodynamic Therapy

Photodynamic therapy (PDT) is an increasingly important treatment modality. After intravenous injection of a photosensitizer such as a hematoporphyrin derivative (HpD) and subsequent intratumoral enrichment for 24–48 h, the tumor is irradiated either superficially or interstitially using a dye laser or diode laser (630 nm). The photosensitizer absorbs the radiation, decomposes and releases oxygen radicals that have a local destructive effect on the tumor.

Photodynamic therapy is currently used for the treatment of superficial lesions such as dysplasia and early stages of carcinomas in dermatology, gastroenterology, urology, gynecology and neurosurgery. Of late PDT has also been used in ophthalmology for the treatment of neovascular processes. The development of new dyes that exhibit a better selectivity for tumor tissue and stronger absorption in the red and infrared range of the spectrum to penetrate deeper into the tissue is currently the subject of intensive research.

29.6.7 Lithotripsy

The destruction of concrements has boomed since the development of extracorporeal shockwave lithotripsy (ESWL), which prior to this was carried out by mechanical methods. In contrast to the first generation ESWL devices, it is now possible to focus the shockwaves with considerably more precision. However, it is not possible to perform extracorporeal shockwave lithotripsy at every site in the body where stones occur. Examples of this are the intra and extra hepatic bile ducts, pancreatic duct, and ureters that are shadowed by bones. These are particularly expedient areas for the use of laser lithotripsy (LLT). In contrast to ESWL, the shockwaves produced in laser lithotripsy are not generated externally and focused on the concrements from outside the body but are produced directly in front of or in the concrements themselves. This means that the shockwaves do not have to pass through all the surrounding structures, the light energy being converted to mechanical energy in-situ.

This has been made possible by the development of Q-switched Nd:YAG lasers, flashlamp pumped dye lasers, and alexandrite lasers. The use of these very strong laser impulses has opened up the area of nonlinear interaction, photodisruption and ablation for medical purposes. Concrement fragment size can be varied by changes to the wavelength, pulse duration, pulse energy, and interval length. LLT is not yet used on a routine basis but its development is a dynamic one. The main indications for its use are for bile duct concrements, in combination with lysis or extraction, and concrements of the oral cavity and the pancreas.

29.6.8 Laser-Induced Thermotherapy

Laser-induced thermotherapy (LITT) has been used for some time to treat pathological tissue changes in different regions of the body in the contact mode. It includes the intraluminal coagulation of vascular changes as well as the palliative coagulation and hyperthermia of metastases in the liver, lung, and brain, which have both become very important over the last few years. For the subcutaneous LITT of smaller congenital malformations (congenital vascular disorder, CVD), a bare fiber is used to puncture and access the area to be treated. In order to effect larger coagulation volumes of up to 3 cm in diameter, special scattering applicators have been developed that deliver laser radiation from a Nd:YAG or diode laser over a relative long exposition time of up

Fig. 29.15
Devices for
MRT-controlled
laser-induced
thermotherapy
(LITT)

to 20 min. Water-cooled sheaths on the applicators allow laser outputs of up to 30 W without carbonization at the interface between applicator and tissue. Minimal invasive procedures such as LITT of isolated liver

metastases, specific brain tumors, or benign prostate hyperplasias require real-time monitoring, such as the imaging modalities ultrasound or MRT, for precise control of the therapy (Fig. 29.15) [29.9].

29.7 Safety Aspects

A laser system that generates radiation energy powerful enough to remove biological tissue is also a potential source of danger to both the patient and the operator, making it in effect no different to a sharp scalpel or an RF surgical device. The long-distance effect of the laser radiation presents an added danger to the eyes for which the protective measure of simply keeping a distance from the divergent radiation exit (fiber end, focusing optics) is usually overestimated. However, by implementing simple safety measures it is possible to achieve an even higher level of safety than for many other devices. This requires knowledge of the basic physical interactions and strict adherence to the respective safety specifications [29.10–14].

29.7.1 Permissible Exposure and Laser Classification

The danger to both the eyes (Fig. 29.16) and to the skin (Fig. 29.17) has led to the specification of maximum permissible exposure (MPE) levels [29.12]. Some examples for medical lasers are shown in Table 29.3. All safety measures should be implemented in such a way that should an unintentional irradiation occur, the MPE values cannot be exceeded.

The damage that laser radiation can incur is dependent on the output power, exposure time and

wavelength. As a result, laser systems are divided into classes according to these parameters, thus giving an indication of the danger potential for each individual device. A simplified version of the laser classes according to IEC 60825-1 is shown in Fig. 29.18. The divisions are such that the class 1 comprises the so-called *intrinsically safe* systems i. e. looking directly into the laser beam is either not dangerous or technically impossible.

Fig. 29.16
Possible hazards
to the eyes from
different laser
types

Fig. 29.17 Penetration depth of laser radiation in the skin and possible skin damage dependent on wavelength (nm)

Table 29.3 Frequently used lasers and their maximum permitted exposures (MPE)

Laser type	Wavelength (nm)	Maximum permitted exposure of the eyes (MPE) according to IEC 60825-1:2007		Maximum permitted exposure of the skin (MPE) according to IEC 60825-1:2007	
		Power density (W/cm ²)	Time (s)	Power density (W/cm ²)	Time (s)
Argon-ion	488, 514	0.0018	1	1.1	1
Helium-Neon	633	0.0018	1	1.1	1
Diode (GaAs)	970	0.0062	1	3.8	1
Nd:YAG	1064	0.0090	1	5.5	1
CO ₂	10 600	0.56	1	0.56	1

Class 2 lasers are lasers emitting in the visible spectral range (400–700 nm). For this class it is assumed that the reflex response (including the blink reflex) limits the exposure duration to about 0.25 s. However, new research has shown that these figures are unreliable. For

lasers of classes 1 M and 2 M, a glance in the beam with visual aids (telescopes, magnifying glasses, surgical microscopes, etc.) can be dangerous although there is no danger for the naked eye under normal predictable circumstances. The radiation from the lasers of class 3R

Fig. 29.18 Laser classification overview (for an emission time of 10³ s)

can be dangerous for the eye, although less so than for class 3B. For lasers of class 3B, looking at a diffuse reflection of the laser beam (e.g. on skin) is permitted but a glance in the direct beam or the specular reflex is dangerous. For class 4 lasers, even diffuse reflections are dangerous to the eye, and the direct beam can cause burns to the skin. Needless to say, the lasers used in surgery and ophthalmology are all attributed to class 4.

29.7.2 Safety Requirements for Laser Devices

Safety requirements for medical laser systems of classes 3B and 4 are specified in the international standards IEC 60601-2-22 *Medical electrical equipment – Part 2-22: Particular requirements for the safety of therapeutic and diagnostic laser equipment* and IEC 60825-1 *Safety of laser products – Part 1: Equipment classification and requirements*. The essential requirement *protection against radiation* of the European Medical Devices Directive 93/42/EEC (MDD, Chap. 4) is implemented from these standards by formulation of a series of constructive requirements. According to these requirements, all medical laser systems must incorporate the features

- A key switch (or equivalent) to protect against unauthorized use.
- An emergency switch for the immediate interruption of emission.
- A stand-by/ready circuit to protect against accidental triggering off of the system.
- An interlock connection for remote interlocking.
- An optical and/or acoustic laser-ready and emission indicator.
- An aiming device to show the radiation's incidence point on the target before triggering.

Furthermore, the actually delivered power or pulse energy should only deviate from the previously set value within definite limits. These settings must be displayed in SI-units (W, J). The failure of an explicit list of components (e.g. shutter, trigger switch, attenuator, monitoring circuits, timer) should not pose any hazard. All protective measures must be effective within tolerance times of approximately 130 ms if tissue damage is to be avoided due to excessive laser output.

The optical end device of the beam guidance system can be a further source of danger. A badly constructed focusing handpiece can heat up to temperatures that can

burn the operator's hands or a micromanipulator with a defective or the wrong integrated safety filter can reflect dangerous levels of radiation directly into the eyes of the operator. As a result, every medical laser accessory must go through an EC conformity assessment procedure for medical devices.

It is important for the manufacturers of medical laser devices to know that these systems are regarded as medical devices of Class IIb according to the classification criteria in Appendix IX of EC Directive 93/42/EEC. Only devices with a successfully completed conformity assessment procedure can be put on the market in the European Union (Chap. 4).

29.7.3 Protective Measures and Application Safety

Regardless of more specific national regulations, some safety measures must be taken if the laser radiation exceeds the maximum permissible exposure (MPE).

- Safety glasses or goggles must be worn.
- Dangerous specular reflections on medical instruments are to be avoided by using roughened surfaces.
- Protective measures should be taken to prevent fire and explosions [29.15].
- Protective filters should always be used when using optical observation instruments.
- Disposable and covering materials should be flame resistant.

The requirements on laser protective filters and laser protective glasses are covered by the standard EN 207 *Personal eye-protection equipment – Filters and eye-protectors against laser radiation (laser eye-protectors)*. The labeling of standardized laser protective glasses is shown in Fig. 29.19. It should be noted that there is no one pair of glasses that offers protection against all wavelengths. Every pair of protective glasses protects exclusively against the wavelength (or range of wavelengths) and the mode of operation (continuous wave, pulsed, or mode coupled) as specified on the glasses themselves!

As a result of pyrolysis of the tissue during thermal laser applications, patients and operators can be confronted with substances that have both toxic and infectious potential [29.1]. According to the latest technology, the only effective protective measure against laser plume is the use of a special smoke evacuator fitted with a handpiece to remove the smoke as close as

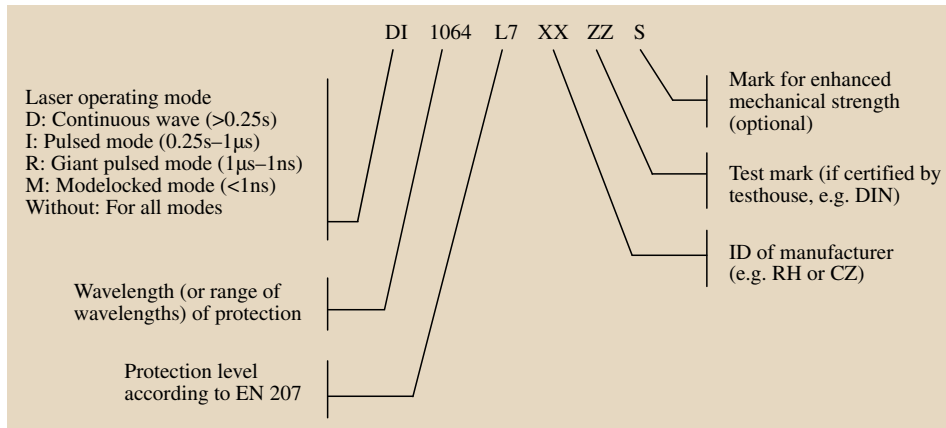

Fig. 29.19 Labeling of laser protective glasses according to EN 207

possible to where it was produced. These devices are equipped with a two-stage filter system: a membrane

filter to catch particles and droplets, and a downstream active carbon filter to reduce unpleasant smells.

29.8 Future Prospects

Against the background of laser applications in medicine, future prospects for further developments are becoming apparent. Technologically there is an increasing trend towards the use of diode lasers, which will allow the realization of more compact and simpler systems. This development will be accompanied by a reduction in costs that will lead to an even wider acceptance of lasers in medicine. The development of suitable components for endoscopic laser surgery will make the realization of newer and enhanced applications possible. In this context, the availability of flexible optical transmission systems for all spectral ranges is a central development aim.

Further developments are to be expected in the field of in-vivo or in-situ diagnostics in which the same ap-

plicator is used for both modalities. This combination of diagnosis and therapy to localize the tissue that is to undergo therapy or even for therapy control itself, will characterize the next generation of *minimal invasive* medical laser systems. The development of these *smart systems* will occur gradually, whereby the new developments in endoscopic methods make a significant contribution.

In addition to the therapeutic applications, there are a large number of diagnostic applications that have not been dealt with here. These will become increasingly more important as will also laser surgery at a cellular level. The last few years have not only seen an increase in indications but also the spread of medical laser systems. It can now be safely said that the laser no longer competes with the scalpel!

Inhalational Anesthesia Devices

Erich Siegel

Anesthesia devices are used in operating rooms in hospitals by medical staff to ensure that operative and diagnostic procedures can be performed on a patient without pain in an unconscious and relaxed state. This chapter provides an overview on the concept of these devices. It describes the intended medical use and based on this the necessary technical components. The principles of these main components are explained in detail: the mechanical or electronic dosing of the gases O_2 and N_2O or air, the dosing of anesthetic agent using the vaporizer principle, the ventilator with a re-breathing system, and the ventilation modes used in anesthesia. To ensure safe anesthesia, both the device and the patient have to be monitored. The measuring principles for the necessary device monitoring parameters are also discussed, such as the concentrations of oxygen, nitrous oxide, anesthetic agent, and carbon dioxide. In addition, the exhaled

volume and the pressure in the breathing system are described.

30.1 Anesthesia Devices in General Anesthesia

Anesthesia devices are designed to assist trained medical anesthesia staff, so that operative and diagnostic procedures can be performed without pain, the consciousness of the patient can be suppressed, and the oxygen supply can be guaranteed.

To meet these aims, the following drugs are delivered by the device:

- Oxygen (approximately 30 vol. %) to ensure adequate oxygenation of the patient during the intervention
- Nitrous oxide (approximately 70 vol. %) or intravenous administration of an opioid, for example, remifentanyl, to prevent the patient from feeling any pain

- An anesthetic agent (isoflurane, sevoflurane or desflurane) administered via the lung, or propofol administered intravenously, to suppress consciousness.

Anesthesia is called inhalation anesthesia if the analgesic (nitrous oxide) and the agent used to achieve unconsciousness (for example, isoflurane) are delivered to the body via the lung.

Anesthesia is called total intravenous anesthesia (TIVA) if the analgesic (for example, remifentanyl) as well as the drug for unconsciousness (propofol) are administered intravenously.

Anesthesia is called balanced anesthesia if one drug is administered intravenously (for example, remifen-

Fig. 30.1 Example of an anesthesia device (Primus, Dräger, Lübeck)

tanil) and the other drug is delivered via the lung (for example, isoflurane).

Since patients are usually relaxed using muscle relaxants during surgery, their breathing musculature is paralyzed, which means that every anesthetic device

must be equipped with a device for automatic, controlled ventilation. The possibility of manual ventilation is also important to allow the physician to intervene during induction and termination of anesthesia and also to provide assisted ventilation during these phases if required.

To ensure that anesthesia is safe and transparent, both the device and the patient are monitored. For this purpose, the parameters of the delivered anesthetic gas, i. e., the inspiratory oxygen concentration and the nitrous oxide and anesthetic agent concentrations, are measured. In addition, the exhaled CO_2 and the exhaled volume are determined and the pressure in the system is controlled. These device monitoring parameters are the parameters to be measured in accordance with current standards.

To test cardiovascular function, the electrocardiography (ECG) and noninvasive or invasive blood pressure are measured. Blood oxygenation is monitored by the oxygen saturation. In addition, the effect of anesthesia must be monitored, i. e., the level of patient unconsciousness, the degree of painlessness, and the level of relaxation.

Therefore, an anesthesia device (Fig. 30.1) consists of the following components, according to its intended medical purpose:

- Drug dosing unit
- Ventilator with breathing system
- Monitoring unit consisting of 3 subunits:
 - One which monitors drug dosing and the ventilator called device monitoring
 - One which monitors the patient called patient monitoring
 - One which monitors the *depth of anesthesia* called anesthesia effect monitoring.

30.2 Functional Principle, Medical Aspects

Figure 30.2 shows the three main components (drug dosing unit, ventilator, and device monitoring) of an inhalation anesthesia machine. During inspiration, the ventilator forces the gas from the breathing bellows through the CO_2 absorber and the inspiration valve into the patient's lung. During this time, the drugs (oxygen and nitrous oxide at concentrations of approximately 30 vol. % O_2 and 70 vol. % N_2O as well as, e.g., 2 vol. % isoflurane) flow continuously from drug dosing to the reservoir bag, which also acts as the manual breathing bag at the same time. During expiration,

the path to drug dosing is opened by the controlled valve. The gas from the reservoir bag flows together with the exhaled gas from the patient to the breathing bellows of the ventilator. All gas that exceeds the desired pressure at the end of expiration escapes through the anesthetic gas scavenging valve. During inspiration, the path to the reservoir bag is closed by the control valve, and the ventilator forces the gas back to the patient.

The amount of fresh gas flow is based on the following considerations.

- How much oxygen and nitrous oxide is absorbed by the patient?
- How much leakage is there from the device?
- Which rebreathing rate should be used?

Taking a 70 kg patient as an example, uptake of 250 ml/min oxygen and about 100 ml/min N₂O is normal in steady state. With a leakage rate of about 50 ml/min, a minimum flow of 400 ml/min is needed in equilibrium. In the induction phase, more than 1300 ml/min is needed. In addition to the minimum level of fresh gas, the physician also has to adjust the desired gas rebreathing rate. The patient must also be provided with an adequate respiratory minute volume during ventilation and also during spontaneous breathing; for a patient with body weight of 70 kg, this is approximately 6 l/min. It is therefore necessary for the patient to receive this amount of gas per minute. However, that does not mean that the fresh gas which is provided by drug dosing is always required to supply this amount of fresh gas to the system. If, as shown in Fig. 30.2, part of the exhaled gas is reused for inspiration, a fraction of the respiratory minute volume is sufficient as the fresh gas flow.

The type of breathing system which reuses a part of the expiratory gas is called a rebreathing system. Often, a fresh gas flow of 3 l/min with approximately 1 l oxygen and 2 l nitrous oxide is used. Depending on the degree to which the system is sealed and if monitoring is used, the fresh gas flow can be reduced further. If the fresh gas flow is reduced to approximately 1 l/min, this is known as a low-flow system. The type of fresh gas flow used does not have any effect on the anesthesia. The factors which are decisive for the magnitude of the fresh gas flow include the experience of the anesthetist, the degree to which the system is sealed, and whether monitoring is used. In a rebreathing system there are two sources of water: first the patient, who exhales warm (37 °C) water with 100% humidity in the system, and second the soda lime in the CO₂ absorber, which produces water and heat through a chemical reaction with CO₂. Therefore, no active humidification is necessary in anesthesia care.

If a low fresh gas flow is used, adjustments induced by drug dosing are slow acting. In other words, it takes a long time until these adjustments take effect in the patient. If, on the other hand, a high flow is used, the system is flushed quickly and adjustments to the agent concentrations are passed on quickly to the patient.

A primary objective of anesthesia is to ensure that the oxygen (O₂) supply to the patient is maintained.

Fig. 30.2 Schematic layout of gas flow of an anesthesia device

This is determined by the inspiratory O₂ concentration and the mean pressure caused by ventilation. In this case, the O₂ supply must be set in such a way that the O₂ partial pressure measured by the blood gas analysis reaches approximately 100 mmHg in patients up to the age of 60 years with normal hemoglobin content. For adults, this corresponds to an oxygen saturation of arterial blood of more than 95%.

The anesthetic agent concentration determines the depth of anesthesia (depth of hypnosis). The lower the end-expiratory concentration, the shallower the anesthesia. The higher the value, the deeper the anesthesia. Determination of the depth of anesthesia itself is difficult and requires an experienced physician using clinical signs such as skin color, heart rate, and blood pressure. Continuous monitoring of parameters derived from the electroencephalography (EEG), such as the bispectral index (BIS) index, allows the depth of hypnosis to be determined objectively.

The ventilator parameter settings are determined both by the patient's oxygen demand and by the fact that the CO₂ needs to be removed. This is achieved as follows. Proportional to the patient's weight, in a first step, approximately 10 ml/kg body weight is set as the breath or tidal volume at a frequency of approximately 10 /min. Thus, a patient weighing 70 kg receives approximately 7 l/min as the respiration volume per minute at a tidal volume of 700 ml and a frequency of 10 breaths per minute. In a second step, the current end-tidal CO₂ value is monitored and compared with the

target value. A CO₂ partial pressure of approximately 35 mmHg is desired. In the third step, the tidal volume

is adjusted to meet the current needs of the patient using the measured end-expiratory CO₂ value.

30.3 Functional Principle of the Main Components

The three main components (drug dosing, the ventilator with breathing system, and monitoring) are discussed in detail in this section.

30.3.1 Drug Dosing

Dosing of O₂ and N₂O

Today, two principles are used for delivering the gases O₂, air, and N₂O, namely mechanical metering valves and electronic mixers. In the case of the metering principle using metering valves, the respective single flow is set in units of l/min (e.g., 1 l/min O₂ and 2 l/min N₂O); however, in the case of mixers, the gas selection O₂/N₂O or O₂/air, the O₂ concentration in %, and the total flow in units of l/min are set (e.g., 33% O₂ and 3 l/min total flow for O₂ and N₂O, to receive the same 1 l/min O₂ and 2 l/min N₂O).

Mechanical Dosing

With this principle (Fig. 30.3), high-precision mechanical needle valves are used for dosing. The pressure in the gas supply is approximately 5 bar and is reduced to approximately 3 bar by pressure reducers, which are arranged in the gas flow direction upstream from the high-precision needle valves. This prevents pressure variations in the gas supply from disrupting the set flow.

The gas flow is set by turning the high-precision needle valve, which in turn changes the area of a ring-shaped opening. In some machines, the flow is measured using a measuring tube (tapered glass tube) in which a specially shaped float moves up and down according to the magnitude of the flow. The measuring tube must be positioned vertically to allow for precise measurements. This is the only way of ensuring that the float can move freely. The flow can also be measured electronically, so that the flow set using the high-precision needle valve can be displayed digitally and also be represented as a bar graph on a screen.

The metering valve buttons are provided with different profiles so that the oxygen valve can also be distinguished by touch (or *blind*) from the other metering valves. They are also protected against accidental readjustment.

Electronic Dosing

In the case of electronic gas dosing (Fig. 30.4), a switchable two-gas mixer is used. Depending on operator selection, it supplies O₂ and N₂O (selection N₂O) or O₂ and air (selection air) in accordance with a preset O₂ concentration and a preset total fresh gas flow. Therefore, the desired O₂ concentration and the magnitude of the total fresh gas flow are set directly and do not have to be calculated from single flows like in mechanical mixers.

In the case of electronic dosing, the gases are dosed successively in time, each one individually, and subsequently mixed in a storage tank. If the mixed gas tank is partially emptied through the withdrawal of gas, the following process takes place. If, for example, 33% O₂ should be delivered and 300 ml is missing from the mixed gas tank, the control unit opens the O₂ gas inlet valve in the first step and 100 ml O₂ is fed into the

Fig. 30.3 Mechanical gas dosing principle

Fig. 30.4 Electronic gas dosing principle

mixed gas tank via flow metering using flow and time measurement. As soon as 100 ml has been delivered, the O₂ valve is closed. All gas inlet valves are temporarily closed. In a third step, the N₂O inlet is then opened and 200 ml N₂O is fed into the tank via the flow and time measurement. This process creates a 33% O₂ mixture in the tank. The N₂O valve is closed again. This type of filling cycle lasts approximately 1 s. If gas is extracted, the pressure falls in the gas tank and the process starts over again.

Elements for Monitoring O₂, N₂O Dosing

Oxygen Deficiency Signal. The oxygen deficiency signal issues an alarm in the event of an oxygen supply failure. This is regardless of whether, for example, it is caused by an empty oxygen cylinder in the machine, a central gas supply disruption or the accidental removal of the oxygen coupling (Fig. 30.3).

This alarm is issued when the minimum supply pressure in the 5 bar oxygen supply line of the machine falls below approximately 2 bar. The alarm lasts for at least 7 s and cannot be switched off.

Nitrous Oxide Cutoff. An oxygen supply failure conceals the danger that pure nitrous oxide might suddenly enter the breathing system. To prevent this, the nitrous oxide in the nitrous oxide supply line is shut off by the nitrous oxide cutoff in the event of a pressure failure in the oxygen supply line (5 bar) (Fig. 30.3). The device's nitrous oxide supply is only reactivated when the oxygen supply has been restored.

Proportional Valve Oxygen Ratio Controller. The oxygen ratio controller (ORC) is a safety feature which monitors the oxygen and nitrous oxide flows to the pa-

tient. It reduces nitrous oxide in the low pressure range and ensures that at least approximately 20–25 vol. % O₂ is present in the fresh gas line.

The ORC works by comparing the N₂O flow with the O₂ flow in order to control the administration of nitrous oxide to ensure that the ratio of nitrous oxide to oxygen never exceeds approximately 3 : 1.

The ORC is called a *proportional valve* because this safety feature is designed to monitor the ratio of O₂ to N₂O. In mechanical gas metering, ORC is implemented pneumatically, and, in electronic mixers, in control software.

Inspiratory Oxygen Measurement. The oxygen deficiency signal, nitrous oxide cutoff, and ORC monitoring elements can only be used to prevent errors when the correct gas is flowing through the provided line. These elements are useless if O₂ is inadvertently mixed with N₂O in the line. This type of error can only be detected through direct measurement of the gas type. Inspiratory oxygen measurement is therefore mandatory in the standards for anesthetic machines because it can detect errors associated with insufficient or incorrect dosing of O₂.

Delivery of Anesthetic Agents Isoflurane, Sevoflurane, and Desflurane

Operating Principle. Today, isoflurane, sevoflurane, and desflurane are used for inhalation or balanced anesthesia as anesthetic agents to achieve unconsciousness. They are also called volatile anesthetic agents, because they are exhalable and evaporate quickly. An anesthetic agent vaporizer converts the anesthetic agent isoflurane or sevoflurane from a liquid to a vapor state and adds them to the fresh gas at a preset concentration. The anes-

thetic agents isoflurane and sevoflurane have relatively high vapor pressure at room temperature. Isoflurane, for example, has a vapor pressure of approximately 300 mbar at 20 °C.

The saturation concentration (vapor pressure/air pressure) for isoflurane is 30 vol. % at 20 °C. The vapor pressure depends on temperature, so the saturation concentration increases at higher temperatures. In the case of isoflurane, for example, the concentration of saturated vapor increases from 30 vol. % at 20 °C to approximately 60 vol. % at 35 °C.

At 20 °C, the concentration of saturated vapor is much higher (20 fold) than therapeutically necessary. For isoflurane and sevoflurane, an anesthetic agent concentration in the range 1–3 vol. % is used. Consequently, the anesthetic agents cannot be inhaled directly and need to be diluted accordingly.

The vaporizer is primarily designed to reduce the high saturation concentration of, e.g., 30 vol. % to the concentration required during anesthesia, e.g., 2 vol. %. For this purpose, the fresh gas flow is divided into two partial flows (Fig. 30.5): a vaporizer flow with gas containing anesthetic agent and a flow which bypasses the vaporizer without anesthetic agent. At the end, both flows are joined again.

The vapor pressure of the anesthetic agent changes with temperature. As a result, if the anesthetic agent vaporizer were only based on this principle, changes in temperature would also affect the delivered anesthetic agent concentration. If a vaporizer based on this principle was set to, e.g., 3 vol. % at 20 °C and the temperature was then increased to 35 °C under equilibrium conditions, the delivered concentration of isoflurane would rise to 6 vol. %. However, anesthetic agent vaporizers should ensure that the delivered anesthetic agent concentration in the respective temperature range should be temperature independent. Therefore, the physical effect of the temperature dependence of

the vapor pressure or saturation concentration needs to be compensated. The principle of temperature compensation is based on reducing the vaporizer flow as the temperature increases to compensate for the increase of the saturation concentration. In this way, less gas passes through the vaporizer chamber as the temperature increases. Technically, this problem is solved by using the different thermal expansions of two metals to widen the bypass opening as the temperature increases.

Each anesthetic agent needs its own separate vaporizer due to the different saturation concentrations and the different effect on the patient.

Anesthetic agent vaporizers must only be used in the fresh gas line because the gas passing through the vaporizer repeatedly would result in uncontrollably high concentrations in the rebreathing system. The vaporizer must also always be used below the boiling point (48 °C for isoflurane). Concentrations cannot be controlled above the boiling point.

Since the boiling point of desflurane is 22 °C, this anesthetic agent requires the use of a different principle from that mentioned above. Desflurane is heated in a heating chamber to 40 °C and the desflurane is added as a vapor to the fresh gas. It is also necessary to know the fresh gas flow to determine the quantity to be added. This is determined via a control loop.

Safety Features

Coded Filling Device. If an incorrect anesthetic agent is administered, under- or overdose is possible depending on the anesthetic agent and the vaporizer. To avoid this, vaporizers are provided with a coded filling device. These devices ensure that the anesthetic agent is only delivered to the intended anesthetic agent vaporizer. The geometric coding of the anesthetic bottle, filling hose, and vapor filling opening is designed to ensure this.

Measuring the Anesthetic Agent Concentration. To detect vaporizer malfunctions, and thus any possible associated under- or overdose, the anesthetic agent concentration is measured during inspiration. It is important to ensure that the monitor is always set to the used agent.

Dosing the Intravenous Anesthetic Agent. Since the intravenous hypnosis agent propofol and the intravenous analgesic remifentanyl are metabolized quickly in the body, within minutes, continuous administration of these drugs is required. For this reason, during anes-

Fig. 30.5 Anesthetic agent vaporizing principle

thetia these drugs need to be administered by syringe pumps, which need to be suitably attached to the anesthesia machine.

A bolus (a certain amount of a drug given in a specific period of time) is administered to raise blood-level concentrations to the desired therapeutic level. The decreasing effect of the drug caused by drug clearance is compensated by a constant infusion rate. The blood concentration cannot be measured directly in the patient. This means that the physician has to depend on monitoring the effect on the patient.

30.3.2 Ventilator and Breathing System

The second component of an anesthesia device is the ventilator. A distinction between its parts must be made according to their tasks: the input unit, the control unit, the breathing system, the bellows unit with drive, the fresh gas supply, and ventilator monitoring (Fig. 30.6). These components facilitate patient ventilation. In anesthesia, controlled ventilation is the most frequently used form of ventilation.

Subcomponents of a Ventilator
