If the classification is used for identification of objects, the general principles or an exemplary reference must be available, from which the ground truth of classification can be created. The features of these samples are then used for parameterization and optimization of the classifier. Through this training, the performance of the classifier can be drastically improved. However, supervised object classification is always problematic if the patterns that are classified differ remarkably from the trained patterns. In such cases, the training set does not sufficiently reflect the real world. A learning classifier has advantages here, because it changes its parameterization with each performed classification, even after the training phase. In the following, however, we assume a suitable set of features and a sufficiently characteristic and large set of samples.

The classification itself reverts mostly to known numerical (statistical) and nonnumerical (syntactic) procedures, as well as the newer approaches of computational intelligence, such as neural networks, evolutionary algorithms, and fuzzy logic. In general, the individual features, which can be determined by different procedures, are summarized either to numerical feature vectors (also referred to as signature) or abstract strings of symbols. For example, a closed contour object can be described by its Fourier-descriptors as a feature vector, or by means of basic line items such as straight, convex, and concave forming a symbol chain.

62.6.1 Statistic Classifiers

Statistical classification regards object identification as a problem of the statistical decision theory. Parametric procedures for classification are based on the assumption of distribution functions for the feature specifications of the objects, and the parameters of the distribution functions are determined from the sample. Nonparametric methods, however, waive such model assumptions, which are not always possible in medical image processing. A classical example of such a nonparametric statistical object classifier is the nearest neighbor (NN) classifier. All features span the feature space, and each sample is represented by a point in this feature space. Based on the signature of a segment that has not been included in the training, which is assigned to its nearest neighbor in feature space, the segment is classified to the associated class of the assigned feature vector. The k nearest neighbor (KNN) classifier assigns the majority class from the k nearest

neighbors in feature space (usually, $k = 3$ or 5). Often, the Euclidean distance is computed in the feature space. An example of the KNN classifier is given in Fig. 62.16.

62.6.2 Syntactic Classifiers

In symbol chains, it is neither useful nor possible to define distance measurements or metrics and to evaluate the similarity between two symbol chains, such as used for feature vectors. An exception to this statement is given with the Levenshtein distance, which is defined as the smallest number of modifications such as exchange, erase, or insert, required to transform a symbol chain into another.

The syntactic classification is, therefore, based on grammar, which can possibly generate an infinite amount of symbol chains with finite symbol formalism. A syntactic classifier can be understood as a knowledge-based classification system (*expert system*), because the classification is based on a formal heuristic symbolic representation of expert knowledge, which is transferred into image processing systems by means of facts and rules. If the expert system is able to create new rules, a learning classifier is also realizable as a knowledge-based system.

It should be noted that the terms expert system or expert knowledge, however, are not standardized in the literature. Therefore, primitive image processing systems, which use simple heuristics as implemented distinction of cases to classification or object identification, are also referred to as knowledge-based.

62.6.3 Computational Intelligence-Based Classifiers

As part of the artificial intelligence, the methods of computational intelligence include neural networks, evolutionary algorithms and fuzzy logic. These methods have their examples in biological information processing, which is particularly much more powerful for tasks of object recognition than today's computers. Therefore, they are frequently used in medical image processing for classification and object identification. Thereby all the procedures have a mathematically-based, complex background.

Artificial neural networks simulate the information processing in the human brain. They consist of many simply constructed basic elements (neurons), which are arranged and linked in several layers. Each neuron calculates the weighted sum of its input excitations,

Fig. 62.16a–j Identification of dental fixtures (IDEFIX) (after [62.9]). An implant is shown in the intra-oral radiograph of the lower jaw (a). For the feature extraction, the image is binarized with local-adaptive thresholding (b). The morphological filtering (erosion) separates individual areas (c) and eliminates interference. In this example, three regions were segmented (d). Further processing is shown for the blue segment. After its fade-out, the morphological erosion is compensated by a subsequent dilation (e), and subtracted from the intermediate image (b). Any coordinate of blue segment from (d) identifies the corresponding region, which can now be extracted (g) and aligned into a normal position using the Karhunen–Loève transform. Geometric dimensions are determined as region-based features and stored in a feature vector (signature). As part of the training, the reference measures of different implant types have been recorded in the feature space. The classification in the feature space is done with the statistical KNN classifier (i), which identifies the blue segment reliably as Branemark implant screw (j)

which is mapped over a nonlinear function (characteristic curve) to the output. The number of layers, the number of neurons per layer, the network's topology, and the characteristic curve of the neurons are predefined within the network dimensioning step. On the one hand, heuristics are usually applied rather than methodological derivations. On the other hand, the individual weights of the excitations are identified numerically during the training of the network. Then, the network remains unchanged and can be used as a classifier. *Evolutionary algorithms* are based on the constant repetition of a cycle of mutation and selection following the Darwinian paradigm of the survival of the fittest.

Genetic algorithms work on a number of individuals (the population). The crossing of two randomly selected individuals and afterwards the mutation changes the population. A fitness function evaluates the population in terms of their goodness to problem solution. Although the selections are equipped with a random component, fit individuals are frequently selected for reproduction. Evolutionary algorithms can solve complex optimization problems amazingly well, but for object classification, they are less successfully used than other methods.

The idea of *fuzzy logic* is to extend the binary (true or false) computer model with some uncertainty

or blur, which also exists in the real world. Many of our sensory impressions are qualitative and imprecise and, therefore, unsuitable for accurate measurements. For example, a pixel is perceived as dark, bright, or even very bright, but not as a pixel with gray scale value 231. Fuzzy quantities are mathematically based on the fuzzy set theory, in which the belonging of an

element to a set of elements is not restricted to the absolute states true (1) or false (0), but continuously defined within the entire interval [0..1]. Besides classification, applications of fuzzy logic in medical image processing can be found also for preprocessing (contrast enhancement), feature extraction (edge extraction and skeleton), and segmentation.

62.7 Quantitative Measurements

While the visual appraisal by experts is qualitative and sometimes subject to strong inter-individual as well as intra-individual fluctuations, in principle, a suitable computer-aided analysis of medical images can deliver objective and reproducible results. First of all, this requires a precise calibration of the imaging modality. Furthermore, partial (volume) effects of the imaging system and particularities of the discrete pixel topology must be taken into account and handled accordingly to ensure reliable and reproducible measurements.

The digitalization of the local area or volume of a pixel or voxel, respectively, always yields an averaging of the measured value in the appropriate field. For example in CT, a voxel containing different tissue is assigned a certain Hounsfield value that results from the

proportional mean of the individual Hounsfield values of the covered tissue classes. Thus, a voxel containing only bone and air preserves the Hounsfield value of soft tissue and, thus, may distort quantitative measurements. In general, this partial (volume) effect occurs in all modalities and must be accounted for appropriately in any automatic measurement.

The common paradigms of Euclidean geometry do not apply in the discrete pixel domain. For example, the discrete representations of two straight lines may not join in a common pixel although the lines cross. Furthermore, different neighborhood concepts of discrete pixels topology have remarkable impact on the result of automatic image measurements. For example, the areas identified in region growing may be significantly larger

Fig. 62.17a–c Quantification of synaptic boutons on a cell membrane (after [62.10]). The cell membrane was segmented with a balloon (Fig. 62.12). Analyzing the impact of internal versus external forces at a certain vertex, local confidences can be determined to fuzzily classify the affiliation of the contour section to the actual cell membrane (a). The cell contour is extracted, linearized, normalized, and binarized before the occupation of the cell membrane with synaptic boutons of different sizes are analyzed by morphological filtering (b). The confidence values are considered for averaging the occupation measure along the cell membrane (c)

if the 8-neighborhood is applied, i. e., if eight adjacent pixels are analyzed instead of the four direct neighbors. We will now discuss some examples for image measurements. For instance, in Fig. 62.16, geometrical features were used for the automatic classification of implant systems. The feature measures were extracted on the abstract level of the region. Frequently, further measures were extracted after object identification, which use the information of the certain object detected, i. e., they operate on the level of objects. For instance, in Fig. 62.16i, we can use the knowledge that the blue segment corresponds to a Branemark implant to parameterize a special morphological filter that is adapted to the geometry of Branemark implants and measure the number

of windings of the screw. Another example of object-based image measurements is given in Fig. 62.17. The result of balloon segmentation of a cell membrane (Fig. 62.14) was labeled automatically with local confidence values based on model assumptions (Fig. 62.17a).

These values indicate the contour segment belonging to a cell membrane and thus a classification via fuzzy logic. To increase the robustness and reliability of measurements, the confidence values are accounted along the contour, which is extracted, linearized, normalized, and morphologically analyzed (Fig. 62.17b), such that, finally, a reliable distribution statistics of connecting boutons according to their size is obtained (Fig. 62.17c).

62.8 Interpretation

Image interpretation may be understood in the sense of analyzing an abstract scene that corresponds to the ambitious goal of developing a *visual sense for machines*, which is similarly universal and powerful to that of humans. The previously discussed processing modules focused on automatic detection of objects as well as their properties. Now, we proceed to analyze the order of individual objects in space and/or time. Thus, the fundamental step of image interpretation is to generate a spatial-temporal scene description on the most abstract level (symbolic image description, Fig. 62.2). A suitable form of representation is the attributed relational graph (semantic web), which can be analyzed at different hierarchy levels. Therefore, the so far considered grid matrix of pixels (iconic image description, Fig. 62.2) is inappropriate for image interpretation. The primitives of the graph (node) and their relationships (edges) must be abstracted from the segmented and identified objects or object parts in the image. So far, only a few algorithms can execute this level of abstraction.

Examples for the abstraction of primitives are given by the numerous approaches to shape reconstruction: shape-from-shading, -texture, -contour, stereo, etc. Examples of the abstraction of relationships can be found

at the depth reconstruction by trigonometric analysis of the projective perspective. Recently, considerable progress has been achieved in symbolic image analysis in the fields of industrial image processing and robotics. Because of the special peculiarities of medical imagery, which were discussed before, the transfer of these approaches into health care applications and medical image processing has only met with limited success so far.

Figure 62.18 displays the automatic extraction of a dental chart based on image processing of a panoramic radiograph. It clearly shows the immense difficulties that have to be overcome by the automatic interpretation of medical images. Initially, the segmentation and identification of all relevant image objects and object parts must succeed so that the semantic network can be built. This includes the instances (tooth 1, tooth 2, etc.) of the previously identified objects (e.g., tooth, crown, filling). The interpretation of the scene based on the network must be carried out in a further, not less difficult step of processing. Thus, all teeth must be named according to their position and shape. Then, crowns, bridges, fillings, and carious processes can be registered in the dental chart. However, the automation of this process, which can be accomplished by dentist in a few minutes, is not yet possible with sufficient robustness.

62.9 Image Data Visualization

Under the concept of image visualization, we summarized all the transforms that serve the optimized output of the image. In medicine, this particularly includes the realistic visualization of three-dimensional data. Such

techniques have found broad applications in medical research, diagnostics, treatment planning, and therapy. In contrast to problems from the general area of computer graphics, in medical applications the displayed objects

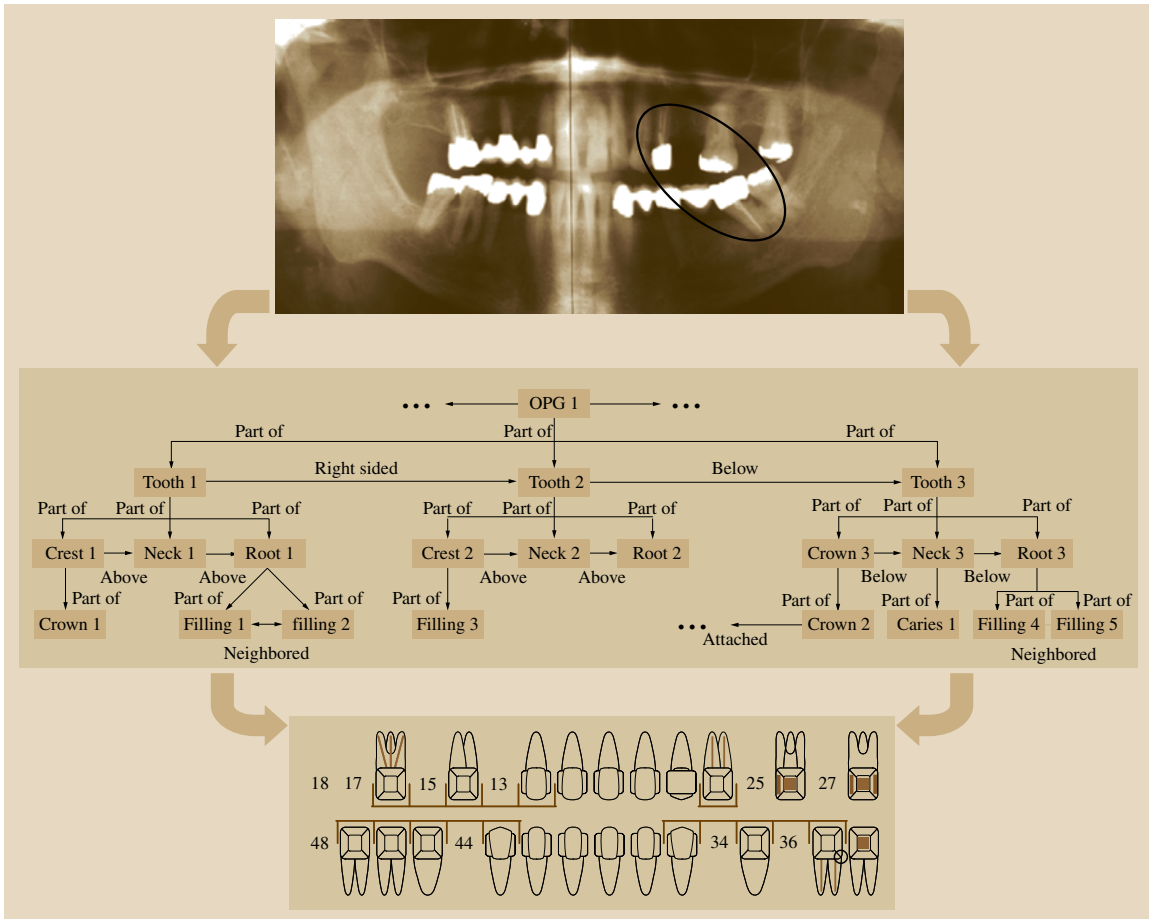

Fig. 62.18 Scheme of automatic image interpretation. The panoramic radiograph contains all relevant information of the dental chart. The symbolic description of the scene is obtained with a semantic network. Despite its already considerable complexity, the shown part of the network represents only the marked ROI. In the dental chart, information is coded differently. The teeth are named in accordance with the key of the Fédération Dentaire Internationale (FDI): the leading digit denotes the quadrant clockwise, the second digit denotes refer to the number of the tooth, counting from inside to outside. Existing teeth are represented by templates, in which dental fillings, crowns, and bridges are recorded. The *black circle* at tooth 37 (say: three, seven) indicates a carious process

are not given implicitly by formal, mathematical expressions, but as an explicit set of voxels. Consequently, specific methods have been established for medical visualization. These methods are based either on a surface reconstruction or on a direct volume visualization, and lighting and shading are also considered (Table 62.2).

62.9.1 The Marching Cubes Algorithm

The marching cubes algorithm was specifically developed for surface reconstruction from medical volumes.

Here, the voxel is no longer interpreted as a cube of finite edge length but as a point. It is equivalent to a point grid for visualizing volumes. In this, a cube is considered with four corners in each of the two adjacent layers. Utilizing symmetry, the complex problem of surface production is reduced to only 15 different topologies, which can be calculated most efficiently since the polygon descriptions that belong to the basic topologies can be stored in a look-up table. Similar to the process of spatial convolution, the cube is positioned successively at all points in a volume dataset

Table 62.2 Taxonomy of 3-D visualization methods (after [62.11]). Triangulation for surface-based rendering is described in textbooks on computer graphics. The marching cubes approach is described in the text. As a simple example of a surface-based direct volume rendering methods, depth shading visualizes the length of rays passing through the volume until they hit the surface. Integral shading codes the sum of voxel values along the ray as gray scale. It is, therefore, frequently used to obtain radiograph-like images based on CT data

Taxonomy of 3-D visualization methods			
Surface reconstruction and rendering		Direct volume rendering	
Surface-oriented methods	Volume-oriented methods	Surface-oriented methods	Volume-oriented methods
Examples: Triangulation	Examples: Cuberille approach Marching cubes	Examples: Depth shading Depth gradient shading Gray gradient shading	Examples: Integral shading Transparent shading Maximum projection

Fig. 62.19a,b 3-D visualization with Voxel-Man (after [62.12]). This 3-D model of the internal organs is based on the visible human data. The Voxel-Man 3-D Navigator provides unprecedented details and numerous interactive possibilities (a). Direct volume rendering and surface-based visualization of segmented objects are combined with integral shading (b)

(marching). After completion of the marching cubes algorithm, a segmented volume is transformed into a triangulated surface. However, the surface is build from a very large number of triangles, which may be reduced significantly by heuristic procedures without any discernible losses of quality. Reducing the number of elements to visualize supports real-time visualization of the volume.

62.9.2 Surface Rendering

To generate photorealistic presentations of the volume surface, the lighting is simulated analogously to natural scenes. According to the lighting model by Phong, ambient light is created through overlapping of multiple reflections, diffuse scattering on nonshiny surfaces, and direct mirroring on shiny surfaces. While the intensity

of the ambient light remains constant in the scene for all surface segments, the intensities of diffuse and shiny reflections depend on the orientation and characteristics of surfaces as well as their distances and directions to the light source and the observation point of viewing. Without *shading*, one can recognize the initial triangles. This is a nasty artifact in computer graphics. Therefore, various strategies for shading have been developed to improve the visual impression significantly. For instance, Gouraud shading results in smooth blunt surfaces and Phong shading also provides realistic reflections. In newer applications, transparencies are also modeled to glance at encapsulated objects. Moreover, textures or other bitmaps on the surfaces can be projected to reach a more realistic impression of the scene.

62.9.3 Volume Rendering

Direct volume visualization is obtained from preliminary calculation of the object surface. The visualization is based directly on the voxel data and, therefore, possible without any segmentation. This strategy allows visualization of medical 3-D and 4-D data by radiolo-

gists for interactive localization of pathological areas. The volume is processed either along the data layers (back-to-front or front-to-back) or along an imaginary light ray. Based on the observer position, rays will be pursued through the volume (ray-tracing). Hereby, the recursive followup of secondarily reflected rays is also possible (ray-casting). Although quite realistic visualizations can be provided to the observer, problems arising from the discrete nature of pixel topology (see above) have led to a multitude of algorithmic variants, which cannot be addressed here.

In general, parameters are extracted from voxel intensity along the rays and applied as gray or color value at the corresponding position in the viewing plane. This procedure is also referred to as shading. With the method of surface-based shading, light source and image plane are placed on the same side of the object, while volume-oriented procedures radiograph the entire object according to x-ray imaging, i. e., the object is located between light sources and the observation (Table 62.2). Combining direct volume with surface-based approaches, amazingly realistic scenes can be created (Fig. 62.19).

62.10 Image Management

Introductorily, we have summarized all image manipulation techniques that serve the effective archiving (short and long-term), transmission (communication), and the access (retrieval) of data (Fig. 62.1). For all three points, the specifics in medical applications and the health care environment have led to specific solutions, which are briefly introduced in the following section.

Already in the 1970s, the invention of computed tomography and its integration with clinical routine involved the installation of the first picture archiving and communication system (PACS), whose main task was the archiving of image data. The core problem of archiving medical images is the immensely large data volume. A simple x-ray image with 40×40 cm (e.g. a chest radiograph) with a resolution of five line pairs per millimeter and $10 \text{ bit} = 1024$ gray levels per pixel already requires a storage capacity of more than 10 MB. In a university hospital x-ray imaging, CT, and MRI accumulate to about 2 TB of image data each year (Table 62.3). This estimate can easily increase tenfold with the resolution-increased novel modalities such as spiral CT and whole-body MRI. For instance, in Germany, according to relevant legislations, data must be kept for at least 30 years. Therefore, efficient storage, retrieval,

and communication of medical images have required effective compression and high speed networks. Due to noise in medical images, lossless compression usually has a limited effect of compression rates of two or three. It is only in recent years that feasible hybrid storage concepts have become available. So, the relevance of storage and fetching of medical image data is decreasingly important.

With increasing digitization of diagnostic imaging, the motto for medical information systems, i. e., to provide the right information at the right time and the right place, is projected to the field of medical image processing. Hence, communication is the core of today's PACS. Image data is not only transferred electronically within a department of radiology or the hospital, but also between widely separated institutions. For this task, simple bitmap formats such as the tagged image file format (TIFF) or the graphics interchange format (GIF) are inadequate, because beside the images, which might have been captured with different dimensions, medical meta information on patients (e.g., identifier (ID), name, date of birth, ...), the modality (e.g., device, parameters, ...) and organization (e.g., investigation, study, ...) must also be transferred in a standardized

Table 62.3 Data volume in 1999 at Aachen University Hospital (about 1500 beds) [62.1]. The data are taken from the Annual Report 1999 of the University Hospital of RWTH Aachen University, Aachen, Germany. The data is based on the Departments of (i) Diagnostic Radiology, (ii) Neuroradiology, (iii) Nuclear Medicine, and (iv) Dentistry, Oral, and Maxillofacial Surgery for a total of 47 199 inpatient and 116 181 outpatient images. Services (such as ultrasound, endoscopic, or photographic) from other departments have been excluded. For modalities of nuclear medicine, 20 slices per study are assumed. For comparison, the total number of analysis performed in the central laboratory of the Institute for Clinical Chemistry and Pathobiochemistry was estimated with an average of 10 measured values per analysis with a highest precision of 64 bit. However, the annual image data volume is about 10 000 times larger

Modality	Resolution (spatial domain)	Resolution (value range)	MB per image	Units in 1999	GB per year
Chest radiographs	4000×4000	10	10.73	74 056	775.91
Skeleton radiographs	2000×2000	10	4.77	82 911	386.09
CT	512×512	12	0.38	816 706	299.09
MRI	512×512	12	0.38	540 066	197.78
Other radiographs	1000×1000	10	1.19	69 011	80.34

way. Since 1995, the communication has been based on the digital imaging and communications in a medicine (DICOM) standard. In its current version, DICOM includes:

- *Structural information* about the contents of the data (object classes)
- *Commands* on what should happen to the data (service classes)
- *Protocols* for data transmission.

DICOM is based on the client/server paradigm and allows the coupling of PACS in radiology (RIS) or hospital information systems (HIS). DICOM incorporates existing standards for communication: the open system interconnection (ISO/OSI) model, the transmission control protocol/Internet protocol (TCP/IP), and health level seven (HL7) standard. Full DICOM compliance for imaging devices and image processing applications is achieved with only a few supported object or service classes, since other DICOM objects, which are not relevant for the current device, are simply handed over to the next system in the DICOM network. The synchronization between the client and server is regularized by conformance claims, which are also specified as part of the DICOM standard. However, the details of implementation of individual services are not specified in the standard, and so in practice, vendor-specific DI-

COM dialects have been developed, which can lead to incompatibilities when building PACS. In recent years, the integrating healthcare enterprises (IHE) initiative has become important. IHE aims at guiding the use of DICOM and other standards such that complete interoperability is achieved.

In today's DICOM archives, images can be retrieved systematically, only if the patient name with date of birth or the internal system identification number (ID) is known. Still, the retrieval is based on alphanumerical attributes, which are stored along the image data. It is obvious that diagnostic performance of PACS would be magnified significantly if images were to be directly available from the similar content of a given example image. To provide the query by example (QBE) paradigm is a major task of future systems for content-based image retrieval (CBIR). Again, this field of medical research requires conceptually different strategies to those demanded in commercial CBIR systems for other application areas, because of the diverse and complex structure of diagnostic information that is captured in medical images.

Figure 62.20 shows the system architecture of the image retrieval in medical applications (IRMA) framework (<http://irma-project.org>). This architecture reflects the chain of processing that we have discussed in this chapter, i.e., registration, feature extraction, segmen-

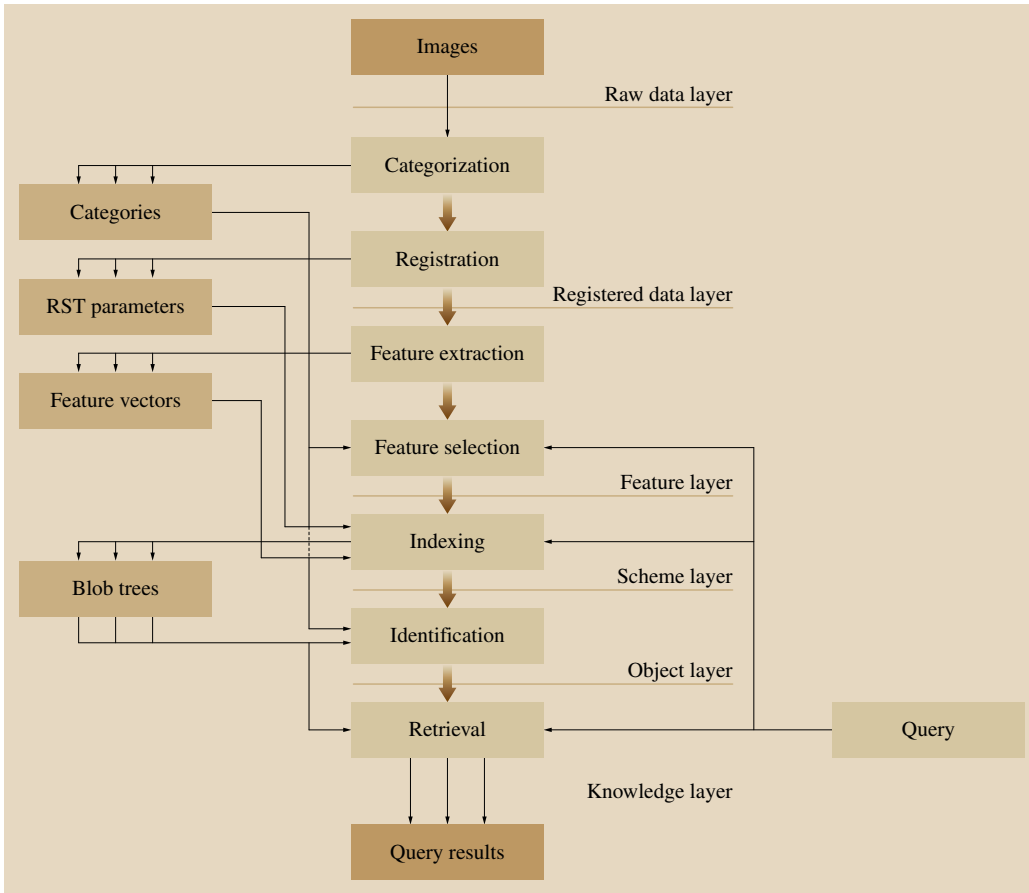

Fig. 62.20 System architecture of the IRMA framework (after [62.13]). The processing steps in IRMA are shown in the *middle column*. Categorization is based on global features and classifies images in terms of imaging modality, view direction, anatomic region, and body system. According to its category, the image geometry and contrast are registered to a reference according to rotation, scale, and translation (RST). The abstraction relies on local features, which are selected specifically to context and query. The retrieval itself is performed efficiently on abstracted and thus information-reduced levels. This architecture follows the paradigm of image analysis (Fig. 62.1). The in-between-representations on the *left side* describe the image increasingly abstract. The levels of abstraction (Fig. 62.2) are named on the *right side*

tation, classification of image objects towards the tip of the pyramid in Fig. 62.2, which is the symbolic interpretation and scene analysis. In IRMA, the image information that is relevant for retrieval is gradually condensed and abstracted. The image bitmap is symbolically represented by a semantic network (hierarchical

tree structure). The nodes contain characteristic information for the represented areas (segments) of the image. Its topology describes the spatial and/or temporal condition of each object. With this technology, radiologists and doctors can be similarly supported in patient care, research, and teaching.

62.11 Conclusion and Outlook

The past, present, and future paradigms in the medical image processing are shown in Fig. 62.21. Initially

(until approximately 1985), the pragmatic issues of image generation, processing, presentation, and archiving

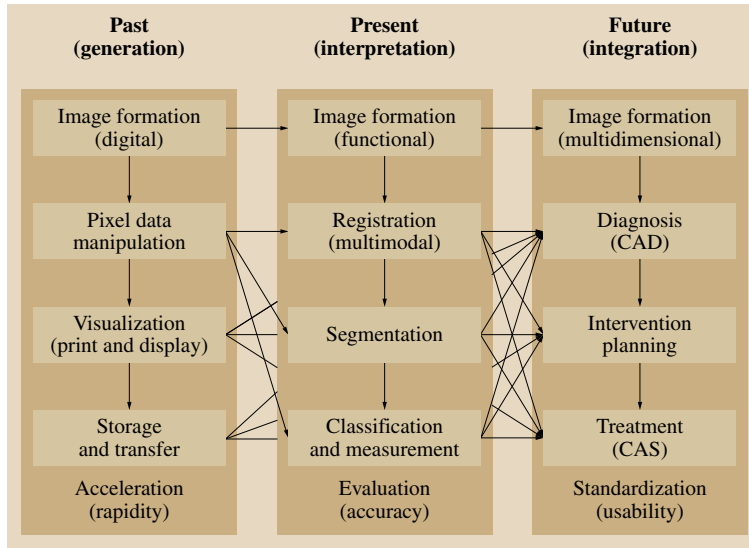

Fig. 62.21 Changing paradigms in medical image processing (after [62.14]). Until now, formation, enhancement, visualization, and management of medical images have been in the focus of research. In future, integration, standardization, and validation will be seen as major challenges for routine applications in computer-aided diagnosis (CAD), intervention planning, and therapy, such as computer-aided surgery (CAS)

stood in the focus of research in medical image processing, because available computers at that time had by far not the necessary capacity to hold and modify large image data in memory. The speed with which the image processing was possible only allowed off-line calculations. Today, the automatic interpretation of medical images is a major goal. Segmentation, classification, and measurements of medical images is being continuously improved and validated more accurately, since validation is based on larger studies with high volumes of data. Hence, we focused this chapter on image analysis and the processing steps associated with it. The future development is seen in the increasing integration of algorithms and applications in the medical routine. Procedures in support of diagnosis, treatment planning, and therapy must be easily useable for physicians and, therefore, further standardized in order to ensure the necessary interoperability for clinical practice is necessary.

Virtual Reality

63. Virtual Reality in Medicine

Wolfgang Müller-Wittig

Medicine over the past decades has undergone significant changes. In particular, surgery has become increasingly more technology based due to advances and rapid developments in device technology and computer graphics. Minimally invasive surgery (MIS) has revolutionized surgery introducing optical systems and small surgical instruments. In computer graphics Virtual Reality (VR) allows a more intuitive interaction with three-dimensional (3-D) computer generated environments. Furthermore, Augmented Reality (AR) provides a real-time overlay of reality with digital information. This transformation opens up new opportunities for diagnostics, medical education, preoperative planning and intraoperative support. The traditional *see one, do one, teach one* educational environment has now changed to simulation-based training where sophisticated surgical procedures can be planned and rehearsed in a safe virtual environment before the patient enters the operating room (OR). In the operating theatre the surgeon's abilities can be enhanced by superimposing computer generated information on the real patient resulting in better navigation and higher precision of the surgical intervention. With the increasing role of quality management and certification in the health care system, medical simulation can lead to improved quality of

care and patient outcomes becoming an integral element finally.

Rapid developments over the last 20 years have significantly influenced surgery. More changes will inevitably emerge in the coming years. Surgery will become increasingly technology based. Two essential developments which have occurred in different domains, namely computer graphics and surgery, form the basis for the topic of this chapter.

In computer graphics, virtual reality (VR) techniques introduced a new dimension in the man-machine interface. VR allows more intuitive interaction with the

computer and an immersive and realistic presentation of three-dimensional (3-D) computer-generated worlds using novel input and output devices. This paradigm shift has the potential to simulate processes in such a way that the user has the feeling that he is interacting with the real world.

In surgery, the paradigm shift happened through the transition from open surgery to minimally invasive surgery (MIS), which has revolutionized surgery. MIS has developed into an indispensable diagnostic and thera-

peutic tool. The goal is to achieve the desired operative result with minimal trauma. The use of MIS covers all surgical fields.

Minimally invasive surgery includes surgical techniques that use optical systems to inspect cavities of the human body and small instruments to perform surgical procedures. An endoscope, with optics and

light source, and other miniaturized instruments are inserted into the operative field through small incisions. With the surgeon holding the optical system with the video camera in one hand and watching the operative field on the monitor, the other hand is free to guide either a probe or a small surgical instrument.

63.1 Virtual Reality

Whereas traditional surgery allows guidance of instruments through direct visual control (one axis, eye to hand, and instrument to patient), endoscopic techniques require the coordination of two axes (eye to monitor and hand, instrument to patient). This coordination technique is called triangulation. Besides this triangulation, endoscopy requires further skills; most surgical procedures can be performed with one

dominant hand performing the critical parts of the procedure, but endoscopy requires true ambidextrous activity. A further feature of minimally invasive surgical procedures is the loss of direct contact between the surgeon's hand and the actual operative field. The surgeon does not directly touch the anatomical structures. Rather, he/she manipulates these via various surgical instruments.

63.2 Medical Applications

The use of computer graphics has opened up new possibilities in medicine. At the beginning of the 1990s, *Satava* envisioned a paradigm shift in surgical training

due to emerging virtual-reality-based medical simulators [63.1–3] (Fig. 63.1). Surgical education is not about training surgeons over a specific time span. Surgical

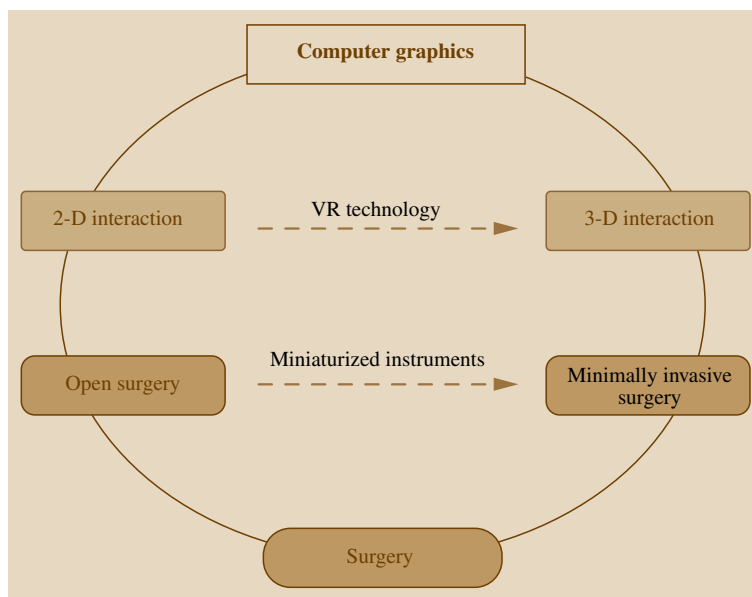

Fig. 63.1 Paradigm shift

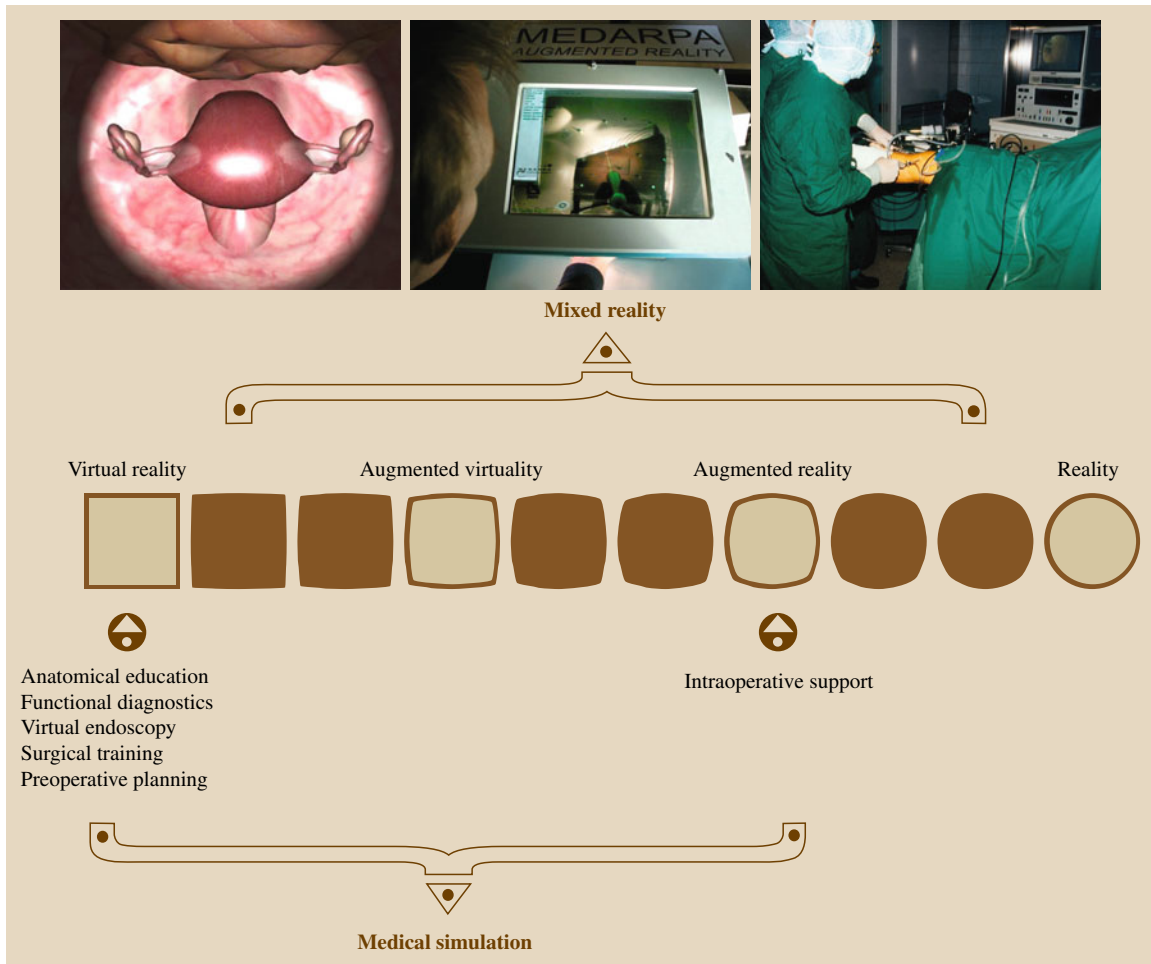

Fig. 63.2 Medical simulation. Application domains along the reality–virtuality continuum between the two poles of the real and virtual environment

training has to be qualitatively measured based on well-defined metrics. The goal was to put more stress on quality assurance in medicine. This topic gained much more attention when the Institute of Medicine (IOM) of the National Academies of the USA declared that as many as around 100 000 people die needlessly each year because of preventable medical harm [63.4]. The IOM recommended greater focus on patient safety and professional standards in healthcare, calling for periodic examinations of doctors and nurses. However, there is no evidence that there have been systematic changes to reduce preventable medical harm. Avoidable medical costs in the USA are estimated at US \$500 billion each year [63.5].

Using the reality–virtuality continuum, introduced by *Paul Milgram* and *Fumio Kishino*, various technologies and their application domains in medicine are described as follows (Fig. 63.2) [63.6]. Along this continuum, reality is a gradated spectrum ranging from real to virtual spaces. In virtual reality (VR), the user interacts with 3-D digital objects in real time. The term *augmented reality* (AR) describes the real-time overlay of reality with digital information [63.7]. A typical augmented reality system includes the following components:

- A tracking system, which captures the user’s real environment

- A display (e.g., a semitransparent head-mounted display) for visualizing the digital information superimposed onto reality
- A mobile computing unit, which is responsible for 3-D registration and image generation.

63.2.1 Anatomy Education

At the beginning of the 1990s, the Visible Human Project, initiated by the National Library of Medicine in the USA, provided complex and multimodal image data of human anatomy for the first time. These detailed digital 3-D representations paved the way for the use of virtual reality to present and teach knowledge in 3-D for anatomy education [63.8]. Traditionally, medical students gain their knowledge in anatomy from preparation of cadavers or from color atlases and anatomy textbooks.

Interaction with computer-based models of the real world through new human–computer interfaces offers advantages in exploring the anatomy. Medical students understand important physiological principles or the interrelationship between anatomical structures in a way that cannot be achieved by any other means, including use of textbooks and real cadavers. Nowadays, numerous 3-D anatomical atlases are available as efficient tools for medical education. Meanwhile, *Voxel-Man* [63.9] and *BodyViz* from Visual Medical Solutions, which offer such high-quality anatomical views, are examples of cost-effective solutions using commodity laptops (Fig. 63.3).

63.2.2 Functional Diagnostics

Functional diagnostics describes simulation environments which allow analysis of the patient-specific status quo. Furthermore, the goal is to predict the surgical outcome and to validate the change in functionality that can be expected after a surgical intervention. Thus, it is necessary to simulate the planned patient-specific target state.

For instance, the project VR Whiplash has the goal of providing better diagnostics of functional disorders causing chronic pain after whiplash injuries by integrating VR and measurements of muscular activities. The problems are caused by diagnostic uncertainty and, as a result, the lack of therapy strategies. Imaging diagnostics can only display structural damage, which is, however, rare, representing only 3–5% of cases. The VR-based approach addresses the remaining large fraction of patients with functional

Fig. 63.3 Virtual ear (Phonak Acoustic Implants, Fraunhofer IGD)

disorders, enabling planning of patient-specific therapy, e.g., individually tailored build-up of cervical muscles [63.10].

This application domain impressively shows how computationally intense simulation processes can be coupled with interactive 3-D real-time environments. Rapid developments in computer architectures and in particular programmable graphics processing units (GPUs) has allowed gradual convergence of these two areas [63.11, 12]. For example, nVidia's computing and graphics architecture Fermi provides better graphics as well as higher precision and acceleration of calculations for medical simulation [63.13].

63.2.3 Virtual Endoscopy

Virtual endoscopy is a diagnostic technique providing computer-generated inner body views similar to actual endoscopic procedures [63.14, 15]. The goal of noninvasive 3-D simulation of endoscopic procedures using reconstructed imaging data [e.g., computer tomography (CT) and magnetic resonance imaging (MRI)] is to allow the endoscopist to simultaneously visualize virtual anatomical structures and interaction in real time (e.g., through manipulation of the viewing orientation). The potential is that many body regions which are not accessible to real endoscopy can be explored with virtual endoscopy (Fig. 63.4).

Wireless capsule endoscopy is a recently developed noninvasive imaging technique offering an alternative in diagnostics. Patients swallow a disposable capsule consisting of a pair of cameras and a wireless transmit-

Fig. 63.4a-c Bronchoscopy simulator (a) based on patient-specific CT data (b,c)

Fig. 63.5 VR arthroscopy training simulator

ter. Finally, a diagnostic video is produced based on the 50 000 images which are shot by such a PillCam during its passage through the colon. Use of this diagnostic

tool is still controversial, but recent studies show that technical progress has increased the accuracy of these systems [63.16].

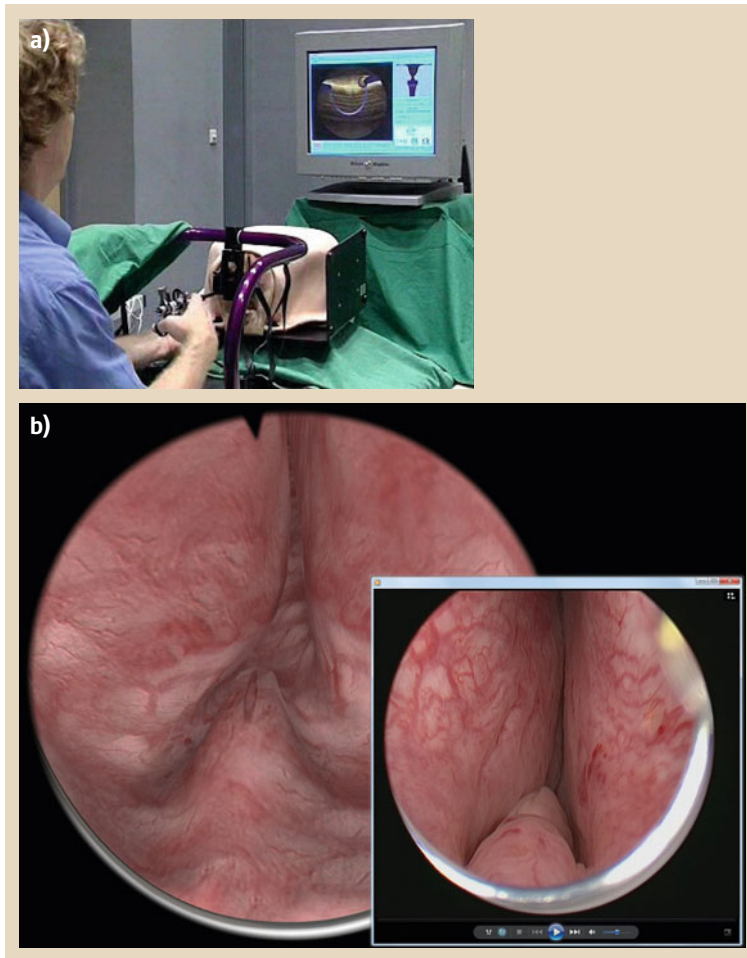

Fig. 63.6 (a) VR hysteroscopy training simulator. (b) Simulator for transurethral resection of the prostate, virtual simulation (*left*) and real operating-room (OR) movie (*right*) (VirtaMed, Zurich)

63.2.4 Surgical Training

Surgical training is one of the most promising application domains in medicine using 3-D graphics and VR technologies. Motivated by flight simulators for pilot training, a VR-based simulation system for knee arthroscopy was introduced for the first time in 1993 (Fig. 63.5) [63.17]. Since that time, various research groups have focused on the development of laparoscopy training simulators [63.18–20].

The concept of the VR-based knee arthroscopy and laparoscopy training simulators is transferable to other surgical areas (Fig. 63.5). Other minimally invasive procedures such as rhinoscopy or hysteroscopy – without direct contact with the patient – can be trained using a virtual situs (Fig. 63.6) [63.21, VirtaMed AG]. Nowadays, various medical training simulators are

available commercially and successful on the market. Meanwhile, numerous medical training centers have established these VR simulators as part of their curriculum [63.22–24].

63.2.5 Preoperative Planning

Virtual reality can also support the surgeon in planning a procedure before surgery (Fig. 63.7). Before performing a surgical intervention on a real patient, the surgeon is able to practice on a virtual patient to simulate the intervention. In this manner, the safest and most effective surgical approach may be selected, requiring less time in the operating room. Here, various variants of the planned surgical procedure are simulated to identify the best path, e.g., to an injured vessel, minimizing damage to healthy structures. Furthermore, a decrease

Fig. 63.7 Preoperative planning system for total knee replacement (after [63.26])

Fig. 63.8a,b
Medical Augmented Reality for Patients (MEDARPA): augmented reality (a) in the operating theater (b)

in the rate of complications is conceivable. Postoperative treatment can be reduced, and subsequently the costs associated with this; for instance, the risk for revision is higher in case of suboptimally aligned knee implants [63.25].

63.2.6 Intraoperative Support

During surgery, the surgeon's abilities can be enhanced by fusing computer-generated data with real objects. The precision of the surgical intervention may be augmented by superimposing synthetic data on the real

patient, giving the surgeon the feeling of having x-ray vision. Deeply embedded anatomic structures are visible; e.g., a tumor can be approached and extracted in the safest possible manner. In this augmented or enhanced reality (ER), surgery can be performed with greater skill. The position of surgical instruments can be monitored and displayed to the surgeon intraoperatively via monitors in the operating room.

In principle, neurosurgery has made use of augmented reality (AR) technology for many years. The microscope image is overlaid by a path selected using patient-specific CT data during the planning phase. This

technology has also entered other surgical domains. Integration of medical simulation into the operating theater is becoming increasingly common [63.27–29] (Fig. 63.8).

It is obvious that, in comparison with surgical training, these AR-based intraoperative navigation sys-

tems have to fulfill very high requirements regarding accuracy. Meanwhile, more and more studies have been performed to evaluate the robustness and accuracy of AR-guided interventions under laboratory and clinical conditions in the operating theater [63.29, 30].

63.3 VR-Based Medical Simulation

In the following, challenges inherent to implementation of real-time simulations in medicine are addressed. Similar to VR applications in general, quality in medical simulation means convincing the various senses of the user in order to achieve lifelike impressions. In this context, the visual and haptic senses play essential roles. The environment and its impact on the user have to be modeled accordingly. The user should be able to interact with this environment, and beyond that should be able to modify it.

Various research in the field of medical simulation has already shown that integration of haptic displays provides realistic haptic feedback [63.31,32]. In this regard, it should be considered that tactile perception is restricted due to the surgical instruments in minimally invasive surgery. In fact, the emerging development

stage in haptic display device technology can already fulfill these requirements to a certain extent.

The quality of visual feedback and the simulation of object behavior while manipulating virtual structures are the challenges of computer-based simulators. In this context, one of the great challenges is simulation and presentation of different tissue types and their elastodynamic characteristics during surgical interventions. In particular, the strong interlink between visual and haptic feedback has to be realized.

A simulation system aims at realistic modeling of a total process in its environment. Consideration of the focus on minimally invasive surgery leads to further analysis of the real environment of a surgeon. The surgeon does not directly touch anatomical structures during minimally invasive surgical proce-

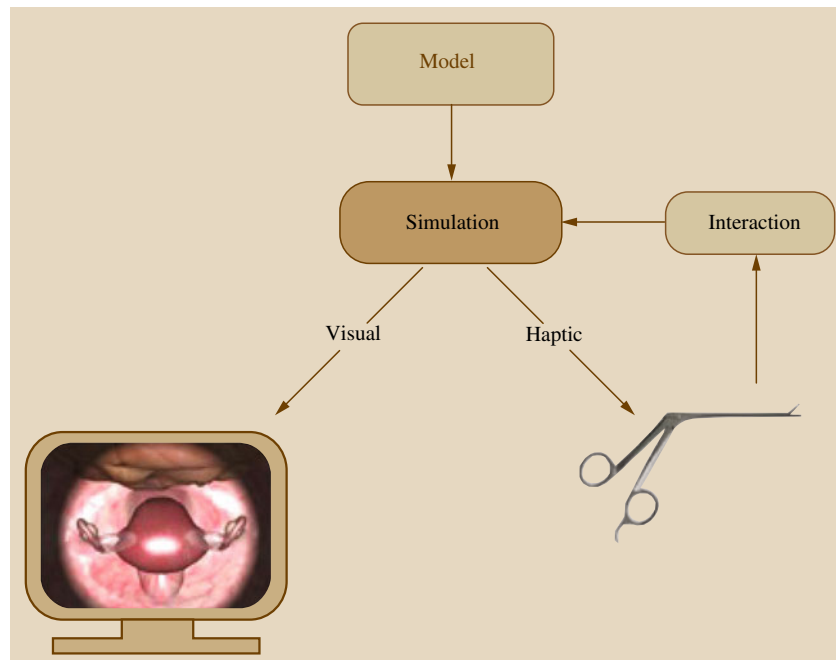

Fig. 63.9 VR-based medical simulation

dures. Rather, he manipulates these with instruments whereas he watches the operative field on a monitor – away from the patient. The surgeon guides his instruments through indirect visual control. Such an operative situation comprises a model (virtual anatomy), surgical interventions (interactions), and surgical instru-

ments (interaction devices) as key elements. Figure 63.9 shows schematically a model of a VR-based medical simulation.

Using this model of VR-based medical simulation, the individual components are described in further detail in the following.

63.4 Model Generation – Virtual Anatomy

The generation of the anatomical region of interest is the first focus in the context of VR-based medical simulation systems. In principle, two approaches can be distinguished for the realization of 3-D models (Fig. 63.10).

On one hand, virtual anatomical structures can be generated using commercially available modeling systems which are also in use in other domains such as architecture. Anatomical models are described via surface models which consist of numerous triangles and which achieve greater realism by projecting realistic textures onto them (Fig. 63.11).

This modeling method will not be further explained in this chapter. Rather, the generation of an integrated patient-specific 3-D model based on medical image data is described in more detail. Such 3-D reconstruction opens up the opportunity to manage individual medical problems with the support of a simulation system.

Here, the anatomical model should not only contain features relevant to visual appearance but should also

consider the tissue-specific characteristics required for simulation of haptic feedback. Furthermore, the concept of 3-D reconstruction should not be limited to a specific anatomical region. It should rather allow generation of 3-D representations of diverse anatomies. Finally, the generation of such a synthetic anatomical region should go beyond visualization of a static model to allow life-like simulation of a dynamic model meeting real-time conditions.

The essential steps in the 3-D reconstruction process of anatomical structures based on medical image data can be addressed as follows (Fig. 63.12).

63.4.1 Data Acquisition

Imaging modalities support both medical diagnosis and therapy planning. Multimodality medical images which have been acquired in daily clinical routine can be used for model generation. Sequences

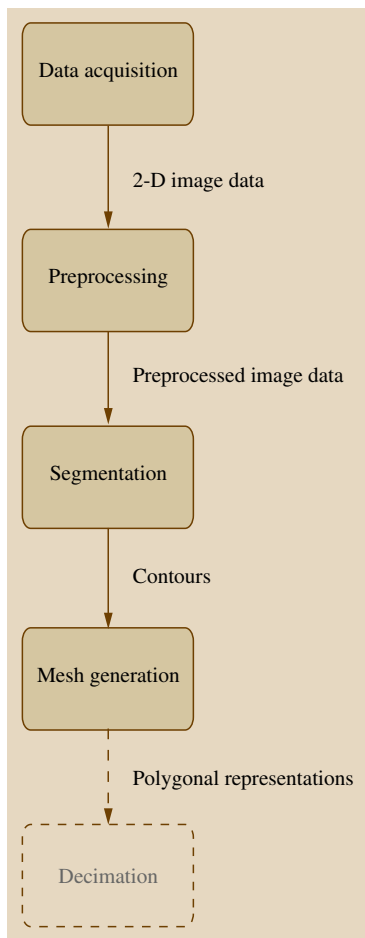

Fig. 63.12
Three-dimensional reconstruction pipeline

63.4.2 Preprocessing

In this first step of the reconstruction pipeline, methods of image processing are applied to the original image data, accentuating the contrast between anatomically relevant structures and the surrounding tissue. Furthermore, signals which are redundant or noisy are removed or reduced (e.g., metallic artifacts). The goal is to improve the quality of the subsequent processing steps.

63.4.3 Segmentation

In general, segmentation describes the process of recognizing objects within an image. The result of segmentation is the classification of an image into various regions which distinguish themselves by specific features. The segmentation of medical image data aims at contour extraction of anatomical structures. Individual anatomical structures can then be identified, selected, and managed separately.

In principle, the segmentation process is challenging, since contours of an object are often presented incompletely and insufficiently. However, segmentation algorithms have been further improved so that correct detection of anatomical structures can be achieved semi-automatically. Only minimal manual intervention is now required in this regard [63.33, 34] (Fig. 63.13).

63.4.4 Mesh Generation

In this step, contours of adjacent slices are connected to generate a three-dimensional structure. Here, appropriate connections between two contours have to be found. The method has to address the fact that anatomical models might consist of highly complex structures and that significant changes between two successive slices might

of image data typically from CT or MRI scanners are the basis for the reconstruction of anatomical structures.

Fig. 63.13
Model-based
semi-automatic
segmentation of
organs

occur. In case of two neighboring slices with arbitrary numbers of contours within them, it has to be guaranteed that the correct contours are connected (the correspondence problem). In case of multiple contours on a slice, the method eventually has to recognize and consider branching of an object from one slice to the next.

An algorithm which constructs meshes based on a 3-D Delaunay triangulation is able to successfully manage these problems. Further details can be found in the work of *Boissonnat* [63.35].

The result of mesh generation is shown in Fig. 63.14. Various complexities can be clearly seen, caused by the different distances between slices in the image dataset. Using this mesh, the anatomical region of interest relevant for the VR-based medical simulation (e.g., interior structures of the knee joint) can be reconstructed at higher resolution.

63.4.5 Decimation

The high resolution necessary for medical data leads to a large number of polygons. As the main objective of simulation is interactive viewing and manipulation of

these 3-D objects in real time, the complex geometry of the reconstructed anatomical models may be reduced. This means that polygons with similar spatial orientation are combined during an additional decimation step. Finally, similar to the modeling process, textures are superimposed on the virtual anatomical structures, providing greater realism. These textures can be derived from an anatomical atlas or real endoscopic procedures.

Meanwhile, virtual anatomical structures can also be generated using a 3-D laser scanner based on a specialized method of stripe projection. High-resolution 3-D scans with submillimeter precision allow highly detailed 3-D digitization of real objects. A mesh generator transforms these 3-D point clouds into 3-D models. In addition, the system provides texturing of the geometric model with images of the object, resulting in a photo-realistic digital model (Fig. 63.15). If needed, models at various levels of detail and complexity can be generated.

A 3-D scanner is also used in radiotherapy to guarantee beam treatment with high precision. The geometric data of the patient's surface can be used to determine the pose of the patient and to detect patient motion.

Fig. 63.14 Mesh generation of femur and tibia

Fig. 63.15 Three-dimensional reconstruction of a head using a scanner (Polygon Technology, Darmstadt)

63.5 Manipulations – Surgical Interventions

Besides 3-D modeling, simulation of surgical instruments is a further focus in the design of VR-based medical simulators. The shape, appearance, and function of instruments must be preserved. The simulation model must allow simulation of both rigid instruments (e.g., endoscope, exploratory probe) and those with moving parts (e.g., grasping forceps, scissors). As the surgeon would do in clinical practice, the goal is to provide an environment in which he is able to maneuver instruments in the virtual anatomy derived from real patient-specific image data, as introduced earlier.

Realization of real-time 3-D interaction is one of the most important requirements. The integration and use of original surgical instruments as *input devices* is intended. VR technology has long allowed the specifi-

cation of new interaction tools beyond the well-known data glove or data helmet.

63.5.1 Modeling of Surgical Instruments

Sometimes 3-D digital models of the surgical instruments cannot be provided by medical equipment manufacturers. However, virtual instruments have to be provided and integrated into the medical simulation system, where they have to be processed further in real time. Thus, the 3-D geometry of surgical instruments is generated by means of modeling systems based on technical descriptions and/or real instruments. These virtual instruments have to have the same functionality as the real ones. Furthermore, a realistic appearance of the instruments has to be produced. Here, modeling methods

such as texturing can be applied to increase the realism of surgical instruments.

63.5.2 Registration of Instruments

Having introduced digital 3-D representations of instruments, these interaction devices have to be applicable in the medical simulation system. This means that they, as virtual replicas of real surgical instruments, also have to function in the same way. Movements of the instruments in the real environment have to be registered and finally transferred without delay to the virtual models which are visualized on the monitor. In this way, the surgeon gets visual feedback.

The tracking technique which is typically used for registration of movements in VR applications is also used here to realize the 3-D interaction using surgical instruments. There are various methods to determine position and registration. With reference to the physical principle used, several categories can be distinguished such as mechanical, optical, and electromagnetic tracking systems. In the following, the electromagnetic approach is briefly introduced.

A sender called a transmitter creates an electromagnetic field. Sensors (receivers) react to this electromagnetic field, delivering position and orientation information. These sensors are attached to surgical instruments, allowing registration of the instrument's movements. Meanwhile, miniature sensors are available which can even be incorporated into medical instruments with very small diameter for dynamic tracking. Cables might be inappropriate, since they limit flexibility and mobility. However, nowadays, wireless electromagnetic tracking systems are available on the market. However, a disadvantage of such tracking methods is that ferromagnetic and metallic materials interfere with the electromagnetic field, leading to distortions in the working volume.

Finally, these electromagnetic tracking systems do not provide such high accuracy with respect to position and orientation as the optical tracking systems which are primarily used in the operating theater. However, they represent a cost-effective, lightweight, and compact solution for dynamic tracking that is widely used in medical simulation systems which do not have high accuracy requirements (e.g., training simulators). Here, registration of objects can typically be achieved with accuracy of 0.8 mm in position and 0.15° in orientation. Thus, small movements of instruments can be tracked dynamically in real time. Based on the delivered sensor data, an updated view of the operating field is calculated

and visualized on the monitor of the graphics personal computer (PC).

Since an endoscope has some specific optics, simulation of this should be discussed in further detail. Endoscopes can be of forward-viewing (0°) or forward-oblique direction of view (e.g., 30°, 45°, 70°). These angle optics increase the field of view by just rotating the endoscope around its axis, thus minimizing instrument motion. Further to this, some endoscopes produce viewing fields of up to 110° through the use of wide-angle optics.

As described above, the position and orientation of an instrument, here an endoscope, can be determined using sensors. Now the optics must be simulated by calculating the camera point of the instrument based on the delivered sensor data. Depending on the optics selected, the actual field of view of the endoscope is updated and visualized on the monitor. In this context, the graphical user interface contains a display window for the endoscopic view.

VR-based medical simulation systems have the advantage that endoscopes with any angle optics can be seamlessly integrated. Here, the arrow helps the surgeon determine the orientation by showing the viewing direction (Fig. 63.16).

A second window provides an overview of the operative field, which is very helpful for the determination of orientation, especially for beginners. This display window shows distinctly and visibly how the light source at the tip of the endoscope (simulated by a point source) illuminates the respective part of the virtual anatomy (Fig. 63.16, top right). In addition, other optics such as a wide-angle lens with its typical convex distortion of the endoscopic image can be simulated.

Furthermore, the simulation environment can be specified using a graphical user interface. Here, a selection of various anatomical regions and numerous surgical instruments are available. In addition, statistics are generated during simulation, allowing objective assessment of trainees' performance. A portfolio of standard training situations and tools for objective assessment are definitely the major advantages of medical training simulators in comparison with traditional training methods for learning endoscopic skills (e.g., *learning by doing* on patients).

Thus, VR technology allows the introduction of novel interaction devices. Three-dimensional real-time interaction and intuitive handling of various surgical instruments is provided in a VR-based medical simulation system. A complete set of virtual instruments such as endoscopes with various optics, exploratory probes, as

Fig. 63.16 Graphical user interface

well as grasping forceps or dissecting scissors can be simulated realistically while preserving both form and function.

Besides registration of instrument movements, fast collision detection between the various instruments and virtual anatomical structures is required. This forms the basis for simulation of tissue manipulation (e.g., deformation or cutting).

Here, deformation is exemplarily introduced as a type of interactive manipulation of anatomy to show the principles of soft tissue simulation. Two approaches for simulation of deformation are described: geometry-based and physically based methods. Deformation behavior of anatomical structures as a result of interventions with surgical instruments can be realized using *bump weighting functions* and mass-spring models or by finite-element methods (FEM), and thereby integrated into the medical simulation system.

The former method allows fast calculation of local deformations, allowing real-time simulation even on today's low-cost computers. A bump-weighting function can be specified to describe the deformation in the area close to the surgical instrument, depending on the penetration depth into the respective tissue. In this way, an individual local deformation behavior can be applied to each tissue type. This geometric approach can be realized with simple and fast transformations.

The latter approach uses methods for a physically based simulation, also addressing global deformations. Here mass-spring models allow the calculation of object deformations in real time using appropriate numerical integration with varying step size. The difficulty is to achieve a robust and stable simulation.

Finally, more and more solutions using finite-element methods are entering the medical simulation arena. Tissue-specific material properties are integrated in the FEM framework. This method achieves a high-quality simulation but unfortunately has high computational costs. Rapidly developing and recently introduced hardware architectures such as GPUs open up new opportunities to manage and speed up these complex and computationally intensive calculations. More details about this research direction can be found in *Taylor et al.* [63.12] and *Peterlik et al.* [63.36].

63.5.3 Integration of Visual and Haptic Feedback

The quality of a simulator session will be enhanced if the trainee manipulates and experiences the virtual situs through multiple sensory channels. It has been shown that visual and haptic perception play a significant role in interactive environments. Considering the specifics of these two sensory channels, the respective components

Fig. 63.17 Haptic simulation (after [63.32])

of the simulation system have to be realized with different update rates. While 20–40 Hz is sufficient for visual output to provide real-time visualization, high frequencies of up to 1000 Hz have to be generated to satisfy the human haptic sense. Finally, the visual and haptic feedback have to be seamlessly integrated and synchronized.

Two main factors have an impact on research work in the field of haptics for VR-based medical simulation systems. One cornerstone is hardware in terms of haptic device technology; the other is the software component controlling haptic displays to generate artificial resistance.

In minimally invasive surgery, the number of degrees of freedom is reduced due to fixation of the instruments at the minimal access ports. Further to this, it can be stated that neither a large working space nor high force levels are needed for the haptic interface. Certainly, in case surgical instruments come into contact with rigid objects such as bony structures, a maximal force has to be generated and the haptic display must deliver the corresponding stiffness.

As of today, six-DoF (degree of freedom) tracking systems are available and very common. Recent years have also seen an increasing number of options in the field of haptic devices. More and more six-DoF, cost-effective haptic displays have entered the market. In addition, there are haptic interfaces designed specif-

ically for surgical interventions. This opens up new opportunities for the medical simulation domain.

The software realizes the haptic rendering by converting an internal representation of a virtual object into a representation suitable for display on a haptic device (analogously to graphics rendering) (Fig. 63.17).

Haptic simulation of minimal invasive procedures must also include the tissue-specific characteristics of anatomical structures (e.g., hard bone tissue; firm, resilient meniscus). The most relevant tissue types are classified with respect to their haptic attributes (e.g., mass, friction, elasticity) and then integrated into the VR-based simulation system. Finally, integration of different simulation models including consideration of the penetration depth of the instrument generates the corresponding object-specific haptic stimuli.

As mentioned above, haptic displays need extremely high update rates of up to 1000 Hz to avoid lag in the simulation loop which might otherwise lead to distorted haptic perception. In this context, fast collision detection is key for a believable haptic interaction. One approach is to split the virtual world into a global and a local part. The global part describes the complete virtual scene, where collision detection might be performed at less than 1000 Hz. The local part represents the region where the actual interactions between the instrument and surrounding anatomical structures take place. This region

is relevant for the haptic simulation. This local region of the virtual scene is selected based on the collision detection results and then further processed by the simulation engine. Then calculations which are required for the haptic feedback are done, enabling the high update rates needed to control the haptic display.

63.6 Outlook

Rapid developments in the two areas of computer graphics and surgery will have further impacts on medical simulation in the future.

In computer graphics, the availability of increasingly powerful processor architectures opens up new possibilities for real-time simulation. In particular, GPUs, beating Moore's law by a factor of three, will allow, as well as higher visual quality and greater realism, the solution of computational power and non-graphics-related problems. Therefore, physically based methods will be integrated with greater accuracy, continuing the trend towards greater interactivity and realism.

The continuing developments will also include haptic displays, although advancements will happen at a different speed here.

The anatomical model will become more sophisticated; microstructures will be increasingly considered. In vivo measurements have been increasingly conducted, which can be the basis for mathematical modeling of the elastodynamic characteristics of organic structures. The derivation of relevant tissue-specific values is expected to lead to quality improvement in the simulation of the elastodynamic behavior of anatomical structures. A large amount of research work is focused on the collection of such empirical data for soft tissue and abdominal organs for subsequent transfer to the simulation model [63.36, 38–40].

Beyond this, simulation will include further aspects of minimally invasive interventions such as coagulation, i.e., the stopping of bleeding by the use of heat. Closely linked to such simulations, physiological functions should also be mentioned, where – besides blood flow – respiration and the heart beat can be seen as the next challenges [63.41]. Realistic real-time simulation of these complex processes is one of the research challenges worldwide [63.42].

There will also be further developments in the field of minimally invasive procedures. The rapid advances in endoscopic operative techniques will continue, and entire traditional surgical domains will disappear. This

The simulation of haptic feedback is an important research topic worldwide. A comprehensive overview and discussion of the various methods cannot be provided in this chapter. *Coles et al.* [63.37] provide an excellent overview of current developments in haptic simulation in the area of medical VR trainers.

will be accompanied by the increasing sophistication of instruments. Furthermore, there is a trend in surgery towards the performance of interventions via natural orifices of the body, enabling further minimization of patient trauma.

Other research work focuses on giving back the *lost feeling* to surgeons by integrating sensors to detect subtle lesions with instruments [63.43]. This includes the realistic integration of specific surgical instruments into haptic simulation. In this regard, fundamental knowledge of haptic perception is the basis for successful coupling of haptic feedback with simulators or robotic systems. One of the research challenges here is to present the forces that are applied to the patient in a realistic manner. Haptic displays do not yet accomplish this [63.44].

The introduction of new minimally invasive techniques into clinical practice has to be done via phased and structured development and validation with adequate postoperative monitoring rather than following a *trial-and-error* approach. In this context, virtual simulation of new operative procedures can make a valuable contribution to the ongoing development of minimally invasive surgery to maintain or increase its significance.

Flight simulators have been an indispensable ingredient in the training of pilots for many years. Medical simulators using VR technology and computer graphics have the potential to play a similar role in surgical training. The challenges inherent to traditional training methods of *learning by doing* or using phantoms or cadavers motivated the search for alternative training scenarios. Finally, this led to the development of VR-based simulators, which are gaining increasing levels of recognition and acceptance in minimally invasive surgery.

Furthermore, studies have provided evidence that skills acquired in a virtual training environment can be successfully transferred to the real world. Skill transfer can be improved if there is a good match between

the training and the real context. VR-based training systems definitely achieve an enhancement of the learning curve without requiring patient contact. Numerous studies carried out in recent years have shown the potential for successful transfer from the simulator to the operating room [63.22, 45–50].

Today, there are already promising signs that use of VR-based training simulators in medical curricula has become a reality. Training centers such as the Queensland Health Skills Development Centre, the Minimal Invasive Surgical Centre Singapore or the Wenckebach Institute in Groningen have made medical simulators a definite part of their training programs; for instance, each year, the European Surgical Institute organizes about 80 training courses for 1000 participants, helping them to develop precision and skills with the support of VR-based simulators. Some changes in the current framework of medical education are also on the way in the USA. The general availability of medical simulators will have an impact on the way medicine is taught and practiced in the future. Thus, the American Board of Surgery already requires surgical residents to perform training sessions on simulators in the field of laparoscopy [63.51, 52].

It has to be recalled that several decades were needed to make realistic flight simulators of today's standard possible. The rapid advances in the field of computer-based training simulators and the successive improvement of their realism in recent years indicate the emergence of such systems in surgical education as well. The *permission to fail* in such simulation environments is an essential advantage over *training in the operating theater*, corresponding to a further enhancement of patient safety. Such simulation has the potential to be used to a greater extent during preoperative planning based on patient-specific data immediately before the real surgical procedure; this can be seen as a *preoperative warm-up*. In Canada, such a dry run has already been performed using the NeuroTouch simulator in the field of neurosurgery.

It is without dispute that quality management and certification are playing an increasing role in the health-care system. This fact will finally lead to an essential reform of medical education. Here, computer-assisted training simulators with their spectrum of objective assessment will become an integral component. Is this the route to a *licence* for surgeons, as is already in place for pilots?

Furthermore, a paradigm shift is on the horizon. Not only will the surgeon receive decision support from preoperative image data, but sophisticated sensors will

allow intraoperative delivery of tissue-specific characteristics. This information will be made available to the surgeon, allowing him to adapt the next surgical step; for instance, a surgical robot selects the drill channel in the bone by considering actual sensory feedback. There is no need to rely *only* on preoperative planning based on the patient-specific image dataset.

The use of robots in the operating theater has been called into question and discussed controversially. It should be considered that common industrial robots were used at that time, which can now be substituted by compact, cost-effective, modern operating-room (OR) robots (from, e.g., Mazor Surgical Technologies). Meanwhile, the benefits of robot-assisted surgery are increasingly being recognized. In the operating theater, the robot is an additional tool for the surgeon that can be selectively used during specific intraoperative steps. In this way, the intervention can be performed with greater precision and quality, resulting in a better final operative outcome. In the meantime,

Fig. 63.18 Medical visualization on a smart phone

the global robot-assisted surgery market is expected to grow from US \$1 billion in 2008 to US \$14 billion by 2014.

Finally, attention should be drawn to a trend which has already entered our daily life, i.e., mobility. This will include medical simulation too; i.e., *medical simulation will go mobile*. Forecasts show that 81% of medical doctors in the USA will be equipped with – be-

sides a stethoscope – a smart phone by 2012 [63.53]. This opens up exciting new possibilities to blend medical simulation with mobile learning environments. Considering the continuous increase of performance and functionality of mobile devices, use of 3-D visualization and AR applications *on the move* has become closer to reality (Fig. 63.18). All these developments will benefit the patient.

Computer-Supported Teaching and Learning Systems in Medicine

Martin Haag, Martin R. Fischer

In 1999, the scenario *University in the Year 2005* predicted that by 2005 half of all students would be studying at virtual universities, while there would be only a small core of traditional universities left. Obviously, this prediction did not come true, and the scenario is far from being realized, even today (Sects. 64.1–64.3). However, there is a visible trend towards using computer-supported teaching and learning systems in medical studies at traditional universities within blended learning (BL) concepts (Sect. 64.5). A meta-analysis by Cook et al. showed that studying supported by internet-based learning is at least equal to traditional forms of teaching [64.1]. In German-speaking countries, the term computer-based training (CBT) is frequently used for computer-supported training, but there are a plethora of other English-derived terms that are also in use, such as computer-assisted instruction (CAI), computer-assisted learning (CAL) and computer-based instruction (CBI). The term web-based training (WBT) [64.2] is used if the applications are based on web technology and accessed via the web. The term e-Learning [64.3] (electronic-learning) is somewhat broader, and – aside from CBT and WBT – also includes other forms of digital learning such as computer-supported cooperative/collaborative learning (CSCL) (Sects. 64.5 and 64.6). Against the backdrop of the historical development and moves toward reforming the medical curriculum, an overview over the relevant aspects of CBT/WBT systems in medical studies are

presented in this chapter; in particular, questions regarding the integration of the curriculum and the sustainability of reforms.

64.1 Historical Development

Towards the end of the 1950s and the early 1960s, the first learning programmes were created on second-generation mainframe computers. At that time, this teaching approach was referred to as programmed teaching (PT).

Psychologists and pedagogues studied the possibilities of the new technology in great detail [64.4]. During that period, the predominant learning paradigm was behaviourism, which had a major impact on the

learning programmes created. The supporters of behaviourism assumed that the human brain only had to be stimulated appropriately to achieve the desired response (the correct answer). In behaviourism, the key element is appropriate feedback for the learner in order to reinforce the correct reaction (the answer) to a stimulus.

Ultimately, the concept of behaviourism is based on rewarding the learner if they correctly answer questions and thus close in on the learning target, or punishing them if they incorrectly answer questions and thus move away from the learning target. To this end, the knowledge to be acquired is broken down into the smallest learning units, which is immediately followed by a question that must be answered correctly. If the learner is unsuccessful, the learning unit is repeated or additional help is offered. The expected success of PT for the most part did not materialize. Disenchantment soon followed the initial euphoria about computer-supported training. There were several reasons for this ([64.5, p. 39], [64.6, p. 17]): no graphical interfaces or attractive user interfaces that could be intuitively operated by people who were not specialists in computing; no authoring systems which would enable the creation of learning and teaching systems without advanced programming skills; and the hardware costs of that generation of mainframe computers were very high.

Towards the latter half of the 1970s, the first desktop personal computers became available. These were easier to handle than mainframe computers, and thus attractive to novice computer users. The available hardware and the cost-to-performance ratio continued to improve. Soon high-definition monochrome and colour monitors became available, and mice appeared as input devices. Tutorials and computer simulations were created for such personal computers (Sect. 64.3.1), but generally without too much success.

Later, however, computer-supported training staged a comeback in the form of hypermedia systems. Hypermedia refers to the merger of hypertext and multimedia. Multimedia [64.7] refers to the combination of various digital media such as text, audio clips, video clips, animations, graphics, and their interactive use on a computer. In hypertext, the individual parts of text are not arranged in a linear fashion, in contrast to book texts for instance. The individual text sections are connected using links. Due to the nonlinear arrangement of text, readers themselves are able to choose if they require extra information on a certain topic and, if so, they can

choose a link to view additional information. This is an important advantage over linear text where the author controls the order in which the individual parts of a text are to be read. In conventional texts, the author also dictates the subject depth (level of detail) of each block of text.

The availability of authoring systems for the Macintosh and Windows operating systems allowed non-specialists to create hypertext with relative ease. The individual text sections created could also contain several different types of media at the same time, allowing the production of multimedia content. Without extremely expensive hardware or in-depth programming knowledge, it was then possible to create very appealing learning programmes in a relatively short space of time. Optical disks and CD-ROMs provided ways to store large amounts of data (high-resolution pictures and digital video).

Aside from the significant hardware advances that sped up the production and use of learning and teaching systems enormously, the field of teaching psychology also made progress. As behaviourism had shown itself to be a rather unsuitable paradigm on which to base teaching and learning systems, it was often replaced with a constructivist approach [64.8]. In this approach, learners are faced with complex, authentic scenarios (for example a virtual lab or patient) which require them to learn how to identify problems, connections and solutions. The aim is to integrate the newly learned material into the students' existing knowledge in such a way that they are actually able to apply it. The constructivist Cognitive Apprenticeship approach is based on assumptions of situated learning [64.9].

Modelling complex behaviour through an expert who is, figuratively speaking, looking over the learner's shoulder in an authentic situation is a central concept. The following methods are used in this approach: (1) modelling, (2) coaching, (3) scaffolding, (4) fading, (5) articulation, (6) reflection, and (7) exploration [64.10]. These approaches are strongly rooted in case-based computer-supported learning environments (virtual patients). The debate over how many instructional and how many constructivist offers should be made to the learner continues, and amongst other things depends on the prior knowledge of the learner and the educational context. A further aspect of constructivism is synchronized and asynchronous cooperative learning, meaning that problem solving should not be done in isolation but in cooperation with others.

64.2 Moves Towards the Reform of Medical Studies

The development of learning and teaching systems in medicine was, aside from developments in technology and instructional psychology, marked by moves to reform medical studies, in particular from the 1990s onwards. These reforms included (amongst others) interdisciplinary teaching that no longer distinguishes between the pre-clinical and the subsequent clinical phases of training. This was an attempt to counter the lamented deficits of non-practice-oriented inert knowledge in traditional training with problem-based learning (PBL) and case-based training with virtual patients, and to emphasize self-determined, independent learning. PBL is thought to enable students to solve clinical problems independently and to develop their capacities for independent, lifelong learning and knowledge management. In a PBL environment, a tutor presents a small group of students with a clinical case, and usually provides only some patient information and the key points of the anamnesis. The case is then typically dealt with using the following method: (1) clarification of basic comprehension issues; (2) problem definition – the group decides which questions it wants to tackle based on the case; (3) gathering ideas and approaches to a solution; (4) systematic ordering of ideas and approaches into a solution; (5) formulating the learning targets; (6) researching at home; and (7) synthesis and discussion of the learning content gathered. PBL was developed at the Canadian McMaster University towards the end of the 1960s, and has spread successfully since. In 1984, Harvard Medical School also adopted an PBL approach that uses the so-called New Pathway [64.11], which aims to transmit not only knowledge but also skills and behaviours which emphasize the relevance of life-long learning (or continuous medical educa-

tion) and of skills in knowledge management. Some instances of moves toward reform in Germany include the introduction of the first pre-clinical PBL curriculum at the Private University of Witten/Herdecke in 1992 and the establishment of PBL courses in clinical studies at Munich University in 1997 in cooperation with Harvard Medical School [64.12]. 1999 saw the introduction of the subject-integrational organ- and topic-oriented Reformed Medical Studies course at the Charité in Berlin, and in 2001 the Curriculum Medicinale (HeiCuMed) in Heidelberg, which also had strong PBL components based on Harvard's New Pathway model.

Benefiting from the new Medical Licensure Act (2002) and earlier examples of reform, all departments now conduct block courses lasting several weeks. Many faculties teach practical skills at specially designed facilities (so-called skills labs). The training of communicative skills in many places is carried out using standardized patient actors who pretend to be patients. In addition, virtual patients are used in a variety of application scenarios to support self-determined, practice-related learning in various contexts.

The new Medical Licensure Act of 1 October 2003 calls for new learning and teaching methods that aim for independent learning and focus more on the acquisition of skills and abilities than was done previously. Changes to the exam system are also worth mentioning – departments must assess and mark 22 core subjects and 12 interdisciplinary subjects using alternatives to conventional multiple choice exams. Such alternatives are, for example, objective structured clinical examinations (OSCE), modified essay questions (MEQ), or key feature problems [64.13, 14].

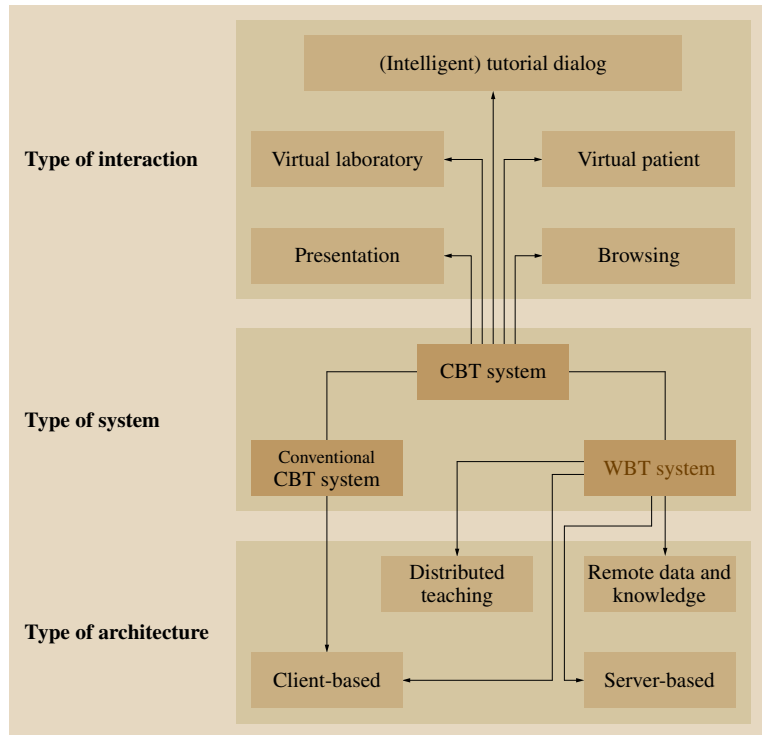

64.3 Developing Learning and Teaching Systems

The development of CBT/WBT systems requires the collaboration of an interdisciplinary team of medical experts, programmers, curriculum developers and teaching psychologists. Prior to development, the learning targets and the planned usage scenarios must be defined [64.15, 16]. Only after this has been done can appropriate forms of interaction be defined, as well as the application architecture (Fig. 64.1).

64.3.1 Interaction Forms

Various types of learning and teaching systems can be distinguished, depending on the degree of interactivity and the topics to be taught. Actual systems themselves can potentially belong to more than one type. Presentation and browsing systems are particularly suitable for transmitting systematic knowledge.

Fig. 64.1 Forms and types of interaction in CBT/WBT systems

Presentation systems are relatively quick and easy to create, as they present certain facts in a linear order. In a manner of speaking, they represent a digital form of the audio slideshow. The interaction between the learner and the computer is restricted to starting the presentation and potentially pressing the pause button or rewinding the presentation. Due to the lack of interactivity, pure presentation systems are rarely used anymore.

On the other hand, browsing systems are characterized by the inclusion of an index or a list of keywords that allow the user to jump directly to a certain chapter or page of the system. It is possible to return there at any point in the programme and at any time. Browsing systems usually contain multiple links between the individual pages (nodes). Marked text can be clicked upon by the user with a mouse, leading to a graphic, a new page, etc. These hypertext or hypermedia functions provided by the programme enable self-determined learning. In browsing systems, the computer also assumes a passive role. It is left to the learner to decide whether to use the system simply as an encyclopaedia or as a learning programme. If used as a learning programme, the learner is able to decide the order in which and how intensively they are going to work through the

chapters. However, this frequently leads to uncertainty over whether all of the relevant material has been found. Many of these programmes therefore contain a question component that allows the user to detect knowledge deficits.

Most learning and teaching systems currently on the market are of the browsing type. Occasionally, virtual patients or labs (see later) also contain a browsing component that provides textbook information which can be accessed if needed.

A virtual laboratory is characterized by a mathematical model of a real process, which provides the basis for a related computer simulation. In this type of learning and teaching system, it is very important that the users are familiarized with the system, so that they understand the model, its abilities, and how to carry out actions.

In tutorial systems, the learners are accompanied through the material by the programme. The system presents the content and occasionally asks questions, which are (amongst other reasons) included to aid the discovery of the solution. If a learner cannot answer a question, they receive appropriate feedback which, for example, may contain hints about the solution or is presented along with certain information that is necessary

Fig. 64.2 Virtual patient in the CAMPUS system

to answer the question. In tutorial systems, the entire programme cycle is controlled by the computer. Systems that are distinctively tutorial in nature are rare on the market. Browsing systems in which questions are placed at the end of a topic, and the learner must answer these to ascertain if they have understood the material, are more common.

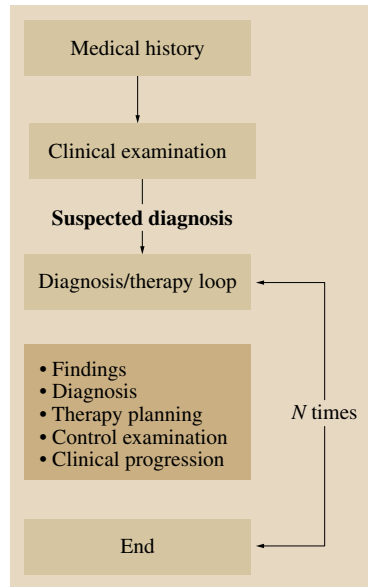

Intelligent tutorial systems, a distinct variety of tutorial systems, employ artificial intelligence (AI) to model user behaviour. To this end, it analyses user behaviour, prior knowledge, preferences, etc., and the AI determines the subsequent programme using this information. The difference from normal tutorial systems is that the programme sequence is not fixed within the programme. The programme usually takes on an advisory function and only intervenes if needed. One of the more difficult aspects of this approach is information modelling. The knowledge that is to be imparted must be structured and linked in such a way that the model is capable of, for example, answering questions from the user. The intelligence of a system lies in its ability to apply the information in the database in a meaningful way.

Case-based training has gained in importance over the last few years, and is increasingly found in the literature under the term “virtual patient” [64.17]. In this

type of interaction, a virtual patient with a certain clinical picture is presented. Following anamnesis, physical examination, examination using technology, lab tests, diagnosis and treatment steps, students conduct the treatment of the virtual patient. There are a multitude of software systems for the development and use of virtual patients [64.18–20]. In order to better judge differences and common features, *Huwendiek et al.* [64.21] developed a typology that distinguished four main categories: general, learning targets and competences, instructional design and technology. There are particularly large variations in the instructional design of virtual patients. For example, two basic types of navigation routes through a case can be distinguished.

In the linear route type, a case consists of a predefined series of steps. At each step, the user must take decisions, answer questions or interpret information that has been presented. There are two possible ways of realising this: card-based and simulative variants. In the card-based variant, a case is represented by a stack of hypermedia cards that the user has to work through in a linear path. Here, the presentation of the virtual patient is rather abstract and not as close to reality as in the other variant. In the simulative variant, the approach to the case follows the real-life treatment pattern

Fig. 64.3
Diagnosis–
treatment loop
in CAMPUS

more closely, and only presents the student with information they have asked for (knowledge on demand). In such a system, for example CAMPUS [64.22], learners take on the role of a doctor who has to examine a patient, produce a diagnosis, and then direct treatment (Fig. 64.2). Following the anamnesis and the initial physical examination, a diagnosis/treatment loop is run (or sometimes more than one), until the case can be concluded (Fig. 64.3). Treatment of the virtual patient is therefore much closer to reality. Because learners take a very active role in such systems, they are normally only suitable for students at an advanced level of study – it is very difficult to comprehend correlations and initiate appropriate actions without basic knowledge. Card-based systems such as CASUS [64.23], for example, offer the opportunity to use virtual patients at very early stages of study or for the rapid revision of material, because the case author has a great deal of freedom when designing cards using the card metaphor, and is therefore easily able to integrate basic knowledge into the case presentation.

By contrast with the linear route type, in the branched route type (as used in OpenLabyrinth [64.24] for example), several paths through a study case are possible. It is also possible to build dead-end routes. This enables case authors to realistically depict the consequences of wrong decisions, for instance. However, the effort required to create a virtual patient increases significantly in comparison with the linear route type.

Generally, the effort required to prepare medical case studies is great, especially if it is necessary to create or maintain appropriate terminology lists. However, this can be significantly reduced by using powerful authoring systems (Sect. 64.3.3).

64.3.2 Architectures of Learning and Teaching Systems

Two fundamentally different types of programme are used in learning and teaching systems:

1. *Conventional CBT systems*

These are delivered on data storage devices such as DVDs and must be installed on the computer of the user. There is no requirement for an internet connection for it to be functional.

2. *WBT systems*

These are based, in contrast to conventional CBT systems, on basic web technology such as HTML, JavaScript, etc., and usually have a client/server architecture. While part of the application runs on the user's computer (the client), the other part is run from a central server.

The differences between these types result in different architectures (Fig. 64.1 [64.2]). The advantages and disadvantages of each architecture must be considered during the concept phase.

The creation of a WBT system is often a more laborious task than the creation of a conventional CBT system, although it does offer many advantages. For example, since WBT systems do not have to be installed, they are (generally speaking) platform independent and thus do not require a Windows PC to run. Such a system can therefore be used whatever the operating system, time or location, encouraging flexible and self-determined learning. Due to these advantages, new developments in this field are currently dominated by WBT systems.

64.3.3 Authoring Systems

Creating e-Learning content is a task that is made considerably easier by using powerful authoring systems, and such systems also enable members of the medical profession who do not have in-depth computing skills to perform this task. One of the most widely available commercial authoring systems is Tool-Book [64.25]. This system uses a book metaphor to simplify the creation and use of learning and teaching

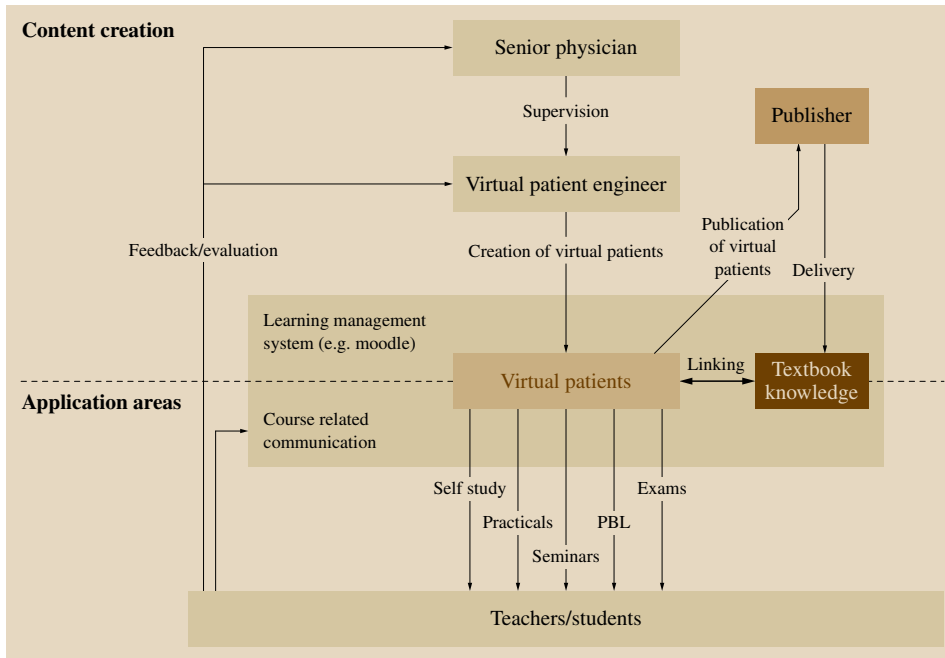

Fig. 64.4 Roles in CBT/WBT systems

systems (usually presentation and browsing systems). Other widely used authoring systems, such as Macro-media Director [64.26], use the metaphor of film – the author takes on the role of director who can control the appearance/disappearance of acting objects on/from the stage. Such authoring systems are particularly useful for the creation of animations. Authoring systems are also used for the creation of virtual patients, who are frequently produced in-house in order to cater for specific

requirements. It has been shown, however, that despite the ease of use of authoring systems, it is often difficult to find authors of virtual patients. One solution is, for example, for the senior physician to assume the role of case author, who passes the work required to prepare the case to a virtual patient engineer (Fig. 64.4) before finally taking control of the prepared virtual patient. Virtual patient engineers are typically students of medicine or doctors in training.

64.4 Learning Environments

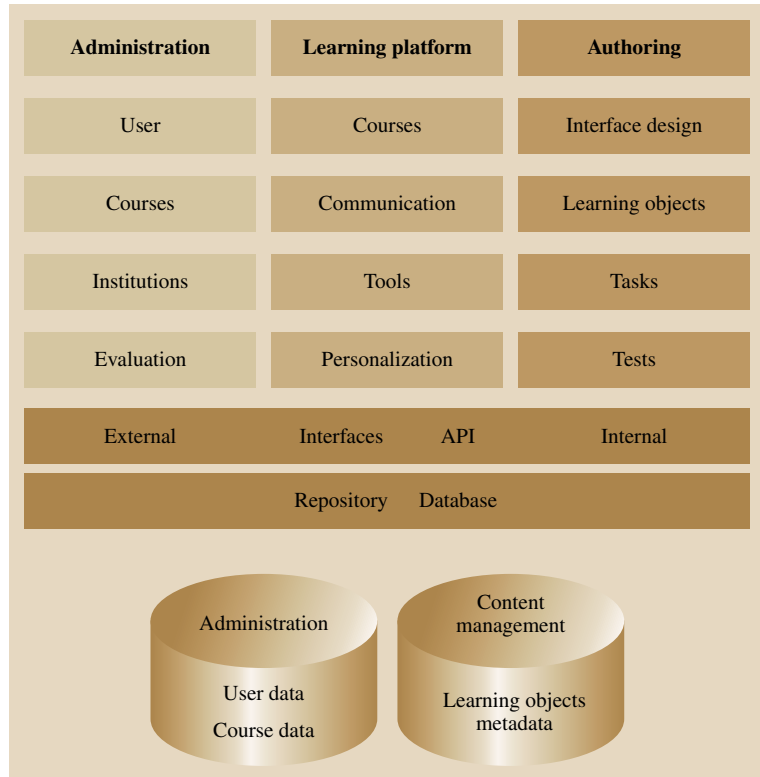

64.4.1 Functionality of Learning Environments

In the last few years, faculty and university learning environments or platforms (learning management systems (LMS)) have established themselves.

In contrast to plain collections of lecture scripts or hypertext collections on web servers, an LMS usually provides for [64.27] (Fig. 64.5):

- User administration (encrypted login)
- Course management, which allows students to book and sign up for courses
- A learning platform that includes learning objects (texts, slideshows, CBT or WBT units) and learning tools (notepad, calendar, etc.)
- An authoring tool that enables tutors to develop web documents without much knowledge of HTML and the internet
- Components for cooperative online work (computer-supported cooperative work, CSCW)
- Shared databases and repositories
- Permissions and roles allocation with differentiated permissions
- Functions that allow evaluation and exams to be conducted online.

Fig. 64.5 Functionality of LMSs
(after [64.27])

There are a large number of LMS systems on the market. Commercial systems aside, there are also some open source systems that are particularly attractive for cost reasons. The selection of an LMS has far-reaching consequences for a university and is not a trivial task. Care must be taken to ensure that the selected LMS possesses the necessary functionality and performance, while the licensing, running costs and cost of training tutors and students in handling the LMS should be as low as possible.

When integrating a CBT/WBT system into an LMS, it is important to make sure that users logged into the LMS system will be able to use the CBT/WBT system without the need to renew their authentication (so-called single sign-on). In addition, the LMS should be able to record the progress of each user, thus allowing them to continue their study units from appropriate points later.

64.4.2 Interoperability and Standards

Integrating a CBT/WBT system into an LMS is a significantly easier task when the LMS has standardized interfaces that support interoperability between

different systems and reusability of learning objects. The SCORM (sharable courseware object reference model) standard [64.28] of the Advanced Distributed Learning Initiative (ADL) from the Department of Defense (DoD) is particularly relevant in this context. SCORM is the reference model for creating web-based exchangeable learning content with the aim of producing reusable, identifiable, interoperable and persistently stored learning objects and courses. These aims are achieved by specifying metadata that identify existing learning objects which can then be saved as SCORM packets and re-identified via the metadata. However, the downsides of standards like SCORM should also be noted; for example, there are potential bureaucracy issues, as the documentation for SCORM runs to more than 800 pages and is thus difficult to review.

In the area of virtual patients, we should mention the MedBiquitous virtual patient (MVP) specification [64.29]. The specification [64.30] currently being developed simplifies the exchange and use of virtual patients across departments significantly – an effect that has already been noticed during the early stages of working with the new standard.

64.5 Application Scenarios for Learning and Teaching Systems

Learning and teaching systems can be used in numerous ways (Fig. 64.4). At most universities, a variety of self-study programs are available in computer labs or media centres. In addition, web-based systems can often be accessed from a student's home computer via the internet. The move towards blended learning (BL) concepts – involving the compulsory integration of learning and teaching systems into lectures – has intensified recently. BL involves not only linking books, handouts, seminars, workshops, 1:1 coaching, and so on using web-based content, but also the use of virtual classrooms (for example to prepare seminars or to do follow-up work on a seminar). One of the options it provides is the use of programmes to systematically transmit knowledge and discuss and deepen learned content in face-to-face sessions. The approach in which the theoretical basics are taught in lectures and then expanded upon using virtual patients is also commonly seen; this gives students the opportunity to apply acquired information without endangering real patients. The combination of learning platforms with systematic learning materials and virtual patients is also used in the preparation of practical clinical teaching; for example, in the *Klinische Fertigkeiten Online* (clinical skills online) project [64.31].

They can also be used for computer-based exams. This application is of particular interest considering

the workload placed on faculties to test and mark the abovementioned 34 subjects. Computer-based exams, for example those using a key feature approach, can be used to conduct valid and reliable exams using a justifiable amount of resources. The medical profession is particularly interested in such approaches that would enable formative exams using virtual patients to be taken alongside summative exams.

However, the technical and legal risks of computer-based exams should also be mentioned; for example, those associated with browser-based and client/server-based exam systems [64.32]. Special consideration must therefore be given to these aspects during development.

Lastly, learning and teaching systems are used in the area of medical CPD, as medium- to long-term residential stays in educational institutions are often neither desirable nor feasible. This is supported in Germany by the introduction of a duty to perform CPD as part of the Law on the Modernisation of Healthcare (GMG). However, there are a multitude of professional development opportunities on offer, some of which are available free of charge due to support from specialist medical publishers, medical associations or the pharmaceutical industry. This may be an obstacle to the spread of learning and teaching systems, should these be offered for a fee.

64.6 Status of and Outlook for e-Learning in Medicine

64.6.1 Information Systems for CBT/WBT in Medicine

There are a wide variety of CBT/WBT systems in medicine, as research on specialist information systems has shown. *KELDAmEd* [64.33] at the University of Mannheim lists over 1200 learning objects, for example. The *Medical Learning Resource Server* of the University of Essen [64.34] currently enables users to search through over 1900 free, web-based learning objects. One problem with such information systems is ensuring that the underlying database is up-to-date. Achieving an objective evaluation of the systems on offer can also be difficult. To simplify the evaluation of systems, the working group *Computer Supported Learning and Teaching Systems in Medicine* [64.35] from the Society for Medical Informatics, Biometry

and Epidemiology (GMDS) [64.36] has published quality criteria for digital publications in medicine [64.37]. These have been translated into various languages. The working group, which has existed for 20 years, has set itself the aim of coordinating development projects in the medical profession and improving the quality of CBT/WBT systems.

64.6.2 Use of CBT/WBT Systems in Medicine and the Problem of Curricular Integration

CBT/WBT systems are currently used by only approximately 5% of medical students, according to the experiences of various universities. In this context, the results of a study conducted at the University of Bern in 2000 are interesting. In this study, over 75% of the peo-

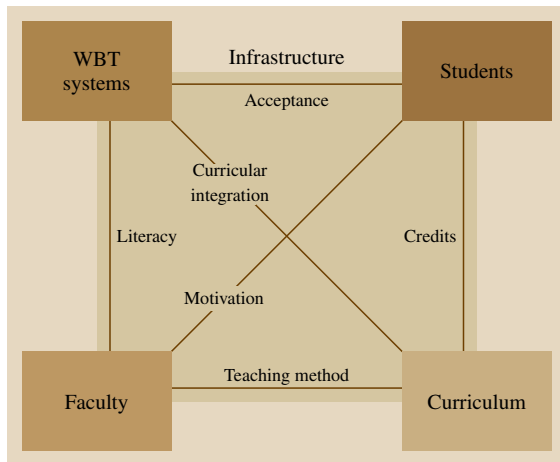

Fig. 64.6 Dependencies in the use of e-Learning

ple questioned preferred studying without a computer, and 90% of all students studied predominantly using printed media. A study from the Ludwig-Maximilians University Munich showed that almost all students completed the CASUS case studies on offer as long as they gained credits by working through the cases, so that they were relevant to the exam results of the students. When no credits were available, only about 10% of students used the case studies. This means that curricular integration of CBT/WBT systems is very important. Increasing acceptance amongst both students and tutors will continue to be a pivotal task in the future [64.38]. In particular, successful curricular integration depends on a suitable combination of CBT/WBT systems with face-to-face teaching and exams [64.39, 40]. In these circumstances, the systems are accepted and intensively used by the majority of students.

It is often argued that the reason for the lack of acceptance of these systems is that insufficient attention is paid to the risks associated with the development and application of CBT/WBT systems. The technical risks of developing a system (are we building the product right) and the application risk in particular (are we building the right product – one that is needed by users?) must be considered.

Even today, a negative attitude to computers can occasionally be encountered amongst both students and tutors. A lack of skilful handling of such systems by tutors and a lack of identification with the system hinder student motivation and student acceptance of the system. It is important to realise that tutors, especially those with active clinical duties, have very high workloads. Therefore, the question of how to get and keep doctors

involved in innovative teaching is a central issue. In this context, established instances of tutor training should be mentioned, for example those that have been conducted at the University of Heidelberg for many years. Career progression towards a Master of Medical Education is also increasing in importance. Upon attaining such qualifications, tutors will possess the relevant system skills needed for the integration of CBT/WBT systems into the curriculum (Fig. 64.6).

Curricular integration only is achievable when the system contains learning incentives for the students; for example, by enabling preparation for faculty internal assessment using CBT/WBT systems [64.13].

One possible way to improve sustainability is to maintain the positive experiences gained in cross-regional cooperation to date. This includes establishing competence centres for medical education, such as those that provide e-Learning and examinations in Baden-Württemberg and Bavaria, which contribute to tutor qualification and sustainable cross-faculty networking across inner-German state borders.

Only when the problems associated with curricular integration have been solved can the vision of creating more flexible learning, reducing costs, and improving quality through the use of CBT/WBT in medical education be achieved. An obligatory national catalogue of learning targets is required to support the long-term, cross-regional establishment of CBT/WBT systems in medical training.

64.6.3 The Need for Research, and Outlook

The current state of research suggests that e-Learning and traditional methods of instruction in medicine have similar levels of effectiveness [64.1]. It has been possible to clearly show that CBT/WBT systems offer advantages in the provision of standardized teaching materials and in communication between students and tutors [64.41]. However, such studies find it difficult to perform methodological comparisons between e-Learning and (for example) face-to-face teaching, because it is difficult to control distorting factors in real-life learning situations. In addition, offers of instruction that differ in numerous ways and could be offered in a more harmonized fashion in the sense of BL are compared. In many studies, offers of e-Learning have been introduced in the last few years and compared with control groups who did not receive offers of instruction. In such cases, it is not surprising that e-Learning intervention proved to be better than no intervention. This type of study can be suspected of triviality and usually

dispensed with, as one does not take an either/or approach in real teaching [64.42]. The use of the internet has been part and parcel of everyday life – including teaching – for some time now, and CBT/WBT systems are now commonly used at almost all academic institutions. In the future, studies that compare the different e-Learning integration models would be desirable, as the specific strengths and weaknesses of the e-Learning approaches offered in various educational facilities are still not clear [64.41,43]. A stronger theoretical grounding for future studies would also be desirable, as it would require more intensive cooperation between the medical profession, educationalists and psychologists. There are a plethora of research questions surround-

ing the foundations of case-based learning, clinical decision-making, cooperative learning in groups and inter-professional learning. In addition, the development of innovative, computer-supported formative and summative exam formats should be at the forefront of additional research efforts. Support for workplace-related evaluation methods could become increasingly important. Many technical challenges in the development of CBT/WBT systems have been surmounted in the last few years. However, there are still important topics (particularly interoperability and standards) that need further work to facilitate the exchange and technical integration of content across universities, which was created with considerable effort.

PACS and RIS

Christian Zapf, Andreas Bermann, Dirk Sunderbrink

The digitization of radiographic imaging has been implemented for all diagnostic procedures in radiology, and digital reading has been accepted by the radiology community. Simultaneous establishment of a uniform and robust communication standard for the exchange and storage of image data (DICOM – digital imaging and communication in medicine) has long fulfilled the prerequisites for the introduction of picture archiving and communication systems (PACS) and radiology information systems (RIS). In industrialized countries, the market penetration of both systems is between 60% and 95%, depending upon market segment and type of service provider. PACS, conceived more than 20 years ago, enables image communication between individual components such as archive systems, diagnostic workstations, postprocessing workstations, and image distribution workplaces. Typically, a RIS comprises a series of software modules supporting radiology workflow such as creation of orders, scheduling, reading, reporting, medical coding, recording of services, and interfaces to a billing system.

A typical RIS/PACS configuration is illustrated by Fig. 65.1. RIS and PACS are the information technology (IT) cornerstones of a radiology department. Nowadays, both systems are jointly deployed and closely integrated. Connection to a higher-level hospital information system (HIS) is typically facilitated through communication servers which link various IT systems together by means of an additional medical data standard, HL7 (Health Level 7 [65.1]). On the one hand, this enables interfacing of RIS and PACS to electronic

patient records (EPR); on the other hand, it supports the medical workflow beyond the boundaries of radiology department. In the future, the rapid growth of data volumes produced by imaging systems will require integration of advanced applications for 3-D/4-D postprocessing (frequently referred to as advanced visualization) and computer-aided diagnosis (CAD) into the radiological workplace in order to provide efficient reading and reporting. The establishment of communication standards on data level is still insuffi-

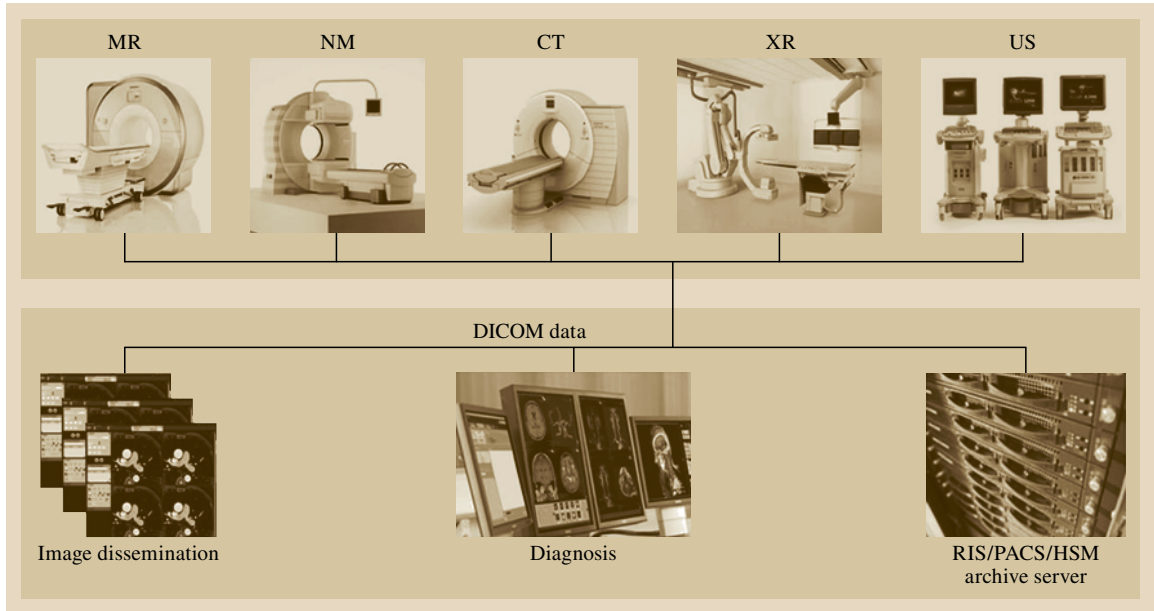

Fig. 65.1 Typical RIS/PACS configuration

cient for the optimization of a clinical workflow. As a result, the Radiological Society of North America (RSNA [65.2]) inaugurated the IHE initiative (Integrating the Healthcare Enterprise [65.3]). IHE has the objective of defining integration profiles according to standardized workflow scenarios, in an effort to validate different multi-vendor software and hardware components.

In the meantime, PACS has gone beyond the boundaries of radiology and has developed into an application for the entire healthcare enterprise. Other clinical departments such as cardiology, neurology, radiotherapy, and most recently, pathology, want to take advantage of digital image management to store their image data in a PACS archive while enjoying similar support for their respective workflows. The individual disciplines vary in the degree of IT system utilization for image data management. However, there is a trend toward standardization of the image data archive beyond departmental boundaries in order to minimize the expenditures for

procurement, installation and maintenance of the systems, as well as to realize economies of scale in data management. A significant potential for optimization of patient treatment lies in the routine application of digitally supported procedures for therapy planning such as in electrophysiology, radiotherapy or computer-aided surgery (CAS), using digital image data from PACS as a planning base.

Innovations in imaging and the rapid growth of image data volumes require support of diagnostic radiology procedures by appropriate information technology such as PACS and RIS. A state-of-the-art multi-slice computed tomography scanner produces up to four thousand slices per procedure. With this amount of data, analog reading using film on a light box is impractical and there is the risk of missing diagnostically significant findings. In the following chapters, the reader will be provided with a description of the individual work steps regarding film- and paperless radiology.

65.1 Radiological Workflow

Optimization of the clinical workflow is the objective with the introduction of RIS and PACS. The focus is on improving quality and reducing cost. This can be

achieved only by a seamless interaction of the individual components. A typical workflow (Fig. 65.2) will illustrate the functionality of the individual workplaces.

Fig. 65.2 Radiological workflow

65.1.1 Orders

A referring physician decides whether a radiology procedure is required for further treatment and orders this from the radiology department.

There are three conventional order scenarios which are to some extent used in parallel. First, orders are transmitted even today via paper, fax or telephone; second, many RIS systems provide their own electronic order modules which may also be web-based; third, many hospital information systems (HIS) offer corresponding order modules CPOE (computerized physician order entry). The advantage offered by this functionality within an HIS module is the uniform application within an enterprise. In scenario three, for example, a hospital has only one module in which a request is generated and transmitted to the connected departmental systems in HL7 format, whereas in scenario two various request modules must be used (one each per departmental information system).

If orders are not transmitted electronically, the relevant data (e.g. patient information) must be manually entered into the RIS. In each case, it is important that the clinical problems as well as the transmission of additional information such as contrast media allergies or laboratory values are as complete as possible in order to plan subsequent activities properly.

65.1.2 Admission/Scheduling

The quality of scheduling determines process efficiency in a radiology department to a large degree. It includes scheduling schemes, allocation of resources to procedures (e.g. rooms and personnel) as well as short-term adaptation to unplanned events that are common in medical care (e.g. emergencies).

Just as with orders, scheduling processes can be configured and supported in different ways by IT. Most simply, appointments can be scheduled by radiology department employees similar to managing an appointment book. Some RIS allow a person placing an order to personally choose an appointment from a selection of date and time slots. In case of further automation, a RIS can independently suggest the

next convenient appointment based on preconfigured rules.

In the next step, resources are allocated to appointments depending upon the type of procedure. In almost all cases, a room with relevant equipment will be required (e.g. a MR scanner in a specific room). Often additional equipment and material (e.g. anesthesia equipment, contrast agents, consumables, etc.) and personnel are required. Therefore, multi-resource scheduling is called for, frequently requiring IT support in the RIS.

Daily planning must respond to unscheduled events such as emergencies, urgent examinations or protracted procedures (e.g. repeated respiratory artifacts in the MR). Since such events occur regularly, most RIS offer simple options for rescheduling, shifting examinations to other rooms or even the inclusion of buffers in scheduling.

Usually the ordering department receives confirmation of the scheduled appointment. Depending upon the level of HIS/RIS integration, a referring physician can track the current status of a patient in a radiology department from the workstation on his desk. A physician can see whether the patient has arrived in radiology, whether the examination has started or whether images or reports are available.

As soon as procedures are allocated to a specific imaging system (modality), the RIS generates a DICOM worklist which is queried by the modality from the RIS. As a result, the querying modality is automatically provided with the most important patient and procedure data. Depending upon the type of archive, RIS and PACS can be configured in a way that a patient's previous procedures are automatically de-archived from the long-term archive, and relevant prior procedures are available for further diagnosis (pre-fetching).

65.1.3 Examination

A DICOM worklist is queried by a modality from the RIS and transferred to the local worklist of the imaging modality. The patient is selected at the modality and the procedure is started. Electronic transfer

guarantees the consistency of patient data. Procedure information such as type, starting time and duration, as well as additional information are registered by the modality and returned to the RIS in the DICOM format MPPS (modality performed procedure step). The MPPS data is also transmitted to the PACS, and additionally, the modality sends the study to the PACS for archiving. Transfer of images to the PACS is primarily performed in the standardized DICOM format, which is designed for manufacturer-independent data exchange between modalities and RIS/PACS. In the current 3.0 version, DICOM defines not only image formats; it also covers transfer protocols and regulates security requirements. The following services, among others, are supported:

- Archiving and transfer of images over networks (DICOM standard, parts 7 and 8)
- Archiving and exchange of images via exchangeable media (DICOM standard part 10)
- Search functions (DICOM query)
- Print functions (DICOM print)
- Workflow functions (DICOM modality worklist, modality performed procedure step)
- Image data compression (DICOM standard part 5, e.g. JPEG, JPEG2000, RLE)

DICOM conformance statements exist for most medical imaging devices. These documents describe the supported DICOM services and provide the basis for multi-vendor image data exchange. At the end of a procedure, an employee of the radiology department additionally enters on the RIS workstation which radiological services were performed and if applicable, information like the contrast agent and catheters used. The data for charge capturing and consumption of high-quality medical devices are especially relevant for medical documentation and billing.

65.1.4 Reading Workflow

Typically, the reading workflow is driven by the RIS. It prepares worklists with completed procedures and those designated for reading. The physician selects the relevant patient together with the procedure and the RIS initiates the display of the current image material and if applicable the prior procedures within the PACS viewing application.

For complex procedures requiring postprocessing, numerous specialized postprocessing applications are

currently available to support and expedite the reading workflow, generating additional valuable diagnostic information. Further, a division of labor between technologist and physician is possible, in which a technologist prepares the image postprocessing from his own worklist and then upon completion, sends the case to a physician's worklist.

Once the analysis of the image material is completed, a diagnostic report is created in the RIS. Frequently the reading physicians work in a multiple-monitor environment (with up to four monitors), simultaneously displaying images and report. After completion of the report both images and report are distributed and archived.

65.1.5 Displaying and Evaluating Images

The first PACS workstations were primarily developed for working with conventional x-ray images. Reviewing images in segments on a monitor, similar to a traditional light box is still in practice. In the meantime, size and shape as well as number and arrangement of segments for image display are generally freely configurable; frequently the corresponding layout configurations can be automatically assigned by a PACS on a procedure-specific basis during loading (DICOM hanging protocols).

Operations to adjust image quality such as brightness, contrast, etc. as well as simple image manipulations such as zoom, pan, rotate, edge enhancement, smoothing, paging through slices, cine mode, etc. are now available at every PACS workstation. Since the diagnostic information of the images can be significantly affected by these adjustments (frequently the images can only be interpreted after adjustment) there is a separate DICOM standard for long-term storage of the changes in the archive (DICOM softcopy presentation state).

In order to perform objective and reproducible measurements for quantitative analysis of tissue structures based on image data, a number of basic functions are offered, such as distance, angle, and volume measurements.

65.1.6 Image Postprocessing

Image data volumes are increasing rapidly, especially in the context of CT and MR examinations. Diagnosis of such complex procedures alone using the tools described above is no longer practicable due to time and

quality constraints. As a result, a number of specialized postprocessing applications have been developed, introducing a completely new paradigm of radiology reading.

The basis for most postprocessing applications is a three-dimensional reconstruction of the two-dimensional slices. Various mathematical operations interpolate the image information between the slices. Reconstruction results are dependent on the slice thickness of the original data. Thinner slices typically produce better results. The most frequent reproduction modes are MIP (maximum intensity projection), MPR (multiplanar reconstruction) and VRT (volume rendering technique) as well as their derivatives (refer to Table 65.1).

MIP is frequently used to display contrast-enriched vascular structures in CT and MR angiography. MPR allows display of clip planes not acquired with the original data (e.g. coronary and sagittal in addition to the axial planes). VRTs show reconstructed objects such as the heart, skull or skeleton, as well as more complex reconstructions such as the colon.

In case of functional examinations such as cardiac ventricle function in MR and CT or functional magnetic resonance imaging (fMRI), the time dimension is critical. A number of postprocessing applications have been developed to add the fourth dimension of time to the evaluation. Image data of different modalities can be merged, resulting in additional diagnostic information. PET-CT examinations are a prime example in which the sensitivity of the PET (positron emission tomography) is combined with the morphological accuracy of CT. This allows, for example, tumors or metastases to be evaluated more precisely. In addition, special measurements, evaluation and automation algorithms have been developed for numerous diagnostic problems.

In recent years, bundling all these options into advanced visualization has inspired a number of modality and PACS vendors as well as new vendors specializing in this area to develop tailored postprocessing applications for dedicated diagnostic problems. The

following list offers a selection of commonly used applications:

- CT calcium scoring
- CT coronary artery analysis
- CT and MR angiography
- CT and MR neuro perfusion
- CT cardio perfusion and ventricle function analysis
- MR cardio perfusion and ventricle function analysis, including late enhancement
- PET-CT oncology including automated compare layouts and lymph node comparisons
- CT neuro DSA
- fMRI
- MR tractography and DTI (diffusion tensor imaging).

Significant progress has been made in the development of postprocessing applications, an area currently receiving significant research and development funding. This trend has the potential to fundamentally change radiology reading, moving away from pure analysis of two-dimensional images to specialized applications tailored to specific diagnostic problems, providing anatomical, morphological, quantitative and functional results. Two essential advantages become obvious: first, this will yield a multitude of previously unavailable but relevant diagnostic data. Such data will allow more precise diagnoses and will increase the sensitivity and specificity of imaging procedures. Second, increased automation will reduce the cycle time for more extensive diagnosis such that it will eventually require less time than traditional diagnosis. The latest generation of postprocessing applications is achieving this through an extensively automated, clinically useful combination of postprocessing steps. A CT coronary artery analysis, for instance, is typically prepared in six steps in which various algorithms are applied:

1. Selection of appropriate series for reconstruction analysis (*best cardiac phase*)
2. MPR and VRT reconstruction
3. Removal of bone structures
4. Removal of lung and soft tissues
5. Removal of the blood pool (large vessels adjoining the coronary arteries and blood-filled ventricles)
6. Analysis of the center lines of the coronary arteries.

State-of-the-art postprocessing applications can perform these steps automatically, sometimes completely

Table 65.1 3-D postprocessing methods

Method	Applications
Maximum intensity projection (MIP)	Angiography
Multiplanar reconstruction (MPR)	Display of selected planes from a volume data set
Volume rendering technique (VRT)	Display of surface structures from 3-D data sets

Fig. 65.3 Example of a clinical post-processing application

without manual interaction. After calling up a procedure in his worklist, the reading physician receives the procedure fully analyzed, and can start reading immediately. Also during subsequent diagnosis, the reader is presented with relevant evaluation tools specific to a procedure. Thus, with just a mouse click, a vascular structure can now be displayed in a *curved planar MPR view* for stenosis evaluation; this view shows the longitudinal slice of the blood vessel along the selected section. Automated stenosis quantification is also considered a standard instrument of vascular analysis. Figure 65.3 illustrates such an application.

Postprocessing applications have developed to a point that they are increasingly used in clinical routine. The traditional distinction between image display, evaluation and postprocessing will disappear. In the future, a radiologist will be provided with clinically useful evaluation applications tailored to answer diagnostically relevant questions.

65.1.7 Computer Aided Diagnosis (CAD)

CAD applications (computer-aided diagnosis, sometimes also called computer aided detection) go one step further. The reading physician is not only provided with customized, largely automated tools; CAD algorithms additionally examine image material autonomously with respect to a clinical question. An attempt is made to identify suspicious structures and present them to the reading physician for assessment

and evaluation. Since CAD applications are significantly involved in supporting a diagnosis, they are assigned the highest risk level by regulatory authorities. As a rule, CAD applications must be validated by clinical studies following the GCP standard (good clinical practice) before regulatory approval is granted. There are currently a number of approved CAD applications commercially available, e.g. for detection of pulmonary nodules, microcalcifications in breast cancer as well as polyp detection in CT colonography. CAD applications have great potential to improve diagnostic quality, especially in the area of screening and early detection, where they might be able to significantly reduce the rate of false negative as well as possibly false positive findings.

Image postprocessing procedures and CAD make it especially clear that the potential of PACS extends well beyond image communication and the simple display of DICOM images. Ultimately, product differentiation will happen through the combination of clinical and IT know-how since the development of these applications requires not only IT knowledge, but also detailed expertise of image acquisition modalities and clinical interpretation of acquired data.

65.1.8 Medical Monitors

Images displayed on a monitor are the basis for radiological diagnosis as well as an information source for all subsequent therapeutic activities. The medical monitor is therefore the most important interface between digital information and the reading physician. For example, minimum requirements for medical monitors were established in Germany (consensus conference Halle 2001). These were subsequently more exactly specified in DIN 6868 Part 57 as well as in the Quality Assurance Directive. Röntgenverordnung § 16 requires an operator to perform acceptance testing prior to using monitors in a productive environment as well as consistency tests at regular intervals.

65.1.9 Report Creation

Once a radiologist has processed and analyzed the image data, a diagnostic report can be created directly in RIS. There are various methods for generating a report:

- The radiologist enters the diagnosis as free text into the RIS.
- The radiologist uses text modules for efficient creation of normal reports and expands the report using manually entered text.

- The radiologist dictates the findings which are later transcribed by a human operator or directly converted to text by a speech recognition system.
- The radiologist creates a structured report. With this method, the findings related to a procedure are set out in the form of values and tables. An advanced reporting system can generate clinically useful text while retaining structured information. This type of reporting is gaining importance especially with regards to more complex procedures (e.g. cardiac examinations). DICOM is providing services to standardize these reports (DICOM Structured Reporting).

Once a diagnostic report is written, it must be checked and approved by a reading physician directly or by a resident/senior physician. Only then can a report be distributed and archived as an electronic document.

65.1.10 Clinical Demonstration

During diagnosis, a radiologist can tag relevant images, identify findings using arrows, circles, etc. and correlate the cases with different clinical case demonstrations. According to this demonstration worklist, procedures can be opened on the target system in their entirety, or only with significant images; in most cases they can be displayed on a screen using a projector. During clinical demonstration, prior findings and images can be quickly accessed from the PACS. Electronic preparation of the

clinical case demonstrations is efficient, saves time, and sometimes the results can only be presented in this way (especially the results of postprocessing applications).

65.1.11 Distribution of Reports/Images

The rapid distribution of results to referring physicians as the final step of a radiological workflow is an important component of the process, influencing the overall efficiency of a clinical workflow. Referring physicians must have timely access to results. In order to achieve this, image data and findings must be accessible from the HIS workstation. Technically, referring physicians can be provided, for example, with web-based access to patient or procedure data of a radiology department. Using a web browser, a referring physician can call up radiological images and view the corresponding report. The physician's access to all images or only the most relevant can be configured, as well as the image quality. In order to reduce network load as well as access times, compressed images can be displayed. It is important that a physician can retrieve the correct images in the context of the HIS workstation. Therefore integration of radiology department IT into higher-level hospital IT system is essential.

In order to display data at a workstation where it is required for a defined treatment activity, special PC systems and input devices are needed. This is relevant for example in operating theaters where sterile or OR-compatible units are required.

65.2 Integrating PACS/RIS into the Hospital Environment

A health care system without comprehensive digital information generation, storage, processing and distribution is almost not conceivable anymore. Among other things, modern information systems support the organization while enhancing cost and performance transparency both within and outside the hospital. In order to support comprehensive workflows while avoiding redundancies, it is essential that existing information and image management systems are integrated. The health care standards DICOM, HL7 and the IHE interoperability model support and foster this integration.

65.2.1 Integrating Information Systems

The intensive interdisciplinary collaboration within and outside a hospital requires access to all relevant and available patient and case data beyond departmental

boundaries. Communication problems and risks can be reduced through reliable integration of different information systems and embedding them into the workflows of the respective service providers. Typically the electronic patient record (EPR) offers a comprehensive entry into related patient and case data, and is the guiding system in a hierarchically structured data model. Departmental information systems (e.g. radiology, cardiology, or laboratory) primarily provide data while assuming a secondary position with respect to data hierarchy.

This process-oriented horizontal integration of different departmental information systems with an electronic patient record would be inconceivable without the continuous update of standards such as DICOM and HL7 and interoperability models such as IHE.

In addition, the integration of data from different information systems and the related comprehensive view

offer the possibility of a systematic analysis to improve business and clinical process (business intelligence).

65.2.2 Integrating Image Management Systems

In addition to radiological or cardiological images in DICOM format, state-of-the-art image management must be able to manage non-DICOM files using, for example, PDF, video and audio formats. The purpose of such a system is the acquisition, structuring and information life cycle management of heterogeneous data records as well providing these records with a very high level of accessibility and performance to all departments and physicians without respect to geographic or time-related limitations. The primary challenge for an image management system is efficient management of extensive volumes of image data.

Data management based on standards assures that image data and other documents can be stored long-term without limitation. Vendor-neutral archives (VNA) provide these functionalities and typically consist of three basic components:

1. A storage subsystem,
2. A standardized interface for data management,
3. A database indexing all storage content and changes to content.

A VNA is a common resource providing data to all IT solutions within and outside the hospital, and should meet the following requirements:

- It must be able to exchange images and diagnostic findings using the DICOM standard with clinical and PACS systems.
- It must contain interfaces that can exchange data with hospital information systems and other IT systems using the HL7 standard.
- It must be able to store all DICOM formats (including all DICOM SOP classes).

65.3 State-of-the-Art IT Infrastructure

During the definition of state-of-the-art hospital IT infrastructures, the following points require special attention:

- Scalability of the architecture from a small to a potentially regional solution

- It must also offer the option to store proprietary data formats (non-DICOM) such as pathology image data.

65.2.3 Teleradiology

Clinical examinations or diagnoses of various disciplines such as radiology, cardiology or pathology do not necessarily take place within a hospital, but can be performed by other service providers (e.g. specialists or laboratories). Generated data is transmitted to a service provider (e.g. for diagnosis, second opinion) in encrypted form. Integration of information systems and use of telematic processes allow virtual collaboration and provision of services. The physical boundaries of a hospital can be overcome taking into account any individual legal requirements for tele-applications, and new services can be offered. Authentication and authorization (who can access which data and when), as well as secure, encrypted transmission are essential for these applications.

65.2.4 Mobile Devices

Web-based software technologies combined with mobile devices offer the ability to ubiquitously access medical image and diagnostic data. Required data can be displayed, for example, in emergency situations or during patient consultation. The data formats range from simple text documents through medical images to video recordings. Thus a physician, for example, can access relevant data and supplement it, thereby significantly reducing the response time for treatment. In addition, there are no longer media discontinuities, and data does not have to be stored or copied multiple times. The exact utility and long-term significance of mobile devices to clinical daily routine has yet to be determined. The assessment and classification of mobile devices by national regulatory authorities are still in initial stages and will influence the application scenarios of these devices.

- Consideration of data security, data consistency and a high degree of data availability
- Compliance with standards for integration of heterogeneous applications and IT systems by different manufacturers for a comprehensive solution without frictional loss at the interfaces

- Modularity of the IT infrastructure to replace or update individual components without disrupting ongoing operations.

65.3.1 Information Lifecycle Management

Data management is an important component of a modern IT infrastructure. Management of image data from acquisition through archiving is a complex process addressed with various technologies to assure data availability, security, redundancy and continuity:

- Short-term storage: Depending upon configuration, it contains examination data of the least 3–12 months. Data can be accessed rapidly. Provision of data is via failsafe storage systems (e.g. RAID).
- Long-term storage and backup: Depending upon legal requirements, data must be archived up to 30 years and must be returned to accessibility within an appropriate time frame. Regular data backup is required in order to restore the original data in the event of loss (disaster recovery).

Commercially-available hierarchical storage management systems (HSM) offer the described data management functionality and additionally provide users the ability to migrate data transparently across different media.

65.3.2 Cloud Computing Solutions in the Hospital

Cloud computing (highly-scalable IT infrastructure making applications available, which can be billed after use) represents a paradigm shift for information technology in a hospital. This especially applies to information systems and image management solutions. Access to available data is via the Internet, and can be performed from any workstation world-wide. Thus clinical applications are no longer executed locally, but are made available via the cloud, and accessed there. Users only need a secure Internet connection in order to access the applications and associated data.

The achievable costs savings represent the most significant advantage for hospital IT managers. Fixed costs, previously generated by a separate IT department, can be transformed into variable costs. A hospital or individual departments such as a radiology department only need to pay for the actually required infrastructure and services, thus adapting the costs to the demand.

The possibilities offered by a cloud also play a significant role for the expansion of cooperation among service providers. This development is shaped by an immense communication requirement among the partners. In its current structure, complex networks must be maintained in order to efficiently structure collaboration. Utilization of cloud computing can cover this need more cost effectively. A complex infrastructure does not have to be created, since all users can simply access the common applications within the cloud. The flexibility inherent in the system allows adaptations due to new partners or other modifications to be performed in a timely manner and without significant financial expenditure.

65.3.3 Regional IT Virtualization

One of the challenges in current healthcare environment is the multi-site and manufacturer-independent communication and exchange of data. Regional IT virtualization plays an important role in scenarios in which several hospitals and other service providers are networked via different RIS, PACS and other IT solutions in order to provide a smooth treatment path. In this regard the following core functionalities are relevant [65.4–7]:

- Global worklist: In a regional setup, radiologists must be able to access a consolidated global worklist without knowing the actual physical location of the relevant data. The global list is thus the sum of all individual worklists of the regional participating hospitals.
- Global access to image data: During the assessment of radiological images, each radiologist accepts all cases falling under his specialty. This is a result of filtering of the global worklist by specialty. Although the images and findings-related data are physically separated, a physician has access to the data. Interoperability models such as IHE XDS (cross-document sharing) define this data exchange.
- Access control and security: granular access rights and multi-entity functionality (support of several clients/independent organizational units within an IT system) are prerequisites for this type of regional IT virtualization.
- Master Patient Index (MPI): A MPI provides functionality in order to combine information from different sources (e.g. departments) under a common identity.

65.4 Summary

Today, radiology information systems and picture archiving and communication systems are established foundations for optimizing workflows within a radiology department. Integration of postprocessing applications in the diagnostic assessment process has the potential to essentially change the reading workflow and allows the increasing data volume to be analyzed more efficiently and with higher quality.

RIS and PACS should be firmly integrated into the entire IT infrastructure in order to achieve optimal utilization. This applies internally to the hospital as well as beyond (e.g. regional associations). This integration follows existing standards such as DICOM, HL7 and IHE.

Current IT trends such as cloud computing offer the possibility of reducing costs and complexity as well as scaling RIS and PACS, dimensioning these according to demand.

66. 3-D Postprocessing in Virtual Endoscopy

Georg-Friedemann Rust

Virtual endoscopy is the simulation of endoscopic interventions using methods of virtual reality and computer graphics. Usually, three-dimensional (3-D) volume data from computed tomography (CT) scans, magnetic resonance imaging (MRI), 3-D ultrasound, rotational angiography or other sources are used to generate a 3-D view of the inside of the studied structures.

In recent years, the spatial resolution of cross-sectional computed tomography imaging has improved greatly. Imaging procedures allow more detailed representation of the organs of the human body. In particular, multislice computed tomography (Chap. 16) opens new opportunities in diagnostics based on its significantly increased spatial resolution and significantly shortened examination time. This improved spatial resolution in conjunction with high-resolution rendering

66.1 What Is Virtual Reality?	1210

References	1216

leads to much greater authenticity of all examined body parts. The high spatial resolution of multidetector computed tomography (MDCT) combines this with a remarkable increase of the amount of data that can be assessed.

The standard method of diagnostic imaging assessment based on analysis of axial slices is reaching its technological limit. Use of more than 1200 axial cuts is no longer a rarity with current CT scanners (2×64 detector rows or more), and the demand for alternative three-dimensional visualization techniques is increasing with the number of axial images assessed. For certain examination types, such as for hollow body organs, 3-D visualization is increasingly becoming the standard method of diagnostic assessment.

This is especially true for the intestine, and generally for hollow body organs where characterization of the cavity is becoming difficult by a significant change in physical density, such as in bronchoscopy or colonoscopy, particularly for endoluminal endoscopic views. This approach can be easily generalized for

visualization of any 3-D surface. This approach can also be extended from endoluminal to extraluminal views, as in angiography, which is described as a possible future application at the end of this chapter.

The problem that often arises in 3-D visualization is the difficulty faced by the viewer in assessing the accuracy and relevance of the presented 3-D surfaces, as reality is only partially reproduced. The relevant questions are then: How authentic is the 3-D surface? What is the *best representation* of the 3-D surface?

In the reconstruction of a 3-D surface, a decision has already been made regarding which part of the dataset is considered. A correction based exclusively on the underlying 3-D surface is very limited and will not solve the inherent limitations of 3-D visualization.

The requirement is therefore to represent the *real* surface in the optimal way as a digital 3-D surface.

66.1 What Is Virtual Reality?

Reality can be represented through a corresponding physical measurement of a physical property, for instance, the physical density in computed tomography imaging (CTI). The real object is not represented in its diverse forms, but only by what we hope will be its most representative physical property. Therefore, very often the choice of this physical property will be a compromise in the corresponding visualization. It is crucial that the choice of this physical property correspond as far as possible with the needs of the application under consideration. In the case of (multidetector) computed tomography (CT), the physical property represented in the visualization is the spatial (digital) distribution of the physical density values of a given cross-sectional cut of the examined body. Based on this digitized density

distribution, the (reduced) reality can be examined in three dimensions through stunningly realistic modeled images, so-called *virtual reality* (Chap. 63).

Virtual reality is a kind of simulation. Depending on the task at hand and the target of the simulation, virtual reality can be adapted to the given application. This provides an opportunity, and at the same time a risk. This is exemplified by the task of visualizing the 3-D endoluminal intestinal surface either as a stunningly realistic view as in optical endoscopy or as an authentic view. This can lead to distinct forms of visualization.

One therefore has to differentiate between the creation of images for medical assessment, where the focus is on authenticity, versus the creation of images as a kind of *modern art*.

66.2 Why Virtual Reality?

The power of virtual reality in cross-sectional imaging is based on its ability to reduce hundreds, if not thousands, of axial cuts into one 3-D volume dataset. This enables assessment to be much more intuitive. In 3-D, topographic relations can be identified more easily, quickly, and safely, which enables interventional therapies to be planned, and prepares the interventionist for the actual situation in situ.

The risks of virtual reality have been briefly mentioned: A 3-D surface is always only part of the

dataset, although hopefully the *right* part, or rather the most relevant part for the current application. On the other hand, herein lies also the opportunity, namely the possibility to focus on a given region of interest of the dataset, although the question of what is the most *relevant* remains open. Even from this brief presentation, it is clear that virtual reality methods present both opportunities and risks, which also makes it difficult to provide general recommendations.

66.3 Advantages of 3-D Visualization

The key advantages of virtual endoscopic procedures are the following.

- Significantly improved spatial representation and understanding of the organ under analysis.
- Significantly longer observation time of the 3-D surface than for corresponding axial cuts. More precisely, the observation time per unit surface area is much longer than for corresponding two-dimensional (2-D) axial images. A detail of the intestinal mucosa (in virtual colonoscopy), for example, will be represented in one or two individual axial layers. Using three-dimensional methods, the observation time for such details is significantly in-

creased compared with the two-dimensional axial slices, because during the fly-through, one is able to observe small details for longer than in corresponding 2-D images.

- Systematic investigation of the considered hollow organ in 3-D, such as the intestine, which is much more difficult and needs a longer learning curve in 2-D than in 3-D.

As an example, consider moving through the intestine, so that all structures are moving for several seconds along the observer's line of sight (Fig. 66.1). The observation time per unit surface area is much longer than if the corresponding

Fig. 66.1 An intraluminal virtual representation of the intestine. In a fly-through, the voxels corresponding to each detail remain in view for several seconds, which is much longer than in exclusively 2-D observation

2-D layers were considered separately. This significantly increases the physician's viewing time per unit area of mucosa surface based on the use of the 3-D surfaces available in virtual endoscopy. It is well known that the detection rate of pathological findings depends significantly on the observation time.

66.3.1 Partial Volume Effect

One of the main advantages of 3-D surfaces in comparison with 2-D surfaces is the ability to present the dataset almost free of partial volume effects. More details will be described in Sect. 66.3.2. The *partial volume effect* occurs when grey-scale values in a single axial 2-D slice of finite thickness (from CT, for example) are calculated from parts of different organs. The density value illustrated in the resulting image is then calculated not just from the density value of the given organ, but may also include density values from other organs or other parts of the organ in the same slice. This occurs when a particular organ is, along with other organs, only partially in the observed slice volume. In this case, the density value (gray value) of a 3-D pixel (voxel) in the CT slice is calculated as an average through the CT slice thickness. Therefore, another term for the *partial volume effect* is *contrast reduction*. Vice versa, visualization that is free of the partial volume effect results in high contrast. The thinner the slice thickness, the weaker the partial volume effect and the higher the resulting contrast.

66.3.2 Two-Dimensional or Three-Dimensional Visualization

The thicker the CT slice, the stronger the partial volume effect and the lower the contrast of the resulting slice image. However, 2-D images inherently suffer from the partial volume effect. In principle, 3-D surfaces can be visualized with a smaller partial volume effect than corresponding 2-D images (Fig. 66.2a), because the visualized dynamic range of the underlying images can be higher than with the standard radiological window level settings. The resulting higher contrast provides correspondingly higher detection sensitivity, particular for small structures such as flat adenomas. Figure 66.2 is an endoluminal view showing a *rough mucosa* (a combination of correlated noise from filtered back-projection and white electronic noise) that is only visible if one applies high spatial resolution in combination with high contrast. With this combination of high contrast (thin slice thickness and wide dynamic range of visualization) and high spatial resolution, the smallest lesions become much more visible than in 2-D images using the well-known *lung* window level setting. This extended image information content is correlated with higher sensitivity for artifacts, including noise. However, highly authentic 3-D visualization is required, and can be achieved through high-contrast images. Quite often, *good-looking images* are more of an issue than the authenticity of the acquired data.

The above-mentioned advantages of 3-D imaging are often negated by misunderstanding of the basis

Fig. 66.2 (a) A 3-D image containing a small intraluminal artifact, and the corresponding location in 2-D images suffering from the partial volume effect (in the *lower left* is the intestinal intraluminal represented cut in half – split colon). (b) The same location as in (a), but with a significant increase in the contrast of the 2-D images. The artifact in the large intraluminal representation (*bottom right*) is now seen as a small artifact in the 2-D images

for 3-D imaging: the use of 3-D imaging should not suggest that the virtual endoscopic view is a real endoscopic view. Creation of virtual views which look like real endoscopic views is only possible if either the 3-D organ surfaces are smoothed or the underlying visualization algorithm implements smoothing effects (simple volume rendering algorithms), or both.

In the case of computed tomography, the intestinal mucosa visible in a 3-D visualization is not the real intestinal mucosa but rather the CT of the intestinal mucosa, which is an important distinction from the point of view of a doctor. This means – and this also provides a simple method to verify the authenticity of the 3-D surface visualization – that all artifacts created by a CT must also be visualized in the reconstructed 3-D intestinal mucosa, including noise, beam-hardening artifacts, pitch artifacts, and edge phenomena. If such artifacts (Fig. 66.2) are not visible, the virtual mucosal surface should be interpreted with great caution.

All of these artifacts, particular memory defects resulting from the gantry, may not be visible in the 3-D surfaces, even when they are present in the original

dataset, either due to the smoothing algorithm (i. e., smoothing over nearest-neighbor voxels) or due to the use of an incorrect form of volume rendering in order to create *beautiful* images that suggest that the given visualization is identical to a real view of the intraluminal intestine, which is a false approach. *Virtual reality* should not manipulate the original measured data, particular if this would prevent relevant details from being found, as this will not be *reality*. Such forms of visualization almost reduce 3-D visualization to a computer game.

66.3.3 Risks of 3-D Visualization

Figure 66.3 shows how structures can be changed even if only a simple smoothing method is applied, such as smoothing over nearest neighbors. Surfaces may appear more physiological, but at the price of loss of both detail and authenticity (Sect. 66.1). The aim of visualization for medical assessment of a 3-D surface (endoluminal or extraluminal view) must be authenticity and not manipulation of images just to produce nice images with a *realistic* appearance. It is required

Fig. 66.3 Memory defect artifacts in an endoluminal view, resulting from memory failure of the CT gantry; the CT manufacturer and processing software cannot be displayed

Fig. 66.4 Effect of smoothing over nearest neighbors in virtual colonoscopy

Fig. 66.5 With a nonoptimal choice of transfer function for volume rendering (ray casting), the noise increases with a corresponding loss of detail of the diverticula (*right rectangle*) and the balancing appears on the right-hand side less pronounced

Fig. 66.6 Nonoptimal use of *diffuse lighting* can have a significant influence on the contrast of the 3-D surface under consideration

Fig. 66.7 Light absorption (*left*) focuses the attention of the viewer on mucus closer to the virtual camera

to assess the smallest artifact as well as the smallest pathology or anatomical variation. Authentic visualization is the only way to distinguish between artifacts

and nonartifacts, and the only way to ensure that the diagnosis is not distorted in order to achieve false esthetics.

Fig. 66.8 Color-coded depth information of a flat lesion

Figure 66.4 demonstrates the effect of smoothing on image quality – in this case not by smoothing over nearest neighbors, but by too flat a transfer function used in the volume rendering. Figures 66.5, 66.6 show the options and advantages that virtual reality may have. In the virtual endoscopic view on the right of this figure, it is possible to see far into the intestine lumen. Usually, one tries to achieve undisturbed vision in order to retain focus on the region of mucosa of importance for the current investigation. The subject of endoscopic observations are the findings for the mucous membrane components that are closest to the (virtual) camera. *Distraction* of the gaze into the distance can prevent this, and in this case can be avoided by applying absorption of light from further away, as shown in Fig. 66.6a.

Figure 66.7 shows the effect of false *diffuse lighting* in the volume rendering algorithm, resulting in loss of contrast and an associated loss of detail.

An interesting application of virtual reality is the use of a virtual view of 3-D surfaces represented not only by a single color or gray level but where depth information is presented through the use of a color map. Such coloring of 3-D surfaces reveals information beyond the surface itself, which may be even more relevant. Using this approach, color changes indicate changes in wall thickening, which is particularly relevant for virtual colonoscopy and is difficult to detect even using computer-aided diagnosis tools. The CT density value at a given depth underneath the intestinal mucosa can also be associated with a color

value (i.e., a temperature scale) and projected back onto the intestinal surface. In this way, one can identify relative wall thickening and features that are very difficult to detect, such as so-called *flat lesions* and hypervascularization of the mucosa of the cavity surface, which are highly relevant for intestinal pathology. An example of a flat adenoma is shown in Fig. 66.8.

Fig. 66.9 With a single virtual high-resolution view of the vessels of the cranial base, the aneurysm in the posterior supply area of the skull can be diagnosed quickly and safely, and also visualized for the therapist in a helpful presentation in the context of other topographical anatomical structures

Fig. 66.10 The combination of 3-D visualization with multiple CT datasets opens up further, highly relevant forms of visualization. To date, only digital subtraction angiography (DSA) has been developed. In this application, the benefits of DSA and high-resolution subtraction CT with 3-D visualization enable high-resolution views of vascular structures in the cranial base, opening up new diagnostic and therapeutic options ◀

The topics discussed above, especially the 3-D visualization methods with the highest spatial and contrast that are technologically possible, are not limited to endoscopic issues such as endoluminal visualization, but of course apply to all 3-D surface calculations, such as for extraluminal 3-D representation of organ surfaces as in vascular imaging, e.g., enhanced intravenous angiograms. Authentic representation of the surface is of particular interest in CT angiography because even the smallest caliber variation may be of medical relevance.

66.4 Conclusions

Virtual endoscopy using multidetector CT scanners and high-performance postprocessing software enables visualization of hollow bodies. Such 3-D visualization procedures are very quick, highly accurate in terms of spatial and contrast resolution, and completely automated, offering greater accuracy than conventional 2-D imaging methods that also suffer from partial volume effects. It is of great importance to learn to differentiate between authentic visualization solutions and just *interesting* images. Manipulation of 3-D surfaces for *pretty* views of 3-D surfaces, such as the intestinal mucosa or CT angiograms, is not a good foundation for virtual

reality. If anything, this only portrays a virtual (false) reality that is of no use in radiological routine. The underlying algorithms used in visualization have special importance, particularly with regard to the detectability of small lesions.

For further and deeper study we recommend [66.1–3], and practical experience based on the Visualization Tool Kit [66.4].

Further short and good examples can be found in the OpenGL Reference Books [66.5].

Not recent research but a good overview is shown by *Earnacao* and *Strasser* in [66.6].

67. e-Health – Ambient Assisted Living and Personal Health Systems

Natasha Avila, Christina Sampogna

This chapter focuses on the healthcare aspects of ambient assisted living (AAL) and the contributions that personal health systems (PHS) may bring. As part of these categories, this chapter examines the areas of self-management, tele-assistance, media and multimedia solutions, fall detection, robotics, bio-parameter monitoring, auto adaptive treatment systems, tele-therapy, tele-consultation, tele-surgical assistance, and smart homes. For each approach, the nature and purposes of the technologies will be examined and examples will be discussed. The chapter will subsequently address the benefits and the challenges ahead for AAL and PHS technologies within the broader context of e-Health. Finally, the chapter concludes with observations and trends.

Advances in information and computer technology (ICT) over the last half-century have led to many innovations crucial for the delivery of healthcare, including the emergence of e-Health. Within the context of e-Health, this chapter examines the contribution of ICTs to the fields of ambient assisted living (AAL) and personal health systems (PHS). Albeit in different manners, both AAL and PHS include products, processes, or services that can contribute to maintaining individuals within their home environment, while providing them with the support necessary in light of their conditions or pathologies. This chapter examines the areas of self-management, teleassistance, media and multimedia solutions, fall detection, robotics, bio-parameters monitoring, auto adaptive treatment systems, teletherapy, teleconsultation, telesurgical assistance, and smart homes. For each area, the nature of the technology, the purposes for which it may be used, as well as examples of developments are outlined. Technological develop-

ments occur within a social, societal, ethical, economic, and global context. This chapter examines the benefits of these technological developments and the challenges ahead for their development, adoption, and widespread use. It concludes with some observations and proposes some trends for future developments.

Health and healthcare systems are the product of a convergence of biomedical, social, technological, economic, ethical and political factors. The delivery of effective, safe and efficient healthcare services and products to patients is a challenge facing governments around the world. The nature and scope of this challenge has become more pressing over recent decades as the global population has grown and will continue to grow, as life expectancy has increased and will continue to increase, as the burden of disease has become better understood and has shifted, and as the costs of healthcare systems and services have become unmanageable in their current state.

67.1 Background

Many healthcare systems were developed during periods where the population they served was smaller and were designed in accordance with that population. In 1960, the world population was under three billion. As of 30 March 2010, the United Nations estimated the human population of the world to have been 6 800 000 000 in 2009 [67.1].

In light of these developments, the current healthcare system model is not sustainable for much longer. The 1980s policies of cost containment are arriving at their limits (wage control and price controls plus investments postponement) [67.2]. To maintain an equivalent healthcare level and availability, the health-related ex-

penditure would need to increase at a constant rate to cope with the geographical and nongeographical changes. As Fig. 67.1 shows, the total costs and expenditures on health have continuously increased during recent decades. Unfortunately, this increase in expenditures has not resulted in improved services. For example, extensive waiting times face patients in hospitals, in emergency rooms, and when seeing a specialist. In Canada, for instance, a recent study found that the total waiting time between referral from a general practitioner and treatment, averaged across all 12 specialties and 10 provinces surveyed, was 16.1 weeks in 2009 [67.4].

Moreover, other trends make the current models of healthcare systems unsustainable. The increasingly ageing population is also an important contributor to this nonsustainability. As Fig. 67.2 illustrates, by 2050 there will be significantly larger portions of the population who will be older than 65 years of age. Asia, Japan in particular, and Europe are the two regions where a significant number of countries face severe population ageing in the near future. In these regions, within 20 years many countries will face a situation where the largest population cohort will be those over 65 and the average age will be approaching 50.

This ageing of the population will result in many societal benefits. This demographical evolution also needs to inform the adaption of healthcare systems and services in order to offer effective, safe, and efficient healthcare services. As Fig. 67.3 shows, currently the

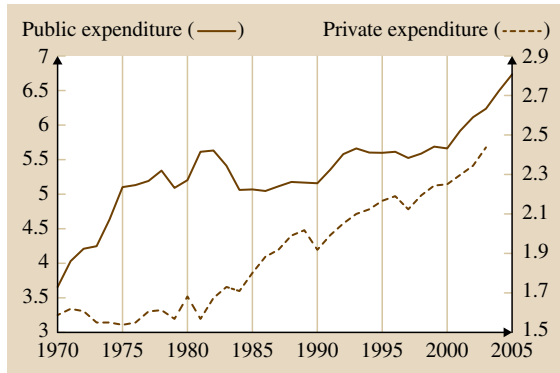

Fig. 67.1 Evolution of public and private OECD total health spending [67.1] as a percentage of GDP (after [67.2])

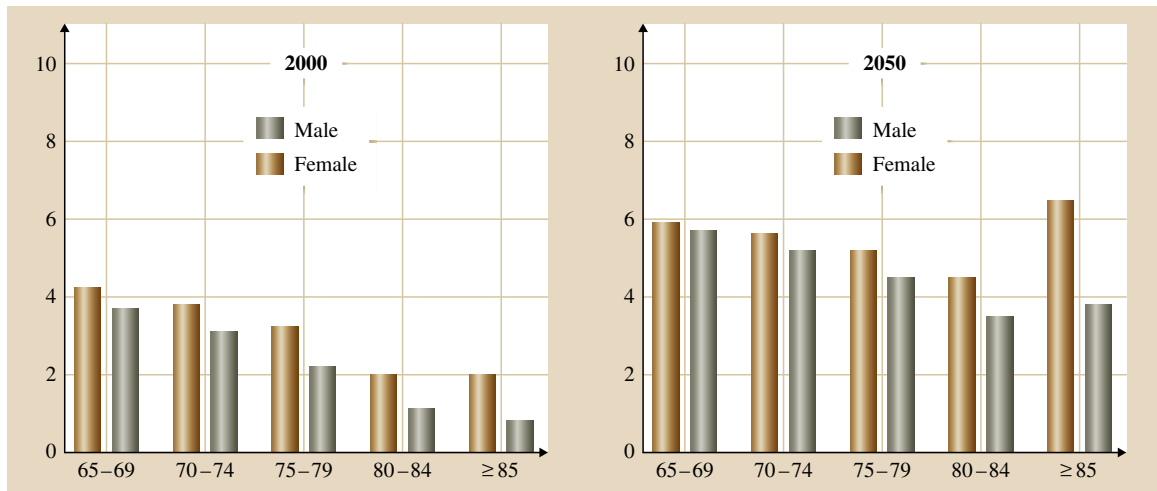

Fig. 67.2 Aging Forecast for OECD countries (after [67.3])

Fig. 67.3 Public healthcare expenditure by age groups as a percentage of gross domestic product (GDP) (after [67.2])

peak of the costs for healthcare services is for the portion of the population aged 75 years and older. The precariousness of the current system is compounded by the converse demographic phenomenon of the shrinking number of working adults. Currently, in Europe, there are 4 adults working to sustain each person aged over 65 years. However, by 2050, this number will decrease and there will be only 2 adults working to sustain each person aged over 65 years [67.5].

Another trend that is significantly impacting healthcare systems is the increased burden of chronic diseases. Chronic diseases are diseases of long duration and generally slow progression. Chronic diseases, such as heart disease, stroke, cancer, chronic respiratory diseases, and diabetes, are by far the leading cause of mortality in the world, representing 60% of all deaths [67.6]. In regards to those living with chronic disease, the statistics are also daunting. 860 million people worldwide suffer from one or more chronic condition. As of 2000, for example, 45% of Americans had at least one, and 23% had two or more chronic conditions. In Europe, chronic conditions account for up to 86% of all deaths.

67.1.1 e-Health

While no tool, process, or technology will address the multitude of issues currently facing healthcare systems, numerous phenomena are emerging that can contribute

to finding better and different solutions. One such field is that of e-Health. e-Health can be described as an overarching term used to describe the application of information and communications technologies in the health sector. It encompasses a whole range of purposes from purely administrative through to healthcare delivery. While there is no globally-agreed upon definition or categorization of e-Health, Fig. 67.4 presents a categorization of e-Health that has been developed and used within the European Communities.

This chapter will focus on the areas of e-Health referred to as ambient assisted living (AAL) and personal health systems (PHS). The European Framework Programmes have focused considerable attention on and have set aside considerable investment for the areas of ambient assisted living and personal health systems. The Framework Programmes (FP) are programs of the European Union with the mission of funding and encouraging research and applications around the EU's key research areas. The term *personal health systems* was introduced in the 1990s (and first introduced in the Fifth Framework Programme, FP5-1998), while the term *ambient assisted living* was first widely used in 2000. Although they sometimes use different nomenclature, other economies are also allocating considerable resources in the areas of AAL and PHS.

Broadly defined, AAL is the use of information and communication technologies (ICT) in a person's daily living and working environment to enable individuals

Fig. 67.4 The four components of e-Health [67.8]

Fig. 67.5 Ambient assisted living application environments [67.9]

to stay active longer, remain socially connected, and live independently [67.7]. As Fig. 67.5 illustrates, AAL adopts a holistic and person-centric approach to ensuring the well-being of the individual. In order to achieve this objective, AAL aims to address more than healthcare aspects. As such, AAL covers many aspects such as mobility, social interaction, hobbies, chores, etc.

From a healthcare perspective, AAL includes any product, process or service that can help directly or indirectly to maintain individuals within their home environment, while providing them with the support necessary in light of their conditions or pathologies. AAL solutions aim to stabilize or even increase the autonomy of the individuals, facilitate medical treatments, and monitoring from home, and/or ease the carrying out of day-to-day tasks. AAL solutions are based on the desire of individuals to remain within their home environments as long as possible and to delay their entrance into institutionalized environments. These approaches provide solutions for the elderly, for incapacitated individuals, individuals recovering from

a condition, surgery or a disease, or for individuals with cognitive, motor, or neurological needs.

Personal health systems may be considered to include wearable and/or fixed/portable systems, based on advanced sensors, microsystems, and telemedicine services for personal health monitoring [67.10, 11]. Some of the objectives that have been attributed to PHS include [67.12]:

- Detection of early signs of health status decline
- Notification of critical conditions to health professionals
- Improvement the sense of union within the family by sharing health information
- Identification of the interdependency between a person's health and their lifestyle
- Offering healthcare to remote, rural or doctor-deprived areas
- Bringing healthcare to developing countries
- Providing real-time multisourced reliable physiological data to health professionals.

The pressing need to develop and diffuse PHS technologies is their contribution to prevention, detection, diagnosis, monitoring and surveillance. For example, the European Heart Network reports that in Europe four

million individuals die from cardiac diseases [67.13]. With portable heart monitoring systems capable of automatically alerting a healthcare centre capable of immediate response many lives could be saved.

67.2 AAL and PHS Approaches

This section will explore different PHS and AAL approaches. PHS or AAL approaches will generally contain one or more of the following components:

1. **Data collection:** The element is in charge of collecting the image, video, sound, text, or measurement of interest. The gathering may be automatic (e.g. use sensors) or manual. For example, the patient may enter text information. The PHS may be devices that are *wearable*, such as a portable heart rate chest belt, while AAL tools may be portable or fixed within their environment, such as a webcam.
2. **Short-term memory:** The element is responsible for ensuring the short-term storage of the data collected. There is a trend for memory chips to increase in capacity and to in reduce size and price. For example, memory cards can currently measure approximately 1.5 cm² and can reach 32 GB [67.14].
3. **Local visualization:** The element will allow the patient to visualize the fixed or continuous data collected.
4. **Communication network:** The element will move the data from the location of the patient to a remote location, where the server(s) is (are) located. There

will generally be three parts: a transmitter (TX), the network itself, and the receiver (RX).

5. **Database(s):** The element will archive the information. This information can be fixed (such as patient ID or age), or incremental such as the data collected. Another type of information that is sometimes used is event tracking, such as user logins to the system (when a user accessed the system).
6. **Analysis:** The element will examine the data collected and the patient information to select a result and/or an action.
7. **Action launcher:** The element will launch an action following the analysis. The typical actions would be a flag in the database, a transmission of an SMS or email, and a local or deported sound or light alert.
8. **Visualization:** The element will allow the health professional, the helper, and sometimes the patient, to visualize the data collected, the patient information, the analysis rules and outcome, and the action initiated.

While not all PHS or AAL approaches will contain all of the components mentioned above, the indispensable component will be the data collection. Figure 67.6

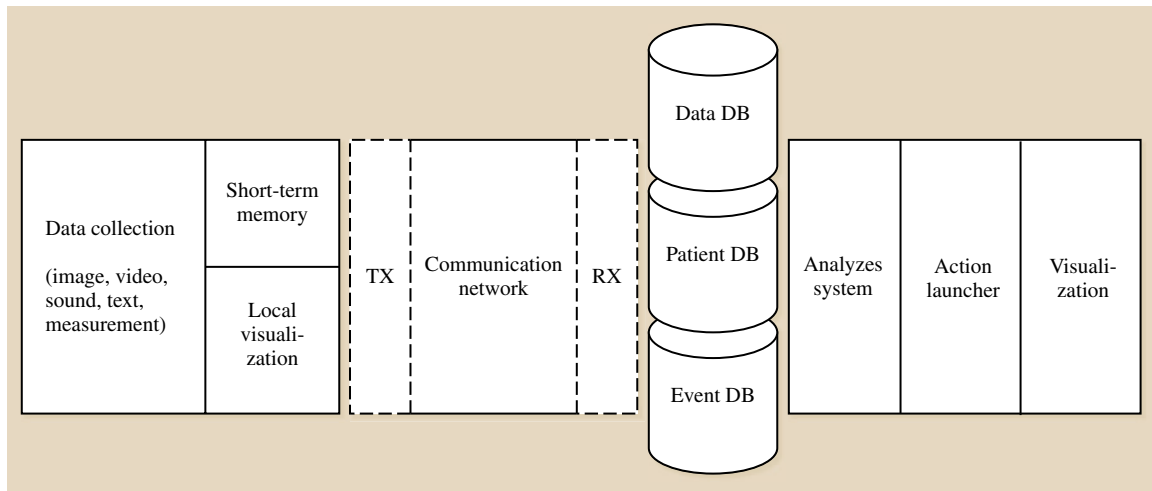

Fig. 67.6 Components of AAL and PHS

presents a visual image of the components of PHS and AAL approaches. In such approaches, the components that are not present as often include the automatic analysis and action launcher.

PHS and AAL approaches can contribute throughout the healthcare delivery process. Moreover, they can intervene in more than one stage of the healthcare delivery process. These solutions may contribute in the prevention, diagnostic, monitoring/surveillance, and treatment/therapy stages.

67.2.1 Self-Management

Self-management tools are devices, instruments, or web sites, normally available to a large number of people, that assist individuals, and sometimes their natural helpers, in healthcare prevention and monitoring.

Health Portals (Prevention – Diagnostics – Monitoring – Treatment)

Description. A health-related portal is a web site that would present information that is perceived by the person to be useful to his or her health prevention or surveillance. There is a large variety of websites, with different levels of information or service quality. Behind the websites will be government agencies, private or public hospitals, universities and research units, associations, companies, patients etc.

The health portals normally have one of the following objectives:

- Information – To facilitate the access to drug, diagnostic, or treatment information; healthcare providers, processes, comparisons; provide patient, helper of GP's testimony.
- Coaching – With some basic input information from the user, to define some risks or recommendations; track measurements.
- Exchange and community creation/reinforcement – To provide a platform where patients and their helpers can exchange on real-time or deported.
- Archiving – To provide a storage space for the person to keep health-related data.
- Reminders – To enable the person or his/her helper to plan reminders such as medication or appointments. In this case, the reminder can be directed to an email, a SMS, or a landline phone.
- Healthcare products – To facilitate the ordering and purchase of drugs or medical equipment.
- Health institution or insurance account management – To facilitate the management and understanding

of the person's account situation for his or her insurance or any other organization involved in the healthcare process.

North America is the most developed region, with a strong patient/consumer demand and usage. The European Union has established guidelines for quality healthcare related websites, i. e. transparency, authority, honesty, privacy and data protection, regular information updating, accountability, responsible partnering, editorial policy, and accessibility [67.15].

Certain countries have established a certification to validate the quality of health-related websites; for example, since 2004 the Haute Autorité de Santé (HAS) in France has had the mission to deliver these certificates. This French Agency used the HONcode certification (established by the Health On the Net Foundation, Switzerland) to validate the website. However, there is no correlation between certificated sites and usage; the most-used sites are the ones that are better *referenced* in web search engines, independently of the certifications [67.16].

Examples. In 2007 Microsoft and Google entered the field with the Microsoft HealthVault and Google-Health. The features of each system are listed in Table 67.1.

At the end of 2008 and the beginning 2009, the company User Centric evaluated the feedback from 30 end-users and concluded that Google-Health was more user-friendly (navigation and data-entry) [67.17]. However, certain features such as device data collection is under development with Google Health but already available in HealthVault. The latter is more focused on B-to-B partnerships. For the moment, both services are available only in North America, but in some European countries they will be launched in 2010–2011.

Reminders (Prevention – Treatment)

Description. The outcome of a treatment will depend on the correctness of the diagnosis, the accuracy of the prescription, and finally on the proper follow up of the treatment. The patient's involvement remains very limited in the first two steps; however, the treatment is mostly his or her responsibility. The World Health Organization calculated that only half of the patients with long-term therapies followed their prescriptions correctly [67.18]. Reminders are a simple way to reduce some of the nonadherence.

Another area where reminders are important are at the beginning of neuro-degenerative diseases. Re-

minders can be useful to organize certain tasks, for example, a vocal or image reminder when it is lunch time. Unfortunately, when the disease is more advanced, reminders are not effective. Reminders can be web services that trigger an SMS, video, voice phone call, or LED; they can also be portable devices that read out a recorded or default message.

Examples. There are systems that do not require an additional device but would use the existing communication material of the user (e.g. fixed line phone, mobile, or email). The reminders can be planned in advance and delivered vocally by a call center [67.19] or delivered automatically using a synthetic voice, an SMS, or an email after scheduling from a web application [67.20].

There are other solutions that would require the acquisition of a specific-purpose device. Examples of portable reminder devices are: a watch showing the item to remember in its display (e.g. cadex watch), a pillbox that beeps and vibrates when it is time for a medication (e-pill), and a device that plays out the recorded message at specified time (e.g. memotext).

Heart Rate Monitoring (Prevention – Diagnostics – Monitoring – Treatment)

Description. A heart rate device is a portable system used to measure the heart rate (normally heartbeats per minute, or bpm). It can be visible and transmitted in

real-time, or archived and transmitted once connected to a PC or communication gateway. Even though there are around ten body parts where the heart rate can be measured easily, for portability reasons most of the available devices use electrodes attached to a chest strap.

The important technical and commercial development of heart rate monitoring portable devices was done by sportsmen and women who used the measurements to improve their training. However, heart rate monitoring can be used for patients to leverage efforts, to alert in the case of a possible risky situation, or to understand the pattern during a timeframe (a day, a week, ...). It consists of a chest or finger band with an electrode strap and a connector; this band sends the heart rate information to a receiver, normally a watch or a mobile phone (Fig. 67.7). The information can be stocked in the device to be downloaded at a later stage into a PC (it can be downloaded using a cabled or a wireless solution). Once archived in the local PC or a remote server, a more detailed analysis can be performed manually or automatically. Newer models may include an accelerometer, which can help to calculate the distance completed and the mean/maximum speed of the journey.

Examples. The market leader is Polar, with a heart rate measurement using a chest strap. The reception/local archiving and visualization is done through a watch. While most other vendors follow this model for their so-

Fig. 67.7 Example of a finger heart rate measurement (after [67.21])

lutions, there are some that use different measurement points, such as the index. Personal heart rate monitors are priced from 50 to 900 USD.

Activity Monitors (Prevention)

In order to monitor the activity performed in a time-frame (a day, a week), there are activity monitoring devices that track the number of steps done, the calories burned, and the total mileage. An example is the clip by fitbit (launched at end of 2009). It has a USB connector to transmit data to a central server, which then prepares and presents the information on a webpage [67.21]. The

Fig. 67.9 The EU funded project A₂E₂

Fig. 67.8 Example of clip activity monitor (after [67.22])

webpage has some analysis capabilities. A competing solution tracks and provides more information to the user by using an armband with added sensors (temperature, accelerometer, and heat flux). The product is commercialized by Bodymedia [67.23].

Motivational Exercising System (Prevention – Monitoring)

Tracking activity or calories burned can sometimes be enough motivation to regularly exercise; however, consumers above 75 years old are not the main customers of activity monitoring systems, and the benefits that can be gained from regular exercise are considerable.

The objective of an EU funded project (A2E2, Fig. 67.9) is to build a system that will induce elderly people to exercise regularly. It tracks the activity performed with ambient and personal sensors; based on the personal profile and the data of those sensors the system will then establish an adapted communication. It consists of a user interface (TV or mobile), a collection and communication system, biosensors, ambient sensors, with the archiving and analysis capabilities in a server [67.24].

Teleassistance (Monitoring)

Description. Teleassistance or home assistance is a service that consists in providing the possibility for the user to reach a person with the appropriate capacities to answer a request or to treat an emergency situation. The National Emergency phone numbers (i.e. 911 in the US and Canada, 112 in Europe) are the most widely used teleassistance service. In the 1970s, associations and companies started to propose a private or associa-

tive service that linked the customer to a call centre. It was intended to deal with isolation and emergency. The emergency is usually just a situation definition and a bridge to the National Emergency teams; there are few cases where a medical presence is available 24/7 to perform a first remote diagnostic.

Teleassistance is the most extended commercial AAL offer. In 2008 for example, there were 1.5 million subscriptions in the UK, 600 000 in Spain, and 350 000 in France (as stated by the president of the French Association of Teleassistance Companies, AFRATA, Claude Mordelet [67.25]). The variation is linear to the financial engagement of the public sector (subsidies).

Traditionally, teleassistance is limited to a home support using a communication device connected to the fixed line, with a reach of around 100 m using a portable pendant or bracelet (with a red button to declare an alert). Pushing a button sends an alert to the screen of the call center who will call back the user; the communication device answers automatically in loud-speakers. The new generation of services expands the offering from the following perspectives:

- Service (keep a double of the house key, order a taxi, do a hairdresser appointment, provide the weather forecast...).
- Intelligence (activity detection, GPS, recorded reminders...).
- Mobility (medium or long-range alert and communication...).
- Environment coverage (include fire detection, window or door breaking detection...).

Consequently, assistance and monitoring start to overlap, and this trend will continue in the coming years. An area where commercial remote assistance is just starting is the monitoring and control of medical equipment such as pumps and prostheses.

The typical system components are:

- The alert system – normally portable devices such as the bracelet or pendant, but they can also be fixed, for example a button fixed to the wall of the restrooms
- The communication gateway – which will receive the local alarm and send it to the remote server
- Storage and presentation – the alerts are stored in a database and presented to the appropriate teams for action.

In the case of a mobile alert system, the first two components can be combined in the same device.

Examples. Examples of new generation services include home safety services, which include environment monitoring, and are widely proposed by the West Lothian County [67.26]. Another example available in France is *témo* [67.27], which uses a mobile alert and communication system with GPS. One of the largest players, Tunstall, started offering environment monitored assistance in addition to the traditional assistance plus some basic telemonitoring services. In Bologna, Italy, a project run by the Department of the INAIL Prosthesis Centre in Vigorzo di Budrio provides a good example of remote assistance to tune medical devices based on patient-located data. The project consists in remotely analyzing and controlling an upper-limb prosthesis via a microprocessor controlled arm (MCA) [67.28].

Media and Multimedia Solutions (Prevention – Diagnostics – Monitoring – Treatment)

Description. Images, audio, and videos can be exchanged in real-time or deferred time; the exchange can be patient to health professional(s), health professional to health professional(s), and patient to patient(s). The approach of sharing audio/video/image in healthcare is useful for second opinion processes, better monitoring (e.g. regular wound evolution follow-up), diagnosis (e.g. detailed images for dermatology problems), or even improve treatments (e.g. identify secondary effects that the patient is not aware of, or does not think important to share).

When the video is real-time, it is referred to as videoconference or videoteleconference (VTC). In order to make the exchange operational, it is necessary to have a large bandwidth, otherwise the images would freeze and the sound would not be synchronized to the image. The minimum recommended bandwidth is 384 kbits/s. When there is a high bandwidth, the screen(s) quality is high and the screen(s) size sufficiently large to allow showing the persons and objects in their real size, the term telepresence is used.

Image and audio sharing is more accessible than videoconferences, since it does not require such an important bandwidth, and digital cameras or microphone are accessible to a larger portion of the population in Western countries, with a trend to having a phone equipped with a digital camera, which allows a real-time dispatch from practically anywhere. The quality of the camera or image will depend on the requirement; however, a 10 mega pixels digital camera can be easily found at less than 100 USD, which would have an

Fig. 67.10 Components of a VTC solution

enough quality for most of the applications. The components of a VTC solution are shown in Fig. 67.10. Image sharing will replace video input/output by an image input, while the audio solution will not have the video input/output.

Examples. In Sherbrooke, Canada, a new service was implemented in 2010, named TASP or *téléassistance en soins de plaies*. At the patient's home, a visiting nurse will film a wound and in parallel, at the Centre Hospitalier Universitaire de Sherbrooke, a nurse receives the video. There is a live exchange between both nurses regarding the progress of the wound healing and the treatment [67.29].

In Argentina, with the commercialized telepresence solutions from Cisco Systems, Dr. Juan P. Garrahan, in the Paediatric Hospital of Buenos Aires uses it for diagnostics, monitoring, and second opinion. Garrahan claims that 85% of consultations do not require a referral to the hospital [67.30] and in many of those cases the

telepresence can be an ideal solution considering that Argentina is 3000 km long.

Telemend is a project funded by the EuropAid Cooperation Office. It has the objective of leveraging telemedicine tools to diagnose infectious diseases (malaria) in Colombia. It used TopCare Kiosk [67.31, 32] (Fig. 67.11) in remote areas of Colombia (Buenaventura and Guaviare). The kiosk is a PC equipped with a microscope, a blood analyzer, and an x-ray scan. The kiosk is manipulated by a nurse who will add the picture taken from a blood sample viewed from the microscope to the patient file. The information is then sent via a mobile network to a remote server, which allows any authenticated doctor to access the information in order to provide a diagnosis or monitor treatment.

Fall Detection

Description. Falls are an important problem in all modern societies. A report presented in 2007 in the WHO Global Report on Falls Prevention in Older Age states that 28–35% of people above 65 suffer a fall each year [67.33]; the number increases for seniors above 70 years old, since the percentage increased to 32–42% [67.34]. These falls are cause of hospital admission in 1.6–3.0 per 10 000 population [67.35] (data from Australia, Canada, and the United Kingdom).

Consequently, research and development has been trying to provide solutions to automatically detect falls in elderly people. The objective being to be able to identify premonitory symptoms of a fall before it occurs. Presently, fall detection causes numerous false-positives, and more reliable solutions are limited in their portability and/or cost.

Fall detection uses one or various portable and/or fixed sensor(s) that will identify the movement characteristics of a (several) body part(s), or the behavior pattern (e.g. electrical activity in the person's environment [67.36]). This information is then analyzed locally or remotely to determine the probability of a fall having occurred; if the outcome is a potential fall, then the noti-

Fig. 67.11 TopCare kiosk (Fraunhofer Institute, St. Ingbert, Germany)

fication system displays or sends an alarm, i. e. an SMS, email, or phone call.

The most common wearable sensor is a portable three-dimensional accelerometer. Possible environmental devices are video cameras, or presence sensors such as infrared or contact sensors (which will determine, for example, if a person is lying on the floor).

More accurate sensors include the monitoring of other parameters such as body temperature. Using accelerometers, it was also demonstrated that using two sensors positioned in different body areas is more reliable than using a single sensor [67.22], and it was proven that monitoring movements at the waist and head [67.37] provides more reliable information at other parts.

Examples. Vivago has chosen to identify a fall by looking into post-fall symptoms using a watch that monitors wrist movements. A reduction or absence of movement during a predefined time will launch an automatic alert. The EU funded project SIMBAD is an example of environmental solutions. In this project, fall detection is performed using wall-mounted pyroelectric infrared sensors. These sensors capture and analyze the movements without the need for invasive environmental elements such as the video [67.38].

Bioparameter Monitoring (Prevention – Diagnostics – Monitoring – Treatment)

Description. Telemonitoring consists in remotely surveying the health status of a patient who is home or institution-based. In order for the monitoring to be data-based, it requires a medical device to regularly or continuously measure the patient's physiological parameters; it is especially pertinent for people with chronic diseases.

The advantages of home vital parameter monitoring are faster data collection and analysis, avoidance of travel time and costs, integration of the monitoring in the patient's daily routine, and the possibility for the health professional to visualize data over long periods of time.

The vital parameters that can be measured remotely are numerous; the most common ones are weight, glucose levels, body temperature, hcg (human chorionic gonadotropic) for pregnancy tests, cholesterol and triglycerides levels, blood oxygen saturation, blood pressure, and heart rate (ECG). The measurements can be taken continuously, at regular periods, or at random periods depending on the pathology, the patient profile, the sensors, and the medical need.

As mentioned in previous sections, some parameters are already widely monitored in self-management tools; in this section, the interest is within a medical usage. There are parameters that can, in certain cases, be meaningful to the patient, but in most cases the interpretation belongs solely to the health professional.

A solution that monitors physiological parameters will be normally built using the following four components:

- The vital parameter measurement: the patient parameter will be measured using a medical device. The devices will follow one of the three types of procedures: noninvasive procedures (no skin breakage or penetration), minimally invasive procedures (when the device goes under the skin but without open surgical intervention such as subdermal implants), and invasive procedures devices (requiring heavy surgical intervention and from medium to long-term hospitalization).
- Local and remote data collection: the data is collected at the patient location and then transmitted to a distant server to be treated.
- Storage and presentation: while monitoring, it is essential that the data be presented in a meaningful manner to the health professional and that it is archived to obtain history and trends that are useful for the monitoring and treatment of a patient.

The vision of the European Union is a future where patients will have a combination of wearable or implantable multisensors combined with environmental sensors [67.12], but there are still some years of development necessary to achieve this.

Examples.

Glucose Monitoring. For diabetes patients, it is a requirement (it is vital for type 1 diabetes or juvenile diabetes) to measure the glucose concentration in their blood. Presently, meters can undertake a correct reading with only 0.3–1 μl of blood, and provide the reading within 3–5 s, archiving up to 2000 readings. Normally, these devices are sold with software that organizes, presents, and can perform some basic analysis. A key feature is the possibility to share the date with health professionals. An example is the Contour USB glucose meter (Fig. 67.12), which resembles a common USB key.

There is also room for niche adaptations for certain populations. An interesting variation of the product described above was FDA cleared in December 2009. It is a glucose meter for children and teenagers, called DID-

Fig. 67.12 Bayer's Contour USB glucose meter (Bayer Diabetes, Basel, Switzerland)

GET. It communicates with the Nintendo consoles DS and DS light, combining games to the readings. It includes web access to a community and the possibility to be rewarded for the results.

Many current commercial solutions have the advantages of ease-of-portability and ease-of-connection to any PC. However, they are limited to the time of reading, for example, no reading is performed during the night while the patient sleeps. Consequently, for certain patients, there is a need for continuous glucose monitoring systems (CGM). These systems continuously track the glucose level without patient intervention [67.39]. They use a sensor inserted under the skin (normally injected by the patient him or herself, refer to image below). The inserted sensor collects the measurement and communicates it to a local receiver/transmitter that then transfers the data directly or via a wireless terminal (mobile phone). The visible data can be sampled every 1–5 min.

Presently, when using a CGMs, the patient needs to replace the injected sensor every 5 to 7 days. Additionally, their accuracy has not yet reached that of traditional blood testing readers, needing calibration with a traditional blood strap reader. The CGM products are Abbott's FreeStyle Navigator, DexCom's Seven+Plus (Fig. 67.13), and Medtronic's Guardian.

Some examples of noninvasive CGM exist, e.g. a watch that uses low electric current to pull glucose through the skin (GlucoWatch G2 Biographer, by Cygnus). However, the FDA was not fully satisfied since it caused skin irritation in 50% of patients and the readings for low glucose levels were not precise. The product is no longer commercialized but developments around it continue [67.40].

Heart Rate Data Monitoring. Heart rate monitoring has been done for many years, i.e., measuring the heart rate or the more detailed ECG. Due to electrodes, microelectronics, and communications developments, the once cumbersome heavy devices that the patient carried for couple of hours while the device stored the data, are

Fig. 67.13 DexCom's Seven+Plus sensor insertion (source: DexCom, San Diego, <http://www.dexcom.com>)

being replaced by real-time highly-portable solutions, some with basic automatic analysis. There are many advantages of monitoring real-time heart activity, such as the immediate detection of an issue, the monitoring of the outcome of treatment, and the efficient collection of information for research purposes.

The efficiency has also been clearly observed: a European trial concentrating in heart diseases was performed with patients leaving the hospital after a stay longer than 48 hours. Three groups were compared: a group receiving traditional care, a group receiving nurse phone support, and finally a group using a telemonitoring system. This system included a pressure, weight, and ECG home monitoring device. The data collected from these devices was sent via Bluetooth to a hub that used the fixed line to transmit the information to a server. The server presented the data to a nurse or technician (care manager) who escalated, if required, to a physician. This study lasted 2 years and accepted 426 patients. The study conclusion was that the nurse service group and the telemedicine group had a lower level of mortality (16–18%) among patients compared to the status-quo care [67.41].

A new stage on portability is the integration of electrodes into textiles (smart textiles) [67.42], e.g. the VitalJacket (for up to 5 d monitoring and 72 h battery autonomy) commercialized by Biodevices (a spin-off of Aveiro University) [67.43]. The Fraunhofer Institute has developed a smart textile ECG monitor using a proprietary mobile terminal and electrodes claimed to be flexible, biocompatible, and biostable [67.44].

Smart textiles facilitate the portability, however, implanted solutions are the next step. At the end of 2007 an implanted ECG monitoring system received FDA clear-

Fig. 67.14 The Sleuth implanted sensor and the handheld wireless receiver (after [67.45])

ance. The Sleuth ECG monitoring system manufactured by Transoma Medical (Fig. 67.14) was first implanted in 2008 with US patients for arrhythmia detection or monitoring; the implant done by Dr. Daoud and Dr. Hummel at The Ohio State University Medical Center in Columbus. The information was regularly collected and sent to a monitoring center where cardiac technicians filtered information before sending reports to the health professionals.

Dr. Daoud stated that [67.47]:

The Sleuth implantable recorder and the wireless communication system provide excellent recording fidelity and ease of transmission of ECG data that is continuously monitored and stored. Also, I can select the arrhythmia detection parameters, and the telemetry tracings are promptly sent in a user-friendly report, making it easy for me and my staff to care for our patients.

Transoma Medical is, unfortunately, an example of the lack of synchronization between covering healthcare needs and finding a workable business model, despite the success and medical acceptance of their solution, in

December 2009, Transoma ceased operations *due to the difficult market conditions* [67.45].

Despite the shown benefits, there are still a few large deployments, but some regions are more active. In Brussels, for example, 500 patients are participating in the *Belgium Heart Failure Project* [67.46] to reduce heart failure spleen mortality. Instead of using ECGs, the patients are provided with a tensiometer and their mobile phone for an SMS communication.

Sleep Apnoea Detection. HealthGear is a system tested to monitor sleep apnoea using a set of sensors communicating the data via Bluetooth to a smart mobile phone that archives, transmits, presents, and performs a basic analysis of the data received [67.48]. The sensor used for sleep apnoea detection is an oximeter for blood oxygen levels and pulse; however, the architecture could support multiple sensors. It was tested with 20 individuals, with very positive outcomes regarding usability; 100% participants declared themselves willing to use it and to recommend it, and the accuracy of the readings and analysis correctly identified cases of obstructive sleep apnoea (OSA).

Others. There are portable solutions that monitor different vital parameters; however their capabilities have not been used in full. A commercially available application is Equivital, with a two-lead ECG, temperature, and movement sensors. It monitors the heart rate, the ECG, the respiratory rate, body temperature, and movement/body orientation (Fig. 67.16). It uses a chest strap that collects information and uses bluetooth to send the data to a local PC or a gateway that then sends it to a remote server. This multisensor device is mainly used by military personnel and professional sportsmen, but its application in the medical area is still underdeveloped.

Auto Adaptive Treatment Systems (Diagnostics – Treatment)

Descriptions. Auto adaptive treatment occurs when a treatment is capable of changing itself based on real-

Fig. 67.15 The Belgium heart failure project (after [67.46])

Fig. 67.16 Multiparameter band strap (after [67.49])

time or delayed information. Note: teletherapy is used to define radiation that is performed at a distance from the body.

Once a patient has been diagnosed, the health professional will determine the most appropriate treatment. The determined treatment and/or therapy may be adjusted in light of the patient response, their efficacy, and secondary and adverse effects. Monitoring of ongoing treatments or therapies and patient response are valuable for adjusting treatments and may even be crucial in cases of extreme medical condition or disease. For example, after a quadruple by-pass surgery, round the clock monitoring of the patient may be essential to ensure that there are no complications, especially when the patient is discharged from hospital.

The ideal case is a continuous monitoring feeding and modifying the treatment as needed, and the whole real-time. Typically, for example, adaptive treatment would enable patients with Type 1 diabetes to have insulin injections based on real-time continuous measurement of their blood glucose levels. Another example is having pumps for patients following cancer therapy, adapting the dose and time of medication based on the real physiological patient needs.

Figure 67.17 illustrates the common elements of auto adaptive treatment systems. Namely, a sensor(s) that collects the vital parameter(s), the analysis algorithms that will define the preferred action (reduction/increase/pause of dose or example), and the delivery treatment device that will behave based on the analysis outcome. If the analysis is done at a distant site,

Fig. 67.18 The MiniMed Paradigm real-time system (after [67.50])

an additional component will be required: the communication channel with its transmitter/receiver both at the patient side and at the remote side.

Examples.

Diabetes. An automatic system for Type 1 diabetes patients is commercially available. This is the MiniMed Paradigm Real-Time system (Fig. 67.18), which consists of a continuous glucose meter (CGM) that monitors the glucose level. With this information the controlling device adjusts the delivery of insulin of the insulin pump [67.39].

Depression. A very different type of treatment relates to psychiatry with depressive patients. The adapted treatment was not the medication but the psychiatric sessions that were performed remotely. A comparative study was done for 6 months to evaluate the outcome of on-site treatment versus telepsychiatry (videoconference between the patient and the health professional). During 6 months, 119 depressed veterans followed either the traditional psychiatry follow-up or remote treatment. The treatment consisted of psychotropic medication, education, and short supportive counseling. The conclusion of this study was that remote treatment of depression using telepsychiatry compared with face-to-face treatment is equivalent from adherence, patient satisfaction, and costs perspectives [67.51].

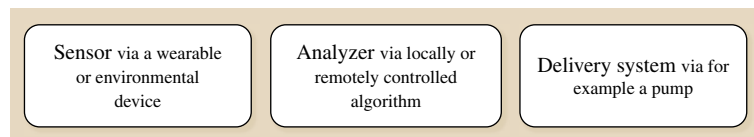

Fig. 67.17 Elements of an adaptive treatments system

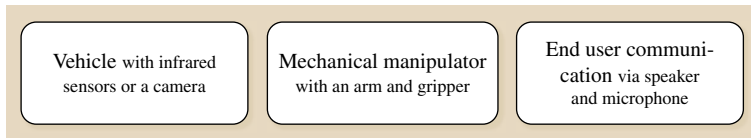

Fig. 67.19 Elements of a nurse robot

Wound Management. There are still but few examples of solutions; however different research groups are working around subjects that directly and indirectly will lead to solutions. The University of Rochester in the US is developing smart bandages with optical sensors that can monitor a change in color [67.53]. In the future, we expect to see the information collected, transmitted, and analyzed remotely, opening the possibility to automatically adapt treatments.

Robotics (Prevention – Monitoring)

Description. This approach consists of the use of robots to help perform certain basic caring actions at the patient's home, at institutions, and at hospitals. Robots are machines that operate autonomously, repetitive, programmable, or adapted tasks. Robots can do repetitive tasks (reminders, medication delivery, cleaning), specialized activities (move [67.54] or guide [67.55] a patient), interactive actions (keep a conversation), or be the communication gateway with health professionals. Most of the study outcomes show patient acceptance [67.55, 56]. In hospitals and institutions, robots help partially solve the issue of the lack of enough appropriate resources.

Nurse robots are normally mobile machines requiring a vehicle to move around the house or hospital without bumping into fixed or mobile objects (Fig. 67.19). Another key component is the mechanical manipulators, for example, an arm to deliver a drug. Finally, the end-user communication element permits us to configure or give orders to the robot, or simply, to enter information for an exchange with the robot (e.g. for a conversation).

The robot is preprogrammed with various levels of adaptation based on:

- External actions
- External inputs
- History.

The country most advanced in the area is Japan, with the technological background and one of the oldest populations.

Examples. A joint project between the University of Pittsburgh and Carnegie Mellon University has created

a robot nurse for elderly people. The project's name is NurseBot, and the first robot is Florence [67.57] (in honor of Florence Nightingale). Its tasks are:

- Medication and regular life reminders (e.g. drink, go to the toilet)
- Keep company via conversation
- Provide a camera, speakers, and a microphone to allow remote health professionals to see and talk to the person
- Simple domestic appliance manipulations, such as open or close the fridge or the microwave.

Samsung has developed Romi [67.52] (Fig. 67.20), a nurse robot with the participation of the nursing school and the psychology departments of the University of Auckland (for the nurse knowledge base). Romi is polyglot (eight languages) and has a camera for face recognition, a microphone for voice recognition, arms and hands, as well as speakers.

The tasks are to:

- Deliver prescribed drugs
- Remind the patient of routines
- Motivate
- Keep a conversation.

Toyota has announced that their nurse robot will be commercialized in 2011, and Honda has spent hundreds of millions of dollars developing its human-like robot. Those are very promising news to see, in a near future, efficient and hopefully cost-efficient nurse robots in the market.

Fig. 67.20 Romi nurse robot (after [67.52])

Fig. 67.21 European project IWARD (intelligent robot swarm for attendance, recognition, cleaning, and delivery) (after [67.58])

The European project IWARD (intelligent robot swarm for attendance, recognition, cleaning, and delivery, Fig. 67.21) is targeted to providing help to institutions, clinics, and hospitals to overcome staff shortages [67.58]. The task is:

- Delivery of objects from point A to point B
- Cleaning
- Patient guidance within the establishment
- Detection of patients in unusual positions, e.g. patients sitting on the floor.

Teleconsultation (Prevention – Diagnostics – Treatment)

Description. For remote or rural areas where health professionals and specialists are not available, the possibility to perform a consultation with a remote expert is essential for the patient (he or she obtains a faster diagnosis and, if needed, treatment) and for society (to provide equal health access to all individuals while managing the health budget).

Another scenario where teleconsultation is important is during the second opinion procedure, since it normally involves two persons who are physically distant. The number of multipathologies patients is increasing with chronic diseases and ageing populations; consequently, different medical specialties require provision of an input to the diagnosis and treatment in order to treat the individual as a whole and not just an organ. The teleconsultation can consist of a phone call, an email exchange, or a chat. However, normally it in-

volves some kind of image/video and/or sensor data exchange.

Examples. A teleconsultation project was carried out in Aarhus, Denmark (collaboration between the local hospital and university), for diabetic patients suffering from foot ulcers. The regular treatment was once a day or every other day. Moreover, twice a month the nurse organizes a remote consultation with the hospital doctor using a visio-phone. The experimentation was in 2005 and at the end of it the hospital decided to integrate the procedure to its regular operations [67.60].

A pan-European project was launched in 2005 with the name Medical Care Continuity project. The objective was to improve the follow-up of patients following the discharge from hospital. It uses a video camera that can be remotely directed by the health professional. Italy claims that these types of initiatives have reduced hospital stays by 22 days and cut hospitalization costs in half [67.61]. Maybe the Italians overestimate the benefits, but the gain for patients and hospitals is certain.

It has been seen that there are not many AAL and PHS commercial off-the-shelf products; this is changing. In 2008, Intel's Health Guide home terminal received FDA approval; it was designed for chronically ill patients to communicate with their health professional (Fig. 67.22). It has:

- Two-way video capabilities
- Interfaces with sensors (e.g. heart rate, glucose meter, oximeter) to capture the information and

Fig. 67.22 Intel's Health Guide terminal PHS6000 with tactile screen (after [67.59])

communicate to the health professional via a centralized server

- A calendar with potential reminders
- A collection of image, sound, or video education material
- A tactile screen.

It has a convenient size of 280 mm × 90 mm × 270 mm, however, it requires a broadband network connection such as ADSL, which limits the usage to home use. This terminal can be used for consultations and monitoring. A study with 200 patients above 60 started in 2010, in collaboration with General Electric and the Mayo Clinic to measure the reduction of hospitalization and emergency entries [67.59].

Telesurgical Assistance (Treatment)

Description. Telesurgical assistance is the action of performing a surgery locally with partial or total remote input. The remote involvement may consist only of a verbal opinion based on the images or sounds received, but it can go to fully controlling the surgery. Telesurgery is presently not used in AAL since it requires a setup and environment that for the moment is only possible at hospitals. However, as technology evolves, we believe that simple minimally-invasive interventions will be performed at home with the help of a trained nurse on site and experts at a remote site.

Components. An Austrian study demonstrated that remote-controlled navigation arthroscopies are reliable and accurate even for small joints (the temporomandibular joint, a facial joint) [67.62]. The same outcome was observed with a comparative local and remote intervention of 50 patients (Nissen fundoplication). The mortality was nil for both groups, and a 22 month follow-up showed comparable symptoms. However, the costs doubled for the remotely operated group with a longer time required (40 min) [67.63]. The costs and time would decrease as more remote interventions are done.

Smart Homes (Monitoring– Prevention – Diagnostics –Treatment)

The smart home relates to the home that is capable of quickly detecting a problem and even of foreseeing it; the home that will react in the most appropriate manner to the event raised; the home that palliates the physical

and cognitive weakness of the elderly inhabitant using technological solutions.

The objective is an equipped home that will maintain or increase the physical and social autonomy of the individual living at home. There is no one-size-fits-all smart home, since it needs to adapt to the specific weaknesses and environment of the person. The smart home would be equipped with a mix of the solutions presented in this chapter, plus the services and other technological solutions related to the nonhealthcare aspects such as entertainment (TV, Audio), education (TV, ...), security (closing and opening of doors/windows; intrusion detection and alert). The use of a single AAL service or tool adds a certain intelligence to the person's environment; the term smart home does not define a solution or approach but rather an attribute.

Despite the existence of standards, such as short-distance wireless communication protocols (such as zigbee, RF, or bluetooth), or standards for medical imaging (DICOM), the immediate and transparent interconnectivity of all needed components is not yet possible. There are associations such as Continua Alliance, IEEE, and mHealth Alliance working around this subject, and consequently, it can be envisaged that in the medium-term, the interconnectivity will be a pure plug-and-use.

Examples of smart-homes projects are Monami [67.64] and i2home [67.65]. The concept of the smart home was also used in a post-operative situation, where the physiotherapeutic exercises were automatically evaluated and the patient could receive feedback to ensure regularity and quality [67.66].

A subset of a smart home is the automatic adaptive environments. There are still very few environments that adapt themselves based on real-time healthcare personal parameters. There are some solutions that allow remote control of electrical or electro-mechanical devices; the control can be manually set or programmed based on the outcome of environmental sensors such as thermometers, light sensors, or fire detection (e.g. Biodom system).

The elements of an adaptive environment will be a sensor that captures health parameters, an analyzer that takes the information, determines the ideal configuration of the environmental device, and controls the device. It will, for example, adapt the heater to the body temperature of the person or the ventilation to the oximeter outcome.

67.3 Benefits and Challenges Ahead

Health and healthcare systems are complex interactions of biomedical, social, economic, ethical, and political factors. Significant advances in information communication technologies (ICTs) have made, and will continue to make, innovation in health technologies and equipment possible. ICTs have begun to positively impact the manner in which health systems provide products and services to patients, including through the development of the field of e-Health and through improved access and quality. More importantly, they hold greater promise for future improvements in health and healthcare systems. However, for e-Health approaches to provide viable and effective solutions to many of the current issues facing healthcare systems around the world, many conditions will need to be fostered and brought together.

The future development and more pervasive adoption of e-Health approaches will depend on identifying where the benefits lie and the numerous challenges and issues that these technologies raise, as well as finding appropriate solutions. Some of the issues that are raised by e-Health technologies and equipment are common to other areas in the health field. For example, issues pertaining to the protection of patient privacy and confidentiality or informed consent are issues that arise within the provision of healthcare services generally. However, different facets of these issues may arise within the e-Health context. Other challenges are specific to the technologies used in and the services provided within the e-Health context and even more specific to AAL and PHS. For example, the reliability of the technologies and the consequences when they fail or the uncertainties pertaining to the legal framework are some of the issues more specific to this emerging field. Other challenges are themselves only beginning to emerge or will emerge in the future with the more widespread use of these technologies.

This section will draw attention to the numerous issues that legislators, political decision-makers, medical professionals, industry, engineering and systems design experts, patients, and civil society will need to consider and address to ensure the appropriate development, adoption, and usage of e-Health technologies and equipment. It will provide an overview of the different social, ethical, legal, societal, economic, and technological dimensions to the roll-out of e-Health solutions.

67.3.1 The Social Dimension

AAL and PHS, and e-Health more broadly, contribute to the achievement of many desired social objectives of improving healthcare services and products for patients and to improving the delivery of such healthcare [67.5]. From a patient perspective, such approaches may enable individuals to have better access to health information, to have better knowledge in regards to their health situation, to better manage their health, to have improved feedback on the impact of health services and interventions, and to make more informed choices about treatments and therapies.

From a health professional and healthcare system perspective, such approaches may enable health workers to make more effective decisions with respect to diagnosis, treatment, therapy, and monitoring. They may enable hospitals to provide higher quality and safer treatments and therapies. They may enable health professionals to contribute to addressing health problems of patients world-wide. They may improve the management of information and access to information for patient care and for administrative services. They may enable better and more timely mapping of public health threats, and they may enable improved training and sharing of knowledge along health professionals.

From a government and policymaker perspective, such approaches may enable governments to be more responsive to changing health needs. They may enable policymakers and public health authorities to be more aware of health risks, and they may foster the development of effective, safe, and efficient healthcare systems.

Stakeholders

The effective, safe, and efficient roll-out of e-Health solutions, such as those provided by AAL and PHS, will need to ensure that the appropriate people at the national, regional, and international levels are involved as early as possible. As such, it will be important for national and regional governments, all categories of health professionals, engineers, and technicians, patient and representative groups, industry, researchers and research organizations, international organizations, NGOs, and civil society to be implicated. Their diverse expertise, knowledge, technological know-how, partnerships, and investments will be essential for developing e-Health globally.

Developments and innovation within ICTs for e-Health and AAL will necessitate more effective involvement of SMEs. As agile entities they are able to make technical and business decisions more quickly and to execute them. Thus, they are better able to focus their research capacity. Well-financed SMEs are able to engage in high-risk, early-stage research and development, build strategic partnerships, and operate outside their local markets. As such, they have an important role in the development of future visions and in converting these into value propositions for patients and clients.

Participatory Involvement

Future innovation within e-Health will include engineering of context-aware and easy-to-use ICT systems that self-improve and self-adapt within their respective environments. Areas of research will include cognitive systems, interaction, robotics, and automation. For the innovations to be developed to be effective, efficient, and useful for the end-user, whether patient or caregiver, the participation of key stakeholders will be crucial. The development of technologies and the evolution of products and services will need to take into account user experience and future needs.

Carried out appropriately, stakeholder participation may be cost-effective, efficient, and eco-responsible in that the selection of technologies to be developed would reflect the needs of patients and their caregivers. Conversely, strategies that are not embedded in clear and realistic needs will be more vulnerable to failure due to lack of participation, acceptance, capacity, and other enabling factors.

There will be many challenges in carrying out stakeholder participation. Such testing will need to consider the breadth of possible users and that of possible uses. It will further need to consider the different conditions under which the technology should be used, the best manner in which to involve the testers and to simulate real world conditions and use, and the manner in which this testing respects legal and ethical frameworks. In testing AAL and PHS approaches, researchers will need to involve participants of the targeted patients. For example, elderly individuals, incapacitated individuals, or individuals with cognitive, motor, sensory, or neurological needs. As the testing will also need to assess usability, models developed involving healthy populations may not be reliable [67.67].

67.3.2 Legal and Ethical Dimensions

Existing medical and health sectors are amongst the most regulated and are covered by national, regional, and international legal instruments. Similarly, e-Health technologies are subject to the myriad of currently-existing national, regional, and international legal instruments. However, there is also a need for new policy, legislation, and regulation specific to address issues arising from e-Health technologies. Some areas where policy and legislation need to be considered include ethical considerations, privacy, confidentiality and security, and cross-border issues.

Research, testing, development, and distribution of products and services within the field of e-Health must abide by the ethical and legal frameworks generally applicable to human subjects, medical products, and technologies. While this section will review the legal and ethical issues, it is beyond the scope of this chapter to exhaustively examine such issues or to review all of the applicable legislation. In addition, many of the technologies will be used for or by individuals who are in a vulnerable state. For example, the technologies may be used for elderly individuals, for individuals with a specific medical condition or disease, or for individuals with motor, cognitive, or neurological needs. These patients may be more vulnerable and thus extra care and attention is needed to ensure the protection of such patients.

Within the principles applicable to human subjects, there is the notion of minimal risk. Minimal risk has been defined to mean that the probability and magnitude of harm or discomfort anticipated in the research is not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests [67.68]. This principle entreats that patients should be exposed to minimal risk. Where it is not possible to abide by the principle of minimal risk, consideration must be given to ways in which risk can be reduced or eliminated or, alternatively, consideration must be given to employing alternative approaches.

Within the medical and health context, the cornerstone of patient protection is informed consent. This principle is recognized in international legal instruments such as the UNESCO *Universal Declaration on Bioethics and Human Rights* (2005) and the *Declaration of Helsinki on Ethical Principles for Medical Research Involving Human Subjects* of 1964 (last revised in 2008). Informed consent is a complex subject

rooted in the principle that patients should be provided with pertinent information by health professionals, especially in regards to the significant risks of a given service, product or technology, as well as of the risks of particular importance to that patient. The objective is to provide useful information to enable patients to make the best decision in regards to their health and well-being. As e-Health systems become more widely implemented and are able to generate improved health and medical information specific to a patient, this will facilitate the informed consent process. Conversely, the potential use of personal health information for numerous and diverse research purposes may make the informed consent process more difficult. As personal health information may be used for broad and diverse research purposes, obtaining the type of specific consent used in most jurisdictions may not be sufficient. Moreover, the issue of secondary use of personal health information and records also challenges the current informed consent approach. Consideration has arisen of whether there may be the need to develop alternative models of consent for such broad and diverse research [67.69].

Policy decision makers and legislators should also address the issue of the possibility of discrimination and stigmatization of patients and patient populations based on medical findings and discoveries. As personal health information is increasingly centralized and completed by medical history and family medical history, a fuller picture of the current and possible future medical conditions of patients may emerge. With this fuller set of personal health information coupled with the constantly emerging medical and health findings, there may be increased risk that patients sharing disease characteristics may be the subject of discrimination or stigmatization, including from employers, insurance companies, and the general community [67.70]. In the development of e-Health strategies, addressing such issues will be key to maintaining public trust.

Privacy, Confidentiality, and Security

AAL and PHS, and e-Health, technologies will generate personal health information and data that will be stored within databases. The term database is used as a generic, catch-all term. Other terms that are used to designate such databases include *health information banks*. This collection and storage can cover quite a large definition of personal health information and data. It can include data and information generated directly by AAL and PHS technologies. It can also include information and data retrieved or derived from other health and personal

records and linked or incorporated within the databases. The aggregation of significant personal health information into one or more databases increases the risks of violation of privacy, confidentiality, and raises issues of data protection and security.

This protection of privacy and confidentiality and ensuring the security of data and information will become more pressing when cross-border exchange of personal health information will be common place. Patients are increasingly seeking medical treatments and therapies outside of their country of residence. In order to provide the most appropriate treatment or therapy, health professionals will seek access to the patient's personal health information. In addition to the technological challenges, such as interoperability, numerous legal and ethical challenges will also arise. For example, when there is divergence between the laws of the different jurisdictions, issues of predominance of law and private international law/conflict of laws will arise.

In order to protect patients and maintain citizen's trust, policy-decision makers and legislators should develop the necessary legal and regulatory framework specific to the e-Health context. While some jurisdictions have already enacted legislation adapted to the specific e-Health context, thereby ensuring accrued protection of the privacy of its citizens, many others [67.5] lag behind and must rely on existing legal framework. Other European countries are in similar situations; many developing countries have yet to adopt legislation specific to e-Health. The province of British Columbia adopted the *Personal Health Information Access and Protection of Privacy* in April 2008. British Columbia is the first province in Canada to create a specific legislative framework governing access and privacy for electronic health information databases [67.71]. Some key aspects for such legislation to address include ensuring that data and information are accorded the highest level of protection, ensuring that measures are in place dealing with unforeseen and unauthorized disclosure or breach of security measures, and ensuring that unauthorized access or disclosure is significantly dissuaded and sanctioned.

Some elements for consideration in the development of principles applicable within the e-Health context include the following:

- Measures should be undertaken to ensure the respect of the individual's rights and freedom.
- Patients should be provided with detailed information of the nature of each e-Health solution/device/application prescribed for their treat-

ment and use, the inconveniences, the type of information and data that will be collected, and the diverse possible uses. The patient's consent should be obtained for the use of the solution/device/application, the collection of the data and information, and its possible uses.

- Patients should be informed and be provided with the opportunity to consent in regards to which information and data will be collected from them and which information and data will be retrieved and derived from their other health and personal records. This information should also specify the manner in which these information and data will be stored and accessed (i. e., text, audio, image, video). Patients should also be provided with the opportunity to specify which type of data and information they do not wish collected or stored.
- Patients should be informed about the uses for which their personal health information will be employed and by which entities. Patients should be provided with the opportunity to consent to the type of entities who should or should not have access to their personal health information.
- Patients should be informed about how they can access their personal health information.
- Personal health information should be available in the official languages.
- Security measures should be put in place to ensure that inappropriate and unauthorized access to patients' information and data are thwarted. Clear accountability for the storage, use, transmission, and maintenance of the information and data should be established.
- Mechanisms should be put in place for recording patients' consents and for enabling patients to subsequently modify or withdraw their previous consents.

67.3.3 Societal and Global Dimensions

The provision of effective, safe, and efficient healthcare services and products is a concern facing governments worldwide. While the specific types of concern may vary from jurisdiction to jurisdiction, many concerns cut across borders and continents. For instance, the issue of ensuring the financial sustainability of the healthcare system is a challenge that all governments face and in the coming years must address. Similarly, the promises of e-Health technologies can also benefit each jurisdiction whether developed or developing, albeit in different manners. For example, a doctor in a distant community

may use teleconsultation and videoconferencing to confer with a colleague on another continent in regards to the health of a patient. The doctor and patient may be in a distant community within a developed country, such as Iqaluit in the far north of Canada, or within a developing country, such as a remote village in the Democratic Republic of Congo.

E-Health technologies and equipment can lead to a positive impact on healthcare. They can contribute to improved prevention, diagnosis, consultation, treatment, cure, and monitoring and surveillance of patients both locally, remotely, and in distant locations. Moreover, they can contribute to improving healthcare through broad and improved dissemination of public health information to citizens, facilitating the sharing of information and training among health workers. For example, the Algerian government established the *Health Algeria* network, a tool for data collection and exchange among the different actors in the health sector. It has been evaluated as one of the most effective actions for creating the environment and backbone necessary for implementing e-Health, as well as for the adoption of AAL and PHS approaches [67.72]. Improved monitoring of the incidence of public health threats and more rapid, targeted, effective, and timely responses can also be achieved through such technologies and equipment. E-Health technologies can facilitate self-study, eLearning and further professional development, as well as foster more effective and targeted research and the dissemination and access to research findings [67.73].

For e-Health to become a positive and effective force in ensuring access to healthcare around the globe, each jurisdiction must contribute to achieving common goals and shared values. Public policy must support effective, safe, efficient, and equitable e-Health systems. They should foster the use of collaborative approaches for the development of e-Health systems. They should foster the development of e-Health technologies and approaches that are supportive of local cultures and languages and that are inclusive of all communities and especially vulnerable groups.

The viability and utility of e-Health in developing countries or in least developed countries is dependent on the accessibility of ICT and health technologies and equipment. As Table 67.2 illustrates, access to needed ICT equipment and technologies is very low in developing and least developed economies. Thus, for developing and least developed economies to benefit more fully from e-Health, many more challenges will need to be addressed. Moreover, due to market distribution and market power, developing and least developed

Table 67.2 ICT infrastructure and access: core indicators, aggregate values (after [67.74])

Level of development	Number per 100 inhabitants					A6. International Internet bandwidth per inhabitant (bits)	A7. Percentage of population covered by mobile cellular telephony
	A1. Fixed telephone lines	A2. Mobile cellular telephone subscribers	A3. Computers	A4. Internet subscribers	A5. Broadband Internet subscribers		
Developed economies	51	92	62	24	19	4755	99
Transition economies	23	77	10	3	2	223	88
Developing economies	15	33	5	4	2	177	74
Least developed economies	0.9	10	0.7	0.2	0.0	7	59

economies face constraints such as insufficient telecommunications infrastructure, high telecommunications tariffs, inappropriate or weak policies, organizational inefficiency, lack of locally created content, and uneven ability to derive economic and social benefits from information-intensive activities [67.74].

Addressing these challenges should be an objective for the global community. Approaches that are available to a doctor in the Canadian far north should also be available to a rural doctor in the DR Congo. AAL and PHS technologies can bring needed healthcare services to the poorest populations located in the most remote, rural, and difficult environments. Equally, these technologies can relay news of health developments from the most remote and difficult to reach places to the rest of the world. For example, through telassistance, health workers in remote areas in Uganda are able to immediately report incidences of communicable diseases such as cholera [67.74].

67.3.4 Economic Dimensions

The aim of e-Health is to contribute to providing effective, safe, efficient, and equitable healthcare. Within this context, AAL and PHS aim to support the decentralization of the provision of healthcare from an institutional setting to a home environment. These approaches provide some solutions for the elderly, incapacitated individuals, individuals recovering from a condition, surgery or disease, or individuals with cognitive, motor or neurological needs. These different segments will represent an increasing percentage of the population over the coming years.

Numerous pressure points militate for the rapid development of AAL and PHS technologies. The ageing of the population, the increased burden of chronic diseases, increasing longevity coupled with rapidly increasing costs all necessitate the reconsideration of the approaches used within healthcare systems. In 2005, 133 million Americans – almost 1 out of every 2 adults – had at least one chronic illness [67.75]. Each year, 7 out of 10 deaths in the United States are from chronic diseases. Heart disease, cancer and stroke account for more than 50% of all deaths each year [67.76]. In Europe, chronic conditions account for up to 86% of all deaths [67.77]. This disease burden coupled with the factor that many patients live longer means that patients will require more diverse services and support from healthcare system.

Increasingly, with a cost-containment objective, patients are being discharged from a hospital context much earlier once their condition has stabilized. Thus, the patient recovery or convalescence is shifting increasingly to a home environment. In the United States, for example, the expenditures for home healthcare rose from 12.6 billion USD in 1990 to 59 billion USD in 2007 [67.78]. As the number of patients being cared for within a home environment grows, there is an increasing need for e-Health approaches to be developed and in place to ensure the delivery of effective, safe, efficient, and equitable healthcare.

In parallel, with a system that is not able to provide all of the required services coupled with the falling number of health professionals per patient, increasingly, we are witnessing the emergence of the phenomenon of family members and other persons becoming caregivers

and providing the necessary services. Such situations have led to an increase in emotional, physical, and financial stress, which in turn has often resulted in health problems for the caregivers. For example, a US National study reported that 15% of caregivers came within this category [67.79].

Primordial for the successful adoption and use of AAL and PHS approaches, and e-Health more generally, is the consideration that the benefits to the participants in the system must be greater than the investments. Benefits may be considered on a short-term scale. For example, the implementation of only one PHS approach, such as videoconferencing, may be beneficial and even cost effective. However, benefits should also be considered from a long-term and holistic approach. The participants for whom such a system should be beneficial include the patients, health professionals, public health authorities and governments, researchers and research organizations, and industry. Investment may include not only monetary contributions but also contributions in terms of expertise, knowledge, know-how, professional resources, time, and materials. Similarly, in evaluating whether the investment of resources will be effective and efficient, a holistic and long-term perspective would be adopted.

Increasing evidence is emerging that the appropriate use of e-Health technologies can lead to improved delivery of healthcare while improving efficiency. In the United States, recent studies have determined that the national implementation of fully standardized interoperability between healthcare providers and key categories of entities (e.g., specialists, laboratories, and insurance funds) may yield savings of approximately \$US 75 billion annually [67.80]. An evaluation of the e-Health approaches implemented within the province of Ontario, Canada, demonstrates the positive results in creating efficient structures while providing effective healthcare services [67.81]. They found improvements in safety and quality of services, such as 35–70% reduction in hospital admissions due to adverse drug reactions, 20–40% increase in immunization compliance, and reductions in avoidable hospital admissions and length of stay. In regards to chronic disease management, due to e-Health approaches, the province was able to increase annual eye exams for diabetics by 20–40% and decrease by 25–50% emergency room visits for asthma sufferers. The province was able to improve access to healthcare for patients in remote areas by increasing the teleconsultations by 10–20%. Through e-Health approaches, the province was able to improve efficiency, for example, by reducing by

5–15% lab tests through avoiding duplication and by increased efficiency of resource utilization (drugs and diagnostics). The e-Health system also enabled the province to improve accountability by facilitating the carrying out of evidence-based population health planning.

Patient and User Acceptance

AAL and PHS approaches, and e-Health generally, benefit patients by providing them with prompt access to their medical history, health-related and medication information, electronic communication, and decision support services at the point of care. These readily available resources help facilitate the health care delivery process, and have been found to have a positive impact on patients' health outcomes, well-being, quality of life, hospital readmission rates, and mortality rates [67.82–85].

While the potential for using such approaches to improve clinical care or patient self-management has been acknowledged by many professionals, patients may not accept these technologies for diverse reasons. The question of patient and user acceptance is a complex issue that involves human emotive and cognitive reactions. Moreover, a distinction exists between patient acceptance of a technology and patient use of the same technology. Studies have found that factors such as poor device usability, insufficient training, lack of skills, and low self-efficacy can dissuade patients from accepting and using such technologies [67.86, 87]. Motor, visual and auditory, cognitive, external, and health limitations must all be taken into account in the design of AAL and PHS approaches [67.88].

Patients' decisions to accept technology may also be related to their diseases and health conditions, attributes of the health technology itself, organizational factors such as support, the environment of use, the patients' personal characteristics, and social influences [67.67, 89–92]. Studies have shown that patients who consider themselves knowledgeable in regards to their disease and how to care for their condition tend to be more likely to accept e-Health technologies. There is a higher likelihood of acceptance of an e-Health technology by a patient if other persons they consider important thought they should use the technology [67.93]. Patients are more likely to accept and use the technology if they believe that it would be useful and that it would be easy to use. Patients are more likely to accept the technology if they believe that they are able to use the technology and that they have the resources to support its use [67.94–96].

While patient acceptance of the technology is crucial, acceptance and use of such technologies must also take into account the needs and considerations of health professionals, patients' caregiver, and public health authorities. For health professionals, reliability of the technology, utility of the measurements and data, and effectiveness of the technology are important considerations. Issues of ease of use, replacability/repairability, reliability, security, or costs are considerations for the caregiver. From the perspective of public health authorities, the elements of reliability and stability of the technology, its effectiveness and safety, the costs of the technology, training, replaceability, as well as the benefits of providing patients with more autonomy are of importance.

67.3.5 Technological Dimensions

The development of ICT technologies has made possible innovations in e-Health, such as AAL and PHS approaches. With these developments considerable benefits have emerged. However, as examined above, there remain many challenges to be addressed.

In order for such technologies to be widely accessible, challenges pertaining to connectivity remain. In order to enable connectivity, issues such as the lack of an enabling telecom policy and regulatory framework, lack of access to energy sources, such as electricity or alternative power sources, insufficient infrastructure and access, and high costs must be addressed for e-Health to be truly globally available. While these issues are more pressing for developing and least developed economies, they also need to be addressed by developed countries of considerable geographical size and with populations located in remote or distant regions.

The Issue of Scaling Up and Evidence Basis

Developing policy relies on the availability of strong, systematic, and objective evidence for and analysis of approaches that work and those that do not, and examination of the required conditions and frameworks. Within the context of ICTs and healthcare, there is currently a shortage of such systematic evidence and analysis, particularly for the application of such technologies at the population level. This is particularly apparent in regards to the scaling up of particular projects or pilot studies.

Many of the studies that have been or are being carried out are pilot studies or specific projects with a very limited scope. While such studies contribute to assessing and better evaluating the broader implementa-

tion of a specific technology, they may not be sufficient in providing a holistic view of implementing concurrently multiple approaches. While some approaches may themselves be effective and efficient, this should not lead to the conclusion that the implementation of other approaches would similarly be effective and efficient.

The large-scale roll-out of systems such as e-Health, involve significant investments and expenditures particularly of public funds. A key challenge facing governments and public health authorities is the development of a methodology that enables the systematic and holistic evaluation of how e-Health can be implemented to deliver the most effective, safe, and efficient healthcare services and products. Another key challenge is the consideration of which conditions and factors must be addressed in order for the scaling up of a particular approach within a holistic system to be effective and efficient.

Standardization, Interoperability, and Compatibility

As a fast-evolving field, many e-Health approaches and solutions face challenges in regards to standardization, interoperability, and compatibility. ICT standards are important in e-Health technologies as these approaches are heavily data and information driven and having seamless access to such information is foundational [67.97]. The lack of global standardization is a significant challenge for the effective use of e-Health technologies and approaches. For example, within Europe, it was found that there is a lack of widely used e-health standards, leading to problems with interoperability. Of the standards that do exist, the study finds that some are conflicting and many are proprietary [67.98]. The study also concluded that within a single health service provider, the standards currently used were supportive. However, the situation was un-supportive for cross-border care provision. One of the barriers identified to the adoption of international e-health standards in hospitals is hospital IT managers, who prioritize internal process functionality above commonly used standards. The respondents also agreed that managers lacked financial incentives to exchange information electronically.

Standardization/harmonization also applies to the data and information to be collected and entered into databases. For example, the lack of standards is a significant challenge in regards to ensuring the most effective and efficient use of data and information that is generated through e-Health approaches. If the identification,

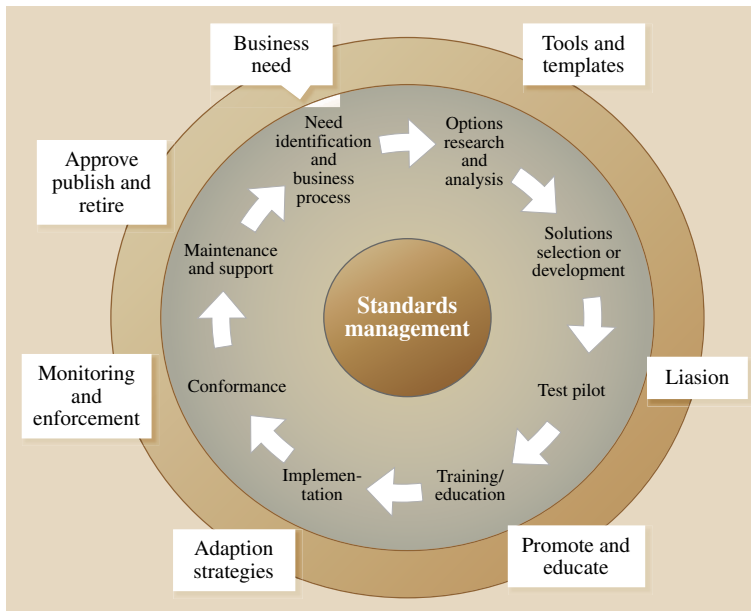

Fig. 67.23 Example of e-Health standards strategy (after [67.84])

data entry, and classification of the data and information are not standardized, the potential for secondary use of such data and information may be limited. The issue of interoperability will also be key in ensuring that resources are used efficiently. Furthermore, as more and more patients choose to undergo medical procedures outside of their country of residence, international

compatibility of information and data will be another significant challenge. As Fig. 67.23 illustrates, a viable approach to developing standards and to addressing issues of interoperability and compatibility necessitates a holistic perspective that takes into account the objectives and needs all of the actors and at the different stages of use.

67.4 Conclusion

67.4.1 Observations

As governments and public health authorities search for alternative means to deliver effective, safe, efficient, and equitable healthcare services and products, the use of information and communication technologies embodied in e-Health is a promising key area. While many aspects of functioning of healthcare systems will continue to need re-vamping, e-Health will enable a patient-centric approach wherein the patient is active in the management of his or her health, while improving efficiency and effectiveness.

The increase in computer and technology literacy offers the opportunity for better integration of healthcare delivery into daily activities. Future generation of patients will be more demanding in regards to information and options for treatments. AAL and PHS

approaches will provide tools for patients and their caregivers to actively monitor their health status, to learn more about their condition or disease, and to understand how to better manage it. e-Health technologies can provide important support for the prevention, detection, diagnosis, treatment, monitoring, and surveillance of a patient's condition or disease. It will permit reaction and adaptation to the changing needs and situation of the patient. Moreover, it will enable adaption within a home environment.

The full implementation of e-Health will need the involvement of all actors within the health sector, whether private or public sector, at national, regional, and international levels. As e-Health holds promise for all populations, rural or urban, remote, or central, and within developing or developed economies, the efforts of implementing this set of technologies, applications,

solutions, and devices need to involve the global community. e-Health may bring many benefits; however, its full implementation will need to address and find solutions for the numerous challenges. New approaches to developing technologies, policies, and legislation will need to be considered.

67.4.2 Areas for Further Work

For legislators, policy decision-makers, medical professionals, industry, engineering, systems and design experts, patients, international organizations, and civil society to be able to ensure the appropriate development, adoption and usage of e-Health technologies and equipment, many more areas of research will need to be addressed. Some of the gaps are listed here.

1. *Internationalization*: some of the most complex issues may need to be considered and addressed at the international level. For example, standardization, interoperability, and compatibility may be issues that are best addressed at the international level in order to ensure that information, data, and technologies can be used and exchanged globally. Another area where intervention at the global level may be beneficial is the development of international instrument(s) (i. e., convention, treaty, etc.) in regards to the issues such as privacy and confidentiality, data protection, discrimination, and ethical standards.
2. *Cost – benefit analysis and evidence*: the issue of cost and expenditures in regards to healthcare systems is a significant challenge facing every government as well as the global community. While many advocates of e-Health highlight the cost containment possibility of such technologies, it is an area that requires further and more in-depth study. Complex issues of measuring impact and savings will need to be addressed; frameworks and statistical methodologies will need to be developed. Simplistic approaches should be avoided as they will lead to inaccurate or incomplete evaluations. For example, some robotic surgery systems cost more than \$US 1 million to purchase and more than \$US 100 000 a year to maintain. Hospitals can save on costs by using such robotic surgery that is less invasive and thus, decrease the length of a patient's stay due to a shorter recovery period. However, calculations taking only this aspect into account may provide an inaccurate picture.
 3. *Privacy and confidentiality*: government decision-makers will need to develop policy for ensuring the protection of privacy and confidentiality of patients and the security of their personal health information and data in support of e-Health. In addressing these issues, they will need to take into account that patients are increasingly traveling outside their country of residence to obtain medical treatments and therapies.
 4. *Standards, interoperability, and compatibility*: the development of internationally-agreed standards will be a key challenge whose resolution will need to be addressed in the near future. Consideration should be given to the manner in which international standard setting organizations can play a more active role in the development of global standards necessary for the effective and efficient development of standards, interoperability, and compatibility in e-Health approaches. Consideration should also be given to the use of open sources.
 5. *Technological developments*: the evolution of information and communication technologies will contribute to improving the delivery of healthcare. While it is difficult to predict the evolution of technology, the development of some key areas should be considered [67.99–102]:
 - New, pervasive, and trustworthy network and service infrastructures to replace current Internet, mobile, fixed, and audiovisual networks, including research in regards to architecture
 - ICT based on nano-scale integration, new materials, photonics, and organic electronics, which will provide new types of devices and intelligent systems
 - Context-aware ICT systems that self-improve and self-adapt within their environments, including the fields of cognitive systems, robotics, and interaction
 - New technologies and devices that respect societal goals of sustainable development. Increasingly, electronic components, devices and systems will need to focus on being smaller, more accessible, more reliable, and greener.

67.4.3 Future Technologies

Wearable and environmental sensors. Smaller, lighter, more powerful sensors equipped with wireless connectivity, permitting the measurement of single or multiparameters, including parameters that can only currently be measured with large and complex equipment.

Human-machine interaction. Devices that facilitate human-machine interaction:

- *Displays.* New lighter, thinner, faster displays. Nanoemissive display and the surface-conduction electron-emitter display, both with higher contrast levels and faster response times than LCDs.
- *Very smart textiles.* Currently smart textiles used in healthcare are mainly passive smart (sense). In the future, they will be active smart textiles (sense and react) and very smart textiles (sense, react and auto-adapt).

68. Electrical Stimulation of the Nervous System

Stanisa Raspopovic, Marco Capogrosso, Silvestro Micera

Modern science, as we know it, is based on the concept proposed by Galileo Galilei, who designed the conceptual framework within which every scientist should act: the natural principles should be mathematically modeled and then verified in the experience.

Models are, then, the base of scientific reasoning; with accurate mathematical models (Sects. 68.2 and 68.3) we can describe reality and predict phenomena that can be verified by experimental evaluation.

One of the most exciting challenges of mankind is the modeling of the human nervous system. Mathematical models of this kind are of fundamental importance not only for neurosciences but also for applied sciences like neural prosthesis in clinical trials (for example, cochlear implants, pacemakers, and deep brain stimulators) or in new, strongly expanding fields, such as neural engineering where such models may help in optimizing state-of-the-art neuroprostheses technologies and to find new approaches for highly dimensional and difficult to observe systems, such as the brain, the spinal cord, or peripheral nerves. A very common question frequently asked by experimentally-oriented scientists is what models serve for.

68.1 Background	1247
68.2 Biophysics Models of Neuronal Response to External Fields	1248
68.2.1 Modeling of Self-Standing Neurons	1248
68.2.2 Modeling Effects of Extracellular Electrical Stimulation.....	1250
68.3 Finite Element (FE) Models.....	1252
68.3.1 The Electromagnetic Problem.....	1252
68.3.2 The Finite Element Method (FEM) ...	1253
68.3.3 Models in Practice	1255
68.4 Conclusion	1256
References	1256

For an exhaustive answer to this critical issue an entire book would be necessary, but in summary:

1. Models are a very powerful tool amenable to testing theoretical hypotheses and minimizing the use of animals in experimentations
2. If searching for optimal parameters for stimulations, or design geometry for electrodes models can minimize the high dimensional space of parameters or give hints for optimization of shape
3. Finally, they can give an insight into the basic understanding of the working principles of neuroprostheses.

68.1 Background

The idea of stimulating the nervous system with the purpose of rehabilitation has its origin in Luigi Galvani's work (1737–1798). He developed the so-called *galvanic* element, by means of which nerves could be stimulated, studying the provoked muscle contractions. Later, in 1792, Alessandro Volta (1745–1827) demon-

strated that the galvanic element uses electricity. So, since then nerves have been considered to be the *electric cabling* of the body. The intuition (confirmed in experiments) suggested that by means of electrical stimulation of nerves and muscles it is possible to obtain (almost) natural movements.

Neuroprostheses, which are devices meant to interact with the nervous system of disabled persons, often exploit electrical stimulation in order to develop assist devices or to deliver a therapeutic protocol.

In special cases, neuroprostheses are aimed to understand (decode) signals from the brain and to deliver signals to the tissue in order to elicit some targeted func-

tion (like deep brain stimulation [68.1], spinal epidural stimulation [68.2, 3] or peripheral functions [68.4–6]). The basic mechanism of how electric fields interact with the nervous system and how the nervous system is able to generate local fields must be investigated in order to understand how neuroprostheses work and how they can be improved.

68.2 Biophysics Models of Neuronal Response to External Fields

The principles of neural tissue excitation were deeply investigated through detailed biophysics models of neurons and fibers.

The biophysical modeling of neuronal cell response to the external electrical field evolved in two steps:

1. Significant theoretical and experimental work was carried out in order to emulate in a proper way the properties of single neural cells with different levels of detail (depending on the application field). This approach evolved until the development of neuronal and neural networks models, which are used in basic research and different everyday applications.
2. When sufficient knowledge about neuron models had been achieved, together with rapid expansion of neuroprosthesis applications, the need for models of cells in presence of artificially induced electrical fields became more and more important. Starting from analytical solutions, through special case applications, this field has now evolved into hybrid field-neuron models, accounting for both nonlinear

cellular dynamics, and anisotropic electrical field distribution.

68.2.1 Modeling of Self-Standing Neurons

It is a common assumption, accepted among scientific community [68.9], that the information is transmitted through the nervous systems by means of short action potentials, traveling along the neural cells by means of complex reactions occurring across the neurons membranes.

The membrane of neural cells is a structure able to maintain a certain fixed potential difference (usually negative) between the intracellular and the extracellular space. As a complex dynamical system, if perturbed (with a sufficient amount of current injection, for example) it generates the *all-or-none* event that is the action potential.

In the first part of the 20th century the great effort in modeling the electric properties of the neural membrane gave birth to the very first electrical cir-

Fig. 68.1 (a) Equivalent electrical circuit, as used by the HH model (after [68.7]) (b) Typical measurement system used by HH in order to measure the effects of different currents. U_{12} is the potential difference across the inside (label 1) and outside (label 2) of the cell, $[Na^+]_1$ and $[K^+]_1$ are ion concentrations (after [68.8])

cuit equivalent representations of the membrane [68.9] (Fig. 68.1a). However, the breakthrough in modeling the generation of action potential was the pioneering work of *Hodgkin and Huxley* (HH) [68.7] who received the Nobel Prize in medicine and physiology in 1963 for this work. The HH model is still the most used, with opportune modifications, because of its clearness, intuitive representation, and many times experimentally confirmed value. The model of Hodgkin and Huxley is based on a set of four partial nonlinear differential equations reproducing the dynamics of the action potential, as related to the different ionic currents flowing through the cell's membrane. The model is based on experimental measures on the active membrane of the giant squid axon. The experiments are based on voltage clamp measurements and space clamp measurements, as can be seen schematically in Figure 68.1. For more details about experimental procedure refer to [68.7, 8].

Ion currents are used to describe the ion exchange between the inner part of the cell and the outer environment that cause depolarization of the cell body, which otherwise is kept at a constant negative potential V_{rest} with respect to the external environment. The equilibrium potential is described by the Goldman equation which relates the membrane equilibrium potential with the equilibrium potential of each ion flux flowing across the membrane [68.10, 11]

$$V_{\text{rest}} = \frac{kT}{F} \ln \frac{p_{\text{K}^+}[\text{K}^+]_{\text{e}} + p_{\text{Na}^+}[\text{Na}^+]_{\text{e}} + p_{\text{Cl}^-}[\text{Cl}^-]_{\text{i}}}{p_{\text{K}^+}[\text{K}^+]_{\text{i}} + p_{\text{Na}^+}[\text{Na}^+]_{\text{i}} + p_{\text{Cl}^-}[\text{Cl}^-]_{\text{e}}} . \quad (68.1)$$

When assuming that the membrane is a capacitor (C_{m}) they defined the principal equations driving the potential difference (V in (68.1)) across the membrane. The total membrane current is the sum of the ionic (I_{i}) currents and the capacitive ones

$$I = C_{\text{m}} \frac{dV}{dt} + I_{\text{i}} . \quad (68.2)$$

Sodium (I_{Na}), potassium (I_{K}), and a leakage (I_{L}) of ionic current were described. Since the ionic currents are actively generated to induce depolarization, the HH model describes this mechanism as an active time-varying conductance that relates in a nonlinear fashion with the voltage difference across the membrane. Conductances of different ions are driven by proper *activation* and *inactivation* variables (m , n , h), which describe the probabilistic nature of an ion gate opening and closing. The total flux of ions across the membrane causes the generation of action potentials.

Thus, the complete equation is [68.7]:

$$C_{\text{m}} \frac{dV}{dt} = g_{\text{Na}} m^3 h (E_{\text{Na}} - V) + g_{\text{K}} n^2 (E_{\text{K}} - V) + g_{\text{leak}} (V_{\text{rest}} - V) + I_{\text{inj}}(t) . \quad (68.3)$$

The results of the model were astonishing. They were able to replicate the action potential generation and shape perfectly with respect to the experimental measurements. Of course, (68.3) gives a very simplified insight into this very complex problem. There are several assumptions regarding the electromagnetic field theory, which hold for the model [68.12].

However, this model is able to merge physiological concepts and knowledge (like ion gates and flows across the cell membrane) with an intuitive electrical circuit model. In this way, the mathematical description is closely related in all its components to the real electrophysiology of the cell. The success of the HH model pushed the intensive studies done by mathematicians and other scientists to simplify or improve the model, depending on the nature of the field in which they exploited the neuron models.

Frankenhaeuser–Huxley [68.13] adapted the HH model for the computation in mammalian myelinated fibers, based on the voltage clamp data from *Xenopus laevis*.

A famous mathematical evolution of the HH model is the Fitzhugh–Nagumo model (FHN model), which is based on the computational work of *Fitzhugh* [68.14, 15] and practical implementation by *Nagumo* [68.16]. Fitzhugh used phase space methods and the model of the Bonhoeffer–van der Pol oscillator in order to elegantly simplify the computation of the HH equations [68.14] and introduced physiological state diagrams. He also implemented the computational model of saltatory conduction in myelinated neuronal fibers, using an algorithmic solution similar to the ones implemented in current neuronal simulators (e.g. NEURON [68.17, 18], GENESIS [68.19]), Nagumo was able to construct an active pulse transmission line using tunnel diodes, making the device able to replicate the neuronal conduction, and showing in practice the validity of modeling approach starting from the HH model.

Modeling of neuronal cells then went in two different directions: towards the simplification (in order to understand the neuronal populations' behavior and also for practical applications as neural networks), and towards very high detail (aiming to represent all possible ionic currents dynamics, molecular effects etc.) [68.20].

Models aimed to study and optimize neuroprostheses devices are in the middle between the highly detailed and simplified models, since they have to properly describe the behavior of the tissue of interest (peripheral nerve or cerebral cortex pyramidal neurons), keeping the complexity low for computational reasons.

It is not the aim of the present text to go into the details of the evolution of further neuronal models. For the interested readers there are several excellent books on this topic such as those from [68.9] or spiking neuron models [68.22]. Nevertheless it is important to keep in mind the concepts depicted about HH and FHN model, since they are essential for the understanding of the functioning of hybrid models for practical applications of electrical stimulation of nerves.

68.2.2 Modeling Effects of Extracellular Electrical Stimulation

Electrical external stimulation requires the modeling of fibers and axons. Electric fields are, in fact, generated inside the tissues and the shape of the external electric potential along the fiber and cell membrane is responsible for the activation or the blocking of the fiber.

To study the electrical conduction properties of fibers, the cable theory [68.9] was exploited. The application of electromagnetic basic principles like the

Poisson equation and the complex nonlinear model of Hodgkin and Huxley gave rise to the representation of the axon as an infinite cable interleaved by nonlinear active components (the node of Ranvier) and linear isolating ones (myelinated tracts). The modeling for extracellular electrical stimulation has its origin in experimental findings.

Louis Lapicque was a physiologist and a pioneer in the field of neural excitability by external stimulation. From Galvani's work it was known that nerves can be electrically excited. However, the stimuli used to excite nerves, derived from batteries and capacitors, were hard to control. Therefore, a central question at the time of Lapicque was how much and how long a stimulation is required to excite a nerve. A further question raised was how can the relation between the stimulus and excitability be explained by the underlying biophysics? Interestingly, after one century these questions are still challenging. In his 1907 study [68.23] *Lapicque* introduced a model of the nerve that was compared to data he obtained from frog nerve stimulation. This model, based on a simple capacitor circuit, would form the basis for later models of the membrane (as shown above in the case of the HH model). A milestone in understanding the effects of electrical stimulation of neuronal cells by external fields is proposed in the brilliant work of *McNeal* [68.24], which was the basis

Fig. 68.2 (a) Electrical cable-circuit representation of a myelinated and an unmyelinated fiber. Making the limit for the intermodal distance (Δx) going to zero an analytic cable equation can be written, myelinated fibers are treated in an analogous way. (b) Stimulation with a monopolar electrode. a) The shape of the electric potential along the fiber, b) and c) the activating function f_n in (68.5) for anodic and cathodic current pulses. Filled areas represent the possible excitation zones (after [68.21] with permission)

for the so-called *activation function approach*. Furthermore, *Rattay* analytically enhanced the findings of *McNeal* [68.21, 25, 26] and made the calculations for the effects of monopolar, bipolar, and ring electrodes stimulation (Fig. 68.2) by using a simple circuitual representation (Fig. 68.2a) and opportune approximations.

These works discovered the proportionality between the excitability of fibers and the second spatial derivative of the electric potential along the fiber (activating function), a very intuitive and useful tool for understanding the basic mechanisms of electrical stimulation effects.

For the case of myelinated fibers, the effect of external field on its excitation is, in fact, given by

$$f_n(t) = \frac{V_{e,n-1} - 2V_{e,n} + V_{e,n+1}}{\Delta x^2}, \quad (68.4)$$

which is the second difference quotient of the extracellular potential along the fiber. In the case of unmyelinated fibers, it simplifies to

$$f_n(t) = \frac{\partial^2 V_e(x, t)}{\partial x^2}. \quad (68.5)$$

Its interpretation is straightforward: An action potential can be generated at the fiber coordinate $x = n\Delta x$ if f_n is positive. In areas where f_n is negative, hyperpolarization is produced. So electrical excitability of fibers is given by the intrinsic cable-like structure of the fiber and is strongly affected by the shape of the electric potential along the direction of the fiber. This model is the point of junction between biophysics modeling and the electromagnetic models for external fields within the nerves.

Recently in analytical and computational treatment [68.28, 29], it has been shown that the activation function-based approach lead to considerable errors in prediction. Yet, it still remains the quickest and most intuitive tool for approximate estimation of the effects of neural stimulation.

With the increase of computational power, models could start to account for the realistic, point by point voltage distribution induced by current injected by means of stimulating electrode and the high nonlinearity present in axonal answers. Presently, the state-of-art models account for anisotropy of extracellular conductivity, present in real nerves, and also for the nonlinear response of cells to the extracellular stimulation. Those two aspects are solved separately: by means of the finite element method (FEM) solving for distribution of voltages generated by the injected currents and by estimating the axonal response to the electrical stimuli

by calculation of neuronal dynamics. The numerical evaluation of neuronal dynamics is usually achieved using dedicated neuron computation oriented software. This kind of model could be called hybrid field-neuron models (or hybrid FEM/neuron models). A conceptual framework for these hybrid models was developed in the work on spinal cord epidural stimulations by *Coburn* [68.3, 30].

More recently, *McIntyre* and colleagues developed a model for extracellular stimulation of the central nervous system cells [68.20], which was consequently applied in different studies, with one aim being to optimize the design of cuff flat electrodes for peripheral nerve stimulation [68.5].

To couple the external electric fields with the fiber or cell, proper models to account for external stimulation must be developed. The state-of-the art, most used approach is the so-called compartmental model-

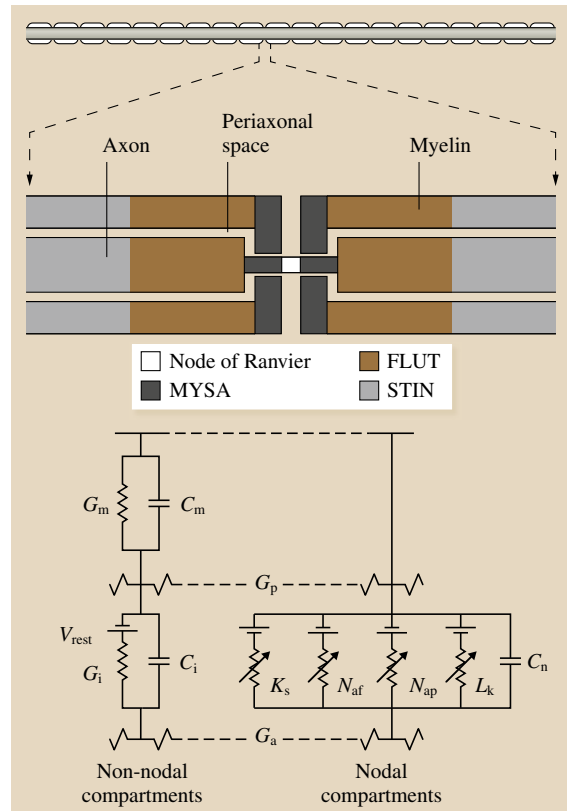

Fig. 68.3 Multicompartmental model of a myelinated fiber. The active part is represented by the Ranvier node while a realistic finite impedance representation of the myelin is exploited (after [68.27] with permission)

ing of fibers, which is based on the subdivision of fibers and cells into elementary circuit representation used to model the different parts of the cell or fiber, like axons, somas, and Ranvier nodes. Free academic software like NEURON or GENESIS can accurately reproduce the mechanism of generation of action potential of arbitrary complex cell representation. One of the most used models that implements compartmental modeling is the MRG model for the mammalian myelinated fiber (Fig. 68.3) proposed in [68.27].

This model represents the nonlinear modified Hodgkin–Huxley equations for the active compartment of the axons (Ranvier nodes) and a detailed realistic representation of the myelinated tracts. The success of this model is due to its capability to reproduce several experimental aspects of cells dynamics and to its availability; indeed this model can be found in the database available in [68.31].

The difference between state-of-the-art models resides basically in two aspects: the first is the membrane dynamics and the second is the representation of the compartments. With membrane dynamics we refer to the differential equations that relate the membrane po-

tential to the extracellular potential; usually models differ for the choice of a particular implementation (Hodgkin–Huxley or Frankenhauser–Huxley) and on the numbers of ion channels implemented.

With compartment representation we refer to the choice of the type and number of compartments. For example, a myelinated fiber can be represented using only two compartments [68.15, 24], namely the active part, the Ranvier node, and the internodal myelinated tracts. The representation of the myelin as a perfect insulator or as a realistic resistive compartment, highly influences the outcome of the model, in particular regarding frequency effects [68.32]. Therefore, care should be taken in the choice of the model with respect to the desired outcome regarding both the biophysical representation and the compartmental representation.

However, even with the most accurate biophysical representation of the cell, or fiber, of interest, the shape of the fields generated in a stimulation process is critical for a correct prediction of nerve activation. So, accurate electromagnetic models of extracellular structures and electrodes should be implemented.

68.3 Finite Element (FE) Models

With the development of fiber models for external electrical stimulation, models of electrical sources and extracellular space became critical. Active fibers or brain, spinal cord, or peripheral nervous system neurons are placed within complex biological structures. These structures are inhomogeneous, anisotropic from an electrical and diffusion point of view, and have odd geometrical shapes. The analytical solution of the Maxwell equations to compute voltage profiles is impossible in such complex spaces and then numerical methods should be implemented

68.3.1 The Electromagnetic Problem

The electrical stimulation process of the nervous tissue is driven by the solution of the Maxwell equations inside proper solution spaces. The principles of external electrical stimulation are based on the hypothesis that current injection into tissues, of a sufficient amount, is able to elicit fiber excitation or inhibition.

Mathematically, the problem is defined by the solution of the Maxwell equations for a given space and a proper representation of the source (which can be a point process or a fully spatial representation of an

electrode). In particular, the basic formulation is the Laplace equation, or alternatively the Poisson equation, for the electric potential V_e

$$\nabla \cdot \sigma \nabla V_e = \nabla \mathbf{J}, \quad (68.6)$$

where \mathbf{J} represents the injected current density and σ the conductivity tensor.

It must be stressed that this equation came from a manipulation of the fourth Maxwell equation in which we neglect the time derivative of the electric fields, using the so-called quasi-static approximation. The approximation is justified by the fact that at low frequencies (as those used for external stimulation e.g. less than MHz) wave effects can be neglected due to the specific conductivity values of tissues.

Detailed studies have been carried out to explore this basic work hypothesis and results seem to validate it, although with some limitation with respect to pulse shape and duration [68.33].

This linear partial differential equation coupled to proper boundary condition (usually of Dirichlet type) gives the solution for the stimulating electric potential. The complexity of the solution depends on the level of

realism of the model, both in terms of geometrical shape and of conductivity properties.

The first models [68.24] used, for the sake of simplicity, an isotropic representation of the extracellular space, seen as an infinite space with constant and isotropic conductivity (or resistivity) σ_m . A current point source I (placed at $r = 0$) was used to represent the stimulating electrode.

In this case, the boundary conditions are

$$V_e(\infty) = 0, \quad (68.7)$$

and thus the simple analytical solution is [68.24]

$$V_e(r) = \frac{1}{4\pi\sigma_m} \frac{I}{r}, \quad (68.8)$$

which shows the characteristic $1/r$ behavior of the monopolar solutions.

For the purpose of understanding the basic mechanisms of fiber activation and blocking, this model is a good compromise. Because, by neglecting a realistic and too complex representation of the extracellular environment, the scientist can focus on the axon properties. However, if the goal is to improve technologies or stimulating strategies of neuroprostheses a detailed representation of tissues and sources is needed.

In peripheral nerve stimulation, for example, fibers are located inside structures named fascicula, which are surrounded by a thin insulating membrane (the perineurium) and everything is embedded into the epineurium, which is the connective tissue that builds up the nerve structure (Fig. 68.4).

As demonstrated in [68.35] the shape and electrical properties of tissues can bias not only (as obvious) the solution of the Maxwell equations, but also the final prediction of the model in terms of a nerve's excitability. Since some of the essential aspects for FES are

the currents necessary to elicit fiber selectivity (that is the ability to activate just the population of without stimulating the other populations), and the capacity to overcome the inverse recruitment problem [68.6] by means of more graduated activation of muscle, it is important to understand how those properties are affected by different tissues representations.

Excitation thresholds, and thus predicted selectivity and steepness of the fiber recruitment, will be affected strongly by different perineurium representations. The realistic representation of tissues inside the Maxwell equations is done by the definition of the geometrical space, and its electrical properties, by means of the tissue specific conductivity tensor. The problem is then defined in a geometrically complex anisotropic non-homogeneous space where analytical solution is not possible.

68.3.2 The Finite Element Method (FEM)

The finite element method (FEM) is a standard numerical process used to solve partial differential equations in one or more variables in arbitrary complex spaces (for details see [68.36]).

It is based on the discretization of the geometrical space into primitive elements (mesh) where the equations are numerically integrated and then assembled into a global solution.

The subdivision of the whole space into primitive elements allows for an element-wise characterization of material properties. For the case of the electrical stimulation of tissues, the finite element method is used to solve the Maxwell equations, usually in Laplace form for the electric potential. Arbitrary complex structures such as cerebral cortex [68.1] spinal cord [68.3, 20] or peripheral nerve [68.5, 6] can be represented and

Fig. 68.4 (a) Histological image of a rat's sciatic nerve. Tibial, sural and, peroneal fascicles are visible (taken with permission from [68.34]). Bar = 100 μm ; (b) a three-dimensional FE model of the nerve surrounded by a flat interface nerve electrode (FINE) (after [68.5] with permission)

Fig. 68.5 An example of a half cat spinal cord meshed with nonuniform hexahedra (after [68.20])

electromagnetically characterized (in terms of conductivities).

The representation of structures as conductors is known as the volume conductor model. It means that structures are treated as volumes and characterized by a conductivity tensor.

The numerical process seeks for a polynomial approximation of the solution of the problem into the defined finite volume Ω . To guarantee a numerical solution, the equation system is *relaxed* into the so-called weak form

$$\int_{\Omega} v \nabla \cdot \sigma \nabla V_e = \int_{\Omega} v \nabla J \quad (68.9)$$

obtained after the multiplication of (68.6) on both sides by the function v , which can be any function with a continuous derivative, and integration on both sides. The role of the function v is to relax the mathematical constraints for the existence of the numerical solution to the problem by the use of the Green's formula. Thus, distributing the derivatives over the two variables we obtain

$$\int_{\Omega} \nabla v \cdot \sigma \nabla u - \int_{\partial \Omega} v \hat{n} \cdot (\sigma \nabla u) = - \int_{\Omega} v \nabla \cdot \mathbf{J}_p. \quad (68.10)$$

In this form the computation of the integral is made easier by only the presence of first-order derivatives.

The subdivision of the whole volume into primitive elements allows for the solution of the weak form in each volume element with a finite set of basis functions. The basis functions serve as a local polynomial approximation of the solution in each primitive element; the degree of these functions along with the size of the elements affect the numerical solution quality. A basis function is a polynomial of given order with small support such that its value is $\psi_i = 1$ on the associated i th mesh node and $\psi_i = 0$ on every other mesh node. With such functions it is possible to represent the solution of the problem as a linear combination of the basis function and the solution at each mesh point

$$V_e(x) = \sum_{i=1}^N V_e(x_i) \psi_i(x) \quad (68.11)$$

and in an analogous way with the function v and the sources \mathbf{J} . Then the integrals can be solved as products between basis functions and conductivity tensor values for each volume element and assembled into a matrix \mathbf{A} named stiffness matrix.

The discretized weak form is then expressed as a linear system

$$\mathbf{A} \cdot V_e = b, \quad (68.12)$$

which by numerical inversion gives the solution V_e for each point of the mesh.

Boundary conditions are critical to the solution of the problem, and care should be taken when defining the problem (which can have different boundary conditions with different stimulating devices). In this kind of problem sources are usually not explicitly represented by a discretized current density as in (68.1) but are expressed through continuity conditions at the boundary between media of different properties (like at the surface of an active site). In this way, the problem to be solved is expressed as a Laplace equation.

The general approach to face this problem is:

1. Choosing the proper source representation, depending on the stimulating device of interest (cuff electrodes for PNS, intraneural electrodes for PNS, microelectrodes for brain stimulation, spinal electrodes for epidural or intraspinal stimulation etc.).
2. Choosing the proper set of boundary conditions for the problem.

3. Discretization and construction of a mesh for the geometrical extracellular space in which the fiber or cell is placed.
4. Computation of the solution of the problem.

The computed solutions should then be interpolated into the fiber or cell model and used as an external stimulation process. One of the first examples of this approach is the pioneer work of *Coburn* [68.3, 30], where he computed the activation of fibers during epidural stimulation of the spinal cord. The flexibility of this approach is reflected in the number of applications applied today: peripheral nerve stimulation [68.5, 6], spinal cord microstimulation [68.20], deep brain stimulation [68.1], and source localization in peripheral nerves [68.37].

The ability to model more and more complex structures and detailed biophysical characteristics of cells and fibers will lead to a better understanding of the basic principles of neurophysiology and to the optimization of actual technologies and strategies for their use. Realistic representation of anatomical structures and electrodes shapes will improve the predictions of models and help in finding new ways for stimulation and recording. Some details about the use of this model in practical applications can be found in the next section.

68.3.3 Models in Practice

The literature is rich with models of cells, fibers, and membrane dynamics, and each of these can be used in practice. So, which mode is suited for each application? The model that one should use in one's own practical or theoretical applications should not necessarily be the *last one* or that used by everybody. Rather it depends strictly on the field of interest. If the aim of a study is only to understand if some device is amenable for a particular application, then also an approximate approach, like the one proposed in the concept of the *activation function* may be an excellent tool to get an answer.

As has already been mentioned, there are many models that are amenable for electric external stimulation. However, if we focus on neuroprosthetic applications, the use of models can be summarized as follows:

1. Search for optimal parameters of stimulation in order to obtain the most effective and efficient stimuli
2. Search for the effect of geometry and placement of stimulating electrodes
3. Search for a basic understanding of therapeutical effect of a certain device, on a cellular or a systemic level.

Stimulation Parameters

Already in the very first experimental studies done in this field research tried to determine the influence of the pulse width (PW) of the current stimuli, together with frequency (f) and amplitude (a). The analysis of the strength–duration relationship for rectangular waveforms as defined by *Lapicque* [68.23] or *Weiss* [68.38] shows that a short stimulus results in greater charge efficiency, while a long stimulus results in greater power efficiency; a PW equal to the chronaxie time optimizes energy efficiency.

The effects of stimulation parameters (PW, f , a) are still the object of very intensive modeling and experimental approaches. PW effects have been studied in, among others, [68.39]. They used a genetic algorithm (GA) coupled to the compartmental model of the axonal population (MRG model) to determine the energy-optimal waveform shape for neural stimulation, making also a preliminary validation of their model in an animal model. The GA found waveforms that could substantially increase the battery life of implanted stimulators (e.g. in deep brain stimulators).

Sahin and *Tie's* work [68.40], is an excellent example of suitable choice of models. They preferred using *Sweeny's* model [68.41], which is similar to HH, in terms of the gate variables except for the absence of the potassium channel. They searched for the most efficient waveform that maximizes the charge injection capacity of the electrode while providing the lowest threshold charge for neural activation. Linear and exponential decrease and Gaussian waveforms were found to be the most efficient pulse shapes, giving very important hints for future experimental studies (at the moment the most conventional and almost exclusively used waveform is the rectangular one). A very common problem in FES (neural and muscular) is the so-called inverse-recruitment (e.g. the artificial activation first of the bigger diameter and then of the smaller diameter fibers, which is the opposite of the natural activation order). This problem can be addressed by studying a proper waveform to minimize inverse recruitment. There are several modeling studies trying to face this problem [68.42–45]. All are based on physical considerations that came up thanks to fiber models. In particular, they try to use two properties of fiber excitation. The first is the fact that larger diameter fibers (which in normal conditions mean also longer internodal distances) have lower excitation thresholds. This can be easily explained by the activation function concept: on larger distances the voltage quotient (68.4) is larger and then the probability of excitation is higher.

Secondly the inverse relationship of the induced voltage changes with the distance (68.8), which makes fibers closer to the electrode more sensitive to excitation. Having these properties in mind, it is possible to study proper waveform profiles that make the excitation of smaller fibers easier than larger ones; usually these waveforms have some kind of hyperpolarizing prepulse to block larger diameter fibers, and then the subsequent excitation should occur first for the smaller one, thus restoring normal recruitment [68.44, 45].

Geometrical Parameters

In searching the geometrical parameters for the optimal electrode design, or its optimal placement, many models were developed. In a recent study for pudendal afferent fibers stimulation [68.46], the FEM model has been coupled to the activation function in order to explore the parameters for different electrode geometries, finding a ring electrode to be the optimal one for the application. The results of the study were also validated in an animal (cats) model.

There are several works regarding the study of stimulation properties of different electrode geometries. Regarding extraneural stimulation, in the works [68.5, 41] intensive simulation on cuff geometry showed that a flat interface can be more selective than a simple cuff and also that selectivity can be enhanced using proper stimulation paradigms on multicontact cuffs. There is not much work on intraneural stimulation, because the meshing task to model the electrode can become a critical issue. Therefore, the majority of works use point sources to stimulate nerves or the spinal cord [68.3, 47, 48]. These models, however, give important hints on which fibers can be stimulated with intraneural electrodes, and most of all they demonstrate that intraneural electrodes can reduce the inverse recruitment

without particular waveforms, but just because of the fact that currents are located within the fibers.

Interpretation of Biophysical Mechanisms

A very important aspect of models is the fact that they can be used to understand the neurophysiological basis of neuroprosthetic devices. An example is the work of *McIntyre* and coworkers [68.1] on deep brain stimulation (DBS). Their models helped the understanding of the physiological mechanisms underlying DBS techniques. They were able to validate their hypothesis in experimental studies and, therefore, gave an insight into what is going on with DBS and why DBS is able to modulate brain activity.

Critical Remarks

The major problem of most of the discussed models is the general lack of rigorous experimental validations. Experimental validation is essential to understand if the hypotheses are valid and to permit us to correct the parameters of the model. Moreover, together with the model output, they can also lead towards falsification of eventual incorrect scientific assumptions. A very important aspect is that models contain only the things we implement inside, and we should be always critical of the results obtained. It would be very dangerous if a model were highly specialized to perfectly reproduce results just in one case (like a kind of overfitting), and then just slight change of parameters would destroy the stability. Therefore, whenever possible, a sensitivity analysis [68.49] should be performed to test the robustness of the model. Having a robust model, with respect to the parameters used for its construction, can also permit us to observe and understand some emerging property of the system under study, which could be difficult to do in the case of very specialized ones.

68.4 Conclusion

Models can then assess different issue in the neuroprostheses design and study. They can help during the design phase by giving hints to geometrical parameters or stimulation parameters, but they can also be used to

understand if mathematical modeling of neural models is able to reproduce experimental results. This exploits the intrinsic property of science, modeling to understand reality and to improve technologies.

69. Operating Tables – the Surgeon's Workplace

Bernhard Kulik

The central element of any operating theater is without a doubt the operating table. Wherever surgical interventions are carried out, operating tables are essential. Accordingly, the variety of tables available is very wide, ranging from simple, mobile operating room (OR) tables, right up to OR table systems with various, special OR table tops.

The type, design and functional properties of the OR table depend on the surgical discipline, the ergonomic requirements of the surgical team and, last but not least, on the financial resources available.

69.5.2 Automatic OR Table System
Cleaning and Hygiene 1271

Simple OR table designs are usually deployed in hospitals with smaller surgical departments as well as in larger hospitals with decentralized operating theaters

Fig. 69.1 Operating table for outpatient surgery

like, for example, those with emergency department operating rooms (Fig. 69.1).

They are also often used for out-patient surgery, in so-called day clinics, or out-patient operating cen-

Fig. 69.2 Mobile operating table with electrical autodrive function

ters. These OR tables can be upgraded and modified by adding various accessories and, depending on the model, can be adjusted manually or electrically. An electrical autodrive function may also be implemented, assuming patient logistics calls for it (Fig. 69.2).

Modern OR table systems are characterized by the fact that the intervention-centric table tops mean they

are optimized, on the one hand, to meet the special requirements of the individual surgical disciplines regarding the best patient positioning and best access to the surgical field and, as such, are a significant factor contributing towards the success of the surgical intervention. On the other hand, however, they also meet technical requirements in terms of stability and hygiene and the use of x-ray equipment.

69.1 The History of the Operating Table

Some 150 years ago, when asepsis was not even on the agenda, operations were normally carried out in the patient's bed. However, because of low bed heights, surgeons started to place their patients on higher tables, in order to gain better access to the surgical field and to give themselves a more ergonomic working position (Fig. 69.3).

The development of OR tables has kept pace with the development of surgery itself. It has occurred more or less in parallel with the continually expanding knowledge and ability of the surgeons and, over time, has been significantly influenced by specialization in the individual surgical disciplines.

Medical developments have called for improved access to the surgical field and, therefore, brought about improved patient positioning. This resulted in the emergence of *OR furniture* with table tops divided up into head, back, seat, and leg plates (Fig. 69.4).

Improvements in operating techniques made it necessary to be able to raise certain parts of the body (at the point of incision), to provide better access to the in-

Fig. 69.4 Segmented operating table top

terior of the body and then to return them again to the flat position, after closing up.

Over the course of the last 70 years, general surgery has divided into individual surgical disciplines. The result of surgical specialization has been the development of special OR tables that differ in terms of the table top geometry and the layout of the various operating elements.

In the case of head operations, for example, no operating elements may be installed in this area of the OR table, as they may not be handled by nonsterile personnel during the operation, which could impact on overall sterility. As a result, special OR tables were developed for head operations.

The development of OR tables, with ever more complex table top adjustment options for other specialist surgical disciplines, followed at the same time.

A further significant factor that influenced the development of OR tables were the achievements of intra-operative imaging. It is impossible to imagine an OR these days without a mobile x-ray amplifier (Fig. 69.5).

The call for the combining of further imaging processes such as CT and MR with OR tables, has led to an increase in the use of materials other than steel, such

Fig. 69.3 Historic operating room furniture

Fig. 69.5 OR table for use with mobile x-ray amplifier

Fig. 69.6 Advanced workplace for image guided surgery (AWIGS)

as plastics reinforced with carbon fiber, as these ensure low-artifact radiolucence (Fig. 69.6).

69.2 The OR Table System

As surgeons required ever more specialized OR tables, tailored to particular operations, the development of mobile OR tables was extended to include, not just the division of the table tops but also to the table columns and/or their separation from the actual table tops, which brought with it further advantages and simplifications. The idea of an OR table system consisting of a column, a removable table top, as well as a transporter for the table top was born (Fig. 69.7a–c).

The predecessors of the current modern OR table systems had a mobile table column mounted on castors, so that the OR table could be moved and was not tied to one place, but the table top was fixed to the column. This had the disadvantage that the compact unit was very heavy for a single person to move, which had an adverse effect on mobility. As a result, the column and the table top were separated.

Modern OR table systems are available both as stationary, i. e. fixed versions, as well as mobile ones. With the stationary version, the table column is anchored to the floor and the electric is fed through ducts in the flooring. The OR table top can be removed and is positioned over the table column using a transporter, (also known as a Lafette) and then transferred from the transporter so that it can then be wheeled away again.

Fig. 69.7a–c OR table system. (a) Column for stationary operating table. (b) Removable table top. (c) Transporter for the table top ▲►

Fig. 69.7 (continued)

As the table column is bolted to the floor, there is no need for the deployment of a mobile OR table base. This gives the surgeons much more leg-room. A further advantage is that additional medical devices that are required, such as a mobile image amplifier or C-arms can be deployed and positioned at the surgical field without difficulties. The significant advantage of a mobile OR table system, on the other hand, is that this system can be moved freely within the operating theater or department. There is no need for electrical installations, as this OR system has rechargeable batteries to

Fig. 69.8 Modular assembly

provide the required power, with sufficient capacity to be able to carry out some 100 operations under normal OR conditions.

OR tables or table systems are controlled using a hand-held device connected either wirelessly using infrared signals or via cable. In this way, the electrically adjustable functions can be activated from a distance, without impacting on the sterile OR environment. Individual segments of the table top, such as leg or head plates, can be removed (Fig. 69.8).

Technological advances in the area of medical technology have led to the development of high quality OR table systems with multifunctional system properties that fulfil today's high medical, hygiene and technical requirements.

69.3 Technology of Operating Room Table Systems

69.3.1 Construction of an OR Table System

The individual elements that make up the construction of an operating room table system can be described as follows:

Table Columns

An OR table system is available with a stationary column, i. e. one that is fixed to the floor, and therefore

fixed to a particular location or with a mobile column, i. e. one that can be moved to different locations. Both types have their own, equally important advantages (Fig. 69.9a–c).

OR Table Tops

OR table columns can be equipped with many different, exchangeable table tops that meet the special requirements of the individual surgical disciplines and whose

Fig. 69.9a–c Operating room table system columns. (a) Stationary column, (b) mobile column, (c) wheeled column

segments can be adjusted independently of each other, to achieve the required position. This means that the OR table top can be divided up in different ways, e.g. 4-, 5-, 6- or 8-way, in terms of:

- Head and foot sections, which can be swiveled up and down and removed if required.
- Middle or back sections that normally have multiple divisions and can be adjusted to achieve special slope angles.
- Leg sections that can consist of a pair of leg plates that are separated laterally or longitudinally and that can be adjusted automatically, with the option of moving or spreading both sections in a particular direction, either at the same time or independently of each other.

The OR table top is designed in such a way that adding or removing individual segments enables it to be lengthened or shortened as required. It should also have a longitudinal shift in order to facilitate whole body movement using the C-arms (Fig. 69.10a–c).

Operating Room Table Pads

The pads need to fulfill various functions. To start with, the patient must be positioned safely and carefully. The comfort of the patient is of less importance here, as the surgical procedure is done under anesthesia; it is more important to provide the greatest possible protection against nerve damage and pressure necrosis. Furthermore, the pads must be such that the surgical team has the best possible access to the area of the operation. As a result, the operation can be completed in the shortest possible time, which is particularly advantageous to the patient. Finally, the pads must comply with the strictest hygiene requirements, meaning that they must be easy to clean and disinfect.

Controllers

The table columns and the respective table tops are controlled wirelessly through an infrared or radio remote control. Alternatively, they can also be controlled using a cabled controller. In special application areas, control is also possible through a foot-operated switch, operated by the surgeon. Additional control options include the wall-mounted operating panel or an integrated OR control system, which controls the most important OR functions such as lights, OR table, endoscopy equipment, etc., either via a touchscreen monitor or through voice control (Fig. 69.11a,b).

Transporter

Using the transporter (Lafette), which is easy both to move and to manoeuvre, the OR table top is transported to the mobile or stationary table column, which then takes over the support of the table top for the duration of the operation. Lafettes are also used for transportation over longer distances and the exchange of table tops in the logistic workflow between bed transfer, pre-operation, operation, post-operation, and the return to bed transfer (Fig. 69.7c).

Accessories. Standard accessories include arm positioning equipment, lateral supports, infusion stands, leg supports, head rings, back and pelvic supports, and hand and body straps, etc.

69.3.2 Mobility and Flexibility of OR Table Systems

Modern OR table systems are characterized by their mobility, flexibility, and compatibility. It is not just the fact that a mobile OR table column allows you to select the location in the operating theater as required, it is also the fact that there is compatibility between the var-

Fig. 69.10a–c Various operating room table tops. (a) Extensible, (b) universal, (c) on transporter

ious, differently-priced OR table systems, both mobile and stationary.

In order to guarantee flexibility, today's OR table systems are designed in such a way, or can be modified, to ensure that they meet the positioning requirements of different surgical disciplines. If you have deployed an OR table system and, should operating and positioning techniques change in the future, you only need to order a suitably modified table top that is compatible with the basic OR table column element. In this case, in an OR department equipped with mobile

operating tables, it would be necessary to order a completely new OR table, which would entail considerable investment.

Today, more than ever, time savings are a significant criterion for the efficient usage of operating theaters. The use of an OR table system, i.e. a table column, two transporters as well as two OR table tops, facilitates a so-called *roundabout system*. While one surgical procedure is being finished up in the operating theater, it is possible to bring the next patient from the bed transfer room to the pre-operation room on the second

Fig. 69.11a,b Control units for table tops. (a) Cable control unit, (b) wall-mounted control unit

table top, in order to administer the anaesthetic. Once the previous operation is complete, the patient has been taken out, and the operating theater has been cleaned, the already anaesthetized patient can be moved into the theater, where he/she can be transferred, while still lying on the table top and potentially already positioned, onto the OR table column. This *roundabout system* offers the advantage that operations can continue without any great time delay factor, whilst also taking the time periods required for the effects of local anaesthetics into account.

Of course, such overlapping working practices can also be achieved using two mobile OR tables. There are, however, both advantages and disadvantages. One disadvantage is that a mobile OR table weighs between 200 and 300 kg, which means that together with the weight of the patient, in a worst case scenario, around half a metric tonne would need to be moved. One advantage is that because all functions are *on board* with a mobile OR table, the patient can be positioned and prepared ahead of time almost 100%, for the surgical intervention. If well organized, this can represent time savings (Fig. 69.12).

Fig. 69.12 Patient workflow

69.4 Safe Patient Positioning

Operation positioning designates the position that the patient's body is placed in, in order to guarantee the surgeon the best possible access to the operation area. Additionally, every effort is made to optimize the presentation of the anatomical structure of the operation field.

The following *standard positions* have proved themselves (Fig. 69.13a–d):

- Supine position/special supine position
- Prone position/exposed stomach position
- Lateral position

Fig. 69.13a–d Standard positions operating room tables for various surgeries. **(a)** Supine position for knee arthroscopy, **(b)** thorax surgery, **(c)** sitting position for neurosurgery, **(d)** adiposity surgery

- Dorsosacral position
- Genucubital position
- Sitting position/half seated position.

The patient ought to be positioned or be placed in the optimum operating position by the anaesthetist and the surgeon in conjunction with the OR care team for administering the anaesthetic and for the operation. Before this, the responsible specialists must decide, based on the general condition of the patient, which stresses or strains the patient can be exposed to, as a result of the positioning on the OR table. The factors that need to be considered here are the patient’s age, weight and constitution, as well as their general state of health in respect of heart, lungs, circulation, metabolism, nervous system, muscle tissue, and skin tissue damage that may have been caused by metabolic dysfunctions, obesity, rheumatoid arthritis, heart and vascular weakness, or circulatory disorders, etc. The factors listed here will significantly affect the strains that a patient can withstand and must be taken into account when deciding on the positioning, as every type of patient positioning represents an additional strain.

An additional factor is that the anaesthetic and muscle relaxants actually increase the strains as they affect breathing, blood supply, and nerves in particular. Pain sensitivity is deactivated while under anaesthesia so that the patient is not aware of pain caused by pressure or strain trauma and cannot react because of interrupted adverse effects reflexes and reduced muscle tone.

This means that the patient can suffer injury even before the actual surgical intervention has started. Extreme care must be taken when making even the simplest positional change during the operation.

Endotracheal anaesthesia is administered when patients are in the normal supine position. Only once the deep anaesthesia state with relaxed muscles has been reached, can the actual operation positioning be done, taking the patient-specific factors into account (see above).

It should be ensured that the patient’s arm that is going to be used for the anaesthetic and the infusion is lying evenly and extended, on a well padded arm positioning device. If necessary, the arm positioning device must be lengthened with a padded Cramer rail. If the positioning is wrong this can lead, for example, to irritation or paralysis caused by damage to the *N. radialis* or *N. ulnaris*, in spite of soft OR table padding. Overstretching the arm past the 90° angle, both abduction and supination, can cause paralysis of the plexus.

When it comes to leg positioning, the foldable leg plates on modern OR tables can be adjusted to suit legs very well, so that pressure is distributed over a large enough area and the best possible operation position can be achieved. The use of leg holders on the other hand, e.g., during gynaecological or urological interventions, carries a certain risk of causing pressure injuries and strains through incorrect positioning or deployment, by, for instance, overstretching legs that have been relaxed by anaesthetic, by the pressure of wrongly adjusted knee crutches as well as by resting the lower extremities on the leg holder bars.

The same care must be exercised when positioning the trunk. Not changing the position of the patient of a longer period of time, can lead to a further problem: decubitus (bedsores or pressure sores).

69.4.1 Decubitus Injuries

As anaesthetics and muscle relaxants can relax the skin tissue such that the arterial pressure is weaker than the external pressure, which is influenced by body weight, the blood supply can be impaired and, as a result, the skin tissue receives insufficient nutrients. Thus, for patients who are kept in the same position for a longer period time, there is an increased risk of skin and skin tissue damage.

A decubitus caused in this way can develop into necrosis (localized death of skin tissue cells), in particular when there is only a thin layer of skin covering the bone. Locations particularly at risk are:

- In supine position: heels, sacrum, elbows, shoulder blades, back of the head
- In prone position: pelvis, hips, knees, points of the toes
- In sitting position: heels, crucial ligaments, elbows, head
- In lateral position: hips, toes, knees.

At the same time, care must be taken that there is no trapping of the skin, which can lead to necrosis as a result of reduced blood flow. This risk is particularly prevalent in longer operations.

Following heart operations during which the patient’s body was cooled down and single-pole high frequency devices were used, large areas of tissue necrosis were identified, which principally were diagnosed as burns. Initial tests regarding the causes of this necrosis points that were identified as burns, by the operation team, the hospital’s technical staff, health and

safety and the manufacturer of the HF surgical equipment were unable come up with any explanation based on a physical cause. Only a differential diagnosis investigation of the suspicion of pressure necrosis, could definitively exclude the possibility of exogenic causes of burning.

A first indication of pressure damage is given by a reddening of the skin that does not recede immediately following a change of position.

Essentially the risk of decubitus is not greater for a person who is overweight than it is for one who is underweight. The difference is that with overweight patients, the area of damaged skin is larger, but in most cases the damage is less pronounced, while with underweight patients, the damaged area is smaller but the skin damage is more pronounced.

Reasons for the Development of Decubitus Caused by OR Positioning

The following list gives possible causes for the development of decubitus caused by OR positioning:

- OR table padding that is hard or worn out.
- Longer operations with increasingly older patients.
- Increased self-weight, particularly with obesity. On the other hand, however, also with cachectic patients where the skin is very close to the bones because of missing or reduced layers of fat under the skin. Areas of the body particularly affected here include the sacrum and the heels.
- Medicinal influences (anaesthetics), which reduce muscle and tissue tone.
- Punctiform loads resulting from positioning necessary during the operation.

Decubitus Prophylactics

Decubitus can be avoided by implementing the following countermeasures:

- Aiming for shorter operation times, as experience shows that skin tissue damage is likely to occur, at the latest, after 2 h.
- Regular and timely replacement of older or worn OR table pads with padding that is thick and soft enough.
- Careful attention to the individual segments of the OR table top and the body of the patient.
- Pressure relief brought about by the application of additional padding at the predisposed locations.
- Avoidance of skin trapping and the formation of folds or creases both in patients' skin and in the

OR table padding during positioning and intra-operative patient positioning.

- Avoidance of the intra-operative distortion of patient positions.
- Carrying out positional changes during longer operations, whereby small adjustments of the motorized joints of the OR table can be used to relieve pressure on tissue and enable reperfusion.

69.4.2 Long-Term Position Injuries and Legal Responsibility

Optimized patient positioning is the best prophylactic against decubitus! As analyses of damage claims by authorized experts show operation position injuries are reported regularly in many damage claims, which represents a serious problem for the patients and increases the costs of the post-operative care.

Improper and incorrect patient positioning on the OR table may cause problems, ranging from temporary impairment up to serious and irreversible injuries. The areas most affected are:

- Nerves that are traumatized, in particular the plexus brachialis
- Eyes
- Skin
- Muscle tissue
- Tendons and ligaments.

There are comparable rules in force in different countries when it comes to clarifying the questions of legal responsibility for sustained position injuries. They indicate that while the task of positioning patients on the OR table before the operation is down to the anaesthetist, during the operation it is the job of the surgeon, taking any anaesthetic-related risks into account. However, essentially it is the joint responsibility of both the surgeon and the anaesthetist.

For the surgeon, this means that he bears the medical and legal responsibility and that any increase in risk in relation to anaesthesia, resulting from a necessary change in position, is justified. The legal responsibility rests with the anaesthetist, as part of his intra-operative duties, to make provisions for the specific risks that result from the positioning and/or to mitigate against them through the implementation of particular preventive measures. Special attention should be paid to the important issue of the risk of burning, in connection with patient positioning, during operations where single-pole high frequency devices are used.

69.4.3 Patient Positioning When Deploying Single-Pole HF Devices

High-frequency (HF) surgery equipment is used to separate specific areas of tissue using thermal energy and at the same time to cause coagulation. For this purpose, single-pole high frequency surgical devices with an active and a passive electrode are used. Because of its shape, a high current density occurs at the active electrode, the so-called cutting or coagulation electrode, as opposed to the large-surface, passive electrode (neutral electrode), which conducts the current away and, therefore, has a low current density.

Possible causes for complications when carrying out single-pole high frequency surgery are, on the one hand, that the patient has not been placed correctly in a position that will ensure that the body is not earthed and, on the other hand, the faulty application of the neutral electrode. In order to avoid localized burning caused by HF surgical equipment, the patient must be positioned in such a way that he/she is completely insulated from the OR table and its accessories, as well as being safeguarded, through a correct installation of the neutral electrode. This means:

- The patient must be positioned in such a way that he/she is not in contact with electrically conductive components such as metal parts of the OR table, holders, damp cloths, etc. with particular attention being paid to the extremities. There must be an electrically-insulating, dry, thick underlay between the patient and the OR table and holder, which must not become damp during the HF surgery, e.g. with blood or liquids used to rinse out the area of the operation.
As dry and nonconductive fabric must be laid between patient and table padding, a minimum conductivity for the padding is laid down, in order to avoid electrostatic discharge. If this were not the case, discharge sparks caused by frictional electricity could be produced, which would represent a dangerous source of ignition energy for flammable anaesthetic gases or alcohol vapors.
- The whole surface of the neutral electrode must be applied well to the patient's body, such that it cannot become detached if the patient moves or is moved. Preferred application points are the upper and lower extremities. This prevents the occurrence of too high a transfer resistance, which interrupts the current backflow through the neutral electrode.

69.5 Preparation: Care, Maintenance, and Hygiene

69.5.1 Manual Cleaning and Disinfection

Following each operation, special attention must be paid to the preparation of the OR table tops and the OR table system transporters that were used for the operation, i. e. they must be carefully cleaned and disinfected. Particularly in smaller hospitals, cleaning and disinfection is often done manually by support staff in the operation area or by the nursing staff themselves. Because of the multiple divisions of the complete OR table system and the high hygiene demands, manual cleaning cannot always be seen to be the most reliable approach. It is also very time and staff-intensive.

Hygiene issues, maintenance work, and any repairs that may be necessary are already allowed for during design and construction. For instance, the upper part of the OR table, as well as the covers of the column and base, consist principally of smooth-surfaced, individual components made of chrome nickel steel that can be removed without any problem. Also, the electrically conductive roller bearings that are used to move and ma-

oeuvre the mobile OR table are easily accessed from above for inspection and cleaning. Here, there are significant advantages with the OR table system since table tops and transporters can be moved effortlessly into the corresponding cleaning rooms. Any repairs can also be carried out well away from the operation area, without disturbing the OR procedures.

69.5.2 Automatic OR Table System Cleaning and Hygiene

A second option is offered by so-called decontamination machines, which automatically carry out the cleaning, disinfection and drying of suitable OR table tops, Lafettes, and OR accessories. This alternative is most frequently used in larger operating centers, as it is neither staff nor time-intensive, unlike manual cleaning and disinfection procedures. A further, not insignificant, advantage is that an automated procedure using a machine, assuming that operating instructions are correctly followed, offers maximum hygiene levels. With manual

Fig. 69.14 Operating room table cleaning and decontamination machine

cleaning, a lot rests on the care practiced by the staff as well as the time invested.

On average, the cycle time of a decontamination machine, including all the individual processes such as cleaning, disinfection, intermediate drying, rinsing, and final drying is 10 min. It should also be said here, that the cycle time is dependent on the level of contamination and is, therefore, variable. All data generated

during this process is recorded, in order to ensure traceability.

From the standpoint of the care staff, this represents not only a simplification of and a significant improvement in working conditions, but it also contributes to the optimizing of safe working processes in the operating area (Fig. 69.14).

Maintenance

As well as the ongoing cleaning and disinfection of the OR table as a prerequisite for aseptic working, it is essential, because of the many electrical, hydraulic, and electro-hydraulic control elements, that the OR table system is regularly maintained, in order to prevent downtimes and to ensure the safety of both patients and OR staff.

Medical Robotics

70. Medical Robotics

Harald Fischer, Udo Voges

In 1990, robot systems for use in medicine were still the subject of research. Then, first research results were implemented in practice, and in 2000, several types of robot systems for various surgical disciplines were in clinical use. Other systems are in preparation. While some systems are applied nearly routinely, others are still in the phase of testing. Research is dedicated to solving a number of open problems and to further developing the systems, for instance, by combining robots with imaging methods or their use in special environments, e.g., in computed tomography or magnetic resonance imaging. Other objectives are further miniaturization and simplification.

After a short introduction to the fundamentals of medical robotics and the developments in this field, an overview of existing systems and their medical applications will be given. Some technical aspects of the use of such systems will be explained. The chapter is completed by an outlook.

70.1 Fundamentals

Usually, the term “robot” is understood to refer not only to robot systems proper but also to telemanipulation systems. Strictly speaking, the only robots are the autonomously working systems known from industry, e.g., automotive manufacturing. The robot always carries out a previously defined task, in the same way. This activity is executed without any further human interference and with high repetition accuracy. The operator can only stop the system (emergency shutdown), but not make an interactive change. A change or modification is possible only by redefining the task, new programming, or new teaching of the robot.

If, however, man acts to control the system, it is referred to as a telemanipulation or remote handling system. Only the movement directly given by the op-

erator is reproduced – if possible, simultaneously – by the working system. The input device (operation unit) moved by the operator is referred to as the master. The manipulator executing the action is called the slave (working unit). Consequently, such systems are also called master–slave manipulator systems.

Interactive systems represent a mixed type of telemanipulation and robot systems. The master is not separated from the slave, and the instrument is often controlled directly by the operator. A target path, working range, or permissible forces are defined in advance. If the operator wishes to leave this target path, he is prevented from doing so by the corresponding forces. The user-controlled instrument can leave the permissible working range only after having confirmed a warning

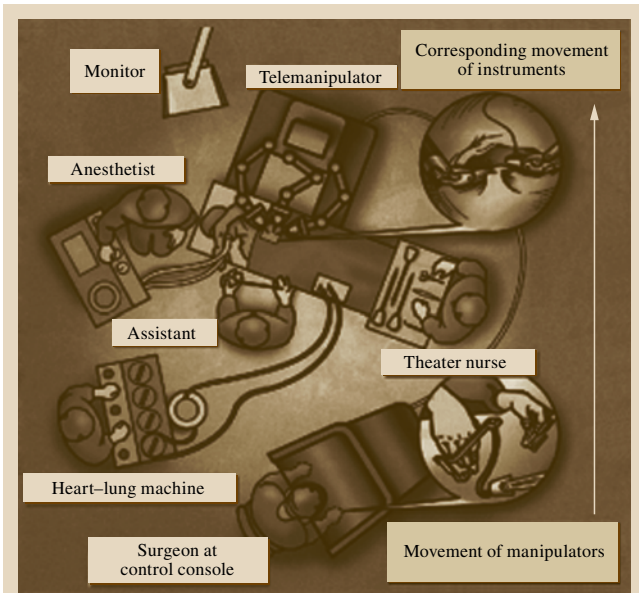

Fig. 70.1 Principle of a telemanipulator system for minimally invasive interventions (Intuitive Surgical, Sunnyvale)

message. In this way, critical operation ranges can be avoided and an operation planned, e.g., on the basis of x-ray examinations can be executed exactly.

Figure 70.1 shows the principle of a master–slave manipulator. This operation telemanipulator is used for cardiac surgery. The surgeon sits in front of the panel with the input systems (master manipulators for each hand), a viewing system, and various foot switches for operation of the instrument functions (e.g., sucking and rinsing). Movement of the master is converted into corresponding movement of the instruments, and the telemanipulator executes the corresponding actions. The assistant waits until the instruments have to be exchanged manually.

The distance between the master and the slave can be bridged in different ways. In case of direct, purely

Fig. 70.2 Purely mechanical coupling between master and slave unit

mechanical coupling of the two devices, the distance is relatively small (several meters at most). Due to the rods, tension ropes, etc. needed, however, this solution can hardly be used in medical robotics.

Figure 70.2 shows such a direct mechanical coupling between the master and slave unit. Frequently, computer systems are used instead of this direct mechanical coupling between master and slave. These systems control the coupling of master and slave. If a single computer only is applied to convert the input information of the master unit into the control information for the slave unit, a distance of several meters is possible by a cable connection. If the master and the slave are controlled by separate computers that are connected via a local area network (LAN), for instance, the distance may be as large as desired. Master and slave can even be connected across continents for telesurgery. In case of larger distance, however, delays between the action of the master and the reaction of the slave and detection of the returned video signal may occur depending on the transmission method used. This means that work has to proceed more slowly and more carefully.

70.2 Development of Medical Robots

The development of medical robotics shall be presented briefly. The systems are described in more detail in Sect. 70.4.

Use of robotics or computer-controlled systems in medicine is characterized by a stepwise process. First, endoscope guiding systems were developed (e.g.,

Robox [70.1], FIPS [70.2], Felix [70.3], Aesop [70.4], EndoAssist [70.5]). These systems are less safety relevant, but they facilitate the surgeon's work.

By means of endoscope guiding systems, the endoscope can be held and guided over a longer period without a human assistant. Such systems are oper-

ated by joysticks, keyboards, language, head movement, etc. Instead of explicit operation, automatic instrument tracking is possible. Major advantages of an endoscope guiding system lie in the facts that no additional assistant is required to act as a cameraman and a stable picture is obtained. The endoscopes applied for this purpose are standard systems.

Endoscope guiding systems have been developed further to become instrument guiding systems. As a rule, these are not suited for holding and guiding conventional instruments, but only specially developed, often not only rigid, but also flexible instruments. These instruments are operated via a master unit in case of the telemanipulation system Tiska [70.6]. In the case of Robodoc robots ([70.7], Caspar [70.8]), by contrast,

the instrument guiding systems execute predefined tasks and have a very limited interactive input system, which mostly serves for correcting an already given track along which the system is to be moved. As use of an individual instrument guiding system is only reasonable for a robot system, and two-handed work as in case of a normal operation should be possible when using a telemanipulator, the step from the instrument guiding system to a system consisting of two instrument guiding systems and one endoscope guiding system was not long in coming (ARTEMIS [70.9], da Vinci [70.10], ZEUS [70.11]).

Using such a system, the surgeon can execute operations alone and does not require any further assistants. For the first time, solo surgery became possible.

70.3 Overview of Systems

This section gives an overview of assistance systems, telemanipulators, and robotic systems.

70.3.1 Assistance Systems

One generally distinguishes between industrial or commercially available systems, and systems for research and university purposes. Generally, these systems serve to hold instruments and cameras. Passive holding systems are positioned by hand and do not contain any actuators (motors) or active systems that are driven to the desired position. Here, only active systems will be presented.

70.3.2 Active Holding Systems

Various active holding and guiding systems were developed by the former Forschungszentrum Karlsruhe. One of these systems is presented in Fig. 70.3. It is applied to guide an endoscopic camera. As the system was designed for minimally invasive surgery (in particular, abdominal surgery), it was provided with a mechanical forced guiding system around the invariant puncture point. Electrically, the system can be moved around this point. The invariant puncture point is the point of penetration of the abdominal wall.

The mechanical construction of the device prevents mechanical stress or loading of the puncture point (invariant point).

Input takes place via a type of joystick or by language. For research purposes, a camera tracking system

is available. Hence, the surgeon can move the camera intuitively to the desired position. The assistant physi-

Fig. 70.3 FIPS endoscope guiding system (Forschungszentrum Karlsruhe, after [70.2])

cian no longer has to guide and position the endoscopic camera and can take over other tasks.

Such a simple camera guiding system has the great advantage of absence of tremors. The electronic assistant holds the camera without any tremors over longer periods, which facilitates operation by the surgeon, as the operative field is not blurred on the screen.

70.3.3 Master–Slave Manipulators

The first scientific telemanipulator was built as a demonstrator and tested by Forschungszentrum Karlsruhe in 1995 (Fig. 70.4). Complicated scenarios were executed successfully and precisely. The flexible distal joints of the instruments for the first time allowed bypassing of structures inside the human body. Thus, complicated interventions (surgical sutures around organs) could be performed endoscopically.

Integration of force and momentum sensors provided for force feedback. While holding his operation unit, the surgeon was able to feel the forces he exercised with the actuators in the operative area. These systems turned out to be much more complicated than initially assumed. Due to the important restrictions, integration of sensors is very difficult. Hence, the wish of the operator to use low-cost single-use tools is not satisfiable.

The master–slave manipulator of the University of Berkeley, USA, also includes force and acceleration sensors in the slave unit, i. e., in the instrument tip. These sensors feed the forces occurring in the slave unit back to the master unit. Exerted forces are fed back to the fingers of the surgeon. Such force feedback is re-

Fig. 70.4 ARTEMIS telemanipulator system (Forschungszentrum Karlsruhe, after [70.9])

quired when the operator (master unit) and manipulator (slave unit) are no longer located in the same operation theater but are decoupled locally. If the end effectors are driven electrically, the forces acting, e.g., between the branches of endoscopic forceps are not fed back.

If gripping on the master unit is too strong, forces on the slave side may be too high and tissue may be damaged. In case of spatial and, hence, mechanical decoupling, force feedback is an advantage, as a type of tactile feedback is regained. The surgeon obtains information about the interaction with various types of tissues. This prevents mechanical damage due to too high gripping forces.

In case of standard endoscopic operations, this feedback is of optical character only and supported by direct mechanical coupling of the endoscopic instruments. This means that the handle is connected directly (possibly via various joints) to the distal end and, hence, to the fingers of the operator. Feedback is then given by a change of color of the tissue while gripping. If the tissue becomes white, the gripping force is too high (the tissue is no longer supplied with blood and discolored).

70.3.4 Biopsy Robots

In the past years, diagnostic imaging methods and the corresponding evaluation processes have improved considerably. With increasing computer speed, it became possible to represent movement scenarios by these new tomographs in real time. Now, so-called surgical robots can be applied for simple tasks, e.g., for the biopsy of mamma carcinomas directly in the magnetic resonance tomograph. Due to the ambient conditions in such a tomograph, however, this process is very difficult. Since 1998, Forschungszentrum Karlsruhe has developed a robot for taking a tissue sample (biopsy) directly in the magnetic field of a tomograph with image control (Fig. 70.5). In November 1999, this manipulator was used for the first time for clinical evaluation [70.12].

MrBot (Fig. 70.6) also is an MR-compatible manipulator for minimally invasive access to the prostate directly in the MR. Various needle drives can be combined, such that biopsies and thermal ablations can be carried out, and even radioactive pellets can be placed precisely.

MrBot is made of nonmagnetic and dielectric materials (Fig. 70.7). Preferably, plastics, ceramics, and rubber are applied. Pneumatic stepper motors have been specially developed to drive the system. Optical sensors send the position signals to the control unit that is located outside of the MRI device.

Fig. 70.5 Robitom, MRI-compatible biopsy robot (Forschungszentrum Karlsruhe, after [70.12])

Fig. 70.6 MrBot, MR-compatible robot for biopsies and therapies (Urobotics Lab, Johns Hopkins University, Baltimore)

Fig. 70.7 MrBot. Motor design for controllable, precise, and safe pneumatic actuation therapies (Urobotics Lab, Johns Hopkins University, Baltimore)

Positioning accuracies in the submillimeter range and magnetic field compatibility of up to 7 T have been achieved. The tip of a needle can be positioned with accuracy ≤ 1 mm.

70.3.5 Commercial Active Holding and Guiding Systems

Presently, two approved active holding and guiding systems are still commercially available, namely FreeHand (formerly EndoAssist) by Prosurrgics (formerly Armstrong Healthcare, UK) and LapMan by MedSys s.a., Belgium. In FreeHand, the camera is controlled by the head; i. e., after activating head control by a foot switch, the camera follows the movements of the head (Fig. 70.8).

LapMan is controlled via an input unit on the instrument of the surgeon. Both systems are not provided with a mechanical forced guiding system, i. e., they can be positioned arbitrarily in space. The invariant point around the puncture point in the abdominal wall is maintained by software control. In principle, the kinematically specified mechanical invariant point and the software-controlled invariant point are equivalent.

Figure 70.9 shows a camera guiding system from Medsys s.a., Belgium. Here, the invariant point is adjusted and maintained by software control. The system

Fig. 70.10 The da Vinci telemanipulation system (Intuitive Surgical, Sunnyvale, CA)

is controlled manually via a special operation unit that is located directly on the instrument handle. The system is controlled by the index finger directly on the instrument handle.

70.3.6 Commercial Telemanipulators

The only telemanipulator system still available on the market is presented in Fig. 70.10.

This system was developed specially for cardiac surgery. In the meantime, it has been applied as a telemanipulation system in various fields of endoscopic surgery (e.g., abdomen, urology, head). Development work started in 1995. The system has been used clinically in Germany since as early as 1999. Worldwide, more than 1000 systems have been installed. In Germany, the system is used, e.g., at Leipzig, Berlin, Dresden, Frankfurt/M., Hamburg, and Munich. First, bypass operations as well as cardiac valve operations were executed in a minimally invasive manner using this system. In the meantime, operations have been performed in the fields of urology (prostate resection), gynecology, and in the head and neck area. The surgeon sits in front of a panel not more than 8 m away from the field of operation. Via screens, he is shown a three-dimensional (3-D) image of the operation area and can operate up to three flexible instruments and the endoscope via two input devices. da Vinci is a closed, integrated system that can only be used as a whole.

70.3.7 Commercial Surgery/Biopsy Robots

These systems are understood to be classical robots applied for surgical precision work, for example, for milling hip shafts. The robots move along trajectories given prior to the operation and execute a program step by step similar to computer numerically controlled (CNC) machines.

Figure 70.11 shows ROBODOC, which was presented for the first time in 1992. It is applied to precisely position hip prostheses. Apart from the robot, this system also includes a planning system by means of which the prosthesis is selected and the optimum position of the prosthesis is calculated. Since 1994, more than 12 000 operations have been carried out with ROBODOC, most of them in Germany. In the beginning, the thigh bone had to be marked with screws in a first operation for exact calculation and online monitoring of the robot milling work. The new system does without marking, which reduces strain for the patient as no previous operation is required.

Fig. 70.11 ROBODOC operation robot (Curexo Technology Corporation, Fremont, CA)

Since 1996, CASPAR from ortoMaquet has been used in Germany. In terms of tasks and functionality, this system largely corresponded to the ROBODOC system. In addition to hip joints, knee joints could be operated with CASPAR. In the meantime, production of CASPAR has been stopped.

In Germany, SurgiScope from Jojumarie was mainly used at university hospitals and as an auxiliary system for precision work in the ear–nose–throat area [70.13]. The system was tested clinically for such work. In particular, it was applied for microscope guiding, for guiding the biopsy needle or endoscope, and as a drilling and screwing assistant. In addition, a novel type of radiation treatment was tested using this system. It was used for precise positioning of so-called radioactive pellets, e.g., in prostate resection, using which the existing tumor should be damaged specifically by radiation. In the meantime, the system has been removed from the market and is mainly used for research purposes.

Figure 70.12 shows the Innomotion system, which was the first commercially available assistance system for use directly in the magnetic resonance tomograph (MRT). The system was developed by Forschungszentrum Karlsruhe in cooperation with Professor Melzer and the industrial partner Innomedic GmbH [70.14–16].

The system was the first CE-approved MRT-compatible system worldwide in 2005. It was mainly applied for percutaneous, image-supported pain therapy of various organs such as the liver as well as of the spinal column, etc.

This precision system interacts directly with the planning software and the tomograph. It is worked on operating the system online with the MRT, i.e., the image sequences can be evaluated and implemented directly by the assistance system by the direct exchange of information. This allows for operation under direct image navigation. Precision of the intervention is increased. All materials applied are MRT compatible. Special optical sensors and pneumatic drives have been developed specifically for this system. The pneumatic actuators (pressurized air-controlled cylinders) are the first of this type worldwide and can be positioned exactly along their trajectory with an accuracy of 0.1 mm. Due to the use of MRT-compatible materials, interference with the assistance system during image acquisition is minimized considerably. In 2008, Innomedic was acquired by Synthes, USA, and Innomotion is now offered for research purposes only.

Another system of this type is B-Rob-II from the Austrian Center for Medical Innovation and Technology (ACMIT), which is presently available as a prototype only.

Under ultrasonic or computed tomography (CT) control, this system can execute biopsies (Fig. 70.13). The needle positioning unit is controlled on the basis of images and achieves precision ± 0.9 mm. The needle

Fig. 70.12 Innomotion, MRT-compatible assistance system (Innomedic GmbH, Philippsburg-Rheinsheim, Germany)

Fig. 70.13 B-Rob-II (Austrian Center for Medical Innovation and Technology, Austria) ◀

Fig. 70.14 AcuBot (Johns Hopkins Medical Institution, Baltimore)

unit can be sterilized and used several times. The system is designed in a modular manner and planned to be used in various clinical fields.

Another system to position needles under direct imaging is AcuBot from Johns Hopkins Medical Institution, USA (Fig. 70.14) [70.17].

The user interface is a 15-inch touchscreen monitor in connection with a two-axle joystick and another operation panel. The accuracy of needle positioning is >1 mm. The needle application unit is permeable to x-rays, so that it can be used directly in the CT.

70.4 Medical Applications

In abdominal surgery (e.g., cholecystectomy, prostatectomy) and in general endoscopic surgery, simple systems, such as camera guiding systems, are certainly applied most frequently. These systems supply a calm, tremor-free image. The camera is guided directly by the surgeon, so an additional assistant is not required as a cameraman.

If instrument holding systems to hold simple instruments such as forceps in a fixed position and to adjust them are used in addition to the endoscope guiding system, the surgeon can execute the operation largely alone, with the assistance of a surgical nurse only. So-called solo surgery is feasible [70.18].

Compared with manual surgery, robot systems allow for more exact surgical operations in, e.g., orthopedics (hip prostheses, knee operations), but also in otolaryngology (jaw and face surgery). The hip robot

can mill out the thigh bone much more exactly than the surgeon. As a result, the prosthesis has a fitting accuracy of more than 90% compared with the manual method with about 30% contact area. Use of bone cement to support the connection between the implant and the bones can be reduced.

In neurosurgery, these exact machines are mainly used for precise guiding and holding of highly flimsy operative instruments and cameras. The very high accuracy of the robot systems is combined with simple tasks, such as holding functions. The neurosurgeon profits from the robot interface to the planning software, such that exact positioning is accomplished on the basis of image data. This is of particular interest in neurosurgery. For example, Innomotion might be modified to such a system by Innomedic GmbH, Germany. Apart from endoscopic cameras, also instruments might

be held and guided precisely. Accuracies of better than 1 mm are needed and feasible.

Use of telemanipulation systems enables the surgeon to perform much more precisely finer and more exact operation steps than conventional endoscopic interventions. In this connection, bypass operations in cardiac surgery and prostatectomies in urology have to be mentioned [70.19]. The highly traumatic classical open operative methods used to date can now be performed endoscopically using these precise manipulators. This is of great advantage to patients.

Generally, telemanipulation systems have the following features:

- Movement sequences can be scaled; for example, a movement of 10 cm given by the surgeon can be converted into an instrument movement of, e.g., 1 cm. More exact actions are possible.
- Movement tremors are filtered out. Tremors are eliminated, safety is increased.

70.5 Technical Aspects

Use of teletechnologies requires rethinking and familiarization [70.20]. The physician has to acquire technical understanding. Not only medical but also technical staff is required in the operation theater. An acceptance threshold has to be overcome, if the physician is no longer in direct contact with the patient, but only via telecommunication systems. In addition, a psychological inhibition threshold may result from a robot or a telemanipulator replacing the physician at the operation table and executing the intervention. It is necessary to communicate to the patient the advantages of the use of such technology. On the other hand, the patient has to trust in a physician being also present at the operating table to monitor the operation.

Such a system already exists in patient monitoring. Figure 70.15 shows the RP-7 from InTouch Technologies, USA. It is used to bring the physician to the patient via telecommunication lines (mainly the Internet). Via camera and screen, the patient can communicate with the physician and the physician sees the status of the patient. Direct presence is no longer required. The control and examination of wound healing can take place via such telenetworks all over the world.

Figure 70.16 shows that not only image and sound are transmitted to the physician but also vital parameters. The simplest control unit of the RP-7 platform

- Indexing is possible. The surgeon can choose an optimum working position and does not have to operate in a tense posture according to the position of the working instrument. Optimal ergonomics for the surgeon is achieved, and fatigue-free operation becomes possible.
- It is possible to choose among various coordinate systems. It is possible to control the instruments in, e.g., world coordinates, instrument coordinates or screen coordinates. Depending on the application and the preference of the surgeon, the most favorable control method is selected.
- Forces can be measured at the instrument tip and transmitted to the surgeon at the operating unit.

Frequently, endoscopic instruments were developed for operations that had been carried out conventionally until that time. These so-called spin-offs allow for simple endoscopic interventions with novel minimally invasive surgery techniques.

is a normal laptop. Via the integrated web camera, the patient can see the physician during the ward round.

Robot and manipulator systems for use in surgery are associated with special requirements on integration in static and dynamic structures of operation theaters at hospitals. A number of concepts have been developed for retrofitting at existing installations and fitting at new constructions specially tailored to the needs of robots. Some of these requirements shall be outlined in detail below.

Construction requirements include sufficient space for rapid and easy coupling of the manipulator system to the operation table, possibly a vibration-free floor, and/or suspension from the ceiling. The operation unit must be installed such that direct view of the patient and the manipulator system as well as of other information (anesthetic data, etc.) is given, if required.

The operation staff has to undergo special training for handling of the devices and elimination of problems possibly occurring during operation. In addition, a technician has to be present for proper installation and operation of the system and correct detection and elimination of problems in due time. The interdisciplinarity of the operation staff is increased. The surgeon is required to have a certain technical un-

Fig. 70.15 RP-7 mobile robotic platform (InTouch Technologies, Santa Barbara, CA)

derstanding. He has to undergo extensive training to learn how to operate the master unit and the complete telemanipulation system, and to familiarize himself with the additional functionality that differs considerably from conventional operations. The operation unit should be operable in an intuitive manner, but the surgeon has to familiarize himself with various settings that are not relevant in other cases (e.g., selection of the coordinate system, scaling, device assignment). This

70.6 Outlook

It was demonstrated by the development and long-term testing of ARTEMIS as well as by the commercial

Fig. 70.16a,b Remote presence with mobile robotic platform. (a) Doctor's office, (b) remote patient (InTouch Technologies, Santa Barbara, CA)

will ensure correct, safe, and rapid action in critical situations.

Hence, simulators and trainers are needed. Similar to flight simulators, use of training and simulation systems for telesurgery seems to be reasonable for continuous training of surgeons [70.21].

surgical telemanipulators and robots applied meanwhile that use of teletechnologies in the operation

theater results in a number of advantages. They include:

- Improved image quality by the use of endoscope guiding systems
- Improved operation quality by the more exact guiding of the instrument with the help of telemanipulation systems
- Improved operation quality by a fatigue-free, more ergonomic posture
- Improved operation quality by the integration of a 3-D viewing system.

Nevertheless, some major objectives remain to be achieved:

- Modular and flexible design of the system
- Flexible and easy-to-exchange instruments or multifunctional instruments
- Adaptation to telesurgery needs
- Various application options in all relevant surgical disciplines
- Wider usability in special environments, e.g., CT and MRI.

System modularity will not only refer to mechanical components, but also to the software. Modularity of the software system can be achieved by a distributed, object-oriented, real-time architecture. Multi-agent systems are designed in terms of both software and hardware. An open system structure will allow for integration of various master and slave systems.

Apart from telemanipulation proper, other teletechnologies will be integrated in the telepresence system to support teleconsulting and teleplanning. Applicability

in various disciplines will continue to be a prerequisite for economic acceptance of such systems.

Use of teletechnologies in surgery will increase. However, they will not be applied in all areas tested. Often, only one operation will be carried out for the press to report that

surgeon A was the first to perform operation B with the help of robot system C. However, there will not be any successors, as the execution of such an operation B with a robot system has more drawbacks than advantages. . . .

or it will take a long time until such operations will be performed widely. During the coming years, some hospitals will have to act as pioneers to identify the potential but also the limits of telesurgery. It will probably take several years until such systems will be used throughout Germany. The costs (often more than one million euros) as well as limited functionality are obstacles.

The successes achieved in the use of telemanipulation and robot systems in surgery demonstrate that such systems have a justified position in medicine and can be used reasonably. Nevertheless, there is need for further research and development. Applications can be extended. Modifications and further developments of the systems are required. If necessary, medical procedures have to be adapted to the possibilities of robotics. Entirely new operative techniques that are not feasible with purely manual operation will have to be tested. Close cooperation between engineers and physicians is required.

Incubators

71. Incubators

Guenther Braun, Roland Hentschel

This article describes fundamental information about neonatal incubators which are typically used on intensive care units (NICU). In a short abstract the historical development is described. State of technology is specified and also unsolved questions identified. Depending on the intended use different incubator types are shown. In addition to the functions of a neonatal incubator also risks of incubator therapy will be presented.

71.1 Historical Background

Incubators are used to stabilize and maintain the thermal balance in premature and newborn babies. In the year 1907 the pediatrician Pierre Budin described in his book *The Nurseling* the connection between mortality and rectal temperature. Newborns whose rectal temperature was warmed to 36–37 °C reached a survival rate of 77%, however in babies with rectal temperature between 32.5 °C and 33.5 °C the survival rate was only 10%.

It is assumed that incubators were used by the Egyptians as early as 200 AD. In the year 1947, a specially designed incubator was launched onto the market by the American physician Chapple. This incubator was the forerunner of present-day incubators, including a transparent acrylic glass cover, a bacteria filter for air intake, an integrated air circulation system, air humidification, and an alarm device against overheating, which was first put into practice in this model [71.1].

Premature babies are not capable of maintaining their thermal balance independently [71.2]. The ratio of body surface to body volume of a newborn is 2.7

times higher than that of an adult. In neonates with birth weight of 1000 g the ratio is 4 times higher.

Loss of warmth can occur basically in four ways:

1. Heat conduction by release of heat to the mattress
2. Convection (cooling by airflow)
3. Evaporation from the skin
4. Thermal radiation from babies to the surrounding area.

Loss of warmth is reduced by vasoconstriction. By increasing vessel resistance, the extremities are cooled first, before the body temperature falls. Comparison between body temperature and peripheral parts of the body enables an early indication of thermal imbalance [71.3].

Only newborn children have brown fat tissue, which lies between the shoulder blades, behind the heart and the large vessels. These energy reserves have limited ability to maintain normal body temperature. Newborns are also not capable of producing warmth by increasing muscle activity (shivering). Due to their thin skin, more

liquid is lost by evaporation from premature babies than from mature newborns.

Cold stress must absolutely be avoided for the following reasons:

- Less intake of oxygen, e.g., with a negative influence on the development of the lungs due to insufficient surfactant production. Hence, breathing problems could develop, which would have to be compensated by artificial respiration.

- Metabolism will be influenced negatively, e.g., hypoglycemia or metabolic acidosis (too low pH). The risk of pathological jaundice (icterus gravis) is increased.
- Increased danger of infection.
- Negative effect on growth.

It is therefore necessary to keep the core temperature constant and dehydration through perspiration at a minimum.

71.2 Construction and Function of an Incubator

Incubators create a microclimate, which can differ considerably from the surrounding air. In this microclimate, temperature, humidity, and oxygen content can, up to a certain limit, be regulated individually. Furthermore, the incubator isolates the patient in terms of protection from pathogens which could be transferred via the air.

As a rule, incubators are designed for body weight up to 5 kg. The user can adjust the height as well as the inclination of the mattress. This allows good ergonomics and easy access to the patient by nursing staff. The incubator can also be lowered to allow for optimal mother–child contact.

71.2.1 Temperature Regulation

The incubator sucks in room air via an exchangeable air filter. The room air is heated by a heating element, which has a fan in the middle. The warm air is conducted via a ventilation shaft along the long sides of the incubator to the patient. As a result, a shield of warm air is formed. This shield reduces the cooling of the incubator when it is open. As a rule, the air is released at the front end. The air temperature is measured by several NTC (negative temperature coefficient thermistor) sensors. The challenge for the manufacturer is to create a draught-free, homogeneous atmospheric environment. The fan (aerator) has to meet special requirements, e.g., it has to run as silently as possible, to avoid stress and the danger of hearing damage to the patient. Incubators run at operating noise of less than 50 dB(A). In future developments, the goal is to lower this noise level even further.

The user has two possibilities to control the temperature of the incubator:

1. Air temperature regulation: The user chooses a suitable air temperature. The temperature is measured

by means of a temperature sensor in the incubator and compared with the *set level (point)*.

The set temperature in the incubator is thus kept constant. If the actual temperature differs from the set temperature, the user will be informed by an alarm signal. As a rule, the alarm limit is $\pm 1.5^\circ\text{C}$ from the set level (point).

2. Skin temperature regulation: The user places a skin temperature sensor on the thorax, and a second one can be attached to the extremities. The desired temperature on the thorax is set by the user.

The incubator regulates the air temperature depending on the skin temperature. If the actual temperature differs from the set temperature, the user will be informed by an alarm signal. As a rule, the alarm limit is $\pm 0.5^\circ\text{C}$ from the set point.

Incubators are not capable of cooling. At high outside temperatures and with large babies, the set temperature cannot be maintained. The temperature can, depending on the type of incubator, be set from 20°C to 39°C at 0.1°C intervals.

71.2.2 Regulation of Humidity

Two construction principles are used to create moisture: either water is evaporated over a heater and then, after cooling, passed into the incubator, or it is created over a heated washbasin in the incubator cell. Humidity is measured using capacitive components.

Moisture is necessary not only to maintain the thermal balance of the baby but also to moisten the mouth, nose, and throat. The relative humidity can usually be set between 30% and 99%.

The user has, depending on the model, two possibilities to control the humidity:

1. Manual humidity regulation: The user chooses a suitable relative humidity. The relative humidity is measured by means of a humidity sensor and compared with the set level.
2. Automatic humidity regulation: In the automatic mode the relative humidity will be increased at higher air temperature.

Depending on the temperature, air can hold different levels of humidity, so that when dropping below a critical temperature accumulation of condensation occurs, whereas at higher temperatures, moisture can be absorbed.

As a result of the ratio of the outside temperature to the high inside temperature, there is the danger of condensation accumulating on the incubator *glass*. This may limit the possibility to monitor the baby. The effect is increased when humidity > 70% is chosen. Numerous manufacturers offer optional interior glass for better isolation. In practice, these have not become well established, especially because condensation between the two glass panels cannot be wiped away by nursing staff without great effort.

Incubators are not capable of drying air. If a humidity set level is chosen which is lower than the surrounding air humidity, the actual value achieved will never be lower than the surrounding humidity.

71.2.3 Regulation of Oxygen

As an option, with all equipment available on the market, the air can be oxygenated. The air, depending on

the construction of the incubator, can be oxygenated up to 70 vol. %.

With stationary incubators the oxygen is supplied via the central gas supply. With transportable incubators for ambulance or helicopter transport, operation is possible via the central gas supply as well as from gas bottles. The oxygen in the incubator is measured by fuel cells, which are applied also in long-term respirators. Due to the potential danger of a wrong dose of O₂, O₂ testing is designed to use two measuring devices. The signals from two fuel cells are compared with each other. If the values differ considerably from each other, the fuel cells can be automatically or manually calibrated by the user.

71.2.4 Scales

Not only body temperature but also body weight is an important diagnostic parameter in neonatology. Today's technology implements scales into the incubator. In this way, *cold stress* is avoided for the newborn when it is weighed in compartment air in the incubator instead of on conventional scales in room air.

71.2.5 X-ray Drawer

To make handling of necessary x-rays easier, in newer incubator models a drawer is built in under the mattress. Common x-ray cassettes can be inserted into this drawer. In this way, the newborn is not laid down directly onto a cold, hard x-ray plate.

71.3 Incubator Models

Incubators are basically divided into three type of models.

71.3.1 Stationary Incubators

These are used for long-term care of premature and newborn babies in recovery rooms and intensive care units (Fig. 71.1).

71.3.2 Transport Incubators

These are used for *in-house transport* from the delivery room to the pediatric intensive care unit or for transfer to other clinics by vehicle or helicopter. The

latter incubators have their own electricity supply via accumulators as well as a gas supply via gas bottles. In the hospital or in the vehicle the equipment can be supplied with energy via the 220 V network and via the central gas supply, in order to save the mobile energy supply. Incubators mounted on a chassis with vibration absorbers are adapted to a standard retractable carriage (gurney). Due to limited space during transport, e.g., in helicopters, as well as the short transport times, the humidification option is not available in these devices. Intensive care transport incubators are equipped with a respirator, a patient control monitor, a syringe pump, and a suction device (Fig. 71.2).

Fig. 71.1 Stationary incubator (courtesy of Draeger)

Fig. 71.2 Transport incubator with gurney (courtesy of Draeger)

71.3.3 Special Incubators

For examinations in magnetic resonance imaging (MRI), there are nonmagnetic transportable incubators, which can be inserted into the MRT. With this apparatus, air humidification and artificial ventilation are also possible as well as being fitted with a pulse oximeter for monitoring the patient. The apparatus is also suitable for thorax and brain examinations.

The problem of *in-house transportation* can be considerably simplified by a novel transport concept. Until now, for therapy each baby had to be looked after in a reanimation unit, then transferred in a transport in-

Fig. 71.3 Incubator for in-house transportation with docking carriage (courtesy of University Hospital Freiburg and General Electric Company)

cubator from the delivery room or the *sectio-op* to the children's ward to the place of treatment. This means repeated relocation (shifting) and therefore cold stress for the newborn, as well as the danger of unintended manipulation of infusion and respiration tubes (Fig. 71.3).

Usually, newborns are initially treated in reanimation units, i.e., a *warming bed* with a heated gel mattress and an integrated radiant heater (radiator). After stabilization in the delivery room, patients are often transferred to intensive care within a few minutes. Babies are not transferred to stationary incubators until they are in the intensive care unit. So, patients are relocated twice at room temperature and experience cold stress. The reanimation unit and the transport incubator must go through a time-consuming upgrade process. To improve this situation, a stationary incubator with an integrated heat radiator is connected to a *docking carriage (trolley)*. Thus, this incubator can be used as an initial reanimation unit. On the docking carriage (trolley), all the necessary relevant equipment can be found for an intensive care unit: respiration equipment, aspiration (suction, extraction), patient monitor, syringe pumps, and a hand anesthesia bag. The docking carriage (trolley) is equipped with O₂ and pressurized air bottles to ensure breathing dur-

ing transport. The trolley is connected to the incubator without using tools. After arrival at the neonatal intensive care unit, the trolley is then connected directly in the intensive care room to carry on with therapy

using the ward's equipment. Using this concept, cold and shifting (relocation) stress can be minimized (reduced). Resources are saved, and handling by staff is facilitated.

71.4 Risks of Incubator Therapy

71.4.1 Temperature

As described above, stabilization of body temperature of newborns is of great importance. Therefore, tightly controlled temperature monitoring is indispensable. For newborns, the rectal temperature is measured every 2 h. If the baby is *thermally stable*, the cycle can be expanded to 4 h. If the baby cools, it is called hypothermia. If the child is warmed by the incubator to over 37°C, it is called hyperthermia.

As a result of increased liquid loss due to hyperthermia, electrolyte dysfunction can result. Further outcomes are hyperventilation and tachycardia. In thermostable children, skin temperature correlates very well with body temperature. Therefore, use of the skin temperature regulation operating mode simplifies the suitable choice of temperature by the user.

On no account should skin temperature regulation be used for children who are in a state of shock, because in this situation unintentional hyperthermia could occur. Also for babies with fever, skin temperature regulation is only to be used with great care, because in this case the skin temperature is higher than the body temperature. Very early premature babies experience extreme perspiration, resulting in high fluid loss, in the first days

of life. A further exception is the patient experiencing shock, or skin – surface temperature due to infection, which will cause unreliable readings on the incubators skin temperature monitoring.

71.4.2 Oxygen Therapy

Oxygen treatment can pose a high potential risk for incorrect dosage. Therefore, when administrating O₂, arterially measured O₂ partial pressure must be determined. With O₂ therapy it is indispensable to monitor the patient continuously with a *pulse oximeter* or a transcutaneous O₂ *probe*. If there is undersupply (*hypoxemia*), then there is the danger of respiratory insufficiency resulting in apnoea. Continuous undersupply of O₂ can cause brain damage.

Overdose of O₂ (*hyperoxemia*) in premature babies before the 39th week of gestation can lead to serious eye damage. It can even cause retinal detachment, a very serious retinopathy.

Oxygen is associated with the danger of explosion and fire hazard. Therefore, for safety reasons, after disinfecting the hands, one should wait until the disinfectant has dried. For this reason no disinfectant or inflammable liquids such as alcohol or *benzine* should be put in or on the incubator.

71.5 Hygiene

Due to the warm climate and high humidity, an incubator is an ideal breeding ground for germs, leading to an additional risk of infection for the newborn. Therefore, after terminating the treatment of a patient, or after 7 days at the latest, a new incubator must be provided

and the used incubator carefully cleaned and wiped with disinfectant.

In particular, excessive build-up of condensation in the interior of the chamber is a risk for early fungal or bacterial contamination.

71.6 Unsolved Problems

The following points should be given special consideration in a newborn's environment:

- Total reduction of noise, and the possibility to regulate light entering the chamber.
- It should be noted that, although no limits on electromagnetic fields in patient healthcare environments have been reported, their effect on heart rate and physiological functions will become an issue [71.4].
- A problem noticed in the field is international standardization of holders for patient gurneys. To ease international patient transport it is desirable to implement international standardization in the future.

Surgical Scissors

72. Surgical Scissors

Reiner Haag, Wilfried Storz

Scissors still represent an indispensable tool for any surgical discipline, in medical practices no less than in clinical departments. It is probably safe to say that among all surgical instruments, scissors are used the most frequently – prior, during, and after the operation. Using scissors is extremely easy, with the benefits being not only excellent, but manifold and almost unlimited. In fact, there is hardly any better universal alternative when it comes to transecting or dissecting tissue or cutting sutures or any other kind of auxiliary materials. Yet in spite of the easy handling, the demands made on the surgeon or nurses are very high and complex as well – and they differ according to the task at hand. This has led to the development of a wide range of scissors that includes no less than 2000 different versions of the product.

72.1 The History of Scissors

The question of where and when scissors were exactly invented has not been finally solved to date, but there are justified reasons to assume that the first scissor-like devices came into use between 1300 and 600 BC.

72.1.1 Paired Knives

In their most primitive form, scissors consisted of two matching knives whose cutting edges were sim-

Fig. 72.1 Paired blades

Fig. 72.2 Paired blades

Fig. 72.3 Spring bow scissors

Fig. 72.4 The chamber with surgical instruments of Brun-
schwieg

ply moved towards each other. As these paired blades were not connected to each other, the user had to work with both hands. The left hand held and supported one of the knives from below while the right hand guided the other, upper knife in such a way that the cutting edges glided closely past each other in a shearing or cutting motion while the user applied moderate pressure (Figs. 72.1, 72.2).

72.1.2 End-Jointed Scissors

End-jointed scissors represented a further advancement. They consisted of two blades that were hinged together at their back ends by way of a bolt. Their use was rather cumbersome, as the two blades had to be pressed upon each other for cutting and subsequently had to be pulled apart manually.

72.2 The Function and Design of Scissors

Depending on their design and field of use, surgical scissors are intended for transecting tissue, bones, organs, dressing materials, and other medical supplies. Moreover, scissors are quite frequently used for dissecting and manipulating certain tissue structures and organs, due to the fact that they are extremely easy to handle and give the surgeon a *feel* that provides valuable feedback information, thus allowing vital conclusions to be drawn.

The fields of use and practical application of surgical scissors are highly varied and extremely complex. This explains why there is such a multitude of different types and variants to choose from. However, the basic design is identical for all the different types of scissors (Fig. 72.5). At the front or distal end there are the blades, the shanks with the eye rings constitute the handle or back end, and somewhere in the middle there is the pivot or box lock.

When cutting with a pair of scissors, the tissue to be severed is grasped with the blades. As the instrument is closed, the cutting point travels along the blades from the box lock to the tips. This is termed the *action* of a pair of scissors. It is essential here that the mechanical tension between the two blades remains constant from the middle of the blades all the way to the tips. A satisfactory cut performance and quality cannot be achieved if this requirement is not met.

The length of the cut depends on the length of the shear blades and/or the length of the tissue seized by the blades. It is important here that the cutting edges of the blades are geometrically arranged in such a way that

72.1.3 Bow Scissors

Compared with end-jointed scissors, spring bow scissors (omega-shaped back end) represent a significant improvement because they can be operated single-handedly and open by themselves due to the mechanical tension in the material. The first products of this sort probably date back to 300 BC (Fig. 72.3).

72.1.4 Pivoted Scissors

As more and more experience was gained in steel processing and user demands grew, pivoted scissors were increasingly used from the 13th century. This, in turn, led to new fields of use, not least in surgery. However, it was not until 1497 when H. Brunschwig, in his surgery book, presented a chamber full of surgical instruments, among them a pair of scissors (Fig. 72.4).

a very acute crossing angle is obtained when closing the scissors. This ensures that the tissue is cleanly transected at each cutting point – and only there.

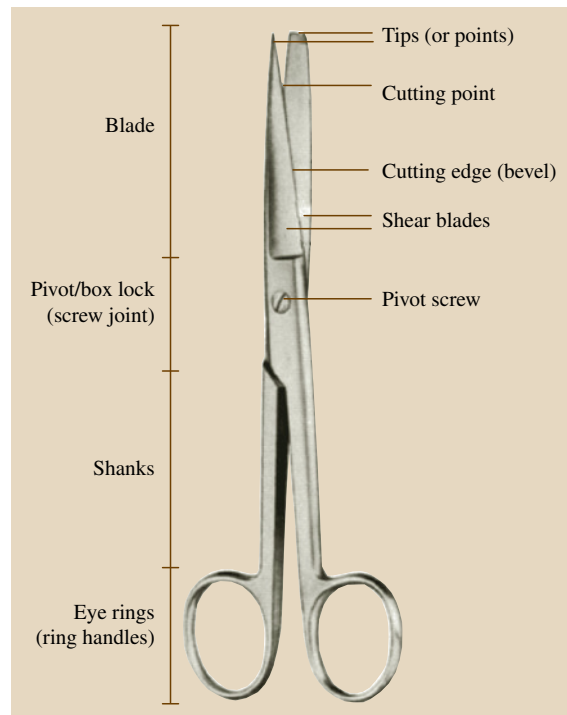

Fig. 72.5 General main parts of a pair of scissors

72.3 Materials

The most fundamental prerequisite for a high-quality pair of surgical scissors is the use of high-quality, forged steel satisfying EN ISO 7153-1:2000 requirements.

Commonly used steels include:

- 1.4117/X38CrMoV15 with a carbon content of 0.38%, a chromium content of 15% and a molybdenum content of 0.5%
- 1.4034/X46Cr13 with a carbon content of 0.42–0.50% and a chromium content of 12.5–14.5%
- 1.4021/X20Cr13 with a carbon content of 0.16–0.25% and a chromium content of 12–14%.

The following general rule applies: the higher the carbon content, the higher the hardness; and the higher the chromium content, the higher the corrosion resistance. The hallmark of hard-metal scissors is their gilded handles. There are two ways of fabrication.

72.3.1 Soldering a Hard-Metal Inset into the Cutting Edge

A hard-metal plate is soldered into the milled-out part of the scissor blade. This plate is extremely hard. However, due to the three different metals involved that occupy different positions in the electrochemical series, potential differences can lead to corrosion as a result of instrument reprocessing. Scissors with significantly curved blades are difficult or even too costly to manufacture using this method.

72.3.2 Welding Hard Metal in Place

Stellite, a hard metal alloy with a carbon content of 2.4%, a chromium content of 33%, and a tungsten content of 13% is welded into the milled-out part of the blade. Since this produces a hard weld, the scissor blade must subsequently be ground in a complex and time-consuming process. However, as only two materials are involved in this case, it is easier to create strongly bent blades.

72.4 Manufacture of Surgical Scissors

The ease with which scissors can be used stands in marked contrast to the complexities of the manufacturing process. The whole cycle is made up of many single working steps. While machining is possible in some respects, there is still a lot of manual craftsman-

72.3.3 Special Coatings

Hard-metal scissors featuring a special, super-hard coating are increasingly offered. Their surface hardness (Vickers hardness, HV) ranges between 2000 HV and 5000 HV.

Commonly used materials for coatings are:

- AlTiN Aluminum titanium nitride, anthracite-colored
- TiN Titanium nitride, gold-colored
- ZrO₂ Zirconium oxide, grayish.

User benefits include:

- Increased life due to the extremely high surface hardness
- Due to their darker color, AlTiN scissors minimize light reflections
- Less friction due to superior surface reticulation (cross-linkage); this results in smoother action and facilitates cleaning.

72.3.4 Titanium Scissors

For special applications, e.g. in an open MRI environment where antimagnetic materials are required, titanium scissors are an excellent choice. As titanium is an amorphous material, however, the manufacturing processes are significantly more complex and time-consuming, so they have to be completely separated from conventional machining processes. To take an example: The use of grinding belts previously used for conventional metal scissors would pose a risk of metal particles being ground into the titanium surface, thus leading to artifacts in the MR image in open MRI procedures and, consequently, to poorer image quality. In the worst case, the image would even be useless. Besides, the brittle material shortens the product's life, reduces cutting performance and makes the opening and closing action less smooth, compared with conventional scissors.

a must in all production stages in order to achieve optimum results. The following table provides an overview of just the most important steps in the process, distinguishing between conventional manufacturing and an advanced process based on robotics and CNC technology (Figs. 72.6, 72.7).

72.4.1 Steps in the Production Cycle

Steps 1–6 of the preproduction cycle and step 1 of the final production cycle are *automated and standardized parts* of advanced manufacturing processes using robots and CNC technology.

Optional Technical Features of Surgical Scissors

Preproduction:

1. Drill core hole
2. Mill joint area projection (box lock corner)
3. Mill shanks

Table 72.1 Technical variants of surgical scissors

Surgical scissors	Description
Standard, without TC (hard-metal inset) (Fig. 72.8)	Low cost
With knife-type grinding	Sharp, knife-type cut
With knife-type grinding and bevel	Sharp and effortless, knife-type cut Minimized traumatization
With knife-type grinding, bevel and microtoothing	Sharp and effortless, knife-type cut Minimized traumatization Prevents tissue slippage
With TC, soldered or welded (Fig. 72.9)	Excellent edge retention
TC, with knife-type grinding	Sharp, knife-type cut Increased edge retention
TC, with knife-type grinding and bevel	Sharp and effortless, knife-type cut Minimized traumatization Increased edge retention
TC, with knife-type grinding, bevel and microtoothing	Sharp and effortless, knife-type cut Minimized traumatization Prevents tissue slippage Increased edge retention
TC, with serrated edge	Excellent edge retention Prevents tissue slippage Increased edge retention as standard
With ceramic coating (Fig. 72.10)	Long-term edge retention Excellent gliding property Glare-free surface Easy to clean
Titanium (Fig. 72.11)	Antimagnetic, thus MRI-compatible Only half the weight of steel scissors Effortless use, prevents fatigue

Fig. 72.6 Manufacturing of scissors in 1980

Fig. 72.7 Manufacturing of scissors in 2010

4. Prepare locations for hard-metal insets
5. Bend upper and lower blades
6. Tap lower shear blade and counterbore upper shear blade
7. Align lower/upper blade
8. Weld lower/upper blade
9. Grind blades on outside and inside

Final production:

1. Grind eye rings on outside and inside
2. Mount/rough-grind
3. Check prior to tempering (hardening)
4. Wash (remove lubricants, etc.)
5. Tempering and annealing
6. Check hardness
7. Mount/prepare for polishing

72.5 Diversification Overview

72.5.1 Surgical Standard Scissors

This type of scissors is usually used for cutting auxiliary materials needed for operations, e.g. dressing materials, flexible drain tubes, and – mostly – sutures. However, these scissors are also used for tissue transection in many surgical fields. Standard scissors are routinely included in almost all surgical instrument sets.

Types of Scissors

Standard scissors are medium strong to sturdy scissors, in straight and bent-up design.

Basis Sturdy Models. Blade tip designs are:

- Pointed/pointed (Fig. 72.12)
- Blunt/blunt (Fig. 72.13)

- Pointed/blunt (Fig. 72.14)
- The classic example blunt/blunt and bent-up, so-called Cooper scissors (Fig. 72.15a,b).

Scissor Lengths

Various lengths of scissors are commonly at the disposal of the surgeon. They cover lengths from 11 to 20 cm.

72.5.2 Surgical Scissors – Dissecting Scissors

Field of Use

Dissecting scissors (Fig. 72.20) are frequently used in surgical interventions – specifically where tissue needs to be transected and dissected in the deeper regions of the surgical site. Tissue cutting is done simply by closing the scissors effortlessly, whereas dissection is

Fig. 72.12 Pointed/pointed blade tip design

Fig. 72.13
Blunt/blunt
blade tip design

Fig. 72.14 Blade tip design
pointed/blunt

Fig. 72.15a,b Blunt/blunt and bent-up scissors, so-called Cooper scissors

performed by spreading the blades repeatedly in a *snapping* action. Blunt dissection (enucleation) is done with the scissors closed.

Wrongly though, dissecting scissors are frequently used also for cutting sutures during ligations. While this is understandable from the point of view of convenience (no need to exchange scissors), such use clearly reduces edge life. Special ligature scissors are available for cutting suture material.

Most Frequent Use

Mainly in soft tissue, abdominal and visceral surgery.

Types of Scissors

Medium-strong to slim, elegant, bent-up scissors, straight dissecting scissors are seldom used.

Most Importantly Used

By Lexer and Mayo (Figs. 72.21, 72.22), Metzenbaum, and Mayo-Stille. The best-known examples are the Metzenbaum scissors (Figs. 72.23, 72.24).

Typical Features

The hallmark of dissecting scissors are their rounded tips and the round back of the shear blades. When closed, these scissors must form smooth, round dissect-

Fig. 72.16 Surgical scissors, length 11 cm

Fig. 72.18 Surgical scissors, length 18 cm

Fig. 72.19 Surgical scissors, length 20 cm

Fig. 72.20 Dissecting scissors

ing instruments without any edges or protrusions on the blades. Another important requirement is their smooth

action ensuring an even cutting performance to give the surgeon a perfect *feel* for the tissue to be divided.

Fig. 72.21 Mayo and Lexer scissors

Fig. 72.22 Mayo and Lexer scissors

Fig. 72.23 Metzenbaum scissors

Fig. 72.24 Metzenbaum scissors

72.5.3 Suture or Ligature Scissors

Field of Use

Once the wound has healed on the surface, the sutures are removed using suture or ligature scissors. To this end, the surface ligation is simply cut with such a pair of scissors and anatomical or dressing forceps are then used to pull out the sutures.

Types of Scissors

An important feature is the slim design of one of the blades to ensure that it can be easily slid underneath the ligation to cut the suture without applying any pressure to the postoperative scar or tension to the suture. Some models feature a *suture groove* at the distal end of one of the cutting blades. This prevents the suture from slipping off the scissor blades. Delicate, pointed-pointed scissors (similar to

Fig. 72.25 Iris scissors

iris scissors) are also used sometimes for this purpose.

Scissor Lengths

Various lengths of scissors are available from 9 to 15 cm.

72.5.4 Wire Cutting Scissors

Field of Use

For certain interventions (e.g. cerclages), flexible metal wires are used as suture or fixation materials. To

Fig. 72.26 Spencer scissors

Fig. 72.28 Northben scissors

Fig. 72.27 Spencer scissors

Fig. 72.29 Northben scissors

Fig. 72.30 Spencer ligature scissors

Fig. 72.31 Spencer ligature scissors

cut such materials, short and stout scissors are required.

Typical Features

The shear blades are extremely short as they are exclusively intended for cutting wires and not for providing a clean cut through tissue or dressing material. Some models include a *wire cutter* for secure grasping of the wire and have angled cutting blades.

Scissor Lengths

Various lengths of scissors are available with lengths from 10 to 16 cm.

72.5.5 Microsurgical Scissors

Microsurgical or microscissors are used across a wide range of fields nowadays, including almost all special disciplines (periodontology, endodontics, plastic surgery, hand surgery, orthopedics, cardiac surgery, vascular surgery, pediatric and neonatal surgery, gynecology, urology, neurosurgery, and ophthalmology).

Every microsurgical operation – including tendon, nerve and vascular suturing usually performed under the microscope – requires precise, light-weight mi-

Fig. 72.32 Universal scissors

Fig. 72.33 Universal scissors

Fig. 72.34 Beebee scissors

Fig. 72.35 Beebee scissors

Fig. 72.36 Microsurgical scissors

croinstruments perfectly fitting the surgeon's hand for ultrafine interventions.

Types of Scissors

Adventitia scissors have sharply pointed tips and straight blades. They are primarily used for freshening up and trimming structures that have already been prepared by blunt dissection. Besides, they are used for cutting fine sutures (>8/0). Dissecting scissors have rounded tips (designed for blunt dissection) and curved blades. They are used for severing nerves and vessels

Fig. 72.37 (a) Adventitia scissors, (b) dissecting scissors, (c) toothed scissors

Fig. 72.38 Microscissors

Fig. 72.39 Microscissors

Fig. 72.40 Microscissors

Fig. 72.41 Coronary scissors

Fig. 72.42 Micro-Hegemann

from surrounding structures (soft tissue, lymph nodes) or from each other while leaving them fully intact. Toothed scissors offer the best controlled cut including the dissection of nerve tissue.

An important differentiation must be made between microscissors with round handles and those with flat handles. Round handles support the rotational movement required when passing the needle through the tissue. Nowadays, round-handle instruments are predominantly used.

Microscissors can be made of steel or titanium. Titanium scissors frequently have diamond-coated cutting edges for increased edge life and significantly lower weight.

Designs

Straight, bent-up, angled (with different angulation).

Important Users

Castroviejo, Micro-Hegemann, Barraquer, Vannas, Yasargil, Jacobson.

Scissor Lengths

Various lengths of scissors are available from 9 to 24 cm.

72.5.6 Vascular Scissors

Field of Use

Vascular scissors are used for cutting and dissecting anywhere in the arterial and venous system of the human circulation (peripheral, central, and coronary vessels). In addition, they are suitable for cutting sutures. Depending on vessel diameter, different models and designs are used, including microscissors. Particularly long vascular scissors (Potts–Smith) are also suitable for opening other ducts of the human body (such as the biliary duct for removing gallstones).

Types of Scissors

A basic differentiation is made between adventitia and dissecting vascular scissors. Adventitia scissors have

Fig. 72.43 (a) 25° angled coronary scissors, (b) 45° angled coronary scissors, (c) 60° angled coronary scissors

Fig. 72.44
(a) 90° angled coronary scissors, (b) 125° angled coronary scissors

two pointed tips, while dissecting scissors have two blunt tips. There are also models with a finely toothed blade to offer an even better, more controlled cut in certain situations.

Designs

Straight, bent-up, angled (with different angulation).

Important Users

Potts, Potts-Smith, De Bakey, Diethrich, Hegemann, Favoloro.

Typical Features

Adventitia scissors have straight blades for an optimal cut offering the smallest possible cutting surfaces. The extremely fine tips are intended for high-precision trimming without obstructing the surgeon's field of view. Dissecting scissors have ergonomically curved blades to ensure that the surgeon can fully concentrate on his task instead of the position of his hand. Safe dissection is guaranteed by the rounded tips.

Scissor Lengths

From 13 cm to 24 cm.

72.5.7 Gynecological Scissors

Field of Use

Exclusive use on the internal female genital organs.

Most Frequent Intervention
Hysterectomy (vaginal/abdominal total extirpation of the uterus with or without adnexectomy).

Types of Scissors

Uterine scissors, parametrium scissors (also called hysterectomy scissors).

Fig. 72.45
Favoloro scissors

Fig. 72.46
Favoloro scissors

Fig. 72.47 Potts-Smith scissors

Most Important Users

Sims, Siebold, Wertheim.

Typical Features

All in all these are very stout scissors with short, bent-up blades. Both tips are always blunt. When

**Fig. 72.50** Vascular scissors**Fig. 72.51** Vascular scissors**Fig. 72.48** (a) 60° angled Potts–Smith scissors button ended, (b) 60° angled Potts–Smith scissors, (c) 40° angled Potts–Smith scissors**Fig. 72.49** (a) 25° angled Potts–Smith scissors, (b) Bent-up Potts–Smith scissors

closed they offer a round tip for dissecting and spreading.

The blades must be very short in relation to the shanks because this provides the leverage required for putting adequate pressure on the cutting edges. The blades as such must be sufficiently thick to prevent their

Fig. 72.52 Angled scissors

Fig. 72.53 Angled scissors

being pushed apart when transecting rough tissue (e.g. in the parametrium), thus ensuring a clean cut.

Scissor Lengths
20–28 cm.

72.5.8 Gynecological Scissors for Obstetrical Use

Fields of Use

For episiotomy to prevent perineal laceration/rupture or facilitate surgical delivery. For cutting off the umbilical cord (omphalotomy).

Fig. 72.54 Gynecological scissors

Fig. 72.55 Sims uterine scissors

Fig. 72.56 Sims-Siebold scissors

Fig. 72.57 Episiotomy scissors, Braun-Stadler

Types of Scissors
Episiotomy scissors, umbilical scissors.

Most Important Users
Braun-Stadler, Waldmann, Busch, Schuhmacher.

Typical Features
Episiotomy scissors are sturdy scissors with bent (elbowed or lunated) blades to protect both the mother and the baby against injury. The crescent-shaped blades are designed for best adaptation to the skull of the baby when inserting the scissors into the obstetric canal. A clean and even cut in such rough tissue must be guaranteed as well.

Umbilical scissors are short, stout scissors which are available in various designs all of which guar-

Fig. 72.62 Umbilical scissors, Schuhmacher

antee a clean and safe transection of the umbilical cord.

Scissor Lengths
14–22 cm.

72.6 Handling and Care

Surgical instruments, including all surgical scissors, may be used only for their intended purpose in the specified medical fields by adequately trained and qualified personnel. It is the treating physician's or user's responsibility to select the appropriate models for specific applications or surgical uses, provide adequate training and information on the proper handling of the instruments, and ensure sufficient experience in using them.

Prior to their first use and before each subsequent use, as well as before returning them to the manufacturer for repair, maintenance, or service, the instruments must be cleaned, disinfected, and sterilized in accordance with standardized processing instructions derived from a whole body of legal and normative provisions (laws, regulations, standards, guidelines, and recommendations).

It should be noted that proper processing and care are essential for retaining the function and value of these high-quality products – which constitute important material assets for any hospital – over many years.

Important standards, guidelines and recommendations include:

- The joint recommendation issued by the Robert Koch Institute (RKI) and the German Federal Institute for Drugs and Medical Devices (BfArM) on *Hygiene requirements for processing medical devices (Anforderungen an die Hygiene bei der Aufbereitung von Medizinprodukten)*. It requires a quality management and validated procedures for processing reusable medical devices.
- DIN EN ISO 15883 standard specifies and defines the requirements for cleaning and disinfecting apparatus (washer-disinfectors) and for validating the processes used.
- DIN EN ISO 17664 standard specifies the information to be provided by the manufacturer with regard to proper reprocessing of medical devices.

72.6.1 General Instructions

The processing cycle for medical devices generally includes:

- Preparatory work (pretreatment, collecting, pre-cleaning, and dismantling where applicable)
- Cleaning, disinfecting, final rinse, drying

Table 72.2 Highest value for contaminations in feed water

Substance/property	Feed water
Evaporation residue	≤ 10 mg/l
Silicates (SiO ₂)	≤ 1 mg/l
Iron	≤ 0.2 mg/l
Cadmium	≤ 0.005 mg/l
Lead	≤ 0.05 mg/l
Rest of heavy metal residues (except iron, cadmium, lead)	≤ 0.1 mg/l
Chlorides (Cl ⁻)	≤ 2 mg/l
Phosphates (P ₂ O ₅)	≤ 0.5 mg/l
Conductivity (at 25 °C/77 °F)	≤ 5 μS/cm
pH-value (degree of acidity)	5–7.5
Appearance	colorless, clear, no sediments
Hardness (total of alkaline earth ions)	≤ 0.02 mmol/l

Note: Compliance with limits should be checked using recognized analytical methods

- Visual inspection for cleanness and perfect condition of the material
- Care and repair
- Functional tests
- Labeling
- Packaging, sterilization, release, and storage.

72.6.2 Materials Used in Scissor Manufacturing

Apart from the standardized materials (DIN EN ISO 7153-1) used, which are described in a separate chapter, there are a number of other parameters that should also be observed during processing because they are important factors for retaining the value of the instruments in the long term.

72.6.3 Water Qualities

Due to the high quantities required in the processing cycle, water is an essential factor for achieving a good cleaning result in any machine cleaning process. Depending on the type of items to be processed, the water quality can adversely affect their long-term value retention, specifically as the overall salt content (evaporation residue) of the water can lead to unwelcome deposits on the processed goods, thus causing damage to the material.

An unfavorable water composition, therefore, can adversely affect both the process used and the appearance and materials of the instruments. Consequently, the water quality should be assessed and taken into consideration from the start, i. e. when planning the sanitary installations. For example, excessive chloride concentrations can lead to pitting on the instruments, while other substances – such as silicates/silicic acids – can cause discoloration (staining, spotting). In addition to all the natural substances contained in the water, rust may also be found in tap water. Rust is invariably a result of corroded piping, forming deposits on the instruments that subsequently lead to stains (extraneous rust) and corrosion. This can be prevented by using demineralized water for the final rinse!

The DIN EN ISO 15883-1 standard (item 6.4.2.2) provides a list of parameters that should be checked and assessed under any circumstances. DIN EN 285 (Appendix B, Table B1) specifies limit values for the boiler feed water of a steam sterilizers. Such water quality can be recommended for the final rinse of machine-based instrument processing cycles. The values in Table 72.2 can be recommended for orientation.

Fig. 72.63 Formation of rust due to multi-hour immersion in physiological saline

72.6.4 Preparation for Cleaning and Disinfection

The first steps are already taken in the operating room (OR). Wherever possible, residues of hemostatic, skin disinfecting or lubricating agents, or acid medicines should be removed before storing the instruments away for reprocessing after use.

Stainless steel instruments should never be immersed in physiological saline (NaCl solution) because extended contact with this medium will lead to pitting and stress-crack corrosion.

Formation of rust is due to multihour immersion in physiological saline. The improper practice of *throwing off* instruments after use is a source of damage, especially for scissors. Hard-metal scissors are particularly critical instruments since their insets are very brittle, in spite or because of their hardness. Improper handling (e.g. allowing them to drop on the tips) can lead to loss of the hard-metal insets (tip break-off or cutting edge nicks). However, nicking cannot occur in scissors with welded-on hard-metal edges.

It is important to store the instruments properly on instrument trays suitable for machine cleaning. Effective cleaning requires jointed instruments (such as forceps, pliers, scissors) to be processed in open conditions in order to minimize overlapping surfaces. Microsurgical instruments such as microscissors must be stored on special racks or using suitable supports for proper fixation (Fig. 72.64).

72.6.5 Manual Cleaning and Machine Cleaning

Machine cleaning should be given preference over manual cleaning. In any case, effective cleaning is a prerequisite for effective disinfection and subsequent sterilization. Thermal disinfection should be preferred over chemothermal disinfection methods. Standardized cleaning and disinfection can best be achieved with machine cleaning. The international standard EN ISO 15883, as well as national guidelines and recommendations require the exclusive use of validated machine cleaning processes.

72.6.6 Machine Cleaning and Thermal Disinfection

For thermal processes, the disinfecting effect is usually determined parametrically. To this end, the F value used for sterilization with moist heat was translated into the A_0 -value concept for thermal cleaning and disinfecting processes using moist heat and as such integrated into the DIN EN ISO 15883 standard. A disinfecting method using moist heat is expected to guarantee that a defined temperature maintained over a defined period of time has a predictable lethal effect on vegetative microorganisms. The appropriate lower temperature limit has been set to 65 °C (149 °F).

The decisive criterion for defining the required temperature impact is the heat resistance (thermoresistance) of the vegetative microorganisms to be killed. This parameter is quantitatively expressed in the D value.

Fig. 72.64 Instrument tray for storing and fixing delicate instruments

Fig. 72.65 Machine processing program with thermal disinfection typically includes the steps shown (after [72.1])

A_0 , the time equivalent (in s) given by the disinfecting process at 80 °C (176 °F) in relation to a microorganism with a z value of 10 ° (50 °F).

Terms/Parameters

- A** Time equivalent (in s) at 80 °C, by which a defined disinfecting effect can be achieved.
- A_0 value** Killing power expressed as time equivalent (in seconds) at a temperature of 80 °C that is process-transferred to the product, for microorganisms with $z = 10$ °C.
- Z value** Temperature change (in K) required for changing the D value by a factor of 10.
- D value** Decimal reduction value, the time (in min) required at a defined temperature for killing 90% of a population of microorganisms.

The structure of the program to be used depends on the (e.g. hygienic) performance requirements and the goods to be processed (Fig. 72.65).

The following steps are processed with thermal disinfection:

1. *Prerinse*: Pure cold water (demineralized if available) to remove coarse soiling and foaming substances.
2. *Cleaning and process chemicals*: Warm or cold water (demineralized if available); cleaning is normally done at 40–60 °C (104–140 °F) for at least 5 min. A differentiation is made between alkaline and neutral cleaners. Neutral cleaning agents usually contain nonionic, low-foam tensides, and products with or without enzymes are used for this purpose. If the recommendations of the vCJD Task Force (see corresponding RKI guideline) are followed,

a cleaner solution with a pH-value higher than 10 must be used.

Should the water used contain excessive chloride concentrations, this can cause pitting and stress-crack corrosion on the instruments. Using alkaline cleaners or demineralized water minimizes such corrosion.

3. *First intermediate rinse* – warm or cold water: Adding an acid-based neutralizer facilitates the removal of alkaline cleaner residues. Even when using neutral cleaners, it is advisable to use a neutralizer if the water quality is poor (e.g. if the salt content is high). This prevents the formation of deposits.
4. *Second intermediate rinse*: Pure warm or cold water (demineralized if available), no additions.
5. *Thermal disinfection/final rinse*: Demineralized water, with thermal disinfection carried out at temperatures of 80–95 °C (176–203 °F) using an appropriate exposure time according to the A_0 concept (DIN EN ISO 15883). Using demineralized water prevents the formation of stains/spotting, deposits and corrosion. If a final rinse agent is added to shorten the drying time, make sure that it is both biocompatible and compatible with the instruments to be processed.
6. *Drying*: Sufficient drying must always be ensured, either as part of the automatic cleaning program or by taking adequate measures. As concerns the process chemicals used, it is mandatory to observe the product manufacturer's instructions regarding concentration, temperature, and exposure time. This is important for obtaining best results while treating the instruments as gently as possible. Automatic liquid dosing devices must be controllable. Other methods will not be discussed here.

72.7 Inspection, Testing, and Care

Sufficient cleanness is a basic prerequisite for successful sterilization. The instruments must be macroscopically clean, i. e., free from any visible residues (to be verified by inspection). Critical areas such as the handle structures, joints or jaw grooves, atraumatic toothings in particular, need to be checked with special care.

Care measures must be taken prior to performing the functional checks. This requires the targeted application of care agents to joints, box locks, threads, and friction surfaces (e.g. of scissors, forceps, punches) following careful cleaning and disinfection. As this prevents metal-on-metal friction, it helps to prevent fretting corrosion.

Requirements for care agents suitable for surgical instruments are:

- Paraffin/white-oil basis
- Biocompatible according to the valid European or US pharmacopoeia
- Approved for steam sterilization procedures and vapor-permeable.

Instruments may never be treated with care agents containing silicone, as this could lead to stiff action and jeopardize the effectiveness of steam sterilization. As the various instruments are designed for specific purposes (e.g. scissors), inspections must be such that instruments which no longer serve their purpose will be sorted out reliably. If in doubt, appropriate inspection and test measures should be agreed upon with the manufacturer of the product. Instruments that are returned to the manufacturer for repair must first be sent through the entire cleaning and sterilization cycle for hygienic reasons.

72.8 Packaging

As a rule, medical devices must be sterilized in suitable packaging (Figs. 72.66, 72.67). Instruments for use in the OR are assembled as complete, intervention-specific sets/trays and packaged as such. For thermostable instruments, steam sterilization should be preferred.

The purpose of packaging systems for terminally sterilized medical devices is to enable sterilization, pro-

Fig. 72.66 Instrument tray according to DIN 58952-3, loaded

Fig. 72.67 Reusable sterilization container according to ISO 11607 and DIN EN 868-8

vide physical protection, maintain their sterility up to the time of use, and allow for their aseptic placement for use in the OR. The general requirements applying to packaging for terminally sterilized medical devices, including validation requirements for forming, sealing, and assembly processes, have been defined in the DIN EN ISO 11607 series. In addition, parts 2 to 10 of the DIN EN 868 series contain test methods and reference values for specific materials used for preformed sterile barrier systems and for packaging systems.

72.9 Current Terminology

Sterile Barrier System

Minimum packaging that prevents the ingress of microorganisms and allows the product to be placed ready for use in aseptic condition at the point of use.

Protective Packaging

Material configuration designed to prevent damage to the sterile barrier system and its contents from the time of assembly to the time of use.

Packaging System

Combination of sterile barrier system and protective packaging

Sterile Barrier System + Protective Packaging = Packaging System

Materials and (preformed) sterile barrier systems considered suitable (depending on the sterilization method used) are:

- Paper bags, sealable transparent pouches, and reels
- Plastic film constructions (composite foils)
- Sterilization paper (smooth, creped)
- Nonwoven wrapping materials
- Form/fill/seal (ffs) processes
- Packaging processes (e.g. four-side closure)
- Reusable sterilization containers.

72.10 Steam Sterilization with Saturated Steam

Reference standards: DIN EN 285:2006+A2:2009 and DIN EN ISO 17665-1 1:2006. The current standard is a validated method of steam sterilization, usually at 134 °C (273.2 °F).

The sterilization and holding times are subject to national regulations and guidelines and, therefore, cannot be defined globally. It is the operator's responsibility to ensure that the reprocessing/sterilization performed with given CSSD equipment, materials, and personnel achieves the desired results. This requires validation and routine monitoring of the process.

72.10.1 Steam Quality

The steam used for sterilization must be free from impurities and must not adversely affect the sterilization process or damage the sterilizer or the goods to be sterilized. To ensure this, the reference values specified in Tables B.1 + B.2 of EN 285 (Table 72.3) for the quality of the boiler feed water and the condensate must not be exceeded. Noncompliance can lead to corrosion due to rust particles from the piping system, for example, or to instrument

Table 72.3 Suggested maximum values of steam impurities in steam sterilizers (after [DIN EN 285 (edition 2009-08)])

	Table B.2 Steam condensate feed line	Steam condensate after contact with sterilized products	Table B.1 Feeding water for steam generation
Evaporation residue	– mg/l	≤ 30 mg/l	≤ 10 mg/l
Silicon dioxide	≤ 0.1 mg/l	≤ 0.1 mg/l	≤ 1 mg/l
Iron	≤ 0.1 mg/l	– mg/l	≤ 0.2 mg/l
Cadmium	≤ 0.005 mg/l	– mg/l	≤ 0.005 mg/l
Lead	≤ 0.05 mg/l	– mg/l	≤ 0.05 mg/l

Hardness	≤ 0.02 mmol/l	mmol/l	≤ 0.02 mmol/l

*Except iron, cadmium, lead

staining (discoloration) due to excessive silicic acid content.

If humidity is retained inside packaging systems, this can also lead to rusty instruments. Adequate measures to prevent residual humidity can be agreed upon with the manufacturer of the sterilizer.

72.10.2 Release and Storage

Follow-up treatment after sterilization includes:

- Intermediate storage of the hot sterile items immediately after removal from the sterilizer, to allow them to cool down (half an hour is usually sufficient)
- Sorting of the sterile goods with inspection for cleanness, dryness, and integrity (including packaging and labeling)
- Checking/assessing the sterilization result based on the quality records of the lot documentation

72.11 Quality Characteristics

72.11.1 Material

A basic prerequisite for best quality is the use of high-quality, forged steel satisfying ISO 7153-1-2000 requirements. The raw materials of reproducible high quality should preferably be of German origin. Commonly used steels are 1.4117, 1.4034 and 1.4021.

72.11.2 Surface

An optimal surface treatment comprises several working steps:

- First, at least 0.3 mm of the surface of the blank must be ground off to remove slag inclusions and surface defects. This creates the basic conditions needed for reliable resistance to corrosion.
- This is followed by mechanical polishing and, preferably, additional electropolishing.
- Finally, the product receives its surface appearance (mirror, matte, or glass bead-blasted finish).

To consistently meet the growing demands in the field of instrument reprocessing (e.g. due to the use of high-alkaline cleaners), a passivation step is increasingly added, especially for high-quality instruments. This optimizes the chromium–iron ratio on the surface of the

- Sorting out and blocking sterilized items that fail to meet the requirements
- Release for use.

These tasks may only be carried out by authorized personnel. Transport should be effected according to commissioning requirements, but always with adequate protection. It is recommended to use containers and transport them in closed trolleys.

Proper Storage

A dust-free and dry environment is an essential requirement for protected storage of sterile goods and prevention of corrosion damage. For the same reason, temperature fluctuations should be avoided. The maximum permitted storage period depends on the type of packaging and the storage conditions. This means up to six months for sterile supplies packaged in compliance with standard requirements and stored in a dust-free room. Storage beyond the expiration date – which has to be determined by the user in each case – is not permitted.

instrument. The objective is to enrich the surface with as many of the *nobler* chromium molecules as possible in order to improve the instrument's resistance to the chemical attacks typically encountered during reprocessing, thus enhancing its resistance to corrosion.

72.11.3 Form

The closed scissor tips must fit perfectly so cutting with the tips is also possible. The fit of the two blades is good in closed scissors if one covers the other exactly.

72.11.4 Action

Scissors should be easy to open and close, with the blades gliding smoothly in place over each other. Moreover, their operation must be balanced to offer an even and controlled cut over the entire length of the blades (i. e. from the start of the cut, with the instrument wide open, to complete closure). Blades with adequate hollow grinding on the inside support smooth action.

72.11.5 Eye Rings

The eye rings are the working surfaces for the fingers. Their ergonomic shape should ensure pain-free

and nonfatiguing handling even for extended periods. The inside of the eye rings, in particular, must provide a smooth, burr-free surface finish.

72.11.6 Quality of Cut

The material to be cut must be transected cleanly and smoothly. No *slippage* may occur and the material must not get squeezed between the blades, either, so they must be sharp. The cutting performance is supported or enhanced by the so-called *bevel* – i. e. additional grinding (chamfering) of the cutting edge of

the lower blade. Ideally, the bevel should form an angle of 75° relative to the cutting edge. An adequate mechanical tension between the shear blades – ideally as low as possible and as high as necessary – ensures a good cutting performance. Test methods differ greatly, given the complex and diverse demands resulting from the different materials to be cut – ranging from human tissues to sutures. For example, coarse surgical scissors are performance-tested using multilayer cotton material, whereas the cutting efficiency of delicate microsurgical scissors is verified with ultra-fine latex.

72.12 Future Developments

72.12.1 Users

The high-quality scissors currently available on the market offer very high quality standards. Nonetheless, the requirements on surgical instruments continue to grow as a result of the new and improved surgical techniques being used. This trend is additionally fostered by the cost and time pressure that also affects the operating room, translating into a growing need for ever better surgical instruments – more durable, precise, and functional.

72.12.2 Industry

In the industrial sector, an enormous range of new opportunities for improving certain functions has been developed in recent years. Innovations from the fields of nano and coating technology, along with new materials such as ceramics, nitinol or carbon fibers, are bound to gradually replace existing functions of surgical instruments over time – and most likely improve them as well. This trend is enhanced by the potential use of new manufacturing technologies.

A relatively recent example from the history of scissors is the development of bipolar scissors. Apart from the conventional cutting and dissecting functions, bipolar scissors additionally offer a hemostatic function due to the simultaneous use of HF current. The clinical advantage derives from the fact that no instrument exchange is required, as the cutting, dissecting and coagulating functions are integrated into a single instrument. An additional benefit comes into play because users are already familiar with the instrument, so there is no real need to change the accustomed surgical technique. This saves the surgeon a lot of

time and besides, he can fully concentrate on his task.

In terms of development and manufacture, completely new steps and methods were required to enable the use of two current potentials at the distal end of a pair of scissors as required for bipolar current application. With the given constraints, this necessitated the use of new insulation materials such as ceramics because only with a ceramic cutting edge (coated or pure) was it possible to fit the instrument with an insulating edge. Its production, in turn, called for a completely new manufacturing technique termed *ceramic injection molding* (CIM) that requires relatively complex molds, but then the resulting parts are always fully identical in size and shape.

Consequently, the metal base body of the scissors must always be fully identical as well. A perfect form fit is particularly crucial where the ceramic element is to be bonded to the metal body, as otherwise a poor fit would lead to fracture of the element during mounting. In addition, the whole process must be well matched to the opposite scissor blade to ensure the smooth action of the instrument under slight mechanical tension. In terms of controlled production conditions, this can only be achieved if the scissors or metal blades consistently have the same size and shape – which also means that manual production steps must be completely eliminated and all parts must be machined, ideally by robot-assisted CNC manufacturing. Only this approach allows the meaningful production of reproducible parts. While on the surface, the design of bipolar scissors needed just a few changes, consistent implementation actually led to enormous production process modifications requiring extremely high investments.

72.13 Bipolar Scissors

For some time now, bipolar scissors (Fig. 72.68) have been used in almost all surgical disciplines. Preferred fields of application in clinical use are (among others):

- Intestinal surgery (e.g. hemicolectomy, sigmoidectomy)
- Urology (e.g. prostatectomy)
- ENT (e.g. neck dissection)
- General surgery (adhesions)
- Gynecology (e.g. hysterectomy).

Outlook

Continued development will be of great importance, with focus on specialized, indication-specific multifunctional instruments. It will certainly be a challenge to enhance the solidity and durability of the scissors while

Fig. 72.68 Bipolar scissors – working principle

Fig. 72.69 Multifunction of bipolar scissors

making their use still easier in daily practice. Moreover, to ensure the greatest possible safety for the patients, it will also be important for users, surgeons, and surgical staff to keep themselves well-informed about the current and future developments taking place in the industry.

73. Intelligent Textiles and Trends

Christian Rotsch, Sibylle Hanus, Danny Schwabe, Heike Oschatz, Andreas Neudeck, Uwe Möhring

Textiles are common materials for many medical applications. They are used, for example, as bandages, medical stockings, or scrubs. Developments during the last 10 years in the areas of wearable electronics, smart textiles and material research offer new possibilities to create medical textiles with a higher level of functionality and allow the development of completely new active medical textiles. This trend was made possible by the interdisciplinary cooperation of engineers and scientists from textile research, electronics, informatics, and mechanical engineering, together with medical experts.

The integration of electronic devices into textile base materials enables new possibilities for personal monitoring and therapeutical systems for sports and medical applications. Regarding the demographic development in industrial countries, such wearable monitoring devices may be very interesting in addition to common systems.

These new intelligent textiles are a result of the combination of textile and nontextile technologies. In addition to common textile properties, new functions will be realized by the integration of conductive leads. Besides the integration of common electronic components (e.g. sensors, amplifiers) in different clothes, the research activ-

ities focus on the development and application of textile and textile-based sensors and actuators.

73.1 Textile Manufacturing Technologies and Applications

73.1.1 Textiles for Medical Application

Novel functional special textiles, resulting from the combination of textile and nontextile technologies, are an interesting alternative to the usual systems for medicine and medical technology. For example, by using different thread materials, textile and nontextile

manufacturing technologies or coatings, common textile structures obtain a new level of functionality.

In addition to known applications of functional medical textiles like compression textiles, scrubs, or antidecubitus systems, active medical textiles offer new applications like the identification of hospital clothing by textile RFID tags for industrial laundry or

Fig. 73.1 Woven LED structure (Philips, Lumalive; TITV Greiz)

the monitoring of vital parameters by textile-based sensors. These so-called smart textiles are made of a textile base structure and, for example, electronic devices.

In addition to the common textile properties, new functions will be realized by the integration of conductive leads. Besides the integration of common electronic components (e.g. sensors, amplifiers) in different clothes, the activities of different research institutes are concentrated in the development and the application of textile and textile-based sensors and actuators. The base of such developments is, beside other materials, a conductive thread material. One example for a commercial product, which was developed at TITV Greiz, is the so-called ELITEX material. By the combination of electronic and textile typical properties, it can be used in all textile manufacturing technologies, like weaving, embroidery, or warp knitting. This is the first step for different product developments. Other attempts were made, for example, by using metal-based wires in combination with textile thread materials.

The goal is to integrate and not only to attach a non-textile technology into the textile structure to combine the advantages of textiles, like breathability, washability, stretchability, or a good wearing comfort with technical functions, like sensing or heating [73.1].

Textiles for medical applications can be separated into

- Functional medical textiles
 - Wound treatment
 - Compression textiles
 - Antidecubitus systems
 - Implants
 - Filtration

- Hygienic textiles
- Electromagnetic shielding
- Active medical textiles
 - Medical agent depot and disposing systems
 - Monitoring textiles, textile-based sensors
 - Therapeutical electrodes, e.g. functional muscle stimulation
 - Electrode systems
 - RFID tags
 - Heating and cooling textiles for thermotherapeutic applications.

A short overview of textile manufacturing technologies is given in the following sections.

73.1.2 Weaving

Woven fabrics are produced by right-angled crossing of at least two-thread systems, named warp and weft. The warp threads move in a lengthwise direction through the loom. The thread are lifted or lowered in a defined order (pattern) by a shedding machine (Fig. 73.2).

Then the weft thread is inserted. This can be done by a projectile, a rapier or by air. After that the weft thread is fixed at the woven fabric end. The high and low position of the warp threads now changes for the next weft insertion. This change is carried out by a dobby machine, where several threads on one frame make the same pattern. By using a jacquard dobby it is possible to control each warp thread individually.

Typical applications of weaving technology for the realization of smart textiles are multilayer structures for energy and data lines, antennas, textile electrodes, or photonic/light emitting textiles. These photonic textiles can be realized by the integration of LEDs in the textile structure (Fig. 73.1).

With a high density of threads up to 120 per cm multilayer matrices e.g. conductive boards can be created.

73.1.3 Embroidery

In the traditional definition, embroidery is a technique of decorative needlework in which designs are created by stitching strands of some material onto a layer of another material.

Up until now, most embroidery used textiles thread-stitches onto a woven or nonwoven fabric, but recently embroidery has become more and more important in technical applications ranging from fiber reinforcement up to electronic circuits. Stitches can

Fig. 73.2 Weaving machine with sheddings, schematic (TITV Greiz)

Fig. 73.3 Embroidered conductive circuit board (after [73.3], TITV Greiz)

be executed in wires and embroidery can be worked onto nontraditional materials such as plastic foils. One unique feature of embroidery is the possibility of placing stitches in any desired direction forward, backwards, and sideways. Very complex multilayer patterns, like conductive circuit boards (Fig. 73.3) can be produced in this way [73.2].

For the realization of embroidered structures two main principles exist. On the one hand, a thread is stitched onto a base material and fixed by a second thread from the lower side of the textile material (two-thread system). On the other hand, the functional thread can be fixed on the base structure (soutage technology) by two separate threads, compared to the two-thread system. Tubes, wires, carbon, or glass fibers can be fixed onto textiles with the soutage technology, for example.

Besides the fixation of fibers and threads it is also possible to fix and to interconnect electronic components (Fig. 73.4). With embroidery technology the

Fig. 73.4 Flex-foil substrate fixed and connected by embroidering technology (after [73.4], TITV Greiz)

Fig. 73.5 Warp-knitted 3-D spacer fabric (after [73.4], TITV Greiz)

components can be fixed mechanically and the electronic interconnection can also be achieved.

73.1.4 Warp Knitting

Warp knitted structures are special mesh structures. The fabric is created by the interloping of the yarns that are being knitted parallel to the length of the textile. A special type of warp knitted textile is the so-called three-dimensional spacer fabric (3-D spacer fabric). The 3-D spacer consists of two warp knitted surfaces that are connected and kept at a distance by third thread system – the pole yarn (Fig. 73.5). The two textile surfaces can be modified individually with respect to the binding or the materials used. Thus, the spacer fabric can be indi-

Fig. 73.6 Prosthesis pad in bras, cover made of spacer fabrics (after [73.4], TITV Greiz)

vidually modified regarding the respective applications. For example, the thickness can be varied from 1.5 mm up to 60 mm.

The typical properties of the spacer fabrics are:

- Pressure stability and good pressure distribution
- Moisture transport by special thread materials in the upper and lower surface
- Good thermal & air circulation and good thermophysiological properties.

Because of the good thermophysiological properties of the spacer fabric, the material is used in several medical applications, e.g. the lining of orthosis or prosthesis pads (Fig. 73.6) in bras. Further applications are compression bandages, antidecubitus mattresses, insoles, or hip protectors.

73.1.5 Braiding

A braid is manufactured by interlacing three or more threads forming a flat or tubular narrow fabric. The yarn is directly fed from the rotating bobbins (Fig. 73.7) to the braiding point. Defined by the movement of the clappers to one another the binding, and thus the structure, of the braids can be varied. The dimension of a braid depends only on the count of the yarn, the number of threads, and the type of binding [73.2]. Braids can be used, for example, for energy transfer by using metal wires or litz wires.

Currently, two main variants of tubular narrow fabrics exist. A thread or another material can be placed inside the braid during the manufacturing process. The

Fig. 73.7 Manufacturing of a braid (example) (TITV Greiz)

Fig. 73.8 Braid with sensor fibre as core material (TITV Greiz; ITA, Aachen)

reinforcement of tubes or the shielding of a conductive thread or wire are typical applications. It is also possible to manufacture a braid without inner core material. Artificial vessels are typical medical applications for these types of braids. Other medical applications of braids are tendon replacements or surgical sutures. For example, PVDF braids are combined with titanium screws for the fixation of artificial tendons [73.5].

With the integration of nontextile materials in the braiding process new applications are possible. Figure 73.8 shows a bending angle sensor. Sensor fibers are integrated in the braid during the manufacturing process.

Besides the described structures braiding technology can also be used to create complex three-dimensional structures e.g. for fiber composites. Complete fiber reinforced components, for example for the aircraft industry, can be produced with 3-D braiding manufacturing machines [73.6].

Fig. 73.9 Overview of different ELITEX variants, base material (Ag, Stutex) is galvanized with silver (Ag), gold (Au), platinum (Pt) and zinc (Zn) (TITV Greiz)

73.1.6 Conductive Thread Materials

The basis for the integration of sensor and electronic devices in textiles is a conductive thread material. Actually, there are different strategies and materials to realize the transfer of data and energy in textiles. On the one hand, there are different possibilities to use common copper or steel fibers to integrate electronic parts in textiles. Some of them can be used in a regular textile process, e.g. weaving. Often there are some problems with the long-term stability of these metallic materials. If these threads are bent many times, for example, during the wearing or washing process they can break. On the other hand there have been many attempts to create conductive textile threads. They have the advantage of a very high stability against bending and low weight. However, normally it is not possible to use these structures as data lines for low-volt signals. The resistance of these materials is too high. Typically, these threads are used as energy lines, e.g. for textile heating systems. Different strategies are pursued to reduce the resistance without losing the advantage of low weight and flexibility.

One possibility is the new galvanization process, developed by the TITV Greiz, Greiz, Germany, to handle textiles. By different electrochemical processes a silver-coated polyamide fiber is again galvanized with a silver coating. So it is possible to reduce the resistance of the base material from about 700–800 Ω/m to 15–20 Ω/m (base yarn count of 235 dtex). The final value depends on the material applied (Fig. 73.9) and the type of finishing process of the yarns. For example, a differ-

ent number of threads can be twisted together so the resistance can be minimized. Woven structures with a resistance of about 1 Ω/m can be realized with these yarns [73.2, 7].

By additional coating processes these conductive threads can be insulated e.g. by a TPU or PVC coating (Fig. 73.10). Another possibility is the coating of the manufactured textiles, e.g. narrow fabrics in which the conductive threads have been integrated (Fig. 73.11).

To realize stable electronic interconnections, different strategies have been used. For example the material can be soldered (Fig. 73.12) or glued under special conditions and it can be crimped with adapted tools. This is an important factor for the industrial implementation of smart textiles.

Fig. 73.10 Insulated ELITEX thread (TITV Greiz)

Fig. 73.11 Photonic textile, conductive narrow fabric, water resistant insulation by coating (TITV Greiz)

Fig. 73.12 Soldered interconnection between commercial IDE cable and woven bus structure (TITV Greiz)

Fig. 73.13 Core mantel thread construction of textile and metallic components (TITV Greiz)

Besides the use of galvanized thread materials, other possibilities to create conductive yarns or fibers also exist.

Examples are:

- Metal Fiber yarns
- Metal wire/textiles yarn construction (Fig. 73.13)
- Metalized yarn, e.g. by chemical or PVD processes
- Carbon fibers
- Fibers filled with conductive particles, e.g. silver, carbon, ICP or CNT particles
- Fibers with a conductive preparation
- ICP (intrinsic conductive polymers) fibers
- CNT (carbon nanotube) fibers.

It depends on the application and the available manufacturing technology which material should be used.

73.2 Sensory Applications of Textiles

73.2.1 EMG and ECG Monitoring

The monitoring of parameters like EMG or ECG is very important for different medical and sports medical applications from the preventive or therapeutical points of view. For surface EMG and ECG electric body signs are recorded by glued, plastic, or metal permanent electrodes separately fixed on the skin. The wearing comfort of these electrodes can be estimated as unsatisfactory for patients, especially during long-term applications. The displacement of the electrodes caused by physical activity and sweat development between skin and electrode is a common reason for wrong measurements. In some cases, the electrolytic gel causes skin irritations.

Reliable monitoring systems are required without negative influence to the wearing comfort especially in the fields of medical care and therapy, sports, and occupational medicine.

The combination of textiles as a flexible and light material with foreign technologies opens new ways to create new intelligent products for body-closed applications for medical and medical technique applications. This includes the integration of conventional sensors and sensor systems in different pieces of clothing, but also the development of textile and textile-based sensors [73.8].

Currently there are several approaches to integrate a monitoring system in vests or shirts. Research insti-

Fig. 73.14 MμGuard monitoring vest monitoring vest with silicone based dry contact electrode (after [73.10])

Fig. 73.15a,b ConText vest with textile-based contactless electrodes. (a) Prototype II, (b) final prototype (after [73.8])

tutes and industrial companies are working on these topics in several national and international research projects. The systems Life-Guard, SmartShirt, Vital-Jacket, LifeShirt and MμGuard are only a few examples of these aspirations [73.9, 10].

These monitoring shirts are designed for long-term monitoring. One aspect to increase the comfort of the wearer is the use of flexible dry electrodes. Conductive silicone-based electrodes are a promising strategy [73.13].

Textile electrode systems can work by direct skin contact or alternatively without contact by capacitive coupling.

There are currently two main strategies to monitor EMG and ECG signals. The electrical current can be measured by contact electrodes and noncontact elec-

trodes. In the first case, a conductive textile structure (Fig. 73.16) can be used to measure the electric signals. The quality of the signals depends on different aspects, e.g. the contact area, the structure of the electrode and the surface, and inner conductivity. Normally the textile electrodes need to be moistened by sweat or special contact gels. Currently, there exist different strategies to coat the conductive thread materials by conductive polymers or ionic liquids. First results are promising [73.11].

In the second case, the idea is to monitor the EMG and ECG signals by noncontact electrodes. In different research projects the idea of a noncontact ECG monitoring has been investigated. Besides the design of the electrodes there are special requirements referring to the electronic components, the shielding, and the analyzing process [73.14, 15].

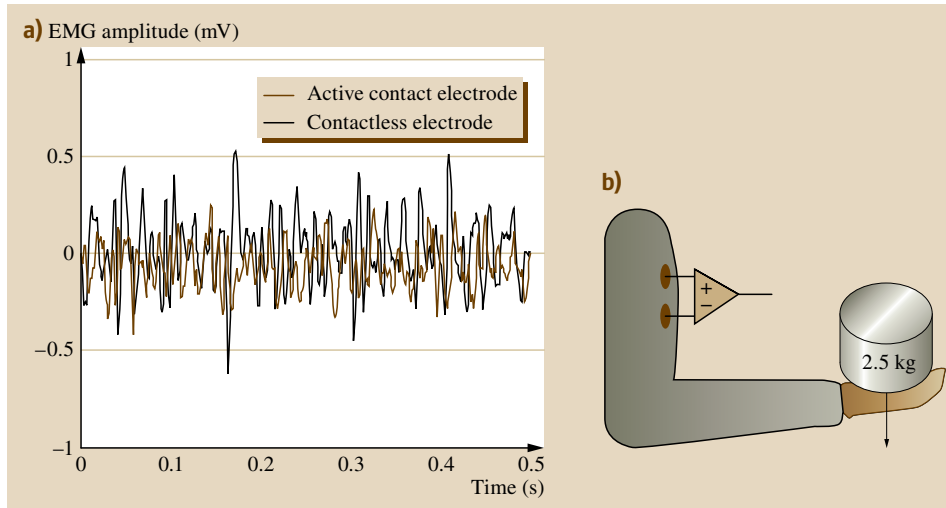

Fig. 73.16a–c Textile electrodes. Examples (a) knitted, (b) embroidered, (c) woven structure (after [73.11, 12], TITV Greiz)

**Fig. 73.17**

(a) Recorded EMG signals with both an active and (b) contactless electrode (after [73.17])

In the EU research project ConText (IST-027291), TITV Greiz worked together with the project partners Philips Electronics Nederland BV (NL), The Catholic University of Leuven (B), Technische Universität Berlin (D), Clothing Plus Oy (FIN), and the Netherlands Organization for Applied Scientific Research, TNO (NL) on the contactless recording of EMG and ECG signals using only several textile and textile-based capacitive sensors with the relating electronic devices [73.16]. The textile sensors in the ConText project were manufactured by weaving, embroidery, printing, and lamination technology. The final prototype of the sensor consists of a laminated structure and woven fabrics for energy and data transfer.

Another possibility for the realization of such a sensor fabric lies in different woven multilayer structures. So it is, for example, possible to create a textile capacitor that can be used as the sensor area. It consists of two conductive layers of ELITEX material that are insulated by two textile layers in the middle. The capacitance of the fabric can be adapted by changing the conductive thread material or the linkage. By a special type of weaving it is also possible to integrate the connectors for the data transfer.

The measuring principle is similar to the contact electrode of a pair of electrodes. These electrodes are built by two conductive layers that are separated by an insulating layer and work as a capacitor. Such a configuration can be used to connect the biopotential signal capacitively to an amplifier. In practice, two electrodes are used and connected to a differential amplifier. The differential signal is then sent to the measurement

system to be sampled, processed, and analyzed. Figure 73.17 shows some results of the comparison of common contact and the first prototypes of the contactless electrodes.

For a real integration of various electronic devices in a textile structure, it is necessary to use textile or textile-like bus structures for the transfer of energy or data. These structures should have mechanical qualities that are comparable to those of base textile, e.g. a shirt or a vest. The woven structures are made of a special multilayer design, which allows the creation of conductive lines of insulated layers on the upper and lower sides. These narrow fabrics can be used for analog and digital data transfer. For sensible measuring applications it is also possible to create shielded bus structures. By means of a special weave it is also possible to create flexible textile narrow fabrics with integrated conductive threads. A very high strain rate is realized without a change of the electric resistance in contrast to other commercially available materials. The resistance of these normally used materials depends on the stress rate. Because of the changing resistance it can be difficult to use these materials for data lines, especially if it is necessary to transfer low-level or low-voltage signals. There are no problems with these new elastic conductive structures. They can be used in elastic clothes, for example. So the stress-strain behavior of the clothes will not be influenced by nonelastic structures, and the stress will not influence the resistance of the bus structures.

Besides the monitoring of EMG and ECG, these sensors also provide information about the physical and

Fig. 73.18 Textile-based capacitive EMG electrode, Con-Text project (after [73.11])

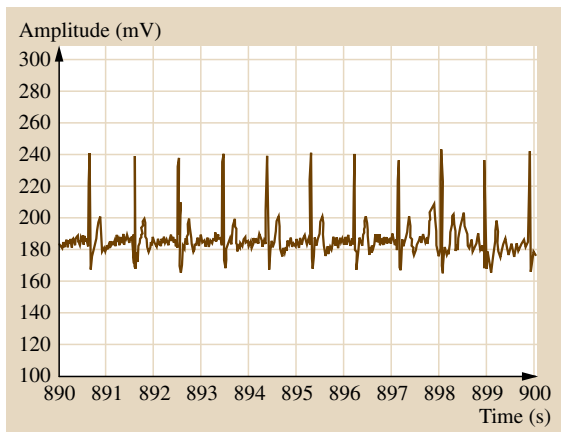

Fig. 73.19 ECG – Signal measured with contactless capacitive electrode (after [73.11], Context project)

mental stress level in addition to the general muscle potential by special algorithms [73.16, 17].

73.2.2 Respiratory Monitoring

Reliable respiratory monitoring is very important for different sport and medical applications. Besides the respiration rate, additional parameters exist, e.g. the breath volume, which deliver important information about the training condition or the sleep behavior of the sportsman or patient.

Different technological possibilities can be used to monitor respiration. The spectrum ranges from simple elongation measurement to monitoring the respiration rate up to the 3-D bioimpedance spectroscopy of the thorax to obtain detailed information about the breath volume and the health status of the lungs e.g. fluid re-

Fig. 73.20 Respiratory monitoring belt (after [73.18], TITV Greiz)

Fig. 73.21 Respiratory monitoring, results (examples) (TITV Greiz)

tention in the lungs. The type of the measuring principle depends on the medical indication.

A very easy and comfortable way to monitor only the respiration rate is the integration of an elongation sensor in an elastic belt or a shirt. The sensor system is limited to only a few electronic components that can be integrated into textiles without influencing the wearing comfort.

The respiratory monitoring belt shown in Fig. 73.20 is composed of an inelastic belt, which can be easily fixed on the thorax, and a sensor unit. The sensor unit is an elastic narrow fabric with integrated sensor fibers. A carbon filled rubber is used as sensor fibers. In the form used here, this material has a nearly linear elongation specific resistance. By inhaling, the change in the resistance can be measured through the sensor's elongation. The peaks in Fig. 73.21 show the moments of the maximum elongations. With an addi-

tional electronic device it is very easy to measure the respiration rate by measuring the change of resistance. A calibration modus at the beginning of the measuring process can be done at maximal and minimal thorax status.

For reliable monitoring it is very important to use a weave that enables a stable fixation of the sensor fibers in the narrow fabric. The narrow fabric and the sensor

fibers should be configured in such a way that they always work in the elastic elongation range in order to obtain long-term stable results.

Such an easy monitoring system may be integrated in different clothes as well as heart rate monitoring belts, e.g. the Polar WearLink (by Polar Electro Oy, Finland) and may deliver additional results during sports, stress tests, or during sleep.

73.3 Active Textiles – Therapeutical Applications

73.3.1 Textile Electrodes for Electrical Muscle Stimulation

Besides the integration or adaption of sensoric functions, conductive textiles provide the possibility to build up actuary systems, like heating devices or textile electrodes for electromyostimulation.

The effect of electricity for medical purposes, specific muscle formation among sportsmen, or for rehabilitation aspects is known today. Electrotherapies use the different effects to the human organism. The main applications are pain therapy and muscle stimulation for training effects. For electrostimulation, metal electrodes or adhesive Ag/AgCl electrodes, which can only be used a few times, are fixed onto the skin at defined spots by therapists or the patients themselves. This can be difficult and uncomfortable, especially near the extremities due to perspiration under the surface of the electrodes and leads to reduced wearing comfort and effect. To improve the wearing comfort and effect, TITV Greiz developed a new system of electrodes on

the basis of conductive yarns. It was integrated in several textile elastic garments like track pants and shirts and improved wearing comfort was achieved.

To reduce the contact impedance between the skin and the electrodes, different finishings and preparations were tested on a technical skin model and with test persons by electrochemical impedance spectroscopy (EIS) [73.1, 11].

Common textile tests like wash stability and tests against abrasion and sanitizing ability were combined with electronic tests regarding the homogeneity of the conductive areas.

In cooperation with the Institute of Physiotherapy of the Friedrich Schiller University of Jena, Germany, these textile electrode systems were tested for the stimulation of femoral muscles. Textile and classic (glued) electrodes were compared with respect to their therapeutical effect during different applications, like transcutaneous electrical nerve stimulation (TENS), electrical muscle stimulation (EMS), or electromyogram (EMG) as biofeedback. Besides the parameters of

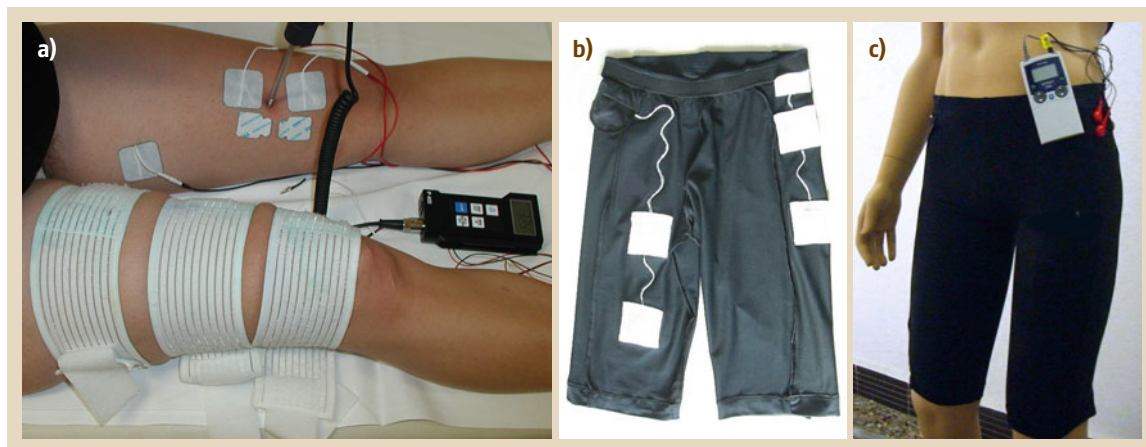

Fig. 73.22 (a) Test person with textile and glued electrodes [73.12]. (b,c) Prototype of a stimulation system for the femoral muscles (after [73.8], TITV Greiz)

Fig. 73.23 Basic implementation of the interactive fabric structure in an interactive textile TTS (TITV Greiz)

the electronic therapy devices, different parameters like skin resistance, skin temperature, and the subjective impression of the test persons were registered. The results of the first study with 25 test persons show a comparable behavior of the common and the new textile electrodes. A target of further developments is the certification of the textile electrodes as a medical product class 2a [73.11, 12].

73.3.2 Textile Interactive Medical Agent Depots and Disposing Systems

The storage and controlled release of pharmaceuticals in the form of transdermal therapeutical systems (TTS) offers interesting alternatives to conventional pharmaceutical delivery in the form of tablets or injections. In addition to bypassing the digestive tract by the direct transition into the blood vessels and the associated lower dose, transdermal systems are easily applicable.

Furthermore, the patient's acceptance increases because the distances between the application forms are much higher in comparison to other pharmaceutical types. The dose is only determined by the type of storage of the pharmaceuticals in the support material. So, the danger of misuse is reduced to a minimum. Typical applications are analgesics (e.g. morphine in long-term applications), or nicotine.

In addition to the benefits of TTS some disadvantages also exist. Insufficient breathability and low moisture transport are two aspects. This can lead to occlusion of the covered skin areas, thereby favoring the occurrence of skin irritations. Furthermore, there are problems with the adhesive strength of the plaster,

Fig. 73.24 Electrochemical modified thread electrodes as an interactive drug store and delivery systems (principle) (TITV Greiz)

which are reduced during the application time. The plaster can also become detached during washing or during physical activity.

Another disadvantage during the application is the start of the release process by removing the protection layer (release liner) of the system. Once the system has fixed on the skin, the release process starts and will not end until the storage is empty or the whole system is removed.

Textile multilayer woven fabrics with different thread preparations e.g. conductive, redox, and ion conductive polymers have been investigated as one possibility of creating interactive textile base structures (Fig. 73.23) that can be used as an agent depot and delivery system. During the many experiments it was found that redox polymer modified ELITEX materials can store agents as anions that are chemically bounded on the polymer chain. The anions can be interactively electrochemically released again by applying a voltage or an appropriate reducing agent. By a suitable textile construction it was possible to create first prototypes of a textile pharmaceutical store and delivery system (Fig. 73.24). It is possible to store and release between 50 mg and up to 500 mg acetylsalicylic acid with such a structure [73.4, 7]. These interactive textile structures can be considered as first steps to textile-based interactive transdermal therapeutical systems. The developed prototypes could be combined with additional iontophoretic electrodes for a defined transfer of the released active ingredients through the skin.

73.3.3 Heatable Textiles for Therapeutic Treatments

Textile-based heating systems were one of the first developments in the area of active textiles. Several com-

Fig. 73.25 Thermal treatment bandage with controller, lumbar bandage (after [73.19], TITV Greiz)

Fig. 73.26 Thermal treatment bandage, temperature distribution (after [73.19], TITV Greiz)

mercial products are already available. Mostly, these heatable textiles are used in sports applications e.g. snow boots, gloves etc. Usually combinations of metal wires, carbon fibers, and metalized fabrics are used in these applications.

Heatable Bandages for Therapeutic Treatment

Besides these commercial or sport applications, textile heating systems can also be used for therapeutical aspects. Among them, thermal treatment methods are the oldest and most commonly used therapies. The attainable effects range from a general improvement of well-being and mental relaxation to the locally defined influence of muscle tone, circulation, inflammation, pain, and the influence of the hormonal and the immune system. Thermal applications show a great diversity, which is multiplied by various application techniques. The whole body or only certain parts of the body are heated up. The heat can be applied in such a way that only the

body surface or the deeper tissues are heated up. The application time can vary between 10 and 60 min.

Recent medical research results show that thermo-therapeutical applications with temperatures between 37 and 45 °C and an extended period of use are very effective. Many of the applications in this area are not mobile or transportable. Therapeutical applications where the patient can move freely often have disadvantages in the dosage of the heat and the wearing comfort.

Figures 73.25 and 73.26 show a lumbar bandage for thermal treatment. It consists of an elastic bandage, two textile heating modules, and the controller device.

The heating modules are woven narrow fabrics with integrated electrical insulated heating threads. In contrast to other production technologies, the integration of the heating fibers is done directly during the manufacturing process of the narrow fabric. Thus, the textile properties e.g. flexibility and drapability, can still be retained.

The modified manufacturing process allows the integration of the heating threads regarding the defined requirements, e.g. distribution and quantity of heat, power supply, and electronic connection [73.19].

The result is a mobile bandage for thermal treatment that meets the medical, electronic, and textile requirements. It is characterized by:

- A high wearing comfort
- Optical attractiveness
- Easy handling
- Nonstationary applications
- Enhancement of patient compliance = treatment results.

Heating System for Long-Term Operations

To keep the patient's body heated during an operation, different kinds of active principles are implemented: active and passive textile passive systems, as well as convective and conductive systems that are based on nontextiles.

An important trend is the combination of heating and pressure reduction. Especially during long-term operations local pressure strain in combination with moisture accumulation results in bedsores that not only bring consequential costs but are also an additional stress for the patient. Systems that include both functional principles can have many advantages in this case, not only economical ones. Three-dimensional structures (3-D spacer fabrics) have many advantages with respect to the prevention of bedsores, because especially three-dimensional knitted textiles are not only able to allow

Fig. 73.27 Spacer fabric heating structure, heating threads integrated in the pole area (after [73.12], TITV Greiz)

air permeability but also moisture transport due to their mesh structure. The proven pressure reducing properties of knitted spacer fabrics are, in this case, a sort of acceptable additional feature.

A wide range of electrical conductive materials for the integration in the spacer fabric's pole area have been investigated, such as multifilament wires, carbon wires, and metalized polymer yarns. Furthermore, possibilities for electrical contact have been investigated, whereupon the focus has been put on economical processes and reversibility.

The research work of TITV Greiz showed that the integration of heating wires into the spacer fabric's pole area without intermeshing must be stated as an

Fig. 73.28 Textile heating system based on a compound of 3-D-spacer fabric and a flat knitted heating device (after [73.4])

optimum (Fig. 73.27). The adaptation of the heating performance to the operation purpose, the free choice of the contact, and economical processing are convincing advantages [73.12].

By measuring the allocation of heat and temperature on the surfaces and determining the clothing-physiological properties, the samples proved their adequacy for applications in the field of medicine (hypothermia prevention) and also in the field of rescue missions (saving victims from cold areas). Along with a battery supported power supply in combination with a controller, mobile systems with the advantages of low weight, high flexibility, and reliability can be developed.

73.4 Passive Medical Textiles for Therapy

73.4.1 Reusable 3-D Knitted Elastic Short Traction Bandages

Three-dimensional (3-D) spacer fabrics are already being used as therapeutic means for decubitus prophylaxis in hospitals and care or as bedding material for orthopedic shoes. The goal of the project was the development of 3-D knitted elastic bandages with adjusted widths for medical applications, especially for the therapy of lymph edema. Particular attention was paid to reusability, economical handling of resources, and their recirculation to the value added chain.

Lymph edema diseases have an increasing tendency. An early and comprehensive treatment is important. Compression therapy is the only possibility to stop the

disease from further diffusion. The method of choice here is the complex anticongestion therapy, which is characterized by an anticongestive first step (manual lymph drainage + special compression bandaging as flanking action) and a conserving second step to keep and optimize the success of treatment [73.20].

With the development of elastic 3-D short traction bandages costs and time can be saved. Better thermo-physiological conditions, the prevention of thermal congestion and optimal breathability help the patients to improve their quality of life. Economical as well as ecological effects are achievable. The new elastic 3-D bandages (Fig. 73.29) are totally different from the products and materials known so far. Two textile outer surfaces and an aired zone between make these ban-

Fig. 73.29 3-D-knitted elastic short traction bandage (after [73.4], TITV Greiz)

Fig. 73.30 Patient with 3-D-knitted elastic short traction bandage and fixed pressure sensor (TITV Greiz)

bandages not only compressible but also cushioning. The bandage of edema patients can be realized with a simplified wrapping technique and without any cushioning with comparable efficiency.

The manufacturing technology with a double Raschel technique allows a number of bandages to be produced at the same time with different widths, specific materials and defined elasticity. So, favor-

Fig. 73.31 Variability of embroidery technology compared to other textile manufacturing technologies (after [73.21])

Fig. 73.32 Embroidered scaffold construction (after [73.1], TITV Greiz)

able conditions for the following processes (relaxation, washing, fixing) can be created. The test series included tests with different materials, weaves, mesh densities, and combinations of material. Elongation values as known from standard short traction bandages were achieved by the use of elastane and partial elastic bicomponent yarns.

Clothing-physiological and skin-sensory tests were made by BPI Hohenstein, Germany, with several 3-D bandages in comparison to standard bandages. It was shown that knitted materials made of spacer fabrics achieved a significantly better comfort note than the standard materials.

Application studies with medical staff showed that 3-D bandages have better handling and wearing comfort in comparison to standard bandage materials

(Fig. 73.30). Although the bandages are more voluminous, an easier wrapping technique was pointed out.

This development is an interesting alternative for bandages, especially for patients with lymph oedema during the complex anticongestion therapy [73.22].

73.4.2 Embroidered Implants for Tissue Engineering

Embroidery is an interesting alternative for the development of three-dimensional textile-based implant constructions like scaffolds and patch grafts for tissue engineering. According to the principle of chemical embroidery, it is possible to create individual and application related scaffolds and patch grafts.

In comparison to conventionally used nonwoven, gel, foam, and foil constructions, embroidered implants offer some advantages:

- Improved mechanical stability
- Function and force flow appropriate construction
- Individual and local defined configuration – pore size, shaping etc. in terms of structure compatibility

- Selective material combination/scaffold constructions (absorbable, nonabsorbable fibers) [73.1].

Embroidered solutions for textile implant constructions offer comparable solutions to woven, braided, knitted or nonwoven materials with the advantage of an individual modification of the mechanical and structural properties by local variation of thread material and embroidered structure. So, embroidered constructions can be realized individually relaying the needed specifications [73.3,21].

Since each implant causes a reaction with the tissue of the patient through the interface between implant and human tissues, the use of biocompatible materials in the embroidery thread technology is essential.

The base material e.g. nonwoven, which serves as a carrier of the embroidered structures, is composed of polyvinyl alcohol and is removed after the embroidery process. A cytotoxic effect caused by the base material must be excluded.

Figure 73.32 exemplifies an embroidered scaffold construction in a 10-layer construction with biocompatible yarns.

Electronics in

74. Electronics in Medicine

Paulo M. Mendes, Celso P. Figueiredo, Mariana Fernandes, Óscar S. Gama

Electronics has long made an undeniable and valuable contribution in the field of medicine. New medical electronic devices are based on available medical knowledge combined with technologies available in the electronics field. Electronics in medicine has a wide range of applications, from diagnostics to therapy, always aiming to provide new tools to improve the well-being of the population.

Nowadays, miniaturization and integration technologies are driving the development of new electronic medical devices that should be portable, wearable, and unobtrusive, but with controlled costs. Regardless of the technologies involved, usually the main goal of such devices is the measurement of physiological variables for use in diagnostics, monitoring, and therapy.

Therefore, this chapter starts with the description of several signals that are commonly recorded, the corresponding electronics and sensing mechanisms used, and problems associated with such acquisition systems, focusing on wireless and wearable devices. It ends with examples of electronic devices in development essentially for remote health monitoring.

This chapter is not about electronics nor on their design, since there are many good books on this topic already, written either specifically for the (bio)medical field or for the general field of electronics. The aim of this chapter is rather to present to the reader those aspects that are common and specific to many medical electronic devices, and to give an overview of what is required and the challenges faced when designing electronics in this field as well as a few such examples under development.

The definition of electronics in medicine has many facets and is hard to define. We may therefore start with the question: What is *electronics in medicine*? Is electronics not always electronics? We use the following definition [74.1, 2]:

Medical electronics – A branch of electronics in which electronic instruments and equipment are used for such medical applications as diagnosis, therapy, research, anesthesia control, cardiac control, and surgery.

74.1 Basics

From our point of view, electronics in medicine encompasses all aspects of electronics that deal with the problems found when electronics are used to understand or solve a medical problem, not necessarily restricted to humans. Electronics in medicine may include the study of the electrical behavior of the human body and how it responds to electrical stimuli. Those stimuli may be in the form of voltages, electric currents, electric fields or magnetic fields. In this case, electronics is used as a model to represent such behavior.

Electronics may be used as a solution to describe biological activities, as happens with the widely used Hodgkin–Huxley model for a neuron cell [74.3], as a solution to help restore lost electrical activity, as is the case with pacemakers [74.4–6] or Parkinson disease [74.7, 8], to help in the replacement of full human body parts [74.9–11], for diagnostics [74.12–15], for therapy [74.16], or for monitoring [74.17–19].

In this sense, it is difficult to write a chapter that includes all the aspects, difficulties, and aspects associated with electronics in medicine. Moreover, there are different perspectives and different views when looking at medical electronics, corresponding to electrical engineering, chemical engineering, ethical aspects, security and privacy issues, physics, and medicine, to mention just a few. However, it is possible to identify two different sides of the same coin: electronics and medicine. On the electronics side, no one is very interested in knowing what is going on behind the electronic system under development. Rather, the system is purely developed to fulfill a set of requirements. From the medical side, what is important is how the system can help to solve an existing problem and how the system can be used, e.g., *please give me a system that enervates the bladder, when placed inside the spinal cord, close to C4–C5*. Fortunately, these two worlds are getting closer, and many great things are expected from electronics in medicine.

Since this field includes many applications, from magnetic resonance imaging (MRI) to electrocardio-

gram (ECG) recording, through biosensors and DNA chips, this is a very broad field, and it is impossible to include and describe all the electronics used in medical applications. Therefore, this chapter introduces the reader to several issues that must be addressed when developing electronic devices for application in medicine. There are many problems that must be tackled and solved when using electronics in medicine. Of course, some of these problems, fortunately, are also shared by other application fields.

74.1.1 Fields of Application

The most obvious application of medical electronics is their use for medical or clinical applications (diagnostics, treatment, and monitoring). However, electronics developed for these applications may have other important fields of applications. One application that is closely related to medical applications is human augmentation, which may apply at different levels, of which two can be highlighted: sensorial [74.20–24] and physical capabilities augmentation [74.23, 25, 26]. For the former, we can give the example of brain–computer interface (BCI) systems that can be used to detect what is happening in the field of vision of a soldier, before he is able to become aware of it [74.27–30]. For the latter, we can give the example of exoskeletons, which can be used to help soldiers in transportation of heavy loads (as in the movie *Avatar*) during long walking periods, or to help an old person with problems in locomotion.

Another very important field of electronics in medicine is its use for ambient assisted living (AAL) applications (Chap. 67, [74.31]). Electronics are used to record, understand, and control those environments. The main idea is to create smart environments that can sense several physical variables to allow implementation of control and decision loops, making that environment *smart*. Such smart environments may be used, e.g., for environmental control, or, focusing on the medical field, to help people with their daily activities.

One major problem they try to tackle is to deal with the ageing of the world population [74.32], for which new innovative technological solutions are expected from the field of medical electronics.

Electronics in medicine may be also used for performance improvement [74.33, 34] and performance monitoring [74.34, 35, 35–37]. These last two applications are closely related, since performance monitoring is a way to understand what can be done to improve it. Monitoring of performance can be done by measuring the physiological signals of the user, or by measuring the outcome of the human action.

Last but not least, many advanced electronics developed for application in medicine may be used for entertainment and interaction purposes [74.23, 38, 39]. All devices developed to monitor posture, position, or muscle signals, or brain activity, can be used as new paths to control new interfaces, leading to a new concept of human–machine interfaces [74.21, 23, 33].

74.1.2 Designing Electronics in Medicine

The design of electronics for medical applications implies the fulfillment of a set of requirements due to the nature of their operation. Such electronics must be designed to be small and capable of being integrated into the environment where they will operate. Another important aspect is that these systems may be required to operate in very harsh environments (inside the stomach, where lots of substances are prepared to digest almost everything), using only a single battery, with no possibility of replacement during tests, and many times only possible using surgical procedures. This requires the use of low-power design techniques, requiring biocompatibility and long-term usage capability.

Since in many applications, the electronics are required to interface with the human body, in order to record signals or to deliver signals or drugs, or to monitor their effect on the human body, one feature of such electronic devices is the ability to register very small variations of the variables under measurement, and many times it is necessary to record many signals at the same time, leading to challenges in terms of analog-to-digital conversion. Most electronics that are used in medicine are designed to sense and transmit a variable, or to control an actuator. In this way, most of the developed solutions have their roots in instrumentation or communications electronics.

Electronic devices in the medical field are usually based on state-of-the-art technologies in order to maximize benefits. They make use of the latest developments

in terms of micro/nanoelectronics, micro/nanosensors, smart material technologies, device integration, device packaging, smart systems, etc. However, beyond all the electronics, most intelligent devices will only succeed if they are also designed to comply with the requirements of the software agents that are used to monitor, detect, and provide alerts based on the measured health condition.

Another important requirement is the ability to operate as a clinical tool. Many electronic devices being developed that claim potential use in the medical field are far from this goal, because there is a big difference between developing a device to monitor the heart rate while jogging versus use in a clinical application. Before clinical use, a long process of certification has to be completed [74.2, 4, 40]. Simultaneously, many such electronics must also be reliable for operation inside a clinical environment, such as a hospital. As is well known, mobile phones are certified electronics devices, but they are not allowed inside many clinical facilities. This is also the situation for many wireless technologies.

Beyond the certification requirements, which are more demanding than in other fields of electronics, the development of electronics for medicine poses its own technical challenges, due to the various operating constraints. Also, legal and cultural aspects, that differ from country to country, have to be dealt with. Moreover, since the developed solutions are, usually, for use by medical doctors, it is also necessary to break the acceptance barrier for some new technologies, despite the certification. Finally, and not less important for many applications, the proposed electronic solutions must gain user acceptance, in particular if they are for use outside the clinical environment.

74.1.3 Medical Electronics Specific Requirements

At first glance, the field of medical electronics may not seem as challenging as it really is. Signal amplitudes and frequency ranges are not that demanding, the operating range is not that large, the operating voltages and currents are, in general, normal, etc. This leads to the use of standard amplifiers, filters, analog-to-digital converters (ADCs), digital-to-analog converters (DACs), microprocessors, microcontrollers, etc. So, what are the problems when designing medical electronics? The problem lies, as in all other electronic fields, in the combination of the requirements specific to such devices.

Fig. 74.1 Main electronic components required for advanced clinical data acquisition

Figure 74.1 shows a schematic of the electronics involved in a typical solution for a biomedical device. This represents a solution for an advanced device, meaning that only the most sophisticated devices require all the modules represented. In other cases, only a subset of such modules will be required; for example, not all electronic modules used in medicine require use of a microcontroller or a bidirectional wireless link.

Bearing in mind the discussion above, a set of challenges may be identified when developing electronics for medicine. These challenges may be found in the areas of data acquisition, filtering, power autonomy, and communications. Furthermore, for AAL applications, it is desirable that devices may be easily worn by the user, leading to miniaturization and wearability requirements. This has also implications in the fashion field, because many people do not like to use electronic devices because they are not fashionable.

The challenge at the data acquisition level results from the combination of a set of requirements particular to this type of systems. The frequency range of interest includes the 50/60 Hz frequency used by power lines. This is a significant problem at various levels. When designing power supplies for operation with these devices, special care is required since the direct-current (DC) voltages are obtained from a 50/60 Hz alternating-current (AC) voltage that will introduce a very strong oscillating component into the supplied power. This interfering component may easily become larger than the signal to be measured, and the minimum signal amplitude that can be measured will be increased. To avoid this, either very careful design of the power supply is required, or a battery is used as the power supply. Since many systems are designed for use on-body and in-body, the battery solution solves many of these problems. However, power lines may also be coupled to the human body, and when measuring biopotentials, inter-

ference is still a problem even when using batteries as the power supply. It is very easy to have a few millivolts superimposed on the measured biopotential due to the power lines, which is of the same order of magnitude as the biopotential itself. One possible solution is to use a notch filter to remove this component. However, this is a challenge because such filters must have a very high quality factor in order to remove only the 50/60 Hz component, because the signal components of interest are around this frequency, and they must have also a high attenuation factor. Attenuation of the order of 30–40 dB is sufficient for most applications, although some may benefit from values up to 70–80 dB. However, this high attenuation introduces a new challenge, namely on how to obtain such devices with very low noise factor. Most designs with off-the-shelf components only enable devices with noise on the order of a millivolt.

Another problem during signal acquisition is associated with subject activity, which has frequency components inside the frequency band of interest, introducing so-called movement artifacts. Since these slow components are inside the band of interest, they cannot simply be removed by standard low- or high-pass filtering. More complex filters, such as adaptive filtering, must be used to remove these components.

At the acquisition level, we have another important aspect, especially for biopotentials, which is the well-known amplifier common mode rejection ratio (CMRR). Since the subject under measurement is at a different potential with respect to the power supply, often the output signal may be a few millivolts, even when both inputs are at the same potential (common potential). The standard solution is to connect the subject to a reference potential, thereby lowering the common mode voltage and reducing its effect on the recorded signal. However, this solution requires the use of an extra electrode, requiring also extra room to accommodate it, which is not desirable when designing miniaturized devices.

Power autonomy is also a very important issue and is easy to understand when we think about other power-limited devices, such as mobile phones. When dealing with medical electronics, this issue may become more complicated, since some devices are required to operate inside the human body for a long period, as happens with pacemakers. In terms of power autonomy, we may divide the systems into three categories: systems to go inside the body (such as endoscopic capsules), systems to operate inside the human body (such as pacemakers), and systems to operate on (outside) the body (such as

wearable devices for AAL). Usually, when recording a single channel [electroencephalogram (EEG), ECG, etc.], it is not difficult to find a solution that operates on a small battery for a few days. The problem is when it is required to record many channels (such as for EEG in epilepsy applications), or when it is also required to actuate another device to obtain the required reading (e.g., a sphygmomanometer). When readings from many channels are required, one option is to design all the electronics based on low-power approaches. The other option, which is also valid for situations where actuators are also present, is to integrate energy harvesting/scavenging technologies. Despite some promising proposals, such approaches are not yet available as solutions to fully power a complete system. However, they may be a potential solution to extend the autonomy of

existing systems, and in the near future it is expected that they may replace batteries in some applications.

We have also to consider communications, in which regard the desirable solution is usually to use wireless communications. However, this introduces new challenges, because this subsystem is typically the most power hungry. To reduce the power consumption of this subsystem, an as efficient as possible power amplifier design must be used, and antennas should also be selected as efficient as possible [74.41, 42]. The challenge regarding antenna design results from the operation of wireless systems in low frequency bands in order to decrease the power required for transmission, but which degrades antenna efficiency because they must be electrically small to fit inside the space available in the device.

74.2 Electronic Sensing

Electronics in medicine may include many applications, as mentioned above; for example, ultrasound and MRI imaging systems are often used in diagnostics, as are ECG recording systems, all of which look very different at a high level. However, looking in more detail, all of them are designed to sense physical variables to aid clinical diagnosis. In this way, in most medical electronic devices, the requirement is to design adequate instrumentation electronics to interface with a transducer that is used to convert a physical variable of interest into an electrical signal, which is finally used to help in the diagnostics.

The success of electronics in medicine relies on their ability to help medical doctors in the determination of a set of parameters that are compared against a range of values considered as healthy. After beating the challenge of determining which parameter is important to measure, and in which range it must be, it is up to the medical electronics to provide solutions to perform these measurements reliably and in a solution that can be easily deployed. In this way, instrumentation is a very important field when dealing with medical electronics. Many medical devices deal with the measurement of specific variables, which may be chemical, physical or electrical. These measurements are supported by appropriate electronics, as well by a transducing mechanism to convert, e.g., an ionic concentration to a voltage, proportional to it.

Some recordings may be obtained by direct measurements, as for measuring body temperature, where

a temperature sensor is used. Alternatively, they may be obtained by indirect measurements, such as measuring breathing rate using a temperature sensor, where temperature changes of air flow are measured to determine the breathing rate. In this way, sensing techniques and sensors are also very important fields when dealing with medical electronics. They are essential, because without sensors there is no medical information to process, analyze, transmit or store.

74.2.1 Health Condition Monitoring

Health condition monitoring requires the use of a set of sensors to monitor a wide variety of signals, either clinical or environmental, forming a sensing component, for example, surface electrodes to measure bioelectric signals, together with the acquisition electronics.

The measured signals can be classified according to their nature and/or type of monitoring. Figure 74.2 presents a few different categories of signals that are commonly measured by sensors, as well as the main parameters assessed.

Physiological signals include bioelectric events and other biochemical and physical parameters that are crucial for assessment of the user's state of health. They can be detected by means of biosensors, which are a particular category of wearable sensors that have the ability to monitor biological properties and processes.

Each signal is important for capturing the entire status of the subject and the surrounding environment. On

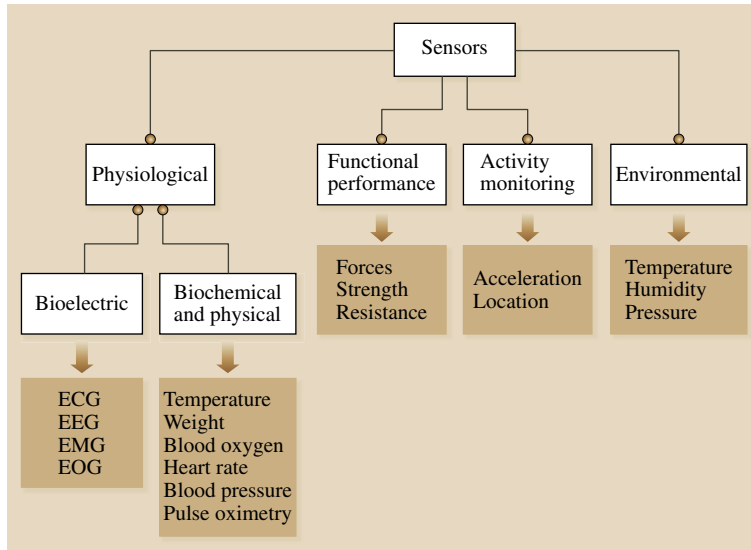

Fig. 74.2 Categories and types of possible biosignals measured to infer an individual health condition

top of such acquisition systems, use of *intelligence* is usually required so that the system can automatically detect any relevant health condition and, based on that, trigger alarms or send warnings to healthcare providers or the patient being monitored [74.19,43].

74.2.2 Biosignals and Transducers

Biosignals offer an interface between the human body and electronic systems, and they are directly related to the physiology and function of organs and organ systems, hence allowing evaluation of the health condition of a subject through their acquisition and monitoring.

An electronic system is used to measure physiological signals. Those signals may be electrical, or if not, they are translated to electrical signals using one of various transducer or translation methods.

Table 74.1 presents examples of the most commonly monitored biosignals for the human body, and their nominal values [74.44–46].

Table 74.1 allows a few conclusions to be drawn regarding the signal and transducer characteristics involved in the process of health monitoring. A few that are important to highlight are: signal amplitude, frequency, power, and the signal translation mechanism.

Signal Amplitude

Bioelectric signals are not difficult to measure from this point of view. From Table 74.1 we can see that the most demanding signals are in the μV range, which, when compared with the radiofrequency (RF) signal at an an-

tenna input (in the range of pV), is very high. When looking for nonelectrical signals, it may also be observed that both signal amplitudes and their dynamic ranges are not very challenging.

One main problem related with signal amplitudes lies in the fact that different signals are in the same range of amplitudes and frequencies. This is a problem since some signals tend to act as interference to others, thus appearing as so-called artifacts. As an example, electrocardiography (ECG) or electrooculography (EOG) signals usually appear overlapped on electroencephalography (EEG) signals. Even simple patient movement, which occurs on the order of a few Hertz, interferes with signals such as ECG, respiration rate, and blood pressure.

Signal Frequency

From this point of view, physiological signals are also not difficult to measure. The maximum frequency is on the order of a few kilohertz. However, since many of them are in the same frequency band, as mentioned above, they tend to interfere with one another. Another common problem is electromagnetic fields coming from power lines (operating in the frequency range 50–60 Hz), which are easily coupled through the power source (that may also introduce a 100 Hz component due to the use of full-wave rectifiers), or because the human body acts as an antenna for those fields. Sometimes the coupled signal may have higher amplitude than the biosignal being measured. One solution is to use batteries to power some electronic devices, avoid-

Table 74.1 Description and properties of commonly monitored biosignals

Biosignal	Range	Frequency	Sensor type
Blood flow	1–300 ml/s	0–20 Hz	Electromagnetic or ultrasonic
Blood pressure	0–400 mmHg	0–50 Hz	Cuff or strain gage
Blood oxygen saturation	95–99%	0–50 Hz	Paired infrared LED and photodiode
Cardiac output	4–25 l/min	0–20 Hz	Fick, dye dilution
Electrocardiogram (ECG)	0.5–4 mV	0.05–150 Hz	Skin electrodes
Electroencephalogram (EEG)	5–300 μ V	0.5–150 Hz	Scalp electrodes
Electrooculogram (EOG)	10–100 μ V	0–10 Hz	Skin electrodes
Electromyogram (EMG)	0.1–5 mV	0–10 kHz	Needle electrodes
Electroretinogram (ERT)	0–900 μ V	0–50 Hz	Contact lens electrodes
Action potentials	–80–80 mV	10–10 kHz	Neuronal electrodes
Local field potentials	0.1–1 mV	0.1–500 Hz	Neuronal electrodes
pH	3–13 pH units	0–1 Hz	pH electrode
$p\text{CO}_2$	40–100 mmHg	0–2 Hz	$p\text{CO}_2$ electrode
$p\text{O}_2$	30–100 mmHg	0–2 Hz	$p\text{O}_2$ electrode
Pneumotachography	0–600 l/min	0–40 Hz	Pneumotachometer
Respiration rate	2–50	0.1–10 Hz	Impedance, electroactive
Temperature	32–40 °C	0–0.1 Hz	Thermistor
Activity		0–100 Hz	Accelerometer, GPS, Wi-Fi
Body weight	0–150 kg	1 time/day	Weighing machine
Glucose	70–180 mg/dL 3–8 mmol/L	1–5 times/day	Glucose meter

ing interference from the power supply. To remove the effect of interference picked up by electromagnetic coupling, the solution is to use an instrument amplifier not with an input impedance as high as possible but rather designed to *kill* the 50/60 Hz component. However, the bioelectric signal has limited power. Another problem, due to the low frequencies involved, is the requirement for high capacity values, leading to large capacitors for filtering blocks. This has implications in terms of device dimensions and response time for the transitions of such systems.

Signal Power

Many of the important signals that need to be measured are biosignals that originate from body electrical activity. One characteristic of such signals is their small amplitude. However, that is not the main problem with their acquisition; the main problem is their low power. Figure 74.3 shows a typical acquisition system used for bioelectric signals. Figure 74.3 shows the bioelectric signal source, the electrodes (which are responsible for the interface between the ionic human body system and the electronic system), and a high-input-impedance amplifier, usually an instrumentation amplifier. Figure 74.4 shows the equivalent electric circuit.

Since the source current is on the order of pA, the available power is also very small. This is a problem when implementing the proposed solution for power line noise cancellation. The interference is canceled, but the biosignal is also attenuated. This means that any small current flow to the instrumentation amplifier will lead to a voltage drop on the electrodes, which will make the available voltage even smaller and more difficult to measure.

Signal Translation

When the biosignal to be measured is not an electrical signal, it is necessary to use a transducer to obtain an electric signal proportional to the physical variable being measured. Oximetry provides a signal obtained

Fig. 74.3 Typical acquisition system for bioelectric signals

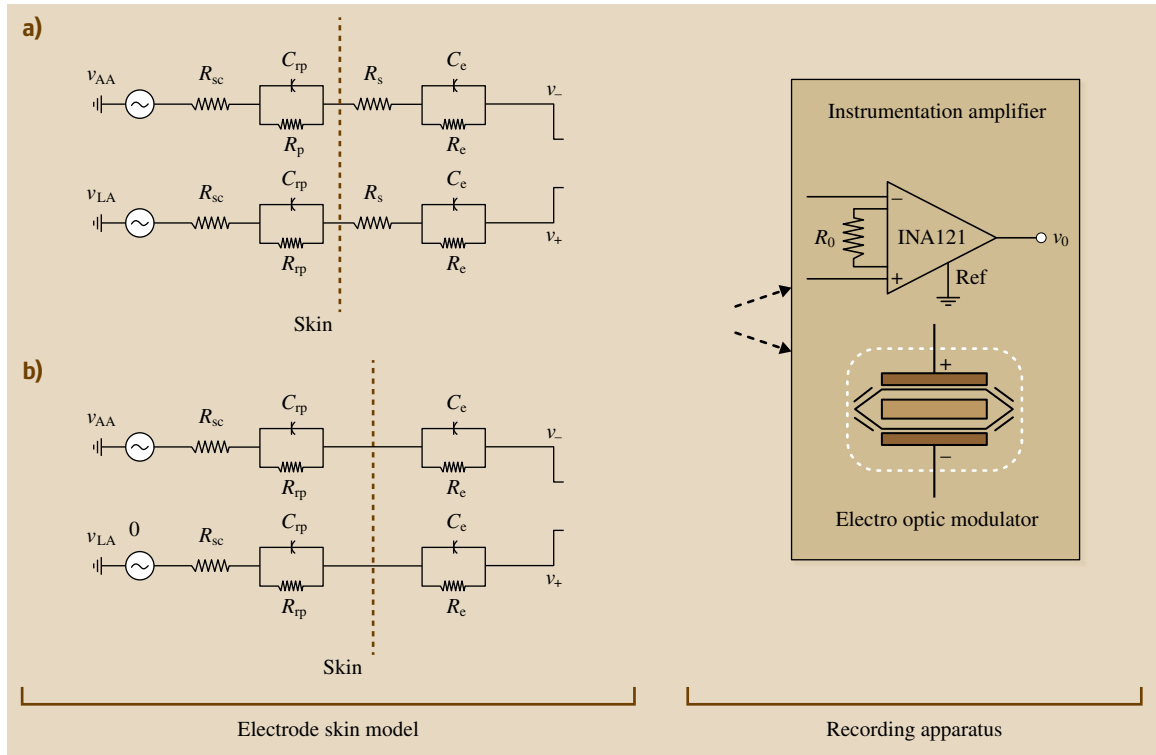

Fig. 74.4a,b Equivalent circuit for biopotential transduction using (a) wet/dry electrodes and (b) capacitive coupled electrodes

from measurements of light, spirometry results in a signal obtained from air flow, and the respiration rate may be obtained from temperature variation or by abdominal volume variation. These are only a few examples, but one key aspect may be highlighted: most of these devices require also an actuator and they tend to be bulky.

In this way, measurements become more difficult when portable devices are required, and even more difficult when wearable devices are considered. When portable or wearable devices are required, often it is difficult to find a solution that is reliable enough and at the same time acceptable for use by the patient.

74.3 Electronics for Wireless Health Monitoring

Wireless health monitoring systems (WHMS) are among the most promising applications of wireless communication technology, and they have been a very active research topic with considerable advances during the last decade. These systems consist of groups of wireless-enabled sensors attached to the human body in a noninvasive or minimally invasive fashion, together forming a wireless body-area network to acquire diverse physiological signals (also known as biosignals) and transmit them via radio to a remote location, for display or monitoring to enable assessment of the user's health

condition. Thorough reviews and surveys on WHMS can be found in [74.47–49].

The development of WHMS envisions the improvement of the quality and efficiency of healthcare, which is currently facing increasing demand and, consequently, increasing global costs. The tendency for increasing healthcare demand is mainly motivated by the ageing of the world population, which is expected to cause an increase in the incidence of chronic diseases and physical disabilities [74.47]. According to the United Nations, the world population is currently

enduring an unprecedented and irreversible ageing process, which will cause a growth in the proportion of elderly people (over 60 years old) to a third of the population in developed countries, and to 22% of the total world population by the year 2050 [74.50]. Therefore, there is a growing need for health monitoring solutions to provide more efficient use of healthcare resources to caregivers and better quality of life to the elderly or diseased, relieving excessive pressure on healthcare demand and costs.

Use of wireless technology in healthcare provides new means for close observation of the health condition of patients. Typically, observation of a patient takes place when he feels some sign of illness and reactively seeks healthcare. Alternatively, his health condition may be followed by a caregiver, requiring the patient either to visit a healthcare facility or to stay there in case of prolonged examination or intervention. This leads to time and location constraints for the patient and can only provide limited periods of observation of his health condition, which may mean that diagnosis of health complications or pathologies may be late or overlooked. Moreover, conventional health monitoring equipment uses wired connections to the patient, hindering the activity of monitored patients.

On the other hand, WHMS inherently provide mobility to the patients, allowing them to be monitored, virtually, anytime and anywhere within the range of the wireless network. Hence, WHMS gives patients the possibility to be monitored in a convenient location, typically at home, with reduced disturbance to their daily activities, helping them to adopt a healthier lifestyle and improving their quality of life and independence. In addition, WHMS also offer the possibility of continuous health monitoring. Following the current trend towards miniaturized and low-power-consumption electronics development, WHMS can be used for long periods of time (e.g., 24 h), providing approximately continuous evaluation of the health condition of a subject. Furthermore, continuous health monitoring is a very useful feature for enhancement of preventive care and quality of treatment. By monitoring a subject continuously, any slight changes in health condition in relation to the long-term circadian pattern can be detected at an early stage by the caregiver, allowing for better decision-making and anticipating the occurrence of severe health complications. Thus, continuous health monitoring offers better treatment possibilities for patients suffering from chronic diseases or enduring rehabilitation processes. Subjects without illness may also be continuously monitored to receive feedback on their activities and modify

their behavior to prevent illness by the promotion of a healthier lifestyle.

74.3.1 Requirements for Wireless Devices

Even though WHMS have the potential to provide great benefit in healthcare, they have not yet matured to a point of general use, as their application to real-life situations and acceptance by caregivers and patients is hindered by a considerable number of application and user requirement issues, including the following:

Ergonomics and Wearability

A WHMS needs to be as small and lightweight as possible so that the user feels comfortable when using it over long periods of time, and it should not affect the patient's daily activities. Ideally, the WHMS should go unnoticed by both the user and others, as the users of WHMS may become stigmatized if it is perceivable. An appropriate solution is integration of the WHMS into textile garments, resulting in wearable or smart-textiles monitoring systems [74.49, 51].

Low Power Consumption

WHMS, as a mobile application, are required to include their own power source, which is typically in the form of a battery, although energy harvesting solutions appear as a possible alternative in the future [74.52]. The power sources of these devices can only offer limited operation time, and therefore it is essential to reduce the power consumption to minimal levels, to ensure appropriate monitoring periods.

Quality of Service (QoS)

The wireless communication protocol implemented on the WHMS must include a proof mechanism to ensure that the biosignal data are reliably delivered to the base station, especially for continuous monitoring and if an emergency situation is detected.

User Friendliness

WHMS operation should be autonomous but perceivable by the user of the system, either the patient or healthcare personnel, and should require as little maintenance as possible, in order to achieve user acceptance.

Privacy and Security

The health condition of a patient must be regarded as private information, therefore data encryption methods and protection against unauthorized access should be implemented.

WHMS are expected to be a valuable tool to address the effects of population ageing on healthcare. They provide benefit to both patients and caregivers, enabling improved quality of life and independent living for patients and improved efficiency and better use of healthcare resources to caregivers. However, the design of such systems is a challenging task, and solutions able to reach wide acceptance by patients and caregivers are yet to be implemented.

74.3.2 Data Acquisition

Acquisition of biosignals from the human body requires similar instrumentation and methods as for any other signal which requires transducers. However, biosignals, namely those which are electrical, typically have small amplitudes and bandwidths and hence are very susceptible to interference or artifacts, which can easily be superimposed on the biosignal to be monitored. Moreover, part of the information contained in the biosignal may not be readily available from the raw signal, requiring further analog or digital processing for feature extraction [74.53]. Therefore, the design of acquisition electronics for biosignals must contain suitable instrumentation to ensure the integrity of the information contained in the biosignal, while any forms of interference or artifacts must be minimized, so that the acquired biosignal is useful for health condition monitoring or diagnostics, since a corrupted signal could provide misleading or meaningless information. Figure 74.5 shows a generic block diagram of instrumentation for biosignal acquisition.

Sensors, represented in the first block, are responsible for the conversion of clinically relevant physical quantities into an electrical output that can be processed by electronic instrumentation. Different sensor types are used according to the physical quantity associated with the biosignal. For electrical biosignals, it might be presumed that sensors would not be required since an electrical property, namely current flow on the human

body, is measured. However, transducers are indeed required for acquisition of electrical biosignals, since the current flow on the human body is due to ion transport whereas current flow in the acquisition instrumentation is due to electron movement. This conversion is provided by biopotential electrodes [74.53], which are placed on the surface of the human body, as close as possible to the organ that generates the biosignal, such as the heart (ECG) or brain (EEG). For nonelectrical biosignals, various types of sensors are used depending on the nature of the biosignal, such as mechanical (e.g., sphygmomanometer for blood pressure monitoring) or thermal (e.g., thermocouple for temperature measurement) devices, and the locations of sensor placement vary according to where the signal is strongest or the measurement most accurate.

Following the sensor stage, the signals obtained are usually weak in amplitude and may have considerable levels of added interference, as mentioned above. Thus, analog processing, featuring low-noise amplification and filtering, is required to increase the amplitude of the acquired signal, match the input range of the analog-to-digital converter, and limit its bandwidth to the range of interest of the monitored biosignal. Care must be taken when designing or choosing amplifiers for analog processing of biosignals. Desirable features for a biosignal amplifier include [74.45, 54] high input impedance (about $10\text{ M}\Omega$ to minimize the current drawn from the monitored signal and hence signal distortion), low output impedance (to provide as much power as possible to the load), high differential gain (10^3 or greater), high common mode rejection ratio (to minimize electromagnetic interference and electrical noise), and frequency response temperature stability. Filtering of the biosignal is usually required, since biosignals are susceptible to interference and artifacts. Filtering of biosignals can be performed in either analog or digital fashion. Analog filters are implemented using modified amplifier stages that attenuate unwanted frequency components from the acquired biosignal while provid-

Fig. 74.5 Typical block diagram of the necessary instrumentation for biosignal acquisition

ing gain to those which are relevant, thus contributing to removal of low- and high-frequency noise. If necessary, electromagnetic interference from power lines may be further attenuated using notch filters centered at 50 or 60 Hz. Besides, analog filtering is also used to limit the bandwidth of the monitored signal according to the sampling frequency of the analog-to-digital converter, thus avoiding aliasing. Although analog filters are essentially used to remove undesirable signal features, their design must ensure that the filter itself does not cause distortion of the relevant frequency components of the monitored signal. To minimize signal distortion, analog filters should be designed to provide a constant modulus and linear phase frequency response over the pass band [74.45, 53].

After the analog filtering stage, the monitored signal is converted to digital format using standard sampling and quantization methods such as sigma–delta or successive approximations [74.55]. In digital format, biosignals can be handled by digital processors, such as microcontrollers or microprocessors, and be further processed using digital filtering techniques. Digital filters offer advantages over analog filters, as they can be easily modified by changes in programming code, as opposed to changing components in analog designs, and they do not suffer from component tolerances or environmental influences such as temperature. Still, digital filtering and processing techniques require that the processor has enough available computational power, depending on the complexity of the algorithms to be executed by the processor. This may not be the case when the processor is already performing other tasks, such as control of acquisition or communications.

Lastly, the biosignal can be displayed to physicians and users, as occurs in common hospital instrumentation (e.g., intensive care monitors) or, in wireless health monitoring systems, sent wirelessly to a remote location either in real time or offline, to allow observation and monitoring.

As described above, signal acquisition appears to be a straightforward procedure. However, many problems can be encountered when performing data acquisition from biomedical devices for use in clinical applications. Many of these problems are due to the fact that the subject under observation is moving, particularly when considering wireless devices. This causes changes in the measurement conditions. These measurement conditions include the registering positioning of the transducer and changes in body impedance due to movement, chest movement due to arm movement, as well as breathing. For clinical applications, data

acquisition may often be conditioned by the requirement that the measurement device must be applied by a caregiver, and not by someone without medical training. Otherwise the signals have no clinical significance.

Signal acquisition may also be conditioned by requirements from the medical side and not from the signal side. In this way, it is a practice to show the acquired signal to a medical doctor and check if the signal is *good enough for diagnostics* and not look at the time and spectral content of the signal and decide all the details based on that. It is difficult to find specifications for the desired characteristics of signal acquisition. For many biosignals, it is therefore hard to specify the sampling frequency, number of bits for digitalization, resolution, signal latency, delay between signals, etc.

74.3.3 System Integration

When developing electronic devices to give mobility to patients, it may be attempted to achieve different degrees of mobility. A system may allow the patient to move inside a clinical facility. In this case, the device must be designed to be portable, so the patient can move around the facility. Alternatively, the system may allow the patient to be monitored at home. This is similar to the previous case, but with additional requirements. Such a system must have a set of alarms to inform the patient that something is not right (not only in terms of their medical condition, but also that something is wrong with the equipment itself or its use). Moreover, since the user may be required to place the equipment himself, it should be planned in such a way that the patient is able to place it without the need for caregiver assistance, otherwise the equipment will not be used or will be used improperly. Also, since the equipment may be required to stay at the patient's home for some time, desirably, it must be designed so that it can be cleaned at his home. Also, it must be more resistant to potential crash accidents. Another approach is to design the electronic device so that the patient can wear it as if it were just another piece of clothing.

Regarding wearable devices, a few different approaches may be adopted. One solution is based on discrete modules that are placed at different locations where signals need to be measured. However, for some applications, this may not be desirable; for example, to record an ECG, it is necessary to have physical connections between the different leads and the instrument's amplifier, and this solution implies the use of a few wires on the patient body. Moreover, with this solution,

it is difficult to clean and control correct placement of the different measuring devices. The other solution is to design the sensors to be integrated with clothes, with the electronics to be attached to those sensors at a conveniently location. This implies integration of wires with textiles and the development of interconnection technologies to interface wires and electronic devices on textiles. Another approach is to embed all the electronics, wires, and sensors on a polymeric foil, leading to a smart sheet of material with the ability to record the desired signals. Still using the integration approach, instead of electric methods, optical fibers with optical sensors may be integrated, thereby reducing the problem of integrating wires and electronics [74.56].

For wearable devices, the system should be developed taking into account that the user must be able to apply it himself. No help will be provided from any health professional. In this way, it must be developed in such a way that, after putting it on as any regular piece of clothing, the system should only require intuitive adjustments to achieve correct operation. Moreover, since it is something to wear, it must be able to undergo the same cleaning processes as regular clothing.

74.3.4 Wireless Communications

As in many other scenarios, wireless communication is a desirable solution for sensors used for data acquisition in biomedical applications. It is possible to distinguish three main situations: communication between devices inside the human body (intrabody), communication between devices on the body, and communications between devices on the body and the outside world (body to air).

A few aspects may be considered when implementing wireless communication for these different situations. For devices inside the human body, the available power of those devices is very limited, it is very difficult to recharge them from outside, and RF losses

are very high since the wireless medium is highly conductive. This implies that the link must be made at low frequencies (kHz to MHz). This is a problem because, at these frequencies, antennas tend to be very large or, if their size is reduced to fit inside the devices, antenna efficiency drops.

For devices on the body, one main characteristic is operation of the device very close to a highly conductive medium. This has implications for antenna design and signal propagation. Antennas must be designed so that the signal propagates close to the human body, otherwise power is wasted, and it may be required to operate in the antenna near field, as opposed to the standard operation in the far field. It is difficult to predict where devices must be placed to obtain an efficient wireless link.

In the latter two scenarios, a module with limited power may be used if easily rechargeable. The main challenge is to hide the antenna on the user environment while maintaining device operation. Solutions such as placing monopole antennas on the user's hat, which may work, are not desired since they are not fashionable. Many small modules are already sold with small antennas on them and seem to be very convenient for direct use. However, these antennas are designed to operate in free air, and when they are placed close to the human body, their operating frequency and bandwidth, as well their radiation diagram, will be modified.

When dealing with wireless communication, one main problem is to guarantee that data are delivered with sufficient quality of service (QoS) for the desired purpose. It is already possible to find many devices that transmit the measured data wirelessly, but it is very hard to find one that can be used for clinical applications. One problem is the lack of solutions to guarantee QoS for biomedical wireless links. Since data are to be used for clinical decisions, they must be obtained through solutions that guarantee that acquired data are correct and complete, otherwise patient health may be at risk.

74.4 Power Supply

All electronics and sensors require a power supply for operation. Electronic devices in medicine must have a very small form factor, including the power supply. In this regard, it is necessary to use batteries with very high charge density. However, despite all the solutions available, there is always a need to recharge the batteries.

Batteries for wireless wearable devices may operate for 1 day or for 1 week, but, as for cellular phones, recharging will always be required for system operation.

Several wireless AAL solutions for monitoring have been proposed in the past few years, e.g., [74.48, 49]. Most of them are based on standards for communica-

tions on wireless local-area and sensor networks, such as Wi-Fi (802.11), Bluetooth (802.15.1) and ZigBee (802.15.4), because of the availability of commercial modules that can be customized for any wireless application. However, a few solutions that make use of other unlicensed industrial, scientific, and medical (ISM) bands exist. Thorough reviews on wireless sensor networks and related standards can be found in [74.17, 57].

Since wireless monitoring is required, those systems must operate on battery power, or they must use an energy harvesting scheme [74.58]. Either way, system power consumption must be kept as low as possible. This leads to the design of systems where power consumption must be optimized. This is done by selecting the most power-efficient components available. If energy is consumed carelessly, the wireless acquisition system may rapidly become completely useless due to lack of available power. To prevent such failure, energy should be carefully saved using different approaches; for example, if the patient is in the normal state, then the sampling rate of sensors can be reduced to save power, or if the battery charge becomes low then its energy should be reserved for more vital tasks; i.e., the monitoring activity should adapt in accordance with the patient's clinical state to save energy. It should be realized that, to save further energy, communication protocols should be simple, and data should be aggregated, compressed, and transmitted in loaded packets, since computation demands much less energy than transmission. However, attention must be paid to the delay, which tends to increase linearly with packet length.

74.4.1 Battery Power Budget Considerations

Since the battery is the main power source for wireless devices, it should be selected to fit the requirements of the electronics which it will supply. The main requirement is its ability to power the electronic device for as long as possible, always considering a minimum period that is acceptable for operation. In many applications this minimum period should not be less than 1 day. After battery autonomy, and many times as important, come the issues of battery dimensions, format, and conformability.

However, other issues must also be taken into account when performing this selection. One is the recharging time, which must be appropriate for the application, since many devices use embedded batteries, which are difficult to replace. This time is usually ac-

ceptable if it is below 3 h, the time that the device may not be used. Also, due to battery lifetime, often it is convenient to use a battery with a protection circuit, which prevents the voltage from dropping below a safe value. In this way, the recharging is faster, at lower currents, and the device will have increased lifetime. Another parameter that is used for battery selection is its nominal current. However, its ability for peak currents also must be taken into account. Higher values of currents may be required, e.g., when a module has wireless communications. When the wireless link is in transmission mode, peak currents may be required. Finally, the operating temperature also interferes with battery lifetime.

Notwithstanding attempts to follow the previous guidelines, battery selection may be a hard task to accomplish, first because often it may not be easy to know beforehand the real power consumption of the device. Power consumption depends, e.g., on the data rate, operating mode (sleep, standby, transmitting, receiving), error rate, antenna efficiency due to antenna positioning, and power level of transmission [74.59]. This implies that tests have to be carried out under real scenarios, or that the battery has to be overspecified.

Another problem is that it is only possible to determine the power consumption accurately when the system is already assembled and ready for operation, where predicted values of system autonomy may diverge from those expected [74.59]. This may be due to several factors, including incomplete manufacturer specifications, only standalone power consumption being taken into account, and power consumption dependence on sampling rates, clock frequency, etc.

Figure 74.6 shows three modules (Wi-Fi, ZigBee, and proprietary) designed with off-the-shelf components that were used for power autonomy testing purposes. The measured current value for the Wi-Fi module, during transmission, exceeds that expected by about 60 mA. Also, in sleep mode, the measured current was 1.5 mA, far above the expected value of 6 μ A.

Fig. 74.6 Wireless modules used for autonomy testing: Wi-Fi (left), ZigBee (center), and proprietary (right)

The measured values of the ZigBee module were similar to the values specified in the datasheet. The ZigBee module presented higher consumption than the proprietary module but lower than the Wi-Fi module. The measured current consumption of the proprietary module was slightly higher than the value specified in the product information. The proprietary module had the lowest power consumption, and the measured power consumption was close to the predicted value.

From the power measurements, it is also evident that it may be worthless to design extremely low-power acquisition electronics, sometimes sacrificing acquisition performance, when the main power consumption may be due to the wireless subsystem that, even for the lower-power solution, is one order of magnitude higher.

Finally, it was verified that all the devices were able to work on a very small battery for periods of 1–3 days, which we believe is acceptable for AAL solutions. The Wi-Fi device, as expected, was more power hungry; however, it transmits at much higher power levels, and the data rate is also much higher. Since all microcontroller units have similar power consumption, it is expected that, if the RF power consumption is reduced, the overall Wi-Fi system consumption of this device may be significantly reduced.

74.4.2 Wireless Power

Most medical electronic devices requiring the use of batteries will need to be recharged. The most desirable solution would be one where the user does not need to pay too much attention to its use. The easiest approach is to use a wireless power link, and even more interesting would be that the device may be recharged without taking it out. This is desirable because it is uncomfortable to remove and replace the device, or because continuous monitoring is required. Another benefit of such solutions is power cable removal, allowing for easy fulfillment of requirements such as devices without connectors or that are completely sealed. Moreover, it allows the development of innovative solutions, such as recharging devices that are inside the body, or to recharge devices as we sleep. For short distances, two solutions may be used for wireless recharging: capacitive or inductive. It is also possible to use microwave links or optical links, or other forms of energy, but these options lie outside the scope of this chapter.

From basic transformer theory, we know that the voltage and current available at the receiver depend on the voltage and current at the transmitter. The inductive solution for wireless power transmission uses

two inductors: the primary and the secondary. On the transmission side, a power amplifier is used to drive the primary inductor. This power amplifier must be matched to the inductor in order for the available power to be transmitted to the inductor and the maximum power to be obtained in the secondary. The inductor acting as a receiver at the secondary side is connected to a power rectifier, after which comes a circuit to control the battery charge. To obtain maximum efficiency, the receiving inductor should also be matched to the load. However, as the battery charges, the current usually decreases and the load presented to the inductor also changes. This implies that, for continuous matching, the matching circuit should change during the charging period.

74.4.3 Wireless Power Link Analysis

To understand the losses expected from this antenna solution, a wireless link was implemented and analyzed. An external (transmitter) subsystem consisting of a Collpitts oscillator was used to generate an AC signal to feed the power amplifier. The implanted (receiver) subsystem has an AC–DC converter for power recharging purposes, and the data link path is preceded by a notch filter for power link rejection [74.60]. In this way, it is possible to power the receiver as well as to receive data transmitted wirelessly. The wireless link was implemented using two coils in parallel with the following dimensions: width, 2 cm; length, 4 cm; thickness, 0.254 mm; number of turns, 18; distance between each turn, 0.254 mm (Fig. 74.7).

As the matching network for the inductors, four capacitors were used, two in series (4.7 nF) and the other two in parallel (2.2 nF), in order to avoid losses due to power mismatch in the wireless link. The match-

Fig. 74.7 Setup based on the inductive link antenna

ing network was trimmed with the help of simulation to optimize the efficiency of the wireless link. The wireless link was designed to operate at a distance of 3 mm between the two inductive coils. To investigate the link performance, measurements, simulations, and analytical models were used. Measurements were made for the inductive wireless link and compared with simulation results. The link efficiency was computed and then compared with the efficiency obtained from analytical models for other antenna solutions. Return loss measurements were performed using a vector network analyzer, enabling efficiency measurements. On the other hand, all simulations were done using Ansoft Designer SV software.

First, the inductive wireless link was characterized without any matching network and compared with the results obtained from simulations. The results showed high losses, but were made with the purpose of providing a way to design the matching network as well as to validate the simulations performed previously. Using the measured results as an input for the simulator, it was possible to design the corresponding matching network and compute the capacitors required for matching. Figure 74.8 shows the result of that matching.

It can be observed that the value of S_{11} was below -10 dB, meaning that the power is being injected, and S_{21} was -3.90 dB, meaning that 65% of the energy is not being transmitted.

After designing the matching network, the wireless link was measured again. The measured S -parameters are shown in Fig. 74.9. The efficiency measured for the

inductive wireless link with real capacitors was not as high as that obtained theoretically, because of capacitor tolerances and quality factors. So, for 1 MHz, the value of S_{11} was -19.25 dB, which means that energy is entering port 1 (the transmitter), although the value of S_{21} is below the theoretical value (-5.02 dB), meaning that more energy is being lost (83.7%).

To test the effect that neural tissue may have on the performance of the system when used to recharge neuronal biodevices wirelessly, the validated model was used for testing the case when a slice of human tissue with thickness of 3 mm was placed between the two coils. Figure 74.10 shows the simulation results for such an inductive wireless link.

These results were not as good as the results shown in Fig. 74.8 for air, due to signal attenuation caused by the tissue. In this case, the dielectric properties were selected to match the neurological tissue behavior. The results of this analysis show that energy was being injected, because the value of S_{11} was simulated and tuned to be below -10 dB (-13.33 dB). On the other hand, as illustrated in Fig. 74.10, S_{21} was -4.51 dB, which means that 75% of the energy was being lost, which includes antenna and tissue losses.

74.4.4 Wireless Power Charger

Despite the losses expected when using wireless power transmission, there are situations where implementation of this option is required [74.61]. Figure 74.11 shows a prototype of a system developed to recharge

Fig. 74.8 Measured S -parameters and matching with ideal capacitors

Fig. 74.9 Measured S -parameters for the full wireless link

Fig. 74.10 Simulated S -parameters, with neurological tissue's properties

Fig. 74.11 Wireless charger device

Fig. 74.12 Wireless power (power mattress and power pillow)

three wireless modules used for AAL applications. With the developed wireless link, it is possible to recharge the three modules in about 2.5 h. The modules have autonomy of approximately 20 h for their planned application.

The solution presented in Fig. 74.11, despite being effective, requires removal of the wearable device for recharging. A desirable solution would have the ability to recharge such devices when the user is performing some activity, close to a location where it is possible to place the charger. One solution that may be adopted is the use of a charger format that may be transformed into a *power pillow* or a *power mattress* (Fig. 74.12).

Another solution is to place chargers on equipment at the gymnasium, or on a desk or desk chair.

The idea behind these concepts is to provide a solution to recharge the wearable devices without removing them. Using this concept, the power is transmitted to the system's battery while the user is lying in bed, either to sleep or when at the hospital for diagnostics or treatment. However, these kinds of solutions, beyond the technical problems that must be solved before their implementation, require also deeper knowledge of the effect that the recharging electromagnetic field may have on user health.

Despite the many benefits envisaged by this technology, it still has a long way to go before it can be widely deployed. This technology suffers from a few problems, which are hard to solve, with link efficiency being one of the most important [74.62, 63]. To achieve efficiencies on the order of 70–80%, very special conditions must be met. Regular links will not reach above 50%, even for short transmission distances. However, this solution may be very interesting for applications where the charging device and wireless module may be placed close together.

74.4.5 Energy Harvesting

Another option available to power wireless devices is the use of some form of energy harvesting. Any form is valid, since it is possible to use that energy to charge a supercapacitor or a battery. Many forms of energy conversion may be used to benefit from the available energy sources: thermal, electric, mechanical or chemical [74.58]. Despite the many proposed solutions, they still cannot provide sufficient power to drive complete medical electronic devices continuously. In fact, it is already possible to find devices operating on this kind of power sources. However, they tend to work in very

specific conditions and for very specific situations. The amount of power that can be obtained from these solutions is still below the requirements [74.58]. Moreover, they require very advanced electronic solutions. All the required electronics must be based on very low-power

designs, and wireless transmission must occur at very low-power levels.

However, and notwithstanding these limitations, this may be a potential solution as an extra power source to help increase battery lifetime.

74.5 Wearable Medical Electronics

Electronics in medicine may be used on fixed devices, portable devices or wearable devices. In this section, electronics in medicine will be addressed from the perspective of wearable devices.

Wearable technology represents a new, emerging field with increasing potential in several aspects of modern healthcare, with greater importance at the delivery point of care services. As a result, remote and ambulatory monitoring inside or outside of the healthcare environment, and support for disabled, rehabilitating or chronically ill patients, is now a reality. The growing demand for wearable devices is being driven by the considerable need for preventive instead of reactive medicine, the global increase of health awareness, and the need for proactive personal healthcare on a daily basis.

Figure 74.13 show examples of the most commonly monitored biosignals on the human body [74.44–46].

One aspect that may be highlighted is that many important biosignals are electric signals, therefore they can be measured with similar instrumentation. On the other hand, different technologies must be available to

monitor all the required signals, since they have different origins. Another aspect is that, to measure all the required signals, sensing devices must be placed in different body locations, which requires the development of specific solutions.

A wearable medical device can be described as an unobtrusive, autonomous, and ubiquitous system that supports continuous, multiparameter monitoring and treatment, and telemetric abilities [74.64, 65]. This contributes to a shift of health services from conventional hospital-centered towards individual-centered healthcare, which together with wireless technologies allows continuous feedback of relevant information to the user and/or clinical professionals. In addition, this approach improves early detection of and timely response to possible health threats [74.64, 66].

Since they are wearable, these devices are truly portable, being supported either directly on the human body or in a piece of clothing. This results in a new set of requirements, including minimal size, light weight, portability, unobtrusiveness, high levels of flexibility and integration, ease of use and comfortable wearing, increased lifecycle, and power autonomy. Such requirements can now be fulfilled, given the trends towards miniaturization of electrical and electronic equipment, as well as novel integration and sensing techniques. In particular, advances in sensing technologies allow monitoring and processing of two types of signals: vital signs such as cardiac activity, blood pressure, and temperature; and other important parameters that are more related to the patient's condition, such as body kinematics, sensorial and cognitive reactivity, and others [74.64, 65].

Due to the overall results of the advances in both the technology and healthcare sectors, it has become possible to establish a new healthcare paradigm: personalized health systems. These will enable decentralization of healthcare towards a system that will give the user a more proactive role in their care, providing better monitoring and feedback through a comfortable and unobtrusive solution. This not only contributes to im-

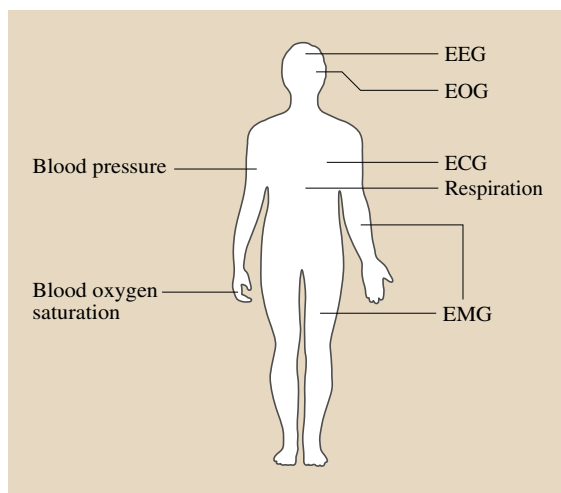

Fig. 74.13 Examples of noninvasively measurable biosignals on the surface of the human body

proved quality of life, but also allows for preventive care by effective diagnosis at the earliest signs of disease. Likely to be of benefit to the chronically ill and disabled, wearable health devices are an attractive solution for patients undergoing rehabilitation, providing them

Fig. 74.14 SensatexSmart Shirt (Sensatex, Inc., Bethesda, MD)

Fig. 74.15 Lifeshirt from Vivometrics (Vivometrics, Ventura, CA)

Fig. 74.16 BodyMedia arm band (BodyMedia, Pittsburgh, PA)

with independent living, since they enable recording and collection of relevant data in the different situations of individual daily life [74.65,67].

A number of wearable devices in the healthcare sector have emerged in the past few years, ranging from simple monitoring of daily routine, to miniaturization and integration of sensors to enhance the overall performance of wearable systems. The Georgia Institute of Technology (Atlanta) jointly with the US Navy proposed one of the first wearable solutions, consisting of a wearable vest embedded with optical fibers and sensors, working also as a data bus – the Georgia Tech Wearable Motherboard (GTWM) [74.68]. All the components are integrated into the fabric, creating a flexible device, which was manufactured essentially for use under combat conditions. The GTWM has the ability to identify the exact location of injuries or physical problems, helping to determine which of them needs immediate attention. This device was placed on the market by Sensatex, Inc., as a product named the Sensatex Smart Shirt (Fig. 74.14).

Companies such as Vivometrics and Bodymedia have also entered the market with wearable monitoring systems. The Lifeshirt (Fig. 74.15) is a product by Vivometrics and consists of a wearable physiological monitor in the form of a chest and shoulder strap, providing noninvasive ambulatory monitoring of pulmonary cardiac function and posture [74.69].

Bodymedia introduced a wearable and wireless body monitor that continuously collects physiological and lifestyle data such as heart rate, heart flux, body and ambient temperature, and galvanic skin response, among others. The Bodymedia Fit consists of an arm-band (Fig. 74.16), a wirelessly connected display, and an activity manager [74.70].

Many research groups have started to develop wearable technologies with main applications in health science. In the work entitled *AMON: A Wearable Medical Computer for High Risk Patients*, a wearable medical monitoring computer is presented [74.71]. The AMON system was developed under a European-sponsored consortium and consists of a wrist-worn unit with monitoring, data analysis, and communication capabilities. This system is mainly intended for high-risk patients in need of constant monitoring. The paper by *Paradiso and De Rossi* describes a project funded by the European Commission jointly with Philips and other partners, both industrial and academic [74.72]. This project, called *MyHeart*, consists of the development of functional clothes with on-body sensors and electronics to acquire, process, and evaluate physiological

data. *Choi and Jiang* have developed a wearable sensor device in the form of a belt-type sensor head, which is composed of conductive fabric and polyvinylidene fluoride (PVDF) film, for monitoring cardiorespiratory signals during sleep [74.73]. *Pandian* and coworkers [74.74] have presented a wearable vest – the Smart vest – with integrated sensors for monitoring of ECG, photoplethysmogram (PPG), body temperature, blood pressure, galvanic skin response (GSR), and heart rate. In a more recent work, *Kanellos* and his coworkers developed a flexible optical-fiber-based pressure sensor comprising fiber-embedded Bragg grating elements [74.75].

The aim of this section is to introduce the enabling technologies behind the design of wearable devices in healthcare, as well as the basic requirements for their design.

74.5.1 Wearable Systems

The ongoing miniaturization of computing hardware and electronics as well as new smart materials and integration techniques have led to the development of noninvasive sensors and actuators for monitoring physiological and kinesiological parameters. These systems can include various types of small physiological sensors, transmission modules, and processing capabilities, facilitating low-cost wearable unobtrusive solutions for continuous all-day, any-place health, mental, and activity status monitoring.

A wearable system can be described as a smart/functional material with embedded sensors, processing and communication units, which may or may not contain attachable peripherals or other appliances. One can refer to this type of system as wearable electronics.

To design a wearable system, three areas of work need to be properly covered. First, it is important to develop unobtrusive wearable sensors to record physiological and kinesiological data reliably. Secondly, these sensors need to be implemented into a substrate material that allows multisensor integration. Finally, it is important to provide the system with acquisition and communication infrastructures, to enhance mobility of individuals, and some degree of intelligence to improve system performance at a clinical level [74.64, 65].

Figure 74.17 depicts an architectural layer for an ideal wearable health system, which is composed of a functional/smart substrate, embedded electronics, and attachable peripherals/appliances.

Wearable system components may be divided into three main categories: clothing, embedded electronics,

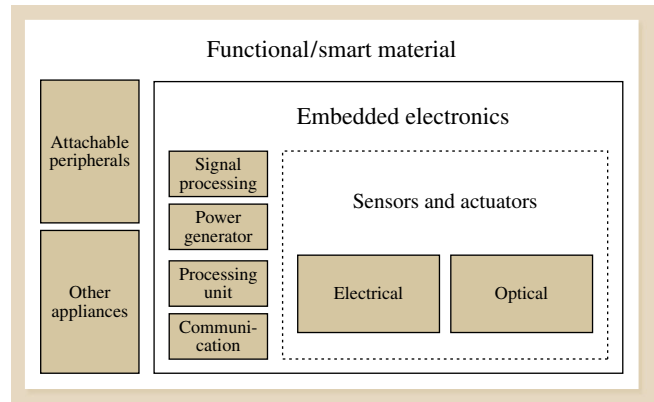

Fig. 74.17 Architectural layer of an ideal wearable health system

and attachable components. The first includes all the substrate materials that act as a functional or smart structure by allowing embedding of sensors, signal processing units, communication infrastructures, actuating mechanism, and power generation, among others. The most common substrate materials used in these systems are textiles or flexible polymeric materials that will enable the design of garments with multifunctional nature [74.76]. The embedded components include all the necessary electronics, optics, or other devices that will provide sensing, actuating, signal processing, communication infrastructures, power generation, and other necessary functions. If necessary and desirable, attachable peripherals and other appliances can be included into the wearable system. Examples of these types of components are personal digital assistants (PDAs), displays, keyboard, and control knobs, among others.

Focusing on the sensing technologies, new approaches are required, especially to provide noncontact methodologies to improve embedding of these components as well as to contribute to the design of totally wearable and highly comfortable functional garments. Sensors are used to monitor all the necessary physiological parameters and the physical environment surrounding the user, allowing the user's health condition to be monitored. They can either be embedded in the material, or the material itself works as a sensing element. These components will be further discussed below.

74.5.2 Categories of Wearable Systems

Wearable systems can be classified according to the level of integration of the components into the smart/functional material, i. e., the substrate. There are

three types of wearable systems according to this classification: first generation, based on attached hardware components and sensors; second generation, where these components are embedded; and third generation, where innovative integration techniques during the substrate material production allow for the design of multisensory clothing and/or accessories.

The first category refers to all devices based on plug-in/out methodologies, where a supporting mechanism for attaching the necessary components is provided. These can include ECG monitoring wristwatches, and sensing components that can be attached to a t-shirt, a vest or even a cap. The problem associated with these types of wearable devices is their lack of comfort, and they are not yet a practical solution from the user perspective. In addition, since they are based on attached components that usually are not completely hidden, these systems generally do not allow for a completely unnoticeable solution.

The drawbacks of the first generation of wearable systems led to the creation of a new generation based on partially integrated/embedded architectures, where all the necessary components are fixed to the substrate material. This not only eliminates the need for qualified personnel or for the user to place the components, running the risk of misplacement, but also allows for a more practical and discrete solution. However, there is still a considerable difference from a normal garment or accessories, meaning that the components do not have a sufficient level of integration into the substrate, providing relatively comfortable solutions but still remaining perceptible.

Research and progress in integration techniques during the fabrication process allowed for the design of a third generation of wearable health devices. This type of system represents the cutting edge of wearable technology, allowing the design of smart, functional, and multisensing materials, which are apparently normal, due to this high level of integration. A very popular example of a third-generation wearable system is the electronic textile e-Textile, which consists of high-knowledge-content garments made from multifunctional fabrics. By blending the components into the user's ordinary clothing, it is possible to achieve an ideal wearable system, minimizing the hassle of wearing the device.

Despite the existence of these three generations of wearable devices, with their drawbacks and advantages, they all provide enhancement of user quality of life, allowing for real-time multiparameter monitoring under various conditions.

74.5.3 Design Requirements

The design of wearable systems requires an additional set of requirements, especially when compared with stationary equipment. If the final goal is to provide a customized multisensing wearable system that can be worn during daily life as normally as before, it is imperative that the wearable system cover the following set of key points [74.64,65]:

Interaction

The device should be able to interact with the environment through a network of sensors placed in different parts of the clothing or accessories, allowing the creation of a certain awareness of the physiological and emotional state of the user, as well as of the surrounding environment. This is extremely important when designing smart and functional devices that are required to monitor, control, manipulate, interact, and actuate on a real-time basis. Data handling, decision support, and feedback are also crucial to establish a good interaction between the device, the components, and the user himself.

Autonomy, Safety, and Reliability

This aspect deals with the power and operational requirements which have to be met, without which autonomous, safe, and reliable operation of the device would be impossible.

Easy User Interface

It is important to maintain an easy interface between the user and the wearable device, minimizing the user's cognitive effort and involvement in the process.

Integration

It is crucial to improve integration of the components into the substrate in order to enable normal clothing and accessories with multifunctional capabilities. In addition, it is also important to interfere as little as possible with the user's physical activity, which is achieved by full integration of components into the substrate material.

Along with these key points come the user and design requirements for wearable systems. From the user's perspective, the most important features are minimal size and light weight, unobtrusive interface, user-friendliness, comfortable wear, ergonomics, portability, and increased lifecycle. When considering other perspectives in terms of design and performance, in addition to taking into account the user's requirements,

there are a few key requirements to consider. Power autonomy, housing conditions, wireless communication, continuous time monitoring, and high levels of flexibility and integration are the main requirements from the design and performance perspectives.

By fulfilling the above requirements it is possible to design a wearable system that allows the user to benefit from its multifunctional and multisensing capabilities, without compromising the user's daily life activities.

74.5.4 Sensors for Wearable Systems

In wearable devices, a wide range of sensors are used to measure physiological and environmental conditions. The first type of sensors – biosensors – are used to monitor a clinical condition or process, therefore measuring biopotentials and other physiological parameters. On the other hand, the second type of sensors – peripheral sensors – are responsible for sensing the surrounding environmental conditions, enhancing the awareness of the system.

Not every sensor can be used in a wearable context, especially from the user's perspective. Not only do their physical attributes, such as size and weight, have to be taken into account, but also their noninvasive character and ease of placement must be considered. In addition, these sensors must ideally produce an electrical output in order to be digitally processed, being durable and reliable and with low power consumption [74.64, 67].

Usually, sensors used in wearable devices are based on conventional sensing elements, such as piezoelectric materials, electrodes, and others, with integrated communication infrastructure (e.g., wireless communication). This eliminates the problems associated with cable management and allows sensors to be positioned

at various locations without any complications. In an ideal system, sensors should not require any contact with the user, since they could benefit from integration into clothing, which from the user's perspective contributes to the design of more practical, comfortable, and easy-to-use devices.

74.5.5 Sensing Methodologies

A number of technologies can be applied as sensing methodologies, such as electrical, mechanical, optical, piezoelectric, among others (Table 74.2) [74.12, 77, 78]. However, it is important to consider the demands associated with sensor integration into textiles or other flexible materials.

Sensors are composed of materials that respond to a physical stimulus, such as a change in temperature, pressure, electric field or illumination. They can range from skin surface electrodes to conductive yarns, providing comfortable and practical solutions for the user. Several materials can be used as the sensing component, and they can be divided into different categories, each with a specific effect.

The general acquisition system of a typical sensor used in wearable devices is composed of several functional blocks, from signal acquisition to output of the final result. Figure 74.18 shows a generic acquisition block diagram for a wearable sensor.

The transducer converts the desired signal or variable into another form of energy, which is then amplified and filtered to remove undesired signal components. The obtained analog signal is converted to digital form by an ADC and further processed using many different algorithms. If necessary, the processed signals can be converted back to analog form to drive

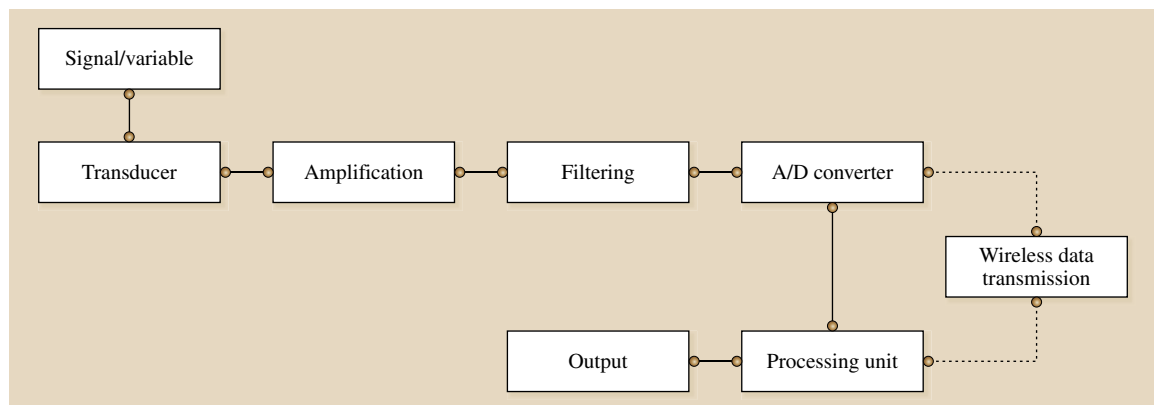

Fig. 74.18 Signal acquisition block diagram of a generic wearable sensor

Table 74.2 Different transducer effects applied in the sensing mechanism of wearable devices

Transducer effect	Sensing devices	Stimulus	Response	Examples of materials	Examples of detected signals
Electrochemical	Bioelectrodes, electrochemical cells	Biochemical activity	Electrical current	Copper, aluminum, Ag/AgCl, stainless steel, conductive yarns, electroactive polymers (EAPs)	EEG, ECG, EMG, EOG, skin electrode impedance
Electrooptic	Electrooptic modulators	Electric field	Birefringence	Lithium niobate (LiNbO ₃), lithium tantalite (LiTaO ₃), deuterated potassium dihydrogen phosphate (KD ₂ PO ₄), electrooptic polymers	EEG, ECG, EMG, EOG
Electrostriction	Electrostrictor transducers Example: pressure sensor	Direct effect (nonlinear) Mechanical stress Reverse effect (nonlinear) Electric field	Electric polarization Dimensional change	Lead magnesium niobate, lead lanthanum zirconate titanate (PLZT), EAPs	Carotid pulse, heart apex pulse, ECG, movement
Electroluminescence	Light emission devices	Electric field	Light emission	EAPs	ECG, EMG
Photoluminescence	Photoluminescence sensors Example: UV radiation sensor	Incident light	Light emission	EAPs	UV radiation
Piezoelectricity	Piezoelectric transducers Example: strain gages	Direct effect (linear) Mechanical stress Reverse effect (linear) Electric field	Electric polarization Dimensional change	Polyvinylidene fluoride (PVDF), barium titanate (BaTiO ₃), lithium niobate (LiNbO ₃), lead zirconate titanate (PZT)-based compounds, EAPs	Carotid pulse, heart apex pulse, ECG [Samjin Choi]
Pyroelectricity	Pyroelectric sensors Example: infrared sensors	Temperature change	Electric polarization	All pyroelectrics are piezoelectrics	Body temperature, ambient temperature

specific devices. For better design, it is often necessary to include wireless communication systems that enable

the sensing component to transmit the data to a control processing unit or even to a database service.

74.6 Electronics in Medicine at Work

After introducing several aspects of medical electronics and several signals that may be recorded by such

systems, this section presents a few implementations of electronic systems designed for medical applications.

74.6.1 Wireless and Wearable Low-Power Health Monitoring Systems

A prototype wearable, low-power acquisition module for a WHMS is shown in Fig. 74.19. The acquisition module provides continuous monitoring of single-lead ECG, temperature, and activity [74.79]. The module is used on the chest of the monitored subject and can be attached using either a chest band or by integration into a textile garment. In addition, the wearability of the acquisition module is supported by its small size and lightweight design, and by the assembly of all of its electronic components on a flexible polyimide printed circuit board (PCB), which in turn houses dry and flexible electrodes [74.80], directly attached to the PCB without use of wired connections. Unlike conventional silver/silver chloride electrodes, these dry and flexible electrodes are able to acquire a biosignal without the need for skin preparation with electrolyte gel, which is suitable for use in long-term and continuous health monitoring systems.

74.6.2 Sensors

The sensors contained in the acquisition module were chosen considering its continuous monitoring and low-power operation features. The acquisition mod-

ule includes three flexible, dry ECG electrodes with a low-power analog front-end for single-lead ECG monitoring, a negative-temperature-coefficient (NTC) thermistor for surface temperature monitoring, and a low-power three-axis accelerometer for activity monitoring.

The analog front-end designed for ECG monitoring is shown in Fig. 74.20. A pair of the flexible dry electrodes at a short distance from each other (65 mm) is used to acquire a single-lead ECG, when contacting the skin on the chest, close to the heart. The remaining electrode is used as a reference driver connection to reduce common mode interference.

The performance of the analog front-end was designed to achieve a trade-off between low power consumption and suitable common mode rejection ratio (CMRR) by appropriate choice of the instrumentation amplifier (current consumption of 93 μA and CMRR of 115 dB). A notch filter was included in the front-end to attenuate electromagnetic interference from surrounding power sources, since the acquisition module should be able to monitor the subject even in electromagnetically polluted environments. Furthermore, a bandpass filter is used to limit the bandwidth of the acquired signal to the ECG frequency range and to attenuate the DC offset. The complete analog front-end achieved current consumption of about 220 μA .

Fig. 74.19 (a) Wearable low-power acquisition module for a WHMS, showing electronics on the top layer and (b) flexible dry electrodes for ECG monitoring on the bottom layer

Fig. 74.20 Low-power ECG analog front-end included in the WHMS prototype

The activity of the monitored subject is estimated by the LIS302DL digital accelerometer which has a configurable range of ± 2 g or ± 8 g, featuring low current consumption (300 μ A). The local temperature at the acquisition module can be estimated within the range of 20 and 40 °C, by the change in resistance in the NTC thermistor.

74.6.3 Wireless Link

The wireless communication interface between the acquisition module and a base station [e.g., personal computer (PC) or PDA] is provided by the Toumaz Sensium (Toumaz Technology Ltd., Abingdon [74.81]). The Sensium is a system-on-chip solution containing a low-power transceiver platform, 8051 microcontroller, and reconfigurable sensor interface. The Sensium allows the creation of wireless body-area networks composed of a base station and up to eight target nodes which communicate using a proprietary protocol aimed at minimization of power consumption. The wireless link between Sensium devices operates in the 868/915 MHz ISM band, providing a 50 kbps data rate.

For the design of the presented acquisition module, the use of the Toumaz Sensium solution with a proprietary wireless communication protocol was preferred over the use of standard protocols for wireless sensor networks or wireless local-area networks, such as Bluetooth (802.15.1), ZigBee (802.15.4) or Wi-Fi (802.11). The use of the proprietary protocol has the advantage of low power consumption, achieving longer operation times suitable for continuous monitoring, and avoiding the crowded 2.4 GHz ISM band, thus aiming to achieve better resilience to interference and improved quality of service. On the other hand, use of the proprietary protocol and transceiver reduced transmission power and data rate to achieve low power performance, thus only allowing transmission distances of 10 m and a data rate of 50 kbps. However, this transmission distance may be suitable for monitoring a subject at home or in specific rooms, or if the subject carries a smartphone or PDA as a base station. In addition, the 50 kbps data rate is sufficient for continuous monitoring of most biosignals, considering their limited bandwidth.

74.6.4 Optical Biopotential Recording

In the past few years, optical-based sensors have become increasingly used in healthcare applications. This is explained by the many advantages of these sensors that include immunity to electromagnetic interference,

resistance to harsh environments, freedom from electrical wires, small size, light weight, and multiplexing capabilities [74.82]. Moreover, many approaches for optical fiber integration have been developed, with particular interest for wearable health devices, leading to easier optical fiber integration into textiles and other wearable materials [74.56, 83, 84].

74.6.5 Optical Electrodes

When dealing with optical electrodes, several modifications must be made to the acquisition system shown in Fig. 74.18. A light source and detector must be included, since the sensing methodology is based on alteration of light properties. Figure 74.21 shows a typical acquisition system for an optical sensor.

In this case, the acquisition system must include a light source that will pass through an optical transducer. In the presence of a particular signal, the optical transducer will suffer alterations, for example, a dimensional change. This alteration will produce a shift in light properties, whether intensity, phase, polarization or other. Afterwards, a photodetector is responsible for collecting this modulated light and converting this modification into a desired result. The latter is dependent on the type of photodetector applied in this stage; for example, a photodiode can be used to convert light intensity into current or voltage. The signal is then processed according to the remaining block diagrams, which are similar to those in Fig. 74.18.

An important feature of optical-based sensors is the ability to enable easier contactless measurements of physiological events, particularly electrophysiological signals. This can be achieved using specific transducer effects by which a material exhibits a particular response in the presence of a stimulus such as an external electric field. Materials exhibiting this type of stimulus–response mechanism are classified as electroactive materials; some such materials are included in Table 74.2. The electroactive component works as the sensing element, which can be in the form of a coating material, such as a hydrogel or a piezoelectric material, or even used as a device such as an electrooptic modulator.

For several years, the standard biopotential recording systems consisted of bioelectrodes, instrumentation amplifiers, and filtering components. The signal was recorded by placing electrodes in contact with the skin, allowing conversion of the ionic current within the body into an electronic current in the electrode leads [74.54]. The coupling between the electrode and the skin was

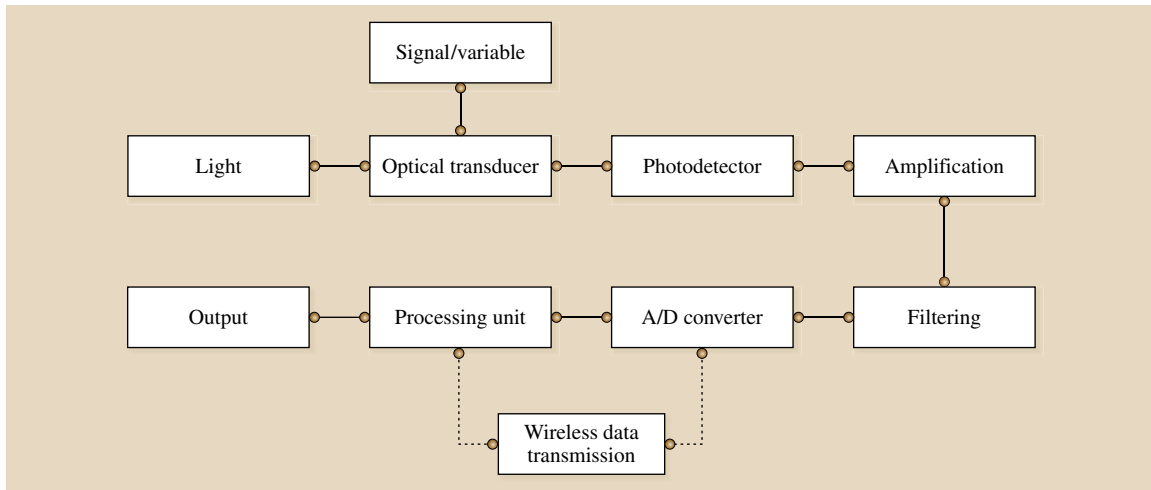

Fig. 74.21 Optical sensor acquisition block diagram

usually made by an electrolyte that could be either a gel/solution for wet electrodes or simply sweat for dry electrodes. This standard recording system, despite its good performance in terms of sensitivity, is not very suitable for wearable applications, since it requires good electrical and/or physical contact with the skin [74.85].

Novel dry and textile-based wearable electrodes have recently been proposed to overcome the limitations associated with such electrodes. These include, for example, conductive rubber electrodes [74.86], Cu-sputtered textile electrodes [74.87], conductive fabric sheets and polyvinyl difluoride (PVDF) film electrodes [74.73], and polymeric dry electrodes [74.88]. However, these still require physical contact with the skin, making optical sensors the strongest candidate for contactless measurements in wearable devices.

In recent work, an electroactive hydrogel was suggested as a transducer for optical-based biopotential measurements for applications in wearable systems [74.89]. This electroactive material, polyacrylamide hydrogel (PAAM), when submitted to an external electric field, undergoes a bending process, altering its mass and volume properties. Likewise, the amount of light passing through the hydrogel and reaching the photodetection stage will change. Although many configurations can be applied in the sensor design, the desirable solution could be a fiber pigtail, with the PAAM hydrogel placed at the tip of the fiber. This material showed an adequate sensitivity and frequency response, as well as the ability to perform better as sample thickness decreases, making it an eligible sensing component for biopotential recording applications.

74.6.6 Optical Signal Acquisition

An example of an optical-based sensor for biopotential acquisition is the electrooptic modulator, which can be used to modulate light (e.g., intensity, polarization or phase) in response to an electric field. The observed modification of the light property is proportional to the biopotential, making it possible to translate this result into a biopotential recording. The electrooptic (EO) sensor proposed is a photonic fiber optic based device, whose main functional stages are optical signal generation, electrooptic modulation, and detection. These EO sensors may be developed and assembled so as to be easily integrated into fabrics or other wearable materials. Figure 74.22 shows an ECG signal obtained using this method as the recording technique.

As shown in this figure, this EO technique has the required frequency response and sensitivity to acquire an ECG signal with its different signal components, such as the QRS complex.

74.6.7 Localization Solutions

One well-known requirement in AAL solutions is the ability to track someone inside an environment using the already deployed wireless infrastructure. Several wireless AAL solutions for monitoring have been proposed in the past few years, e.g., [74.48, 49]. One solution is to use the Wi-Fi infrastructure and deploy small modules, worn by the subject being monitored. Then, using the Wi-Fi network infrastructure, the module

Fig. 74.22 ECG signal recorded with an electrooptic modulator

can be used for tracking purposes [74.48, 49]. Despite the well-known benefits of this technology, its acceptance requires wearable devices, which must be small, lightweight, and with enough power autonomy for comfortable operation [74.61].

Figure 74.23 shows a system that enables localization of a walking user inside a building, using a device that was developed to be used as a wristwatch [74.61]. This is the smallest localization device known for use in localization applications, based on a Wi-Fi infrastructure. This module was designed to fulfill clinical environment compliance, which requires a hermetically sealed module made from clinically compatible materials. Since it is to be worn as a wristwatch, wearability and fashionable design were taken into account. Moreover, for ease of use and cleaning, the module uses wireless recharging technology.

Since the localization device had to be designed to be worn on the subject's wrist, the module should not greatly exceed the dimensions of a wristwatch. Also, and to reduce deployment costs, the localization technology is based on the installed Wi-Fi network, so the localization device must use a Wi-Fi module. The designed module uses an off-the-shelf low-power Wi-Fi tag. The tag communicates with existing wireless lo-

cal area network (WLAN) infrastructure to help control centers to keep track of the subjects being monitored. A key feature of this device is its waterproof capability and the requirement for simple cleaning methods. In this way, a wireless recharging capability was implemented, which enables full recharging of the battery when the module is placed on a base station for around 2 h. Moreover, as onboard sensors, it has a motion detector and a photonic wrist removal detector.

Localization Ability

Figure 74.24 shows the software front-end used in combination with the developed module.

Initial tests showed a resolution of 2–5 m (90% of the time) for an indoor environment. Those tests showed that the tag meets the project requirements. The performance obtained makes the tag viable for all the expected project scenarios, namely in hospitals and healthcare markets.

Module Autonomy

Since the module was expected to be as small as possible, the platforms under test were powered by a 150 mAh, 3.7 V, $20 \times 30 \times 4.0 \text{ mm}^3$ Li-ion battery. However, the indicated supply battery may change, due to different autonomy constraints.

All the tests were carried out using a small resistor in series with the battery, and the voltage drop was measured. From that, the current consumption was extracted. Table 74.3 shows the results obtained when using this procedure.

At the moment, this device is used only for localization purposes. In normal operating mode, the device sleeps for 20 s, then awakes, detects its position, and sends it to a nearby wireless access point.

From Table 74.3, it can be observed that, during transmission, the measured current value exceeds the expected value by about 60 mA. Also, in sleep mode, the current measured was 1.5 mA, far more than the ex-

Fig. 74.23 Magtag, side-by-side with a wristwatch

Fig. 74.24a,b Tracking operation. (a) Testbed access point location. (b) Tag positions used for localization error assessment

Table 74.3 Wi-Fi module power consumption

Operating mode	Current consumption	
	Measured ($V_{cc} = 3.3\text{ V}$)	Expected
Tx mode	270 mA @ 18 dBm	212 mA @ 18 dBm
Rx mode	50 mA	40 mA
Sleep mode	1.5 mA	6 μA

pected value of 6 μA . To test battery autonomy, a 6 s transmission interval was used, for which the battery life was 20 h. All these tests were carried out with all the active sensors turned off.

74.6.8 Ambient Assisted Living Applications

Ambient assisted living (AAL) (Chap. 67) is an emergent technology that envisions offering new solutions for healthcare [74.31]. Those solutions will improve the quality of life of the elderly population and reduce costs associated with healthcare. However, before that happens, new solutions, including both hardware and software, must be available in order to acquire and store the required signals, to process and extract information from those signals, and to detect a set of features required to produce alarms and/or electronic assistance.

Despite the availability of several platforms for signal acquisition [74.49], a few technological issues must be solved before they can be used. The platforms must offer quality of service, be wearable, and operate for a comfortable period of time. Quality of service is re-

quired, otherwise no company will be able to offer such a highly critical service. When hiring a service for health monitoring, it must not fail, or the people involved must be aware of how safe the system is. Also, nobody will be willing to wear a device that reveals that he is being monitored, and it is also unpleasant to wear a device that needs to be recharged too often. At least, it must be able to operate for one full day. In this way, the system may be replaced when the person goes to bed or gets up.

Once the relevant data are available, an AAL system will allow remote monitoring of one, or a set of subjects, and their health and activity. Based on this and a set of information associated with each subject, it is possible to offer different levels of services. One will be self-reminders that are preset by the subject; the other will be reminders by some family member or caregiver; and finally, a health service based on clinical data may also be offered, if good enough health engines are available to extract the health condition.

Intelligence at Application Level

Figure 74.25 shows a snapshot of an application developed to collect data from several sensors, both biometric data (monitoring health and activity) and data from home automation [74.43]. Based on home automation, it is possible to infer the daily activity of a subject and help him in their routines.

This interface includes three main blocks. One block acts as a pill dispenser with the possibility to send text messages through the short message ser-

Fig. 74.25 Patient monitoring software snapshot

vice (SMS) and/or multimedia message service (MMS) with previously recorded familiar voices to provide advice regarding prescriptions. The second block provides a day (timeline) progress bar with emergency status (colors from green to red) linked to the continuous health monitoring system. The third block is a sensor panel showing data from several sensors for ECG, temperature, humidity, water flux, weight, door opening/closing, and arterial pressure with voice messages corresponding to high or very low arterial pressure readings.

Acquisition Hardware

The software operates based on the data acquired from the various sensors. Figure 74.26 shows the main blocks of the acquisition hardware. It is presented as worn by a person, but it is equally valid for data acquisition from home automation.

Since a few of those sensors must be mobile and must be placed on the person, the acquisition system

must be designed to have special features. It must be wireless, offer quality of service, have low power consumption, be wearable, and operate for at least 1 day on batteries. This led to the use of a modified version of a ZigBee-based platform.

For data acquisition, a small and power-efficient module was designed. Moreover, since the set of signals that may be relevant for this system are highly heterogeneous, the module was designed so that it can be configured for different applications. The most demanding signal in this scenario is the electrocardiogram, corresponding to measurement of the electrical activity of the heart muscle, which may range from about 0.5 mV to a maximum of 10 mV. It has a spectral range of 0.05–150 Hz for diagnostic ECG and 0.5–40 Hz for monitoring ECG.

The requirements of the front-end of an ECG sensor circuit include the capability to sense low-amplitude signals in the range of 0.05–10 mV, high common mode rejection ratio (CMRR), high input impedance,

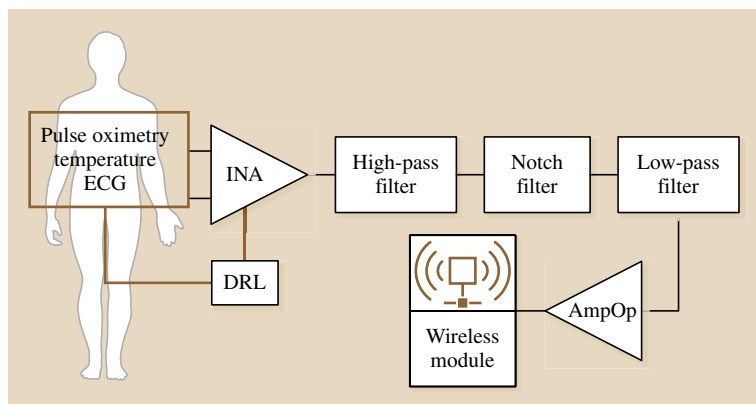

Fig. 74.26 Block diagram used for the data acquisition system (DRL – driven right leg; INA – instrumentation amplifier)

low input leakage current, flat response for 0.5–40 Hz, low weight, low power (<1 mA), and signal amplification over a range specified by the analog-to-digital converter (ADC).

The first stage of amplification is one of the most important components of the system. This amplifier presents excellent features for acquisition of biopotentials such as high input impedance, high differential gain, and high common mode rejection ratio. The integrated circuit (IC) used was the INA333 from Texas Instruments. The ECG is often contaminated with undesired spectral components. To attenuate these, the circuit must include a high-pass filter, notch filter, and a low-pass filter. All the implemented filters are active filters, so operational amplifiers were used. The ICs chosen to build the filters were the OPA2369 from Texas Instruments. The OPA2369 was chosen mainly because of its low quiescent current (0.7 $\mu\text{A}/\text{channel}$), and low offset voltage (250 μV). The high-pass filter must attenuate frequencies from zero to the cutoff frequency, thus it blocks the undesired DC components. The proposed filter is a second-order Sallen–Key high-pass filter with a Butterworth response. The filter's main features are its quality factor (Q) of 0.707, its unity gain, its cutoff frequency f_c of 0.45 Hz, and its slope of $-40\text{ dB}/\text{decade}$. The ECG is frequently contaminated with 50/60 Hz power-line interference, or electrostatic charge. The strategy to attenuate this kind of interference involved a notch filter or band stop filter centered at 50 Hz. The implemented notch filter is a second-order Sallen–Key with gain of 1.5, Q of 1, f_c of 50 Hz, and slope of $-40\text{ dB}/\text{decade}$. The low-pass filter is used to attenuate frequencies beyond the desired frequency for ECG measurement. These frequencies can come from sources such as radiofrequency and communication equipment. A second-order low-pass Sallen–Key filter with Butterworth response was implemented. The filter has unit gain, Q of 0.707, and cutoff frequency of 40 Hz. The filtered signals have to be amplified so that the ADC from the ZigBit module can measure it. The gain of this amplification stage is about 60, so the

Fig. 74.27 Frequency response of the front-end electronic acquisition system

total gain of the system is 300. Finally, a driven right leg (DRL) circuit was also implemented. This circuit is used to amplify, invert, and feedback the common mode signal to the body, preventing saturation of the amplifiers, and reducing the output voltage due to CMRR. Figure 74.27 shows the frequency response for the described system.

Despite the low-power design, the system was designed to achieve high rejection of the 50 Hz component. This allows for a higher degree of system miniaturization, since when registering ECG signals with very close electrodes, interference may become a problem.

Since this is intended to be a flexible platform to acquire data and feed an AAL system, it was designed to be small and modular. Figure 74.28 shows the device dimensions.

The main achievement was the low current consumption for ECG acquisition (90 μA) and the small size (33 \times 30 mm²). This module, combined with a transceiver module, allows acquisition of almost every signal produced by any transducers that may be found useful for use in AAL systems.

The developed platform was designed to acquire signals from a range of sensors, and to transmit them

Fig. 74.28 Photograph of developed PCB layout

to a base station where the signals were registered and processed to monitor a subject during their daily life. The module is very low power, allowing operation for 1 day, and the wireless data were delivered with quality of service, making it suitable for AAL applications in controlled environments.

74.6.9 Wireless Link Design for Biomedical Applications

When a patient's clinical state turns from a noncritical situation into a critical one, a context change occurs, and consequently, the healthcare network should adapt its performance requirements to this new situation [74.90]; for instance, higher monitoring activity and lower transmission delay of vital signals might be required when the clinical situation of a patient changes from noncritical to critical. Hence, healthcare networks should provide QoS facilities for e-emergency services, since these clearly demand high reliability, guaranteed bandwidth, and short delays.

A personal healthcare system consists of a group of sensors attached noninvasively to a patient for sensing of physiological parameters. These body sensor networks (BSN) have been used in hospitals during recent decades using conventional wired equipment, hence not allowing the patient to move around freely. However, recent advances in wireless sensor technology are changing this scenario by allowing mobile and permanent monitoring of patients, even during their normal daily activities. In such healthcare systems, the information sensed at the patient's body is transmitted to a wireless base station, located no more than a few tens of meters away, and then delivered to a remote diagnosis center through a communication infrastructure.

Healthcare systems should be able to accomplish at least one crucial aim: to monitor a patient and, when an emergency occurs, immediately trigger an event to alert the patient and/or warn a remote caregiver. In this way, both the patient and the caregiver can ensure timely implementation of the appropriate procedure in accordance with the clinical episode. In addition, the system should be able to trigger an alert anticipating the case where the patient is unaware of the seriousness of his/her health situation.

Wireless sensor networks (WSN) are expected to be used in emergency healthcare applications in the near future. Since e-emergency systems should be totally reliable and efficient in order to provide valuable assistance to patients, quality of service (QoS) must be

present at distinct protocol levels, including the media access control (MAC) layer.

Vital Signals Requirements

Emergency medical care requires monitoring of several vital signals simultaneously; for example, a patient in an ambulance is monitored for blood pressure, heart and respiration rates, and temperature. Besides these primary signals, other information may be captured to help diagnosis and medical decision, such as electrocardiogram (ECG), blood glucose level, blood oxygen saturation, heart and breathing sounds, or even imaging in cases of trauma. All these data should be promptly accessible for comparison, computer-aided analysis, and decision-making. However, to achieve a more encompassing picture of the clinical situation, information about the patient's personal characteristics (risk factors, degree of disease, age, etc.) and environmental context (e.g., in bed or mobile, alone or not, at work or at home, etc.) should also be provided [74.91].

Table 74.4 presents the electrical characteristics of the vital signals usually monitored in emergency medical care [74.92, 93] and Table 74.5 shows the range of typically monitored values.

If some signal exceeds its threshold, the local supervisor node should trigger an alarm to inform a caregiver or the patient himself. Table 74.5 presents typical

Table 74.4 Vital signal electrical characteristics

Vital signal	Frequency range (Hz)	Sampling rate (Hz)	Resolution (bits)
ECG (per lead)	0.01...60–125	120–250	16
Temperature	0...0.1–1	0.2–2	12
Oximetry	0...30	60	12
Arterial pressure	0...60	120	12
Respiration rate	0.1...10	20	12
Cardiac rate	0.4...5	10	12

Table 74.5 Alert detection parameters

Alert type	Detection parameter
Low SpO_2	$SpO_2 < 90\%$
Bradycardia	$HR < 40$ bpm
Tachycardia	$HR > 150$ bpm
HR change	$\Delta HR / 5 \text{ min} > 19\%$
HR stability	Max HR variability from past 4 reads $> 10\%$
BP change	Systolic or diastolic change $> \pm 11\%$

thresholds for SpO_2 , heart rate, and blood pressure signals for alert detection [74.94].

QoS Considerations for e-Health

Some authors argue that differentiation based on data priority is inherent to wireless sensor networks (WSN), since it is normal to have sensors to monitor distinct physical parameters simultaneously, just as happens in BSNs. Here, the importance of the collected information is necessarily distinct, and therefore the network must prioritize the transmission of critical data when a sudden clinical change in the patient occurs; for example, in patients with cardiac diseases, heart activity information is more important than body temperature data. Depending on the patient's clinical condition, the priority assigned to a vital signal can change dynamically.

Most current BSNs only offer best-effort service [74.95], which is not the most adequate for e-emergency. The given examples indicate that those networks require QoS support in critical cases. This would ensure adequate bandwidth for higher-priority streams for efficient data delivery, even in case of interference or fading.

QoS mechanisms are usually deployed in networks to guarantee consistent service levels concerning certain parameters, such as packet loss ratio, transmission delay, jitter, and available bandwidth. These are the traditional end-to-end parameters used to characterize the performance of any communication infrastructure, including BSNs; for instance, the total delay to an ECG signal being displayed in the monitor should be less than 3 s for useful real-time analysis by a cardiologist [74.95]. To guarantee that jitter does not affect the estimation of the R-wave fiducial point, which considerably modifies the spectrum, ECG signals require a minimum sampling rate of 250 Hz. It should be noted that no significant difference between ECG traces are detected when sampling the signal at rates between 250 and 500 Hz, but significant reduction in peak amplitude values and inaccurate interval measurements are obtained at 125 samples/s [74.96].

Approaches over than prioritization may additionally be used to provide QoS; for example, for efficiency reasons, a large packet length is chosen for noncritical situations. However, as soon as an emergency occurs, the packet size is reduced to meet the low-delay QoS requirement, and signals considered irrelevant to this emergency episode are sampled at a lesser rate, or not at all. Moreover, the computation power may be lowered to a minimum, since all data must be forwarded, as opposed to regular operation where, to save energy,

the cardiorespiratory rhythm can be computed onboard before sending it. Alternatively, an ECG signal could be processed in the sensor itself to extract its relevant features. In this way, only information about an event is transmitted (e.g., QRS features and the corresponding timestamp of the R-peak), hence reducing the traffic load and saving energy.

The vital signals captured from the patient's body must be delivered to a remote diagnosis and supporting center, through some available communication infrastructure, such as the Internet or a mobile cellular network. As a result, the delivered QoS depends necessarily on the network infrastructure chosen for the delivery of the mobile health services. Therefore, to meet the required QoS, the mobile health services platform needs to be able to acquire and use contextual information about the QoS offered by communication network infrastructures available at the patient's current location and time. High availability and reliability are the most desirable features that these network infrastructures should offer, as well as QoS guarantees for bandwidth, end-to-end delay, jitter, and loss.

e-Health Wireless Systems with QoS

Despite the number of healthcare systems already developed, few encompass QoS requirements. To assess how QoS support is being deployed in healthcare sensor networks, some projects were analyzed, as well as the QoS requirements that the respective authors considered important to incorporate in their implementations. Based on the related literature, QoS projects for e-health can be grouped according to the topics: (a) frameworks with QoS, (b) QoS through reconfiguration, and (c) algorithms for QoS enhancement [74.90].

The target deployment of each project is diverse, such as remote patient monitoring using standard protocols and mobile communication networks, mobile telemedicine under heavy traffic conditions, signal reconstruction, and BSN lifetime improvement. Thus, the QoS support approach is also distinct in each project: transmission priority scheduling along with data compression, self-reconfiguration of the BSN by data feedback, restoration algorithms to recover missing packets, and power management model for energy saving. Table 74.6 presents an overview of diverse QoS aspects that the authors have considered important to benefit their projects with, as well as the target environments where the projects are intended to be deployed. The target deployment of each project is diverse, such as remote patient monitoring using standard protocols and mobile communication networks,

Table 74.6 Examples of QoS solutions for healthcare systems

Topic	Description	QoS goals	Target deployment
Frameworks with QoS	DiffServ based on transmission priority scheduling, data compression	Low delay and loss rate for vital signals, better bandwidth utilization	Remote medical applications using zigbee and mobile cellular networks
	Wireless diffserv infrastructure	Low loss rate, guaranteed bandwidth	Reliable network for mobile telemedicine under extreme traffic conditions
QoS through reconfiguration	Send feedback information into BSN to self-reconfiguration	Application level improvement	Remote and local patient monitoring
	Middleware system for reconfiguring bsns	Application level improvement	Increase BSN lifetime while respecting the qos needs
Algorithms for QoS enhancement	Restoration algorithms	Recover missing packets	Reconstruct a more functional signal for the doctor
	Power management model based on application states	Energy saving	Reserve power to the patient's more vital tasks

**Fig. 74.29** Layout of the hospital room, with a patient being monitored in each bed

mobile telemedicine under heavy traffic conditions, signal reconstruction, and BSN lifetime improvement. Thus, the QoS support approach is also distinct in each project: transmission priority scheduling along with data compression, self-reconfiguration of the BSN by data feedback, restoration algorithms to recover missing packets, and power management model for energy saving.

Case Study

Aware of the diverse QoS approaches presented above, Fig. 74.29 shows an experimental testbed to deploy QoS solutions based on a real clinical scenario [74.97]. The scenario is based on a hospital room containing six beds with one patient per bed. Each patient is monitored by a personal BSN, and one BS collects the vital signals of all patients. The vital signals being monitored are temperature (T, Temp), oximetry (OXI), arterial pressure (ART), respiration rate (RR), and ECG data. All monitored signals must be transmitted through a low-rate

channel to the BS with appropriated QoS, as specified next.

According to the IEEE 1073 group, a wireless ECG electrode should generate 4 kbps of data, and the latency introduced by framing the data samples and the transmission delay should be below 500 ms. Since ECG signals are the most demanding in terms of QoS, we take this value as the maximum delay that any vital signal should have in this study. Continuous healthcare monitoring normally uses a three-electrode ECG device, therefore this situation is assumed in our study. According to Table 74.1, each BSN produces a maximum aggregated rate of 10 424 kbps, hence resulting in a maximum total traffic inside the hospital room of 62 544 kbps. Besides guaranteeing this minimum goodput and latency below 500 ms, the e-health system must also guarantee null packet loss for every vital signal, low energy consumption, and balanced energy drainage in every BSN.

ZigBee is a short-range, low-power, low-data-rate standard for wireless sensor networks that supports

a maximum data rate of 250 kbps in the 2.4 GHz band. Therefore, a ZigBee WSN is able to handle the whole traffic generated inside the hospital room without congestion. Nevertheless, other factors which may significantly affect QoS have to be considered, such as access to the wireless channel and errors which often occur during transmission.

Simulation results have shown that ZigBee is not adequate for several sensors to transmit ECG signals to a BS with full efficiency. The packet delivery efficiency starts to drop when three or more ECG devices belong to the same network channel. This is because ZigBee relies on carrier sense multiple access with collision avoidance (CSMA-CA), a contention-based MAC protocol that is vulnerable to collisions. Lost packets may be retransmitted, but there is a maximum number of five retries allowed by ZigBee before declaring channel access failure. ZigBee seems to be more adequate for BSNs that do not have large amounts of data to transfer with only several small data packets per hour, such as implanted medical sensors.

Diverse MAC protocols have been developed for wireless networks using contention-based or scheduled access techniques [74.98]. Traditional contention-based protocols assume that traffic is distributed stochastically. However, traffic in a WSN tends to be highly correlated and/or dominantly periodic, and so such protocols may not perform well in these conditions. Some CSMA-based protocols have been developed (e.g., Sensor-MAC (S-MAC) [74.98]) to help save energy in sensor network applications where nodes remain idle for long periods until detecting an event (e.g., surveillance), hence normally generating very little traffic in the network. Hence, it is inadequate to apply such MAC protocols in networks requiring high throughput and low latency, such as emergency biomedical applications. Time-division multiple access (TDMA) protocols divide time into slots that sensors can use to transmit data without needing to contend for the medium. Since quality of service is easier to assure in a collision-free environment than in a contentious-prone medium, and as a base station is available to keep the WSN scheduled and synchronized, a solution may be to use a TDMA-based MAC protocol to satisfy the QoS, such as the low-power, real-time protocol (LPRT) [74.99].

LPRT is a simple, beacon-based, low-power, real-time protocol that uses the available bandwidth dynamically and efficiently. Its highly grained superframe starts with the transmission of a beacon frame (B) by the BS, followed by the contention access period (CAP), also called the contention period (CP) [74.99]. The CAP

may be used for the (dis)association or configuration of a body sensor network (BSN). The contention-free period (CFP) follows the CAP. The CFP is composed of the normal transmission period (NTP) and the retransmission period (RP). The NTP is used for sensor nodes to transmit new data. Lost data are retransmitted in the RP. Data packets are sent in contiguous slots of the CFP. The attribution of slots in the CFP is announced through a list of allocation fields carried in the payload of each beacon. Each allocation field contains the association identification and the initial transmission slot (ITS) for every sensor node in the WSN. Data frames transmitted to the BS during the NTP are acknowledged by the ACK bitmap present in the beacon of the next superframe.

The beacon size may become relatively large, since it is directly dependent on the number of sensor nodes associated with the BS. A sensor node transmits data in the superframe only if the corresponding beacon carrying the list of allocation fields is received, and a single retransmission procedure is used in case of transmission failure. These characteristics may lead to a significant packet loss ratio if communications occur in a wireless channel with an appreciable bit error ratio (BER). To improve its robustness against bit errors, a solution based on short-size beacons has been proposed.

Proposals to Improve LPRT

To define a MAC protocol more robust to channel errors, solutions based on short-size beacons, autonomous transmissions, and multiple retransmissions have been added to LPRT. RP is defined after the CAP so that a packet is retransmitted away from an eventual burst error condition responsible for the transmission failure that occurred during the last NTP. RP is not placed after the NTP to avoid a sensor node transmitting in the NTP with a variable packet size.

Short-Size Beacons. To assure good performance of the e-emergency WSN, the percentage of lost beacons should be very low. A strategy to accomplish this goal is to send beacons with a convenient transmission power, since the bit error ratio (BER) of the channel decreases as the signal-to-noise ratio (SNR) increases. In addition, the beacon frame length should be as small as possible. So, whenever possible, the beacon payload contains only the ACK bitmap to acknowledge the frames correctly received during the NTP of the last superframe, and the CAP size of the current superframe (assuming that the start slot of the CAP is known). In this case, sensor nodes must run an algorithm to compute which slots

should be used to (re)transmit data without interfering with each other, in accordance with a predefined order schema. Using this strategy, the energy consumption in each BSN improves too, since smaller-size beacons are received by the sensor nodes.

According to the received ACK bitmap, each sensor node must calculate the corresponding superframe slots to transmit its data. If a sensor node does not receive a beacon or a short sequence of beacons, it may continue to send its new data in the NTP (i. e., autonomous transmissions), since a sensor node clock drift of the order of microseconds should permit the WSN to continue to be synchronized during a few consecutive beacon intervals. However, the sensor node cannot retransmit any data in the RP, because the ACK bitmap is not available and so it does not know how the RP slots are being allocated to the sensor nodes.

To save energy, it might be tempting to retransmit the lost data aggregated to the new data sent in the NTP, instead of retransmitting it in the RP. However such a strategy should be avoided, because the number of slots allocated in the NTP to each sensor node becomes variable. Consequently, if a sensor node does not receive the beacon, it has no way to know a priori which slots to use for transmission. Indeed, if a sensor node does not receive the ACK bitmap, it does not know which sensor nodes are going to transmit aggregated data in the current superframe, making it impossible to compute the new slot allocation schema. This situation does not occur if the NTP is used only to transmit new data packets. Hence, aggregated retransmissions in the NTP are not recommended, except in cases where aggregation does not imply taking more slots, such as for packets carrying temperature data.

Besides the ACK bitmap and the CAP size, a beacon may need to send reconfiguration instructions if a new clinical situation is detected in some BSN; for instance, higher monitoring activity and lower transmission delay of the vital signals might be required when a patient's clinical situation changes from noncritical to critical. In this case, the BS should inform all sensor nodes about the new situation and eventually reconfigure the WSN.

Retransmission in the RP. The retransmission order in the RP depends on the ACK bitmap received from the BS. Using an increasing slot sequence, firstly data of all sensor nodes having the highest priority and the bit false in the ACK bitmap are retransmitted successively. Then, data of all sensor nodes having the second highest priority and the bit false in the ACK bitmap are retransmitted successively, and so on. If there are

not enough slots to permit all required retransmissions, then schedule truncation is done to guarantee that no retransmission occurs in the NTP. It should be noted that retransmissions may not be the appropriate error recovery mechanism if losses are due to fading.

Retransmission in the CAP. If a sensor node does not receive the beacon, then it fails to receive the ACK bitmap, and therefore it does not know if the BS correctly received the packet sent in the NTP of the last superframe. Retransmitting that packet properly in the RP is impossible, because such a sensor node cannot compute the slot allocation schema of the RP. A solution to overcome this problem is to retransmit it during the CAP using the slotted CSMA-CA. This procedure should improve the packet loss ratio at the expense of some energy consumption and CAP slot wastage, since the sensor node may be transmitting a duplicated packet. Indeed, a packet already received by the BS may be retransmitted again in the CAP of the next superframe if the sensor node does not receive the beacon.

Simulation Testbed

To test the solutions proposed in the previous section and to compare them with LPRT, the Castalia simulator was used. For this purpose, a case study and distinct MAC protocol operation modes were programmed in Castalia. For each test run, a simulation time of 1 h was defined. Extending the simulation time would not significantly affect the results. During that time period, the BS sends around 16 363 beacons, carrying in the payload only the ACK bitmap (4B). It is assumed that the BER is equal in both communication directions.

In some graphics the probability P of a fully loaded packet being received at destination is used instead of the BER. The two parameters are related by

$$\text{BER} = 1 - P^{1/(8 \times \text{MPS})}, \quad (74.1)$$

where MPS is the maximum physical frame size. Considering $\text{MPS} = 133 \text{ B}$, the BER changes between 0 and around 6.5×10^{-4} as P decreases from 1 to 0.5 through the simulation runs. Typical values for BER in a good real wireless channel are of the order of 10^{-5} and in a bad channel may be less than 10^{-3} .

Operation Modes

Five distinct operation modes were defined for the simulation framework: 0, 1, 2, 3, and 4 [74.100]. In operation mode 0 there are no retransmissions in case of lost frames. This operation mode serves basically to define the limiting lines in the plots by considering the worst

case, corresponding to no error control mechanism in the system.

In operation mode 1 lost packets are retransmitted once at RP, and these retransmitted packets are not acknowledged. This operation mode implements basically the LPRT protocol.

In operation mode 2, packets with payload size above a certain threshold may be retransmitted during RP at most twice. The threshold was set at 40 bytes, so ECG and ART sensors have two chances to retransmit lost data. The second retransmission occurs only if the frame is not correctly received by the BS during the first retransmission. For this reason, the first retransmission must be acknowledged, although the second retransmission does not need to be. Packets with payload size below the defined threshold may be retransmitted once in the RP and are not acknowledged.

In operation mode 3, packets with payload size above a certain threshold may be retransmitted at most thrice in RP.

Finally, operation mode 4 is similar to operation mode 2, but if a sensor does not receive a beacon, it tries to send in the CAP the packet transmitted in the NTP of the last superframe. In all operation modes, frames transmitted in the NTP are acknowledged through the ACK table sent in the payload of the next beacon. No operation mode allows aggregated transmissions in the NTP or RP.

Compared with mode 1, the improvement achieved when the WSN operates in modes 2, 3, and 4 is clear from Fig. 74.30 and Fig. 74.31. These operation modes present ECG packet loss below 1% while the probability P is a little above 0.8. Such improvement is due to the multiple retransmission process occurring in the superframe. When the WSN operates in mode 3 instead of mode 4, the improvement in ECG traffic is significant for $P < 0.75$. However, for ART traffic it is almost irrelevant whether mode 3 or 4 is used. This is because the probability of losing an ART packet is lower than the probability of losing an ECG packet, as the packet size is smaller in the former.

Since the oximetry, respiration rate, and temperature sensors may only retransmit once in RP, no significant difference is noted in such traffic when operating in modes 1, 2 or 3 (Fig. 74.32). However, an improvement is noticed in oximetry and respiration rate traffic when operating in mode 4. Temperature traffic does not exhibit such improvement because it cannot make use of the CAP.

To better evaluate the cost of the various operating modes in terms of consumed energy, we firstly con-

Fig. 74.30 Loss rate for ECG and temperature traffic

Fig. 74.31 Loss rate for ART traffic

sider that samplings performed by the sensing devices consume no power. Figure 74.33 presents for each operation mode the average lifetime per initial energy of the battery for each sensor type, relative to the simulations run with probability $P = 0.75$.

To determine how many minutes a type of sensor would live under such conditions, the values on the y-axis must be multiplied by the energy available in the battery when the sensor starts working. The available

Fig. 74.32 Loss rate for OXI, and RR traffic

energy E in a battery with n cells, having U (volts) and capacity of C (mAh) for each cell, is $E = nUC \times 3.6J$; for instance, the 3V, 40mAh rechargeable Li polymer battery used by an ECG sensor node contains 432J of initial energy before starting to power a sensor. So, according to Fig. 74.33, an ECG sensor operated in mode 4 and powered by that battery would live for $3.68 \times 432 \text{ min} \approx 26.5 \text{ h}$. For every sensor type, the energy consumption is not significantly increased if the probability $P > 0.75$ and the operation mode is 1, 2, 3 or 4.

Next, it was considered that each sampling performed by the sensing devices consumes 0.01 mJ of energy. Figure 74.34 presents the results for this situation. The effect of sampling rate on the lifetimes of the sensors is clear.

As ECG sensors have both the highest sampling rate and the largest transmitted packet size, the energy drainage is faster than for the other sensor types. The differences observed in each sensor type for the various operating modes are almost indistinguishable.

Conclusions

Since wireless e-emergency networks should be reliable and efficient, they need to support QoS at distinct protocol levels, including the MAC layer. The deployment of LPRT in an e-health system leads to low power consumption, controlled latency, and throughput efficiency. However, as simulations have proved, this approach lacks reliability if the wireless channel

Fig. 74.33 Lifetime for sensing consumption of 0 mJ

Fig. 74.34 Lifetime for sensing consumption of 0.01 mJ

presents a given bit error rate. To define a MAC protocol that is more robust to bit error conditions than LPRT, some solutions based on short-size beacons and multiple retransmissions were tested. The results showed that such strategies lead to meaningful improvements in packet loss rate, without significantly increasing energy consumption.

Despite presenting the best performance regarding the loss rate parameter, we foresee that a network operating in mode 3 may face scalability problems, since considerable bandwidth wastage occurs in the RP. Since operation mode 4 offers better scalability and a good compromise in terms of packet loss rate, we believe that an e-health network operating in this mode and using short-size beacons may present interesting performance.

Appendix

Table A.1 Electromagnetic spectrum

Table A.2 Frequency- and signal voltage range of different bioelectrical signals (after J. Eichmeier: *Medizinische Elektronik*, 3rd edn. (Springer, Berlin, Heidelberg 1997) p. 26)

Bioelectrical signal	Abbreviation	Frequency range (Hz)	Signal voltage range U (mV)
Lead, intracellular	L_{ic}	$0-10^4$	50–130
Action potential	AP or E	5×10^4	–
Electroencephalography	EEG	1–100	0.005–0.1
Electrodermography	EDG	0–1	0.1–5
Electrogastrography	EGG	0.02–0.2	0.2–1
Electrohysterography	EHG	0–200	0.1–8
Electrocardiography	ECG	0.2–200	0.1–3
Electrocorticography	ECoG	$10-10^4$	0.015–0.3
Electromyography	EMG		
surface electrode		$10-10^3$	0.1–5
depth electrode		$10-10^4$	0.05–5
Electroretinography	ERG	0.1–100	0.02–0.3

Energy bioelectrical signals: $3 \times 10^{-12} - 7 \times 10^{-15}$ W s

Radionuclides (Selection) and Dosimetric Base Items

Table A.3 Radionuclides (selection) (after W. Kauffmann, E. Moser, R. Sauer: *Radiologie*, 2nd edn. (Urban Fischer, München 2001) p. 14)

Radionuclide	Half-life ($T_{1/2}$)	Radiator	β energy (MeV)	γ energy (MeV)	Application
^3H	12.26 a	β	0.018		D, M

Table A.4 Dosimetric base items (after G.H. Hartmann: *Konzepte in Strahlenphysik und Dosimetrie*. In: *Medizinische Physik*, Vol. 2, ed. by W. Schlegel, J. Bille (Springer, Berlin, Heidelberg 2002) p. 73)

Base item	Derivation	SI-unit	Stochastic
Energy imparted	$R_{\text{in}} - R_{\text{out}} + \sum Q$	J	•
Linear energy	ϵ_1/l	J m^{-1}	•
Specific energy	ϵ/m	$\text{J kg}^{-1} = \text{Gy}$	•
Absorbed dose	dW/dm	$\text{J kg}^{-1} = \text{Gy}$	
Absorbed dose rate	dD/dt	$\text{J kg}^{-1} \text{ s}^{-1} = \text{Gy s}^{-1}$	
Kerma	dE_{tr}/dm	$\text{J kg}^{-1} = \text{Gy}$	
Kerma rate	dK/dt	$\text{J kg}^{-1} \text{ s}^{-1} = \text{Gy s}^{-1}$	
Specific ionization	dQ/dm	$\text{C kg}^{-1} = \text{R}$	
Ion dose rate	dJ/dt	A kg^{-1}	
Exposure	dQ/dm	C kg^{-1}	
Dose equivalent	$q \cdot D$	$\text{J kg}^{-1} = \text{Sv}$	
Equivalent dose rate	dH/dt	Sv s^{-1}	

International System of Units – SI, CGS and Prefixes

Table A.5 International systems of units (SI)

Quantity	Name	Symbol	Expression in terms of other SI units or SI base units
SI base units			
Length	Meter	m	
Mass	Kilogram	kg	
Time	Second	s	
Electric current	Ampere	A	
Thermodynamic temperature	Kelvin	K	
Amount of substance	Mole	mol	
Luminous intensity	Candela	cd	
SI derived units			
Area	Square meter	m ²	
Volume	Cubic meter	m ³	
Speed, velocity	Meter per second	m/s	
Acceleration	Meter per second squared	m/s ²	
Wave number	Reciprocal meter	m ⁻¹	
Mass density	Kilogram per cubic meter	kg/m ³	
Specific volume	Cubic meter per kilogram	m ³ /kg	
Current density	Ampere per square meter	A/m ²	
Magnetic field strength	Ampere per meter	A/m	
Amount-of-substance concentration	Mole per cubic meter	mol/m ³	
Luminance	Candela per square meter	cd/m ²	
Mass fraction	Kilogram per kilogram, which may be represented by the number 1	kg/kg = 1	
Plane angle	Radian	rad	m/m = 1
Solid angle	Steradian	sr	m ² /m ² = 1
Frequency	Hertz	Hz	1/s
Force	Newton	N	m kg/s ²
Pressure stress	Pascal	Pa	N/m ² = m ⁻¹ kg s ⁻²
Energy work, quantity of heat	Joule	J	N m = m ² kg s ⁻²
Power radiant flux	Watt	W	J s = m ² kg s ⁻³
Electric charge, quantity of electricity	Coulomb	C	A s
Electric potential difference, electromotive force	Volt	V	W/A = m ² kg s ⁻³ A ⁻¹
Capacitance	Farad	F	C/V = m ⁻² kg ⁻¹ s ⁴ A ²
Electric resistance	Ohm	Ω	V/A = m ⁻² kg s ⁻³ A ⁻²
Electric conductance	Siemens	S	A/V = m ⁻² kg ⁻¹ s ³ A ²
Magnetic flux	Weber	Wb	V s = m ² kg s ⁻² A ⁻¹
Magnetic flux density	Tesla	T	Wb/m ² = kg s ⁻² A ⁻¹
Inductance	Henry	H	Wb/A = m ² kg s ⁻² A ⁻²
Celsius temperature	Degree Celsius	°C	K
Luminous flux	Lumen	lm	cd sr = m ² m ⁻² cd = cd
Illuminance	Lux	lx	lm/m ² = m ² m ⁻⁴ cd = m ⁻² cd
Activity (of a radionuclide)	Becquerel	Bq	s ⁻¹

Table A.5 (continued)

Quantity	Name	Symbol	Expression in terms of other SI units or SI base units
Absorbed dose, specific energy (imparted), kerma	Gray	Gy	$\text{J/kg} = \text{m}^2/\text{s}^2$
Dose equivalent	Sievert	Sv	$\text{J/kg} = \text{m}^2/\text{s}^2$
Dynamic viscosity	Pascal second	Pa s	
Moment of force	Newton meter	N m	
Surface tension	Newton per meter	N/m	kg/s^2
Angular velocity	Radian per second	rad/s	
Angular acceleration	Radian per second squared	rad/s^2	
Heat flux density, irradiance	Watt per square meter	W/m^2	kg/s^3
Heat capacity, entropy	Joule per Kelvin	J/K	$\text{m}^2 \text{kg}/\text{s}^2 \text{K}$
Specific heat capacity, specific entropy	Joule per kilogram Kelvin	$\text{J}/(\text{kg K})$	$\text{m}^2/\text{s}^2 \text{K}$
Specific energy	Joule per kilogram	J/kg	m^2/s^2
Thermal conductivity	Watt per meter Kelvin	$\text{W}/(\text{m K})$	$\text{m kg}/\text{s}^3 \text{K}$
Energy density	Joule per cubic meter	J/m^3	kg/m^2
Electric field strength	Volt per meter	V/m	$\text{m kg}/\text{s}^3 \text{A}$
Electric charge density	Coulomb per cubic meter	C/m^3	$\text{A s}/\text{m}^3$
Electric flux density	Coulomb per square meter	C/m^2	$\text{A s}/\text{m}^2$
Permittivity	Farad per meter	F/m	$\text{s}^4 \text{A}^2/\text{m}^3 \text{kg}$
Permeability	Henry per meter	H/m	$\text{m kg}/\text{s}^2 \text{A}^2$
Molar entropy, molar heat capacity	Joule per mole Kelvin	$\text{J}/(\text{mol K})$	$\text{m}^2 \text{kg}/\text{s}^2 \text{K mol}$
Exposure (x- and γ -rays)	Coulomb per kilogram	C/kg	$\text{A s}/\text{kg}$
Absorbed dose rate	Gray per second	Gy/s	m^2/s^3
Radiant intensity	Watt per steradian	W/sr	
Radiance	Watt per square meter steradian	$\text{W}/(\text{m}^2 \text{sr})$	

Table A.6 Centimetre-gram-second system (CGS units)

Quantity	CGS unit abbreviation	Equivalent in SI units
Length	cm	10^{-2} m
Time	s	
Mass	g	10^{-3} kg
Velocity	cm/s	10^{-2} m/s
Force	dyn	10^{-5} N
Energy	erg	10^{-7} J
Power	erg/s	10^{-7} W
Pressure	Ba	10^{-1} Pa
Viscosity	P	10^{-1} Pa s
Wavenumber	cm^{-1}	100 m^{-1}
Stokes	cm^2/s	$10^{-4} \text{ m}^2/\text{s}$
Magnetic field	G	10^{-4} T
Magnetic field strength or intensity	Oe	$1000/(4\pi) \text{ A/m}$
Luminance	cd/cm^2	$10^4 \text{ cd}/\text{m}^2$

Table A.7 SI prefixes

Acknowledgements

C.16 Computed Tomography

by *Thorsten M. Buzug*

The author would like to acknowledge the great support from Philips, Siemens, and General Electric with photographs of their products. Special thanks go to Annette Halstrick and Dr. Hans-Dieter Nagel, Philips Medical Systems, Hamburg as well as Leon de Vries, Philips Medical Systems, Best. Furthermore, I have to thank Doris Pischitz and Jürgen Greim, Siemens Medical Solutions, Forchheim as well as Dieter Keidel, General Electric, Solingen. I also have to acknowledge the help of Tobias Knopp for copyediting the text of this chapter.

C.18 Medical Infrared Imaging

by *Gerald C. Holst, Thorsten M. Buzug*

T.M.B. would like to thank Arcangelo Merla, Functional Infrared Imaging Laboratory, University G. d'Annunzio, Italy, for supporting this chapter with Fig. 18.7. Additionally, T.M.B. would like to thank IASTED and ACTA Press for permission to reuse Fig. 18.6, and IEEE for permission to reuse Fig. 18.8.

C.19 Endoscopy

by *Martin Leonhard, Klaus-Martin Irion*

The authors would like to thank Melanie Schwitkowski for her considerable assistance during the writing of the chapter and Horst Christoph Weiss for his contribution on the reprocessing of endoscopes and instruments.

C.22 Near-Infrared Spectroscopy (NIRS)

by *John McNulty, Michael Born, Robert S. Pozos*

The authors would like to extend their thanks to Eddie Kwon, Jon Lopez, and C. Draskovich for their assistance in many experiments.

C.24 Magnetic Particle Imaging

by *Jörn Borgert, Bernhard Gleich, Thorsten M. Buzug*

The authors would like to thank Sven Biederer, Maren Bobek, Claas Bontus, Marlitt Erbe, Jürgen Kanzenbach, Tobias Knopp, Michael Kuhn, Kerstin Lüdtker-Buzug, Jürgen Rahmer, Timo Sattel, Ingo Schmale, Joachim D. Schmidt, Jürgen Weizenecker, and Oliver Woywode for valuable discussions and comments.

J.B. and B.G. acknowledge the support of the Federal Ministry of Education and Research, Germany (BMBF), grant number 13N9079.

C.25 MR-Guided Interventions and Surgery

by *Andreas Melzer, Erwin Immel, Rachel Toomey, Fabiola Fernandez-Gutierrez*

Andreas Melzer gratefully acknowledges the funding of the Scottish Office for the Northern Research Partnership and support of the MR endoscopy project by Olympus and J. Lewin, J. Duerk, M. Wendt, Dept. of MRI at Case Western Reserve University, Cleveland, OH, USA. A. Buecker, E. Spüntrup, N. Krämer and Dept. of Radiology University Aachen, Germany, are recognized with gratitude for their work on Vena Cave Filter animal study. The authors acknowledge the funding of the European Framework 7 for the Marie Curie Initial training Network www.IIOS.eu.

C.26 Devices and Materials in MRI

by *Gregor Schaeffers, Andreas Melzer*

We would like to express our gratitude to Dr. Hans Engels for reviewing and commenting on this chapter, Thomas Bertsch for performing MR testing of stents and preparation of Fig. 26.8a,b, Dr. Bernd Guttman for conception and preparation of Fig. 26.10, Daniel Sachtler for testing and images prepared for Fig. 26.1a–d, and Sentürk Konak for MR testing and images for Fig. 26.11a,b.

Andreas Melzer gratefully acknowledges the funding of the Scottish Office for the Northern Research Partnership.

D.33 Application of Shock Waves and Pressure Pulses in Medicine

by *Friedrich Ueberle*

I would like to dedicate this publication to my very esteemed colleague Dr. Wolfgang Hepp, who unfortunately passed away. He was dedicated to the development of ESWL since its pioneer days. I would like to thank all colleagues from the ESWL community for their always friendly and cooperative support.

D.36 Mechanical Circulatory Support Systems

by *Roland Hetzer, Ewald Hennig*

We thank Dr. med. Dipl. Psych. W. Albert for contributing Sect. 36.7. We also thank Anne M. Gale of the Deutsches Herzzentrum for editorial assistance with the chapter.

D.37 Neural Interfaces for Implanted Stimulators

*by Xiao Liu, Andreas Demosthenous,
Nick Donaldson*

The authors would like to acknowledge the financial support from the UK Engineering and Physical Science Research Council under Grant EP/F009593/1. They would also like to thank Mr. Peter Langlois and Dr. Anne Vanhoest for useful discussion on this work.

D.42 Rehabilitation and Therapeutic Robotics

*by Loredana Zollo, Dino Accoto, Silvia Sterzi,
Eugenio Guglielmelli*

The authors would like to warmly thank Antonino Salerno and Massimo Vespignani for their fruit-

ful collaboration to the implementation and the experimental validation of the CBM-motus control system.

E.55 Intraoperative Neuromonitoring

by Werner Kneist, Daniel W. Kauff

The authors are grateful to Prof. Dr. med. Th.J. Musholt for the Figs. 55.4, 55.5 and 55.6a. Many thanks to Prof. Dr. med. A. Keilmann for Fig. 55.6b and to Prof. Dr. med. M. Herrmann from the Institute of Anatomy of the University of Ulm for hand drawing, the photograph of Fig. 55.8, helpful discussion, and demonstration of the morphologic conditions for nerve-sparing surgery of pelvic organs.

About the Authors

Dino Accoto

Università Campus Bio-Medico di Roma
CIR – Center for Integrated Research
Rome, Italy
d.accoto@unicampus.it

Chapter D.42

Dino Accoto is an Assistant Professor in Industrial Bioengineering at the Università Campus Bio-Medico di Roma. He received the PhD in biomedical robotics from the Scuola Superiore Sant'Anna in 2002. Since 2004, he has been with the Laboratory of Biomedical Robotics and Biomicrosystems at Università Campus Bio-Medico di Roma. His main research interests are in wearable robotics, microengineering and biomechatronics.

Albert J. Augustin

Städtisches Klinikum Karlsruhe
Augenklinik
Karlsruhe, Germany
albertjaugustin@googlemail.com

Chapter B.13

Albert J. Augustin is currently a Professor of Ophthalmology and Chairman of the Department of Ophthalmology at the Klinikum Karlsruhe, Germany. Prior to this, he was Professor of Ophthalmology at the University of Mainz where he was Head of the Laboratory for Pathophysiology of the Eye and Assistant Medical Director at Bonn University Eye Hospital. Dr. Augustin is the recipient of numerous awards and has published a number of books and over 140 papers. His main research activities relate to pathobiochemistry and pathophysiology of oxidative damage to the eye in age-related macular degeneration, diabetic retinopathy, proliferative vitreoretinopathy and retinal ischemia. He also established a combination therapy for wet AMD and initiated trials investigating the efficacy and safety of Triple Therapy.

Natasha Avila

e-medicis
Paris, France
natasha.avila@emedicis.com

Chapter F.67

Natasha Avila is the Founder and Managing Director of e-medicis. Prior to this she held positions at General Electric Healthcare where she was responsible for the European Operation Services of the IS product line around medical imaging and managed Lucent's professional services unit in France. She worked as a Consultant in the US, Germany and UK for the telecommunications and banking industry. She has a Master of Engineering from Cornell University and a MBA degree from Cambridge University. She is member of the French Society of Geriatrics.

Michael Bateman

University of Minnesota
Department of Biomedical Engineering
and Surgery
Minneapolis, MN, USA
batem034@umn.edu

Chapter D.43

Michael Bateman obtained his Masters degree in Mechanical Engineering from the University of Bristol, UK, in 2004. He went on to work for CG Versatile Fittings, UK, as a product design engineer for a year before moving to Minnesota to pursue a career in biomedical engineering. He is currently in the fourth year of his graduate studies at the University of Minnesota in Biomedical Engineering and is striving for his PhD degree in 2011.

Andreas Bermann

Siemens Healthcare
Imaging and Therapy Division, SYNGO
Erlangen, Germany
andreas.bermann@siemens.com

Chapter F.65

Andreas Bermann received his degree as medical doctor from the University Medical School of Düsseldorf. He is now responsible for the product definition of the medical imaging software syngoTM at Siemens Healthcare. With his team of highly specialized software engineers, physicists and medical doctors he is developing software for imaging modalities, advanced visualization applications and PACS. In 1998 he achieved his Masters Degree in Business Administration from the University of Bayreuth.

Ulrich Böckler

Sorin Group Deutschland GmbH
München, Germany
ulrich.boeckler@sorin.com

Chapter D.32

Ulrich Böckler is holder of the European Certificate in Cardiovascular Perfusion (ECCP). For several years he was Chief of the Perfusion Department at the German Heart Centre Munich. He is currently working as Product Manager heart lung machines (HLM) for Sorin Group Deutschland GmbH.

Armin Bolz

Karlsruhe Institute of Technology
Institute for Biomedical Engineering
Karlsruhe, Germany
armin.bolz@kit.edu

Chapter D.38

Armin Bolz received his PhD in Physics from the University of Erlangen. He spent some years with Biotronik as head of R&D for pacemakers and defibrillators. Since 1999 Armin Bolz is a Professor for Biomedical Engineering at the Karlsruhe Institute of Technology (KIT). His current research interests are cardiovascular diagnostics, electrostimulation and defibrillation. He also actively supports young start-ups to transfer latest research results into products.

Jörn Borgert

Philips Technologie GmbH
Forschungslaboratorien
Tomographic Imaging Group
Hamburg, Germany
joern.borgert@philips.com

Chapter C.24

Jörn Borgert received his PhD degree in Theoretical Physics from the University Kiel, Germany. He is now Senior Scientist at Philips Research. His current research interests are tomographic imaging and, in particular, magnetic particle imaging (MPI). He received the innovators award of the Federal Ministry of Education and Research of Germany for the application of MPI in breast cancer treatment in 2008.

Michael Born

San Diego State University
Department of Biology
San Diego, CA, USA
Michael.j.born@gmail.com

Chapter C.22

Michael Born received his Bachelor of Science degree in Bioengineering from San Diego State University. He is currently attending graduate school at Northwestern University in Chicago, Illinois where he is working on his Masters Degree, also in Bioengineering.

Guenther Braun

University Medical Center Freiburg
Paediatrics and Adolescent Medicine
Freiburg, Germany
guenther.braun@uniklinik-freiburg.de

Chapter G.71

Guenther Braun received the Masters degree 1996 in Biomedical Engineering from the University of Applied Science in Ulm. Currently he is responsible for the biomedical department of the University Childrens Hospital in Freiburg.

Dirk Büchel

Medical Faculty of Tübingen
Tübingen, Germany
buechel.dirk@t-online.de

Chapter A.6

Dr. sc. hum. Dipl.-Ing. Dirk Büchel is a usability expert who developed the standard procedure for the usability engineering process and final usability testing of medical products within his dissertation.

Thorsten M. Buzug

University of Lübeck
Institute of Medical Engineering
Lübeck, Germany
buzug@imt.uni-luebeck.de

Chapters C.16, C.18, C.24

Professor Thorsten M. Buzug received his PhD in 1993 from the University of Kiel. After a postdoctoral position at the German Federal Armed Forces Underwater Acoustics and Marine Geophysics Research Institute he joined the Philips Research Laboratories Hamburg. As leader of the Philips research cluster Medical Image Processing he was responsible for several. In 2006 he has been appointed as Director of the Institute of Medical Engineering at the University of Lübeck. His research is focused on medical imaging and image computing.

Marco Capogrosso

Chapter F.68

Scuola Superiore Sant Anna
ARTS lab
Pisa, Italy
m.capogrosso@sssup.it

Marco Capogrosso received the MS degree in Applied Physics from the Faculty of Mathematical, Physical and Natural Sciences at the University of Pisa in 2009. He is currently working towards a PhD degree in biomedical robotics at the Scuola Superiore Sant Anna, Pisa. His research interests are in neural modelling, finite element models, functional imaging, and neuroscience.

Peter H. Cossmann

Med Tech Consulting
Wettingen, Switzerland
peter.cossmann@medtechconsulting.ch

Chapter D.35

Peter H. Cossmann received his Master degree in Medical Physics from the ETH Zurich and his PhD from the University of Bern. He is currently Head Consultant at Med Tech Consulting in Wettingen. He was former Head of Medical Physics of the Institutes for Radiotherapy at Hirslanden Klinik Aarau and Zurich. Dr. Cossmann holds Lectureships in Biomedical Engineering and Physics and his current areas of research include on-board imaging, cone-beam computed tomography, gating and dosimetry.

Andreas Demosthenous

University College London
Electronic and Electrical Engineering
London, UK
a.demosthenous@ee.ucl.ac.uk

Chapter D.37

Andreas Demosthenous is a Professor of Analogue and Biomedical Electronics in the Department of Electrical and Electronic Engineering, University College London, UK. His main area of research is analog and mixed-signal integrated circuits for biomedical, communication, sensor and signal processing applications. He has numerous collaborations for interdisciplinary research and has published over 150 articles in journals and international conference proceedings.

Thomas M. Deserno

RWTH Aachen University
Aachen, Germany
Deserno@leee.org

Chapter F.62

Thomas M. Deserno (born as Lehmann) is Professor of Medical Informatics at RWTH Aachen University, where he heads the Medical Image Processing Group within the Department of Medical Informatics. His research interests include discrete realizations of continuous image transforms, applications to quantitative measurements for computer-assisted diagnoses, and content-based image retrieval from large medical databases.

Nick Donaldson

University College London
Medical Physics & Bioengineering
London, UK
nickd@medphys.ucl.ac.uk

Chapter D.37

Professor Donaldson studied Engineering at Cambridge University and did a PhD at University College London. He directs the Implanted Devices Group and has been Principal Investigator for many projects related to implants and functional electrical stimulation. His research interests include implant technology, neuroprosthesis that use nerve signals as inputs; stimulators of nerve roots; and electrical stimulation for recreational exercise of paralyzed legs.

William K. Durfee

University of Minnesota
Department of Mechanical Engineering
Minneapolis, MN, USA
wkdurfee@umn.edu

Chapter B.14

William Durfee is with the Department of Mechanical Engineering at the University of Minnesota. He received the AB degree in Engineering and Applied Physics from Harvard University and the MS and PhD degrees in Mechanical Engineering from MIT. His professional interests include design of medical devices, rehabilitation engineering, advanced orthotics, biomechanics and physiology of human muscle including electrical stimulation of muscle, product design and design education.

Günter Edlinger

g.tec medical engineering GmbH
Graz, Austria
edlinger@gtec.at

Chapter E.52

Günter Edlinger studied control engineering and received his PhD in biomedical engineering from the University of Technology Graz where he was an Assistant Professor from 1993 to 2001. He is co-founder and CEO of g.tec medical engineering GmbH and has been working there since 1999. His research interests comprise invasive and noninvasive brain computer interfaces, neurophysiological instrumentation aspects and inverse problems.

**Amir Eftekhar**

Imperial College London, South
Kensington Campus
Centre for Bio-Inspired Technology
London, UK
a.eftekhar@imperial.ac.uk

Chapter E.56

Amir Eftekhar is a Research Associate in the Centre for Bio-Inspired Technology, one of the founders of the Institute of Biomedical Engineering, and now a part of the EEE department. His research involves applications of interfaces for neurological studies including electrode technology for interfacing with the central and peripheral nervous system, front-end electronics (analog/digital) for implantable or portable systems to interface with these electrodes and advanced signal processing methods.

**Mariana Fernandes**

University of Minho
Department of Industrial Electronics, DEI
– Campus de Azurém
Guimarães, Portugal
mfernandes@dei.uminho.pt

Chapter G.74

Mariana Fernandes received the Integrated Master degree in Biomedical Engineering from the University of Minho (2002-2007). She is currently pursuing the PhD degree within the MITI/Portugal Program in bioengineering at the Department of Industrial Electronics, University of Minho. Her research area is the development of wearable and contactless technologies to monitor bioelectric signals.

Eduardo Fernandez

Universidad Miguel Hernández
Bioengineering Institute
Elche, Spain
e.fernandez@umh.es

Chapters B.11, D.41

Eduardo Fernandez is a Professor of Cellular Biology and Director of the Visual Rehabilitation and Neuroprosthesis Unit in the Bioengineering Institute of the University Miguel Hernández (Spain). He received a MD degree from the University of Alicante (1986) and a PhD in Neuroscience in 1990. He is actively working on the development of visual neuroprostheses and brain machine interfaces. He is also working on brain plasticity and cortical reorganization in severe vision loss.

Fabiola Fernandez-Gutierrez

University of Dundee
Institute for Medical Science and
Technology
Dundee, UK
f.fernandezgutierrez@dundee.ac.uk

Chapter C.25

Fabiola Fernandez-Gutierrez received a degree in Telecommunication Engineering and a Master degree in Automatic Control, Robotics and Telematics from the University of Sevilla, Spain. She is now working on her PhD at the Institute for Medical Science and Technology on the European Project Integrated Interventional Imaging Operating System (IIOS) focusing on the design and improvement of ergonomics workflow for multimodality image-guided procedures.

**Celso P. Figueiredo**

University of Minho, Campus de Azurém
Department of Industrial Electronics
Guimarães, Portugal
celso.figueiredo@dei.uminho.pt

Chapter G.74

Celso Pitães Figueiredo received his MSc degree in Biomedical Engineering – Medical Electronics from the University of Minho in 2007, Guimarães, Portugal. He is currently working towards his PhD in Biomedical Engineering at the University of Minho, in collaboration with the Fraunhofer Institute for Biomedical Engineering, St. Ingbert, Germany. His thesis involves the research and development of wearable and wireless systems for health monitoring.

**Harald Fischer**

Chapter G.70

Creamedix GmbH
Weingarten, Germany
haf1@creamedix.eu

Harald Fischer received his Diploma and PhD degree in Biomedical Engineering from the Technical University of Karlsruhe, Germany. He worked for several years as the Head of the Institute of Biomedical Engineering and Biophysics at the Karlsruhe Institute of Technology (formerly Research Center Karlsruhe) in the field of robotic surgery and new materials for surgical interventions. He is now the CEO of Creamedix GmbH producing medical implants out of shape memory alloys. His research interests are new materials for medical applications, medical coatings and cell growing applications.

Martin R. Fischer

Private University Witten/Herdecke
gGmbH
Fakultät für Gesundheit
Witten, Germany
martin.fischer@uni-wh.de

Chapter F.64

Dr. Fischer is a General internist and Endocrinologist and is Professor, Dean for Education, and Director of the Institute for Teaching and Educational Research in Health Sciences at the Faculty for Medicine of Witten/Herdecke University, Germany. He received the Master of Medical Education (MME) from the University of Berne, Switzerland, and is also certified in medical informatics.

Óscar S. Gama

Universidade do Minho,
Campus de Gualtar
Departamento de Informática
Braga, Portugal
osg@di.uminho.pt

Chapter G.74

Óscar Gama finished his education in Electronic Engineering at the University of Oporto in 1989 and received a Master degree in Informatics from the University of Minho (Braga) in 2003. He is currently a PhD student in the Electronics Department of the University of Minho. His research focuses on self-reconfiguring e-health wireless sensor networks with quality of service.

Stephan Garbe

University Hospital of Bonn
Radiology Department
Bonn, Germany
garbe@uni-bonn.de

Chapter D.45

Stephan Garbe received his PhD in Physics from the University of Münster in 1995. After a postdoctoral position at the Risø National Lab, he worked as Medical Physicist first at the Department for Radiotherapy at the University Hospital of Essen and later at the Department for Radiology at the University Hospital of Bonn. Since 2007 he is Head of the Medical Physics Department. His current research interests are in-vivo dosimetry, dosimetric verification in IMRT and quality assurance in radiotherapy.

Belinda Garner

Imperial College London, South
Kensington Campus
Institute of Biomedical Engineering
London, UK
b.garner@imperial.ac.uk

Chapter E.56

Belinda Garner received her Bachelor of Science (Honours) degree in Neuroscience/Anatomy and Cell Biology and her PhD degree in Behavioural Neuroscience from the University of Melbourne, Australia. Her research interests include understanding the role of stress in the development and maintenance of psychiatric disorders and in the development of novel technology for monitoring brain and peripheral nerve function.

Armin Gärtner

Ingenieurbüro für Medizintechnik
Erkrath, Germany
armin.gaertner@t-online.de

Chapter F.58

Armin Gärtner successfully completed his engineering studies at the University of Applied Sciences in Gießen, Germany and has been working in the hospital sector for many years. He is an Official Expert for medical technology at the Chamber of Industry and Commerce – District Düsseldorf and owner of an engineering office for medical technology. He is Member of the Standards Developing Organization 80001 and author of numerous publications and specialized books regarding subjects of medical engineering and information technology.

Bernhard Gleich

Philips Technologie GmbH
Tomographic Imaging Group
Hamburg, Germany
bernhard.gleich@philips.com

Chapter C.24

Bernhard Gleich received his Diploma in Physics from the Institute of Surface Chemistry and Catalysis, University Ulm, Germany. He is now Senior Scientist at Philips Research. His current research interests are tomographic imaging and magnetic particle imaging. He is one of the inventors of magnetic particle imaging (MPI).

Rudolf Götz

Aloka GmbH
Willich, Germany
R.Goetz@aloka-europe.com

Chapter C.17

Rudolf Götz received the Dipl.-Ing. in Electronic Engineering from the FH Karlsruhe in 1972 and the Dipl.-Ing. in Medical Engineering and Biological Cybernetics from the University of Karlsruhe in 1979. Currently he is product manager for ultrasound at ALOKA GmbH, Germany.

Christoph Guger

g.tec medical engineering GmbH, Guger
Technologies OG
Schiedlberg, Austria
guger@gtec.at

Chapter E.52

Dr. Christoph Guger studied Biomedical Engineering at the University of Technology Graz and Johns Hopkins University in Baltimore, USA. Then he did research work at the Department of Medical Informatics at the University of Technology Graz and received his PhD degree in 1999 with the design of the first real-time brain computer interface (BCI) system with continuous feedback. He also developed the real-time analysis with common spatial patterns which is still the fastest and most accurate approach for oscillatory BCI. He is co-founder of g.tec where he works since 1999.

Eugenio Guglielmelli

Universita' Campus Bio-Medico
CIR – Center For Integrated Research
Rome, Italy
E.Guglielmelli@unicampus.it

Chapter D.42

Eugenio Guglielmelli (MSc 1991, PhD 1995 both in Electronical Engineering from the University of Pisa, Italy) is Full Professor of Bioengineering at Università Campus Bio-Medico (Rome, Italy) where he serves as the Director of the Laboratory of Biomedical Robotics and Biomicrosystems. His main research interests are in human-centred robot design, biomechatronics, biomorphic robot control, neurobotics, rehabilitation and assistive robotics.

Martin Haag

Heilbronn University
Medical Informatics
Heilbronn, Germany
martin.haag@hs-heilbronn.de

Chapter F.64

Martin Haag is a Professor for Software Engineering and Head of the Lab e-Learning in Medicine of the Centre for e-Learning Technology at Heilbronn University, Germany and head of the Centre for Virtual Patients at the University of Heidelberg, Germany. His research group focuses on development of virtual patients and secure electronic examinations.

Reiner Haag

Lawton GmbH & Co. KG
Fridingen, Germany
reiner.haag@lawton.de

Chapters D.34, G.72

Reiner Haag received the Diplom Ingenieur degree in Electronics and Mechanical Engineering from the University of Applied Science Furtwangen, Germany, in 1985. After 6 years in R&D and 10 years International Product Management in electrosurgery he had gained 2 years of experience in sales of endoscopic instruments. He has eight publications and 3 patents. Since 2002 he is General Manager at Lawton Medizintechnik, a Company producing special high-end surgical instruments.

**Peter Haas**

Chapter F.59

University of Applied Sciences and Arts
Dortmund
Medical Informatics
Dortmund, Germany
haas@fh-dortmund.de

Academic Studies Medical Informatics 1977–1982, Project Manager in a large-scale hospital for the implementation of a radiological information system from 1983 to 1984, Project Manager and later Head of Department of Medical Informatics at the University of Heidelberg 1985–1989, Marketing Manager Public Authorities Software AG 1989–1990, Director Sales, Marketing, training hospital information systems vendor 1991–1993. Since 1994 Professor for Medical Informatics. His research activities concern information systems in healthcare and electronic patient records, health telematics, knowledge management based systems in healthcare.

Andreas Hahn

Sorin Group Deutschland GmbH
General Management
München, Germany
andreas.hahn@sorin.com

Chapter D.32

Andreas received the MS degree in Electronics and Telecommunications from the TH Karlsruhe and the Doctors degree from the Technical University of Breslau. He is more than 35 years active in medical industry. Starting as R&D Engineer, Head of R&D for medical lasers, VP operations of MBB Medical Technology, he is now General Manager of Sorin Group Deutschland GmbH within CP BU. He is Member of the Operations Council for the Sorin Group. Board member of Laser- und Medizin-Technologie LMTB GmbH. He holds more than 30 patents for medical lasers and heart-lung machines.

Sibylle Hanus

Textile Research Institute
Thuringia-Vogtland
Textile Structures and Materials
Greiz, Germany
s.hanus@titv-greiz.de

Chapter G.73

Sibylle Hanus received the diplomas in Physical Technics and Engineering Economics from the University of Applied Sciences Zwickau, Germany. Since 1999 she is working at the Textile Research Institute Thuringia-Vogtland, Greiz, Germany as scientist in the development of medical textiles, especially in the field of invasive medical devices. Since 2008 she is team leader of the group Textile Structures and Materials.

**Michael Heinlein**

Chapter F.57

Mednovo Medical Software Solutions
GmbH
Berlin, Germany
info@mednovo.de

Michael Heinlein is co-founder and co-owner of Mednovo Medical Software Solutions GmbH, founded in 2002. As Managing Director, he focuses on marketing, sales, support, business development and organization. Mednovo is providing software solutions in healthcare and offers an overall IT concept, optimizing the process of a daily routine in hospitals, clinics and medical engineering companies.

**Ewald Hennig**

Chapter D.36

Deutsches Herzzentrum Berlin
Berlin, Germany
Hennig@dhzb.de

Ewald Hennig received a PhD in Aeronautical Engineering from the Technical University Berlin in 1965. There he was with the Department of Biomedical Research until 1971. In 1972 he joined the Research Group "Mechanical Heart Assist and Total Heart Replacement" of E. S. Bücherl at the Free University of Berlin as Technical Director of Experimental Surgery. In 1985 he was Visiting Professor at the Second Medical University of Shanghai. Since 1988 he has been a member of the DHZB-MCSS Research Group (Prof. Hetzer) as Senior VAD Coordinator. Research activities concern BiVAD and TAH with rotary blood pumps.

Roland Hentschel

Universitätsklinikum Freiburg
Neonatologie/Intensivmedizin, Zentrum
für Kinder- und Jugendmedizin
Freiburg, Germany
roland.hentschel@uniklinik-freiburg.de

Chapters E.54, G.71

Roland Hentschel is Head of the Department of Neonatology and Intensive Care Medicine, University Children's Hospital Freiburg, since 1996. He is specialized in Neonatology, Intensive Care Medicine and Pediatric Pulmonology. In 2003 he was appointed University Lecturer for neonatology and pediatrics. His main research and clinical work focuses on newborn lung function (grantee of the German Research Council (DFG) from 1990–1996), mechanical ventilation, transfusion medicine, and ethics in neonatology.

Roland Hetzer

Deutsches Herzzentrum Berlin
Berlin, Germany
hetzer@dhzb.de

Chapter D.36

Roland Hetzer, MD, PhD, is Chairman of the Deutsches Herzzentrum Berlin since its foundation in 1986. He received his training in surgery at the Hannover Medical School and specialized in Cardiothoracic and Vascular Surgery after completing his fellowship training at the Pacific Medical Center and Stanford University. He became staff member (1978) in this field at the Hannover Medical School and Associate Professor (1983) when he started heart transplantation. At Berlin within the complete scope of cardiothoracic surgery he is heading the largest programme of mechanical hearts worldwide.

Lothar Heuser

Klinikum der Ruhr-Universität Bochum
Institut für Diagnostische &
Interventionelle Radiologie,
Knappschafts Krankenhaus
Bochum, Germany
lothar.heuser@rub.de

Chapter C.15

Lothar J. Heuser was fellow at the Departments of Diagnostic Radiology und Radiation Therapy at the University of Cologne where he received his *venia legendi* and became an Associate Professor. Since 1986 he is Professor of Radiology and Chairman at the Ruhr-Universität Bochum and Chairman of the Department of Diagnostic and Interventional Radiology, Neuroradiology and Nuclear Medicine. Current research interests are digital image processing and interventional procedures.

Ullrich Hieronymi

Dräger Medical Deutschland GmbH
Lübeck, Germany
ullrich.hieronymi@draeger.com

Chapters E.47, E.48, E.49, E.50

Ullrich Hieronymi received his biomedical engineering graduate and Doctor of Engineering Science from the Ilmenau College of Advanced Technology in 1971 and 1975, respectively. For 17 years he took the biomedical engineering part in a research department for intensive care medicine of a Berlin hospital. Since 1992 until 2011 he worked as a monitoring application specialist in the medical device industry. After his semi-retirement he now proofreads texts on monitoring.

Robert Hitchcock

University of Utah
Bioengineering
Salt Lake City, UT, USA
r.hitchcock@utah.edu

Chapter D.40

Robert Hitchcock is an Assistant Professor in the Department of Bioengineering at The University of Utah and Director of the University's bioDesign program. He has over 26 years of experience bringing new products to the marketplace and has been involved as an engineer, manager, consultant and executive with a number of leading medical device companies.

Gerhard Hoffmann

Orangedental GmbH & Co KG
Biberach, Germany
gh@orangedental.de

Chapter C.20

Gerhard Hoffmann is a Ing.(grad) in Hospital Engineering at the University of Applied Sciences Gießen. He has many years of an experience in medical technology industry. As Director of Sales his focus is on dental diagnostic imaging systems where he specializes in digital inclusion and cone-beam computed tomography (CBCT).

Klaus-Peter Hoffmann

Chapters B.9, B.10, B.11, D.39, D.40, D.41, E.46

Fraunhofer Institute for Biomedical Engineering
 Medical Engineering and Neuroprosthetics
 St. Ingbert, Germany
klaus.hoffmann@ibmt.fraunhofer.de

Dr. Hoffmann is currently a Professor of Biomedical Engineering at the Hochschule für Technik und Wirtschaft des Saarlandes. He is acting as the Head of the Department Medical Engineering and Neuroprosthetics at the Fraunhofer Institute for Biomedical Engineering in St. Ingbert. His main research interests include smart interfaces in Clinical Neurophysiology as well as implantable microsystems especially sensors and actuators for neuroprosthetics.

Gerald C. Holst

Chapter C.18

JCD Publishing Company
 Winter Park, FL, USA
Jerry@JCDPublishing.com

Dr. Gerald C. Holst is a lecturer and consultant for thermal imaging system design, applications, and testing. He developed software that simulates imaging system performance. He authored 6 books which are published by JCD Publishing Company. Dr. Holst is a SPIE Fellow and chairs the SPIE conference on Infrared Imaging Systems since 1990.

Sebastian Hoth

Chapter B.12

University of Heidelberg
 ENT Hospital – Audiology
 Heidelberg, Germany
sebastian.hoth@med.uni-heidelberg.de

Professor Sebastian Hoth, Head of the Audiology Unit at the University ENT Hospital in Heidelberg, studied Physics at the University of Erlangen and was awarded his PhD in 1982. He completed his post-doctoral thesis in 1996 and was appointed Professor in 2004. His scientific activity is dedicated to objective audiometry, cochlear implant and other implantable hearing systems. Parallel to this, he is deeply involved in audiology education, the training of students and the formation of professionals.

Stephen A. Howard

Chapter D.43

University of Minnesota
 Department of Biomedical Engineering
 and Surgery
 Minneapolis, MN, USA
howa0255@umn.edu

Stephen Howard is a PhD graduate student in Biomedical Engineering at the University of Minnesota. He earned his Masters degree in Biochemistry and Chemistry at Gustavus Adolphus College in St. Peter, MN. He is interested in the effects of fatty acids on the membrane proteins and ion channels, particularly looking at signal modification and performance pre and post ischemia.

Bernhard Hug

Chapter D.34

KLS Martin GmbH + Co. KG
 Umkirch, Germany
Bernhard.Hug@klsmartin.com

Bernhard Hug studied Biomedical Engineering in Gießen and Berlin and received his PhD from the Faculty of Mathematics and Natural Sciences of the Humboldt-Universität zu Berlin, Germany. He is Head of Development for Electrosurgical Accessories at KLS Martin, a company of the KLS Martin Group. A main focus of his research activities is the clinical application of electrosurgical technology in different medical specialties.

Paul A. Iaizzo

Chapters B.14, D.43

University of Minnesota
 Department of Surgery
 Minneapolis, MN, USA
iaizz001@umn.edu

Paul Iaizzo earned the PhD degree in Physiology, and is Professor of Surgery, Integrative Biology and Physiology, Anesthesiology, and Carlson School of Management at the University of Minnesota. He heads the Visible Heart® Laboratory, where his main research focus is translational systems physiology and his research group has developed a unique isolated working large mammalian heart model.

Erwin Immel

University of Dundee
Institute for Medical Science and
Technology
Dundee, UK
e.z.immel@dundee.ac.uk

Chapter C.25

Erwin Immel graduated 2006 from a Five-Year Degree in Medical Engineering at the University of Applied Science in Gelsenkirchen, where he received a Master of Science degree. Before starting his PhD, Erwin worked as Research and Development Engineer at Biophan Europe. The research topic of his PhD projects (University of Dundee) is the improvement of the visualization of vascular implants such as vena cava filters, stents, and prosthetic heart valves in MRI.

Klaus-Martin Irion

Karl Storz GmbH & Co. KG
Tuttlingen, Germany
K.Irion@karlstorz.de

Chapter C.19

Klaus-Martin Irion is the Global Vice President of Research and Technology at Karl Storz, Tuttlingen, Germany. He received his engineering diploma and his doctorate from the Faculty of Electronic Engineering of the University of Stuttgart. His scientific work focused on high-frequency ultrasonic image processing and tissue characterization at the Institute of Biomedical Engineering, Stuttgart. Dr. Irion is over 20 years with Karl Storz. Before taking over his position as Global Vice President of Research and Technology he was Head of R&D/Electronic Engineering.

Heinz-Michael Just

Klinikum Nürnberg
Institute of Hospital Epidemiology,
Medical Microbiology and Infectious
Diseases
Nürnberg, Germany
just@klinikum-nuernberg.de

Chapter A.3

Heinz-Michael Just, MD, is a specialist for microbiology, virology and hospital epidemiology, for hygiene and environmental medicine and a specialist for infectious diseases. He is Head of the Institute of Hospital Epidemiology, Medical Microbiology and Infectious Diseases, Klinikum Nürnberg, Germany. He is also a Member of the Commission for Hospital Hygiene and Infectious Disease Prevention (KRINKO) appointed by the Ministry of Health as well as a Member of the Committee for Biological Agents (ABAS) appointed by the Ministry of Labour.

Daniel W. Kauff

University Medicine of the Johannes
Gutenberg University Mainz
Department of General and Abdominal
Surgery
Mainz, Germany
Kauff@ach.klinik.uni-mainz.de

Chapter E.55

Daniel W. Kauff received his medical doctorate from the University Medicine of the Johannes- Gutenberg University of Mainz, Germany. Since 2008, he is working as a physician and research associate at the Department of General and Abdominal Surgery, University Medicine of Mainz, Germany. His current scientific interests are colorectal surgery and intraoperative pelvic neuromonitoring.

Rüdiger Klar

Universitätsklinik Freiburg
Institut für Medizinische Biometrie und
Medizinische Informatik
Freiburg, Germany
ruediger.klar@web.de

Chapter F.60

Prof. em. Dr. rer. nat. Rüdiger Klar studied in Bonn and Hamburg and worked two years in a software company at Hannover. From 1986 till 2007 he was Head of the Department for Medical Informatics at the University Hospital Freiburg. His scientific and practical work deals with patient care systems, telemedicine, medical classifications and IT standards, health economy and medical decision making. He is member of several international scientific societies and editorial boards of scientific journals. He was President of the German Society of Medical Informatics, Biometry and Epidemiology and is still active in this field.

Werner Kneist

University Medicine of the Johannes
Gutenberg University Mainz
Department of General and Abdominal
Surgery
Mainz, Germany
werner.kneist@unimedizin-mainz.de

Chapter E.55

Werner Kneist is currently an Associate Professor in the Department of General and Abdominal Surgery of the University Medicine of the Johannes Gutenberg University Mainz. His research focuses on colorectal surgery with a special interest in the oncological and functional outcome. Over the past years he and his interdisciplinary group have developed a series of innovative techniques for intraoperative neuromonitoring of pelvic autonomic nerves.

Klaus P. Koch

University of Applied Sciences Trier
Department of Engineering
Schneidershof, Trier, Germany
koch@fh-trier.de

Chapter F.61

Klaus Peter Koch received his PhD in 2003. From 1998 to 2007 he worked at the Fraunhofer Institute for Biomedical Engineering. Currently he is Full Professor at the University of Applied Sciences Trier, Germany. His research interest is system integration for neural implants, design and simulation of electrodes for recording and stimulation, active implantable electronics and artefact models.

Heike Kramme

Titisee, Germany
kramme-titisee@t-online.de

Chapter A.1

Heike Kramme is a Graduate in Administration Sciences after studies in Law and Management Sciences focusing on health care at the Universities of Freiburg and Constance, Germany. Heike Kramme has many years of professional experience in human resources management, among others in publishing. She has various publications about health policy and health economics.

Rüdiger Kramme

Titisee, Germany
kramme-titisee@t-online.de

Chapters A.1, A.4, B.7, B.8, D.28, E.47, E.48, E.49, E.50

Rüdiger Kramme is a Graduate Engineer and studied Biomedical and Hospital Engineering as well as National Economy in Gießen und Freiburg, Germany. He has many years of professional experience in sales, marketing and human resources development in medical device industry for consumer and investment capital goods. He also is a Lecturer for Medical Engineering at the University of Applied Sciences in Gießen. Rüdiger Kramme has authored numerous scientific publications in magazines and books. He is the founder and Editor of the standard work *Medizintechnik – Verfahren, Systeme, Informationsverarbeitung* and the Dictionary *Technische Medizin* published by Springer.

Ursula Krechel

University Clinic Freiburg
IT-Department
Freiburg, Germany
Ursula.krechel@uniklinik-freiburg.de

Chapter B.9

Uschi Krechel has studied Electronic Engineering at the Technical University of Aachen, Germany and worked as an Application Engineer in German companies building electrophysiological equipment such as EMG, EEG, Electronystagmographs for 13 years. Among these were Toennies and Jaeger. Currently she works as an IT Specialist at the University Clinic of Freiburg, Germany.

Harald Kronberg

Michelstadt, Germany
haraldkronberg@freenet.de

Chapters E.49, E.51

Harald Kronberg received the Master degree and the PhD in Physics both from Göttingen University. He then spent seven years in applied research of the Göttingen Max-Planck-Institute of Experimental Medicine. In 1984, he joined the Applied Research Department of Hellige in Freiburg, now part of General Electric Healthcare. Until his retirement end of 2009, he was Marketing Manager of GE's patient monitoring platforms.

**Klaus A. Kuhn**

Chapter F.59

Technische Universität München (TUM)
Institute of Medical Statistics and
Epidemiology
München, Germany
klaus.kuhn@tum.de

Klaus Kuhn is a Full Professor of Medical Informatics at the Technical University Munich and a member of both the Medical and the Informatics Faculty. He holds degrees in Medicine, Mathematics, and Computer Science. He chaired the Editorial Board of Medinfo 2007, the World Congress of Medical Informatics. He is past President of the German Association of Medical Informatics, Biometry, and Epidemiology, and he is a Fellow of ACMI. His research interests are information systems with a special focus on translational research.

Bernhard Kulik

Chapter G.69

Maquet GmbH & Co. KG
Rastatt, Germany
b.kulik@maquet.de

Bernhard Kulik is Director of Product Management Operating Room tables at Maquet GmbH & Co. KG in Rastatt, Germany. He has co-authored some chapters in medical textbooks published by Springer Medizin Verlag, Heidelberg.

Timothy G. Laske

Chapter D.43

Medtronic, Inc.
Mounds View, MN, USA
tim.g.laske@medtronic.com

Tim Laske has a BS degree in Biological Sciences and Mechanical Engineering from Michigan Technological University. He received his Masters degree in Mechanical Engineering from the University of Michigan, Ann Arbor, and his PhD in Biomedical Engineering from the University of Minnesota where he serves as an Adjunct Associate Professor. Currently, Tim is a Senior Product Development Director in the Structural Heart Business at Medtronic and a Bakken Fellow. He is responsible for research and development for current and future heart valve repair and replacement products.

**Martin Leonhard**

Chapter C.19

Karl Storz GmbH & Co. KG
Research and Technology
Tuttlingen, Germany
m.leonhard@karlstorz.de

Martin Leonhard is Head of Technology Management at Karl Storz, Tuttlingen, Germany. He received his physics diploma and doctorate both from the University of Ulm. He worked on time-resolved spectroscopy at the Max-Planck-Institute in Martinsried and on medical laser applications at the Munich-Großhadern University Hospital. He was Deputy Head of Marketing Europe before taking his current position to identify and evaluate future technologies for Karl Storz.

**Xiao Liu**

Chapter D.37

University College London
Department of Electronic and Electrical
Engineering
London, UK
x.liu@ee.ucl.ac.uk

Xiao Liu received the B.Eng. degree from Xi'an Jiaotong University in 2003, the MSc degree from University of Southampton in 2004, and the PhD degree from the University College London (UCL) in 2009. He is currently a Research Associate at UCL. His research interests include analogue and mixed-signal integrated circuit design for biomedical applications, neuroprosthesis and microelectronic sensor design.

Martin Maier

Chapter E.53

Philips Healthcare
Böblingen, Germany
martin.maier@philips.com

Martin Maier holds an engineering degree in Telecommunications from the University of Applied Science in Esslingen and an MBA in International Marketing from the European School of Business in Reutlingen. During his career Martin has gathered experience in the area of production, software quality engineering, software development, product support and product marketing. In his current role as Global Senior Product Manager he is responsible for the lifecycle of a complete product family in healthcare industry.

Giovanni Maio

University of Freiburg
Institute of Bioethics and History of
Medicine
Freiburg, Germany
maio@ethik.uni-freiburg.de

Chapter A.2

Giovanni Maio has the Chair of Bioethics at the University of Freiburg. He owns a Master degree in Philosophy, a PhD in Medicine and a habilitation thesis in Medical Ethics. He is Director of the Interdisciplinary Center for Ethics and Director of the Institute of Bioethics and History of Medicine. He is member of ethics committees of the German Parliament and of the Medical Association. He has written over 200 publications on biomedical ethics and takes a critical look on the mere technological self-conception of modern medicine.

Albrecht Malkmus

GE Medical Systems Information
Technologies
Freiburg, Germany
albrecht.malkmus@ge.com

Chapter A.5

Albrecht Malkmus received the Masters degree in Electronic Engineering and Information Technology from the University in Frankfurt, Germany. He is currently the Regulatory Affairs Leader and Member of the Quality Management Department at GE Medical Systems Information Technologies in Freiburg, Germany. He is member of the German National Standardization Committee and the Regulatory Affairs Working Group of the ZVEI.

Kei Masani

Toronto Rehabilitation Institute
Lyndhurst Centre
Toronto, Ontario, Canada
k.masani@utoronto.ca

Chapter D.44

Kei Masani received the PhD degree in Physical and Health Education from the University of Tokyo, Tokyo, Japan. He is now a Scientist at Toronto Rehab, Toronto, Canada. He received the Young Investigator Award from the Japanese Society of Biomechanics in 2000. His research interests are in understanding human movement and movement variability, from the view of neuro-mechanical interaction and sensory-motor integration.

Ulrich Matern

wwH-c GmbH
Tübingen, Germany
ulrich.matern@wwH-c.com

Chapter A.6

Ulrich Matern is a surgeon (Associated Professor, Medical Faculty of Univ. Tübingen, Germany) and CEO and owner of wwH-c GmbH Tübingen, Germany. wwH-c operates the Experimental-OR as a lab for research, development and testing of medical and hospital technologies as well as a teaching and training centre for hospital engineers, physicians and nursing staff. Dr. Matern represents the German Society of Surgeons within the German Standardization Committee for Usability. He is working as a consultant for hospitals worldwide regarding planning of new facilities and also auditing hospitals using the Best Hospital Practice standard that was developed by wwH-c together with TÜV.

John McNulty

San Diego State University
Department of Biology
San Diego, CA, USA
jmcnulty24@gmail.com

Chapter C.22

John McNulty received his Bachelor of Science degree in Biology from San Diego State University. He is currently working as a Research Assistant in the lab of Dr. Robert Pozos in San Diego, California. John is in the process of applying to medical school where he wants to pursue a career in surgery.

**Andreas Melzer**

University Dundee
IMSaT
Dundee, Scotland, UK
a.melzer@dundee.ac.uk

Chapters C.25, C.26

Andreas Melzer, MD DDS, is Professor of Medical Technology and Founding Director of the Institute for Medical Science and Technology IMSaT at the University Dundee. Funded by Northern Research Partnership it is hosting GE's first European Centre of Excellence for MRI-guided interventions and surgery. 60 scientist are working in the field of multimodality image-guided diagnosis and therapy, biophotonics, ultrasound, MRI, interventional and surgical technologies and nanobiotechnology.

**Paulo M. Mendes**

University of Minho, Campus de Azurém
Department of Industrial Electronics
Guimarães, Portugal
paulo.mendes@dei.uminho.pt

Chapter G.74

Paulo Mendes received the PhD degree in Industrial Electronics from the University of Minho, Portugal, in 2005. Since then he has been an Assistant Professor at the University of Minho and a researcher in the micro/nanotechnologies and biomedical applications research group (Algoritmi). He has published more than 90 journal and conference papers. His main research interests are in wearable devices, wireless sensor networks, and antenna miniaturization for biomedical applications.

Silvestro Micera

ETH Zürich, ETL K 10.1
Institut für Automatik
Zürich, Switzerland
micera@control.ee.ethz.ch

Chapters D.39, F.68

Silvestro Micera received the University degree in Electrical Engineering from the University of Pisa in 1996 and the PhD degree in Bio-Engineering from Scuola Superiore Sant'Anna (SSSA) in 2000. From 2000 to 2009 he has been Assistant Professor at SSSA where he is now the Head of the Neuroprosthesis Group. He is currently Adjunct Assistant Professor at the ETH Zurich.

Kostis Michelakis

Imperial College London, South
Kensington Campus
Institute of Biomedical Engineering
London, UK
k.michelakis@imperial.ac.uk

Chapter E.56

Kostis Michelakis is Research Fellow and Bionanotechnology Facility Manager in the Institute of Biomedical Engineering at Imperial College London. His current research is concerned with micro/nano-fabricated devices and systems at the interface between biochemistry and microelectronics. He has worked in the area of micro/nano fabrication for over 20 years. He received his PhD from the University of Athens and has previously held posts at FORTH (Greece) and the Department of Electrical and Electronic Engineering of Imperial College London.

**Uwe Möhring**

Textile Research Institute
Thuringia-Vogtland
Greiz, Germany
u.moehring@titv-greiz.de

Chapter G.73

Dr. Uwe Möhring received the doctorate for metal organic catalysis from the Julius-Maximilians-University Würzburg in 1995. Prior to his appointment as Managing Director of TITV Greiz in 2001, he worked for Degussa Corporation. At the TITV Greiz he brought together a team of 60 interdisciplinary scientists for textile microsystems technology and special surface technologies of textiles. The focus is on medical applications of textiles and the development of textile electrodes and sensor structures as well as special intelligent textiles for health and disease management.

**Wolfgang Müller-Wittig**

Nanyang Technological University (NTU)
Fraunhofer IDM@NTU
Singapore
wolfgang.mueller-wittig@fraunhofer.sg

Chapter F.63

Wolfgang Müller-Wittig is Director of the Project Centre for Interactive Digital Media at Nanyang Technological University. He is also an Adjunct Associate Professor at the NTU School of Computer Engineering. He received his Dr.-Ing. in Computer Science from the Technische Universität Darmstadt, Germany. His research interests include highly interactive 3-D computer graphics for manufacturing, engineering, edutainment, cultural heritage, and biomedical sciences.

Andreas Neudeck

Textile Research Institute
Thuringia-Vogtland
Greiz, Germany
a.neudeck@titv-greiz.de

Chapter G.73

Andreas Neudeck received his Master of Education from the Applied Pedagogical University of Halle, Germany and a PhD in Physical Chemistry from the same University. After his PhD he joined the Leibniz Institute for Solid State and Materials Research Dresden (IFW) for a Habilitation Fellowship of the DFG. During his DFG Fellowship he spent one year at the Université Paris 7. He obtained his Habilitation (DSc) in Physical Chemistry from Dresden University of Technology in 1999. Since 2000 he works at the Textile Research Institute Thuringia-Vogtland (TITV), Germany and is now responsible for the Advanced Research as Representative Head of Research and Development.

Wolfgang R. Nitz

Siemens AG Healthcare Sector
Erlangen, Germany
wolfgang.nitz@siemens.com

Chapter C.23

Wolfgang R. Nitz received his Master degree in Power Electronics from the University of Siegen and holds a Master degree in Experimental Nuclear Physics from the University of Karlsruhe. He received his PhD from the University of Würzburg and is an Assistant Professor for Experimental Radiology at the University of Regensburg. He has been awarded the first Wilhelm-Conrad-Röntgen-Preis in 2001 for his work on vascular interventions under MR guidance. He is currently heading the patent and licensing management of the MR business of the Siemens AG.

Heike Oschatz

Textile Research Institute
Thuringia-Vogtland
Textile Structures and Materials
Greiz, Germany
h.oschatz@titv-greiz.de

Chapter G.73

Heike Oschatz received the diploma in Textile Technology from the University of Applied Sciences Reichenbach, Germany. Since 1990 she has been working at the Textile Research Institute Thuringia-Vogtland (TITV Greiz), Germany, as a scientist in the field of textile materials. She is working as project manager in several national and European projects with focus on textile technology and the development of special woven or knitted textiles for clothing, medicine and technology.

Ernst Pelikan

University Medical Center Freiburg
Hospital Computer Department
Freiburg, Germany
ernst.pelikan@uniklinik-freiburg.de

Chapter F.60

Ernst Pelikan received his Diploma in Physics from the Albert-Ludwigs-University of Freiburg, Germany in 1983. He joined the Hospital Computer Center at the University Medical Center Freiburg in 1984, where he is the Head of the Department of Communications and Networks since 1989. His research interests are in network design, network security, standards-based medical data exchange and telemedicine.

Thomas Peyn

Dräger Medical AG & Co. KG
Department for Respiratory Care
Lübeck, Germany
thomas.peyn@draeger.com

Chapter D.27

Thomas Peyn, electrical engineering technician and training manager, has been with Dräger since February 1996. Firmly convinced that clinical application of sophisticated technology is the basis for enhanced therapeutic success his focus and passion is education and training especially within the field of applied health care technology.

Doris Pommi

Siemens Healthcare
Forchheim, Germany
doris.pommi@siemens.com

Chapter C.21

Doris Pommi is product manager for interventional radiology at Siemens Healthcare in Germany. She has a background as Medical Laboratory Scientist (MTRA) and marketing consultant.

**Milos R. Popovic**

University of Toronto
Rehabilitation Engineering Laboratory,
Institute of Biomaterials and Biomedical
Engineering
Toronto, Ontario, Canada
milos.popovic@utoronto.ca

Chapter D.44

Milos R. Popovic received his PhD in Mechanical Engineering from the University of Toronto, Ontario, Canada in 1996, and the Dipl. Electrical Engineer degree from the University of Belgrade, Yugoslavia in 1990. Dr. Popovic is the Toronto Rehab Chair in Spinal Cord Injury Research. He is also a Professor in the Institute of Biomaterials and Biomedical Engineering at the University of Toronto. His fields of expertise are functional electrical stimulation. His interests are in the areas of neuro-rehabilitation, physiological control systems, assistive technology, and brain machine interfaces.

**Robert S. Pozos**

San Diego State University
Department of Biology
San Diego, CA, USA
bpozos@gmail.com

Chapters B.10, C.22

Dr. Robert Pozos, Professor of Biology at San Diego State University, has had extensive experience studying physiological signals in humans in extreme environments. His expertise is in the area of thermal regulation in hot and cold environments. The importance of the role of peripheral circulation in various environments has been addressed using various technologies specifically near infrared spectroscopy. Utilizing this technology, he has demonstrated that the peripheral circulation has complex controls that respond differentially in different anatomical areas.

Anna Radomska-Botelho Moniz

Imperial College London, South
Kensington Campus
Institute of Biomedical Engineering
London, UK
a.radomska@imperial.ac.uk

Chapter E.56

Anna Radomska is a Research Associate at the Institute of Biomedical Engineering in the Imperial College London. The main fields of her research cover development and applications of chemical sensors and biosensors in clinical and biomedical analysis. She received her PhD with distinction in Analytical Chemistry from Warsaw University, Department of Chemistry in 2004. During her PhD she developed several potentiometric and optical biosensors which were successfully used for monitoring, control and assessment of haemodialysis therapy.

Stanisa Raspopovic

Scuola Superiore Sant Anna
ARTS lab
Pisa, Italy
s.raspopovic@sssup.it

Chapter F.68

Stanisa Raspopovic received his MS degree from the Department of Engineering at the University of Pisa, Italy. He is currently working towards the PhD in Biomedical Robotics at the Scuola Superiore Sant Anna, Pisa. His research interests are in neuroprostheses, neural interfaces in animal and human models, neural modelling, and processing of PNS and CNS signals for understanding neural control.

**Annette Reinhardt**

Klinikum Nürnberg
Institute of Hospital Epidemiology
Nürnberg, Germany
annette.reinhardt@klinikum-nuernberg.de

Chapter A.3

Dr. Annette Reinhardt studied Medicine in Regensburg, Erlangen (Germany) and Winterthur (Switzerland). Since 1993 she has been employed as Doctor of Medicine at the Department of Hospital Hygiene, Clinical Microbiology and Infectious Diseases of the Klinikum Nürnberg, Germany. During her career, Dr. Reinhardt has gathered experience in medical microbiology and healthcare-associated infection surveillance. Her main activity is hospital hygiene with a focus on adapting existing recommendations.

**Cristiano Rizzo**

Micromed S.p.A.
Mogliano Veneto (TV), Italy
cristiano.rizzo@micromed-it.com

Chapter E.52

Cristiano Rizzo received his Master Degree in Electronic Engineering with Biomedical Specialization from the University of Padova, Italy in 1996. Working for Micromed S.p.A since 1987 as a programmer, he moved to the Micromed French office in 1994 for 2 years. Back in 1996 as Project Development Manager he is actually in Marketing and Sales.

Eckhard Roggenkamp

Klinikum Nuremberg
Institute of Hospital Epidemiology
Nürnberg, Germany
*eckhard.
roggenkamp@klinikum-nuernberg.de*

Chapter A.3

Eckhard Roggenkamp earned his Diploma as Engineering at the University of Applied Sciences Lübeck, Germany. Since 1977 he is at the Institute of Hygiene, Microbiology and Infectiology at the Klinikum Nürnberg, Germany. His major tasks are controlling of sterilization processes for medical devices, validation of washer-disinfectors, inspection of ventilation in buildings and rooms of health care, advising the clinic in all technical concerns of hygiene. He is Vice-chairman of the DIN Commission Disinfection Apparatus.

Christopher Rolfes

University of Minnesota
Department of Biomedical Engineering
and Surgery
Minneapolis, MN, USA
rolf0053@umn.edu

Chapter D.43

Christopher Rolfes graduated from St. Olaf College in 2006 with a double major in Physics and Mathematics. After this, he worked for a year as a post-baccalaureate researcher at the National Heart, Lung and Blood Institute in Bethesda, MD. While at the NHLBI, he helped to develop programming for an automated microtome, which is capable of producing three-dimensional reconstructions of mouse hearts with micrometer scale resolution. He is currently a PhD graduate candidate in Biomedical Engineering at the University of Minnesota.

Christian Rotsch

Fraunhofer Institute for Machine Tools
and Forming Technology IWU
Department Adaptronics and Acoustics
Dresden, Germany
christian.rotsch@iwu.fraunhofer.de

Chapter G.73

Christian Rotsch received his Diploma in Physical Techniques with the specialization in Biomedical Engineering from the University of Applied Sciences Zwickau, Germany. Between 2004 and 2009 he worked at the Textile Research Institute Thuringia-Vogtland, Germany, as scientist, project and group leader of the smart textiles group in several national and European projects. Since 2009 he works at the Fraunhofer Institute for Machine Tools and Forming Technology. His field of work is the development of active and adaptronic devices for medical applications.

Georg-Friedemann Rust

Rendoscopy AG
Gauting, Germany
gfr@rendoscopy.de

Chapter F.66

Georg-Friedemann Rust studied Physics and Medicine. His PhD was performed at the DESY, German Electron Synchrotron Radiation Laboratory in Hamburg together with the IMDM, University Hospital Hamburg, Eppendorf. Dr. Rust changed to the Ludwig-Maximilians University, Department of Clinical and Interventional Radiology. During the Research activities he worked in different fields, such as 3-D Visualization and x-ray dosage issues. During his further research activities and established scientific cooperations with the International Atomic and Energy Commission (IAEA) of the UN. He also founded together of the Bavarian Government a spin-off company, named Rendoscopy AG. Dr. Rust is currently working as a radiologist in the General Hospital Bogenhausen, Munich.

Christina Sampogna

University of Cambridge
Newmarket, Suffolk, UK
Christina.Sampogna@cantab.net

Chapter F.67

Christina Sampogna is an international lawyer, policy advisor, and economist whose experience covers government, industry, public sector, non-profit sector, and international organizations. Having completed studies in Economics (BA) and in Law (LL. L, LL.B.), she received her LL.M. from the University of Cambridge and her D.E. A. in European Community Law from the College of Europe, Bruges. Professionally qualified in diverse jurisdictions, Christina has developed expertise in numerous legal domains and industrial sectors, including emerging technologies (life sciences; information and communication technologies), health, international trade, and environment/sustainable development.

Gregor Schaefers

MR:comp GmbH
Gelsenkirchen, Germany
schaefers@mrcomp.com

Chapter C.26

Gregor Schaefers obtained his Dipl.-Ing. (FH) degree in Medical Engineering from the University of Applied Sciences Gelsenkirchen, Germany in 2001. He is co-founder, shareholder and Managing Director of MR:comp GmbH, testing laboratory for MR safety and compatibility. He is a member of DIN, ISO, IEC, ASTM standardization committees working in development and optimization of MR testing methods.

Rolf M. Schlegelmilch

SMT medical GmbH & Co.
Würzburg, Germany
r.schlegelmilch@smt-medical.com

Chapter B.8

Rolf Schlegelmilch has more than 30 years of experience in the medical equipment industry. With a focus on diagnostic applications he specializes in pulmonary function and vascular testing, life style and activity monitoring, as well as anti-aging diagnostics. He earned a degree in Mathematics and Economics from the University of Würzburg and worked in several management functions. He is a founder and Managing Director of SMT medical.

Oliver Scholz

HTW Saarland,
University of Applied Sciences
Saarbrücken, Germany
oliver.scholz@htw-saarland.de

Chapter F.61

Oliver Scholz is currently heading the Bio-telemetry Working Group of Fraunhofer IBMT. His main field of research is biomedical telemetry and bio-monitoring incorporating wireless links for medical implant control plus wireless powering and physiological data acquisition. In recent years, this expertise directed him more and more into communication and powering systems for micro robots.

Frank Schön

Aloka Holding Europe AG
Zug, Switzerland
F.Schoen@aloka-europe.com

Chapter C.17

Frank Schön is Marketing Director of Aloka Holding Europe AG. He studied Medicine, Business and Computer Sciences at the Universities of Mainz and Hagen, Germany. He was educated in Internal Medicine and Cardiology at the University Clinic of Essen. After several years of practicing medicine he started in 1999 with Aloka Ultrasound in Germany. After positions in R&D of Aloka Tokyo, Managing Director of Aloka Germany from 2005 to 2010, he is now responsible for International Marketing in Europe.

Arthur Schultz

Hannover Medical School
EEG Monitoring Research Group
Hannover, Germany
ab.schultz@t-online.de

Chapter E.51

PD Dr. Dr. Arthur Schultz, Anaesthesiologist and Medical Computer Scientists (GMDS), is University Lecturer at Hannover Medical School, Hannover, Germany. He is also Head of the Interdisciplinary EEG Monitoring Research Group at Hannover Medical School/Clinic Region Hannover focusing on the automatic classification of electroencephalograms (EEGs) recorded during anaesthesia and intensive care.

Barbara Schultz

Hannover Medical School
Informatik/Biometrie
Hannover, Germany
ab.schultz@t-online.de

Chapter E.51

PD Dr. Barbara Schultz is a University Teacher at Hannover Medical School, Hannover, Germany, and a Member of the Interdisciplinary EEG Monitoring Research Group at Hannover Medical School. Her main research area is electroencephalography (EEG) in patients in the operating theatre and in the intensive care unit with a focus on automatic classification of the EEG.

Dirk Schulze

Chapter C.20

DDZ Breisgau
Freiburg, Germany
dirk.schulze@ddz-breisgau.de

Dirk Schulze received the PhD degree in Dentistry from Hamburg University in 2007. He has been with University Freiburg until the end of 2009 and is currently working in a private dental imaging center. His research activities are in further processing dental CBCT data, cephalometric analysis and evaluation of radiation exposure due to dental imaging devices.

Wilhelm Schütte

Chapter D.45

Kreiskrankenhaus Gummersbach,
Academic Teaching Hospital of the
University of Cologne
Department of Medical Radiation Physics
Gummersbach, Germany
wilhelm.schuette@kkg-gummersbach.de

After his graduation in Physics (Dipl. Phys.) in 1986, Wilhelm Schütte has been working as a Medical Physicist at the Department of Medical Radiation Physics of Gummersbach Hospital (Academic Teaching Hospital of the University of Cologne). He has published numerous articles in national and international scientific journals. His interest is in dosimetry of high-energy radiation, radiation treatment planning and IMRT.

Danny Schwabe

Chapter G.73

Textile Research Institute
Thuringia-Vogtland
Greiz, Germany
d.schwabe@titv-greiz.de

Danny Schwabe received the Diploma in Textile and Leather-Technology at the University of Applied Science Zwickau (FH Reichenbach), Germany. Since 2002, he is working at the TITV Greiz as a scientific employee in the field of 3-D warp knitting. He investigated several projects dealing with medical textiles such as compression bandages, operating-table covers, heating textiles and hip protection pads.

Sanjiv Sharma

Chapter E.56

Imperial College London, South
Kensington Campus
Institute of Biomedical Engineering
London, UK
sanjiv.sharma@imperial.ac.uk

Sanjiv Sharma is a Research Officer in the Institute of Biomedical Engineering at Imperial College London. His main research areas are micro and submicron fluidic systems, noninvasive and label free detection systems. He did his PhD in Chemistry at the Regional Research Laboratory, Bhopal, India. He has held research positions in France (Institut de Physique Nucléaire d'Orsay and Hospital St. Antoine, Paris) and Germany (Walter Schottky Institut, Technische Universität München).

Erich Siegel

Chapter D.30

Dräger Medical AG & Co. KG
Lübeck, Germany
erich.siegel@draeger.com

Erich Siegel received the Master degree and the PhD degree in Physics both from the University of Karlsruhe, Germany. He was assistant and lecturer at the department of applied physics at the University of Bonn. More than 20 years he is engaged in the field of medical technology at Dräger Medical in Lübeck, Germany, where he now is Training Manager of anaesthesiology.

Florian Solzbacher

Chapters D.40, E.46

University of Utah
Electrical and Computer Engineering
Salt Lake City, UT, USA
florian.solzbacher@utah.edu

Dr. Solzbacher is Director of the Microsystems Laboratory at the University of Utah, Co-Director of the Utah Nanotechnology Institute, President of Blackrock Microsystems and an Associate Professor in Electrical and Computer Engineering with adjunct appointments in Materials Science and Bioengineering. His research focuses on harsh environment microsystems and materials, including implantable, wireless microsystems for biomedical and healthcare applications. Professor Solzbacher received his MSc EE from the Technical University Berlin in 1997 and his PhD from the Technical University Ilmenau in 2003.

Silvia Sterzi

Università Campus Bio-Medico
Physical Medicine and Rehabilitation
Rome, Italy
s.sterzi@unicampus.it

Chapter D.42

Silvia Sterzi, MD, is Associate Professor of Physical Medicine and Rehabilitation at THE Campus Bio-Medico University in Rome, Italy, where she serves as the Head of the Department of Rehabilitation and Director of Postgraduate School of Physical Medicine and Rehabilitation. Dr. Sterzi is a Member of the European Board of Physical Medicine and Rehabilitation.

Wilfried Storz

Gebrüder Martin GmbH & Co. KG
Tuttlingen, Germany
wilfried.storz@klsmartin.com

Chapter G.72

Wilfried Storz holds the position of Officer with general commercial power of attorney in the Central Marketing Department of Gebrüder Martin GmbH. His special areas of responsibility are surgical instruments for various medical disciplines and sterilization containers. Besides he has been an active member of the DIN NA 027 Precision Mechanics and Optics Standards Committee (NAFuO), which is part of the Surgical Instruments Working Committee (NA 027-02-01 AA).

Dirk Sunderbrink

Siemens AG – Healthcare Sector
Imaging and Therapy Department
Forchheim, Germany
dirk.sunderbrink@siemens.com

Chapter F.65

Dirk Sunderbrink received a degree in Medical Health Engineering from the University of Applied Sciences Hamburg and in Industrial Engineering from the University of Applied Sciences Bielefeld, Germany. He joined Siemens in 1995 and served for more than 10 years in sales and business management for radiological information systems. Currently he holds the position of Global Marketing Manager for cardiology in angiography business unit. Prior to joining Siemens he was product manager for MRI and CT of Toshiba Medical Systems Germany.

Hajo Tanck

Mednovo Medical Software Solutions
GmbH
Berlin, Germany
info@mednovo.de

Chapter F.57

Hajo Tanck earned his degree in Business Informatics from the University of Applied Sciences Flensburg, Germany. His professional career is closely connected to the healthcare sector. Mr. Tanck works for Mednovo Medical Software Solutions GmbH in the sales department and project management and is responsible for the support of complex projects.

Prashant Tathireddy

University of Utah
Electrical and Computer Engineering
Salt Lake City, UT, USA
p.tathireddy@utah.edu

Chapter D.40

Prashant Tathireddy received the PhD degree in Chemical Engineering from the University of Utah and has been with the Department of Electrical and Computer since September 2005. He received Fraunhofer's 'Outstanding Research Scientist Fellowship' Award in 2007 and was posted as a guest scientist for over a year at the Fraunhofer Institute for Biomedical Engineering (IBMT), St. Ingbert, Germany. Professor Tathireddy's current research focuses on design, fabrication process development and testing of chronically implantable medical microdevices.

Rachel Toomey

University of Dundee
Institute for Medical Science and
Technology
Dundee, UK
r.toomey@dundee.ac.uk

Chapter C.25

Rachel holds a BSc (Hons.) in Radiography and a PhD in the area of medical image display from University College Dublin. She is currently employed at the Institute for Medical Science and Technology, University of Dundee. Her research interests include image perception, development of training models and integration of imaging modalities in the operating theatre.

Iasonas F. Triantis

Chapter E.56

Sensors Systems and Circuits Research Group
Department of Electronic and Electrical Engineering
London, UK
i.triantis@ee.ucl.ac.uk

Iasonas Triantis is a Senior Researcher in microelectronics for electrical impedance tomography for cancer imaging at the Electrical and Electronic Engineering Department University College London. During his PhD at the same department, and later as a Research Associate at Imperial College London, he designed neural sensing and stimulation chips and researched alternative neural interfacing methods. He also managed a neural interfacing group and a laboratory.

Jakub Trzebinski

Chapter E.56

Imperial College London, South Kensington Campus
Institute of Biomedical Engineering
London, UK
jakub.trzebinski09@imperial.ac.uk

Jakub Trzebinski received his Bachelor degree (Honours) from the National University of Ireland, Galway and currently is a PhD student at Brunel University and Imperial College London working on electrochemical biosensors, in particular glucose sensors. His research area includes understanding and favourably modifying biosensor-tissue interactions.

Friedrich Ueberle

Chapter D.33

Hamburg University of Applied Sciences
Department of Life Sciences/Biomedical Technology
Hamburg, Germany
friedrich.ueberle@haw-hamburg.de

Friedrich Ueberle received his Diploma in Electrical Engineering from the University of Karlsruhe, Germany. During his PhD he was involved in research for piezoelectric lithotripters. Afterwards, he continued shock wave research and application for 14 years in industry. Since 2002, he is a Professor for Biomedical Device Technology at the Hamburg University of Applied Sciences. His research focuses on ultrasound, shockwaves, medical imaging, and sensors.

Hans-Peter Uhlig

Chapter A.4

Dresden, Germany
cu-uhlig@t-online.de

Hans-Peter Uhlig works as a Consulting Engineer in Dresden, Germany specializing in electrical installations for medical facilities. He is member of the Saxon Chamber of Engineers. Since more than 10 years he contributes to standardization of electrical installations for medical facilities within the German Commission for Electrical (DKE), Electronic and Information Technologies of DIN and VDE. He has authored and co-authored one specialist book and several other publications.

Jörg Vienken

Chapter D.31

Fresenius Medical Care
Bad Homburg, Germany
joerg.vienken@fmc-ag.com

Joerg Vienken has a degree in Chemical Engineering from the Technical University of Darmstadt and a Doctoral Degree in Biophysics and Engineering from the Technical University of Aachen (RWTH), Germany. Since 25 years he is working in leading positions in the medical device industry. He currently serves as Vice President BioSciences at Fresenius Medical Care in Bad Homburg, Germany. He is member of the Editorial Board of several scientific journals dedicated to biomaterials, artificial organs and medical device technology.

Udo Voges

Chapter G.70

Karlsruher Institut für Technologie
Institut für Angewandte Informatik
Eggenstein-Leopoldshafen, Germany
udo.voges@kit.edu

Udo Voges received his Diploma in Mathematics from the Ludwig-Maximilians-Universität in Munich, Germany and his PhD degree in Computer Science from the Universität Karlsruhe, Germany. He is Senior Scientist at the Karlsruher Institut für Technologie (KIT), Institut für Angewandte Informatik. His research interests are in medical engineering, systems engineering and system safety.

Birgit Wacker

Philips Healthcare
Böblingen, Germany
birgit.wacker@philips.com

Chapter E.53

Birgit Wacker received the degree in Informatics from Hochschule Furtwangen University, Germany in 1988. She started her career at Hewlett Packard as software development engineer for clinical information systems and is now working for Philips Healthcare in international marketing of healthcare IT solutions.

Golam Abu Zakaria

Hospital of the University of Cologne
Department of Medical Radiation Physics
Gummersbach, Germany
zakaria@khh-gummersbach.de

Chapter D.45

Golam Abu Zakaria received his PhD in Medical Physics from Heidelberg University. He currently is chairman of the Department of Medical Radiation Physics at Gummersbach Hospital (University of Cologne) and Professor of Medical Physics/Biomedical Engineering at Gono University, Bangladesh. He has published more than 65 journal and conference papers.

Christian Zapf

Siemens AG – Healthcare Sector
Imaging and Therapy – SYNGO
Erlangen, Germany
christian.zapf@siemens.com

Chapter F.65

Christian Zapf received his Master degree in Computer Science from Clemson University, SC, USA. He joined Siemens Healthcare in 1993 and his primary focus has been on radiology and cardiology IT (RIS, CVIS), image management solutions (PACS), and the magnetic resonance business. As Vice President Business Strategy for the SYNGO business unit of Siemens Healthcare, he is currently responsible for the strategy of the radiology and cardiology IT business of Siemens Healthcare.

Frank Zgoda

Laser- und Medizin-Technologie GmbH
Berlin, Germany
f.zgoda@LMTB.de

Chapter D.29

After studying chemistry and physics at the Freie Universität Berlin, Germany, Frank Zgoda joined the Laser- und Medizin-Technologie GmbH Berlin in 1989. He is consulting manufacturers of innovative medical devices in the fields of laser safety and medical device safety and develops and delivers laser safety courses for physicians, LSOs, and supervisors. He is a member of the German standards committee on medical lasers.

Loredana Zollo

Università Campus Bio-Medico di Roma
Laboratory of Biomedical Robotics and
Biomicrosystems
Rome, Italy
l.zollo@unicampus.it

Chapter D.42

Loredana Zollo received her PhD in Bioengineering in 2004. In 2004, she entered as post-doc fellow at Università Campus Bio-Medico di Roma and joined the Laboratory of Biomedical Robotics and Biomicrosystems. In 2008 she became Assistant Professor in Bioengineering. Her research interests are in the fields of rehabilitation and neuro-robotics. She is co-chair of the IEEE-RAS TC on Rehabilitation and Assistive Robotics.
