Abstract. We present the w constraint combinator that models while loops in Constraint Programming. Embedded in a finite domain constraint solver, it allows programmers to develop non-trivial arithmetical relations using loops, exactly as in an imperative language style. The deduction capabilities of this combinator come from abstract interpretation over the polyhedra abstract domain. This combinator has already demonstrated its utility in constraint-based verification and we argue that it also facilitates the rapid prototyping of arithmetic constraints (e.g. power, gcd or sum).

1 Introduction

A strength of Constraint Programming is to allow users to implement their own constraints. CP offers many tools to develop new constraints. Examples include the global constraint programming interface of SICStus Prolog *clp(fd)* [5], the ILOG concert technology, iterators of the GECODE system [17] or the Constraint Handling Rules [8]. In many cases, the programmer must provide propagators or filtering algorithms for its new constraints, which is often a tedious task. Recently, Beldiceanu et al. have proposed to base the design of filtering algorithms on automaton [4] or graph description [3], which are convenient ways of describing global constraints. It has been pointed out that the natural extension of these works would be to get closer to imperative programming languages [4].

In this paper, we suggest to use the generic w constraint combinator to model arithmetical relations between integer variables. This combinator provides a mechanism for prototyping new constraints without having to worry about any filtering algorithm. Its originality is to model iterative computations: it brings while loops into constraint programming following what was done for logic programming [16]. Originally, the w combinator has been introduced in [9] in the context of program testing but it was not deductive enough to be used in a more general context. In this paper, we base the generic filtering algorithm associated to this combinator on case-based reasoning and Abstract Interpretation over the polyhedra abstract domain. Thanks to these two mechanisms, w performs non-trivial deductions during constraint propagation. In many cases, this combinator

can be useful for prototyping new constraints without much effort. Note that we do not expect the propagation algorithms generated for these new constraints to always be competitive with hand-written propagators.

We illustrate the w combinator on a relation that models $y = x^n$. Note that writing a program that computes x^n is trivial whereas building finite domain propagators for $y = x^n$ is not an easy task for a non-expert user of CP. Figure 1 shows an imperative program (in C syntax) that implements the computation of x^n, along with the corresponding constraint model that exploits the w combinator (in CLP(FD) syntax). In these programs, we suppose that N is positive although this is not a requirement of our approach.

```
power(X, N){              power(X, N, Y) : −
    Y = 1;                    w([X, 1, N], [Xin, Yin, Nin], [Xin, Yout, Nout], [_, Y, _],
    while(N ≥ 1){             Nin # >= 1,
        Y = Y ∗ X;            [Yout # = Yin ∗ Xin,
        N = N − 1};              Nout # = Nin − 1]).
    return Y; }
```

Fig. 1. An imperative program for $y = x^n$ and a constraint model

It is worth noticing that the w combinator is implemented as a global constraint. As any other constraint, it will be awoken as soon as X, N or Y have their domain pruned. Moreover, thanks to its filtering algorithm, it can prune the domains of these variables. The following request shows an example where w performs remarkably well on pruning the domains of X, Y and N.

```
| ?- X in 8..12, Y in 900..1100, N in 0..10, power(X,N,Y).

N = 3, X = 10, Y = 1000
```

The w combinator has been implemented with the *clp(fd)* and *clpq* libraries of SICStus prolog. The above computation requires 20ms of CPU time on an Intel Pentium M 2GHz with 1 Gb of RAM.

Contributions. In this paper, we detail the pruning capabilities of the w combinator. We describe its filtering algorithm based on case-based reasoning and fixpoint computations over polyhedra. The keypoint of our approach is to re-interpret every constraint in the polyhedra abstract domain by using Linear Relaxation techniques. We provide a general widening algorithm to guarantee termination of the algorithm. The benefit of the w combinator is illustrated on several examples that model non-trivial arithmetical relations.

Organization. Section 2 describes the syntax and semantics of the w operator. Examples using the w operator are presented. Section 3 details the filtering algorithm associated to the combinator. It points out that approximation is crucial to obtain interesting deductions. Section 4 gives some background on abstract interpretation and linear relaxation. Section 5 shows how we integrate abstract interpretation over polyhedra into the filtering algorithm. Section 6 discusses some related work. Section 7 concludes.

2   Presentation of the *w* Constraint Combinator

This section describes the syntax and the semantics of the *w* combinator. Some examples enlight how the operator can be used to define simple arithmetical constraints.

2.1   Syntax

Figure 2 gives the syntax of the finite domain constraint language where the *w* operator is embedded.

W	$::= \mathbf{w}(Lvar, Lvar, Lvar, Lvar, Arith\_Constr, LConstr)$
If	$::= \mathbf{if}(Lvar, Arith\_Constr, LConstr, LConstr)$
$Lvar$	$::= \text{var } Lvar \mid \varepsilon$
$LConstr$	$::= Constr \; LConstr \mid \varepsilon$
$Constr$	$::= \text{var } \mathbf{in} \text{ int..int} \mid Arith\_Constr \mid W \mid If$
$Arith\_Constr$	$::= \text{var } Op \; Expr$
Op	$::= < \mid \leq \mid > \mid \geq \mid \neq \mid =$
$Expr$	$::= Expr + Expr \mid Expr - Expr \mid Expr * Expr \mid \text{var} \mid \text{int}$

Fig. 2. syntax of the *w* operator

As shown on the figure, a *w* operator takes as parameters four lists of variables, an arithmetic constraint and a list of constraints. Let us call these parameters $Init, In, Out, End, Cond$ and Do. The $Init$ list contains logical variables representing the initial value of the variables involved in the loop. In variables are the values at iteration n. Out variables are the values at iteration $n + 1$. End variables are the values when the loop is exited. Note that $Init$ and End variables are logical variables that can be constrained by other constraints. On the contrary, In and Out are local to the *w* combinator and do not concretely exist in the constraint store. $Cond$ is the constraint corresponding to the loop condition whereas Do is the list of constraints corresponding to the loop body. These constraints are such that $vars(Cond) \in In$ and $vars(Do) \in In \cup Out$.

Line 2 of Figure 2 presents an *if* combinator. The parameter of type $Arith\_Constr$ is the condition of the conditional structure. The two parameters of type $LConstr$ are the "then" and "else" parts of the structure. $Lvar$ is the list of variables that appear in the condition or in one of the two branches. We do not further describe this operator to focus on the *w* operator.

The rest of the language is a simple finite domain constraint programming language with only integer variables and arithmetic constraints.

2.2   Semantics

The solutions of a *w* constraint is a pair of variable lists $(Init, End)$ such that the corresponding imperative loop with input values $Init$ terminates in a state where final values are equal to End. When the loop embedded in the *w* combinator never terminates, the combinator has no solution and should fail. This point is discussed in the next section.

2.3   First Example: Sum

Constraint sum(S,I), presented on Figure 3, constrains S to be equal to the sum of the integers between 1 and I: $S = \sum_{i=1}^{n} i$

```
sum(I){                          sum(S,I) :-
   S = 0;                           I > 0,
   while(I > 0){                    w([0,I],[In,Nin],[Out,Nout],[S,_],
       S = S + I;                       Nin > 0,
       I = I - 1;                       [Out = In + Nin,
   }                                    Nout = Nin - 1]).
   return S;
```

Fig. 3. The sum constraint derived from the imperative code

The factorial constraint can be obtained by substituting the line
Out = In + Nin by Out = In * Nin and replacing the initial value 0 by 1. Thanks to the w combinator, sum and factorial are easy to program as far as one is familiar with imperative programming. Note that translating an imperative function into a w operator can be done automatically.

2.4   Second Example: Greatest Common Divisor (gcd)

The second example is more complicated as it uses a conditional statement in the body of the loop. The constraint gcd(X,Y,Z) presented on Figure 4 is derived form the Euclidian algorithm. gcd(X,Y,Z) is true iff Z is the greatest common divisor of X and Y.

```
gcd(X,Y){
   while(X > 0){
       if(X < Y){              gcd(X,Y,Z) :-
           At = Y;                 w([X,Y],[Xin,Yin],[Xout,Yout],[_,Z],
           Bt = X;                     Xin > 0,
       }else{                          [if([At,Bt,Xin,Yin],
           At = X;                         Xin < Yin,
           Bt = Y;                         [At = Yin, Bt = Xin],
       }                                   [At = Xin, Bt = Yin]),
       X = At - Bt;                    Xout = At - Bt,
       Y = Bt;                         Yout = Bt]).
   }
   return Y;
```

Fig. 4. The gcd constraint

3   The Filtering Algorithm

In this section we present the filtering algorithm associated to the w operator introduced in the previous section. The first idea of this algorithm is derived from the following remark. After n iterations in the loop, either the condition is false and the loop is over, or the condition is true and the statements of the body are executed. Consequently, the filtering algorithm detailed on Figure 5 is basically a constructive disjunction algorithm. The second idea of the algorithm is to use abstract interpretation over polyhedra to over-approximate the behaviour of the loop. Function w^∞ is in charge of the computation of the over-approximation. It will be fully detailed in Section 5.3.

The filtering algorithm takes as input a constraint store $((X, C, B)$ where X is a set of variables, C a set of constraints and B a set of variable domains), the constraint to be inspected ($w(Init, In, Out, End, Cond, Do)$) and returns a new constraint store where information has been deduced from the w constraint. $\tilde{X}$ is the set of variables X extended with the lists of variables In and Out. $\tilde{B}$ is the set of variable domains B extended in the same way.

Input:
    A constraint, $w(Init, In, Out, End, Cond, Do)$
    A constraint store, (X, C, B)
Output:
    An updated constraint store

w_filtering
1 $(X_{exit}, C_{exit}, B_{exit}) := propagate(\tilde{X},\ C \wedge Init = In = Out = End \wedge \neg Cond,\ \tilde{B})$
2 **if** $\emptyset \in B_{exit}$
3   **return** $(\tilde{X}, C \wedge Init = In \wedge Cond \wedge Do\ \wedge$
4         $w(Out, FreshIn, FreshOut, End, Cond', Do'), \tilde{B})$
5 $(X_1, C_1, B_1) := propagate(\tilde{X}, C \wedge Init = In \wedge Cond \wedge Do, \tilde{B})$
6 $(X_{loop}, C_{loop}, B_{loop}) := w^\infty(Out, FreshIn, FreshOut, End, Cond', Do', (X_1, C_1, B_1))$
7 **if** $\emptyset \in B_{loop}$
8   **return** $(\tilde{X}, C \wedge Init = In = Out = End \wedge \neg Cond, \tilde{B})$
9 $(X', C', B') := join((X_{exit}, C_{exit}, B_{exit}), (X_{loop}, C_{loop}, B_{loop}))_{Init, End}$
10 **return** $(X', C' \wedge w(Init, In, Out, End, Cond, Do), B')$

Fig. 5. The filtering algorithm of w

Line 1 posts constraints corresponding to the immediate termination of the loop and launches a propagation step on the new constraint store. As the loop terminates, the variable lists $Init, In, Out$ and End are all equal and the condition is false ($\neg Cond$). If the propagation results in a store where one variable has an empty domain (line 2), then the loop must be entered. Thus, the condition of the loop must be true and the body of the loop is executed: constraints $Cond$ and Do are posted (line 3). A new w constraint is posted (line 4), where the initial variables are the variables Out computed at this iteration, In and Out are replaced by new fresh variables ($FreshIn$ and $FreshOut$) and End variables

remain the same. $Cond'$ and Do' are the constraints $Cond$ and Do where variable names In and Out have been substituted by $FreshIn$ and $FreshOut$. The initial w constraint is solved.

Line 5 posts constraints corresponding to the fact that the loop iterates one more time ($Cond$ and Do) and line 6 computes an over approximation of the rest of the iterations via the w^∞ function. If the resulting store is inconsistent (line 7), then the loop must terminate immediately (line 8). Once again, the w constraint is solved.

When none of the two propagation steps has led to empty domains, the stores computed in each case are joined (line 9). The $Init$ and End indices mean that the join is only done for the variables from these two lists. After the join, the w constraint is suspended and put into the constraint store (line 10).

We illustrate the filtering algorithm on the `power` example presented on Figure 1 and the following request:
`X in 8..12, N in 0..10, Y in 10..14, power(X,N,Y).`

At line 1, posted constraints are:
`Xin = X, Nin = N, Yin = 1, Y = Yin, Nin < 1.` This constraint store is inconsistent with the domain of `Y`. Thus, we deduce that the loop must be entered at least once. The condition constraint and loop body constraints are posted (we omit the constraints $Init = In$):
`N >= 1, Yout = 1*X, Xout = X, Nout = N-1` and another w combinator is posted:

```
w([Xout,Yout,Nout],[Xin',Yin',Nin'],[Xout',Yout',Nout'],[_,Y,_],
  Nin'>= 1,[Yout' = Yin'*Xin', Xout' = Xin', Nout' = Nin'-1]).
```

Again, line 1 of the algorithm posts the constraints `Y = Yout, Nout < 1.` This time, the store is not inconsistent. Line 5 posts the constraints
`Nout >= 1, Yout' = Yout*X, Xout' = X, Nout' = Nout - 1,` which reduces domains to `Nout in 1..9, Yout' in 64..144, Xout' in 8..12.` On line 6,
w^∞`([Xout',Yout',Nout'],FreshIn,FreshOut,[_,Y,_],Cond,Do,Store)`
is used to infer `Y >= 64.` `Store` denotes the current constraint store. This is a very important deduction as it makes the constraint store inconsistent with `Y in 10..14.` So `Nout < 1,Y = X` is posted and the final domains are
`N in 1..1, X in 10..12, Y in 10..12.` This example points out that approximating the behaviour of the loop with function w^∞ is crucial to deduce information.

On the examples of sections 2.3 and 2.4 some interesting deductions are done. For the *sum* example, when S is instantiated the value of I is computed. If no value exist, the filtering algorithm fails. Deductions are done even with partial information: `sum(S,I),` `S in 50..60` leads to $S = 55, I = 10$.

On the request `gcd(X,Y,Z),` `X in 1..10, Y in 10..20, Z in 1..1000,` the filtering algorithm reduces the bounds of Z to 1..10. Again, this deduction is done thanks to the w^∞ function, which infers the relations $Z \leq X$ and $Z \leq Y$. If we add other constraints, which would be the case in a problem that would use the *gcd* constraint, we obtain more interesting deductions. For example, if we add the constraint $X = 2 * Y$, then the filtering algorithm deduces that Z is equal to

Y. On each of the above examples, the required computation time is not greater than 30 ms.

Another important point is that approximating loops also allows the filtering algorithm to fail instead of non terminating in some cases. Consider this very simple example that infinitely loops if X is lower than 10.

```
loop(X,Xn) :-
   w([X],[Xin],[Xout],[Xn],
        X < 10,
        [Xout = Xin])
```

Suppose that we post the following request, `X < 0, loop(X,Xn)`, and apply the case reasoning. As we can always prove that the loop must be unfolded, the algorithm does not terminate. However, the filtering algorithm can be extended to address this problem. The idea is to compute an approximation of the loop after a given number of iterations instead of unfolding more and more the loop. On the `loop` example, this extension performs well. Indeed the approximation infers `Xn < 0`, which suffices to show that the condition will never be satisfied and thus the filtering algorithm fails. If the approximation cannot be used to prove non-termination, then the algorithm returns the approximation or continue iterating, depending on what is most valuable for the user: having a sound approximation of the loop or iterating hoping that it will stop.

4   Background

This Section gives some background on abstract interpretation. It first presents the general framework. Then, polyhedra abstract domain is presented. Finally, the notion of linear relaxation is detailed.

4.1   Abstract Interpretation

Abstract Interpretation is a framework introduced in [6] for inferring program properties. Intuitively, this technique consists in executing a program with abstract values instead of concrete values. The abstractions used are such that the abstract result is a sound approximation of the concrete result. Abstract interpretation is based upon the following theory.

A lattice $\langle L, \sqsubseteq, \sqcap, \sqcup \rangle$ is complete iff each subset of L has a greatest lower bound and a least upper bound. Every complete lattice has a least element $\bot$ and a greatest element $\top$. An ascending chain $p_1 \sqsubseteq p_2 \sqsubseteq \ldots$ is a potentially infinite sequence of ordered elements of L. A chain eventually stabilizes iff there is an i such that $p_j = p_i$ for all $j \geq i$. A lattice satisfies the ascending chain condition if every infinite ascending chain eventually stabilizes. A function $f : L \to L$ is monotone if $p_1 \sqsubseteq p_2$ implies $f(p_1) \sqsubseteq f(p_2)$. A fixed point of f is an element p such that $f(p) = p$. In a lattice satisfying ascending chain condition, the least fixed point $lfp(f)$ can be computed iteratively: $lfp(f) = \bigsqcup_{i \geq 0} f^i(\bot)$.

The idea of abstract interpretation is to consider program properties at each program point as elements of a lattice. The relations between the program properties at different locations are expressed by functions on the lattice. Finally, computing the program properties consists in finding the least fixed point of a set of functions.

Generally, interesting program properties at a given program point would be expressed as elements of the lattice $\langle \mathcal{P}(\mathbb{N}), \subseteq, \cap, \cup \rangle$ (if variables have their values in $\mathbb{N}$). However, computing on this lattice is not decidable in the general case and the lattice does not satisfy the ascending chain condition. This problem often appears as soon as program properties to be inferred are not trivial. This means that the fixed points must be approximated. There are two ways for approximating fixed points. A static approach consists in constructing a so-called abstract lattice $\langle M, \sqsubseteq_M, \sqcap_M, \sqcup_M \rangle$ with a Galois connection $\langle \alpha, \gamma \rangle$ from L to M. $\alpha : L \to M$ and $\gamma : M \to L$ are respectively an abstraction and concretization function such that $\forall l \in L, l \sqsubseteq \gamma(\alpha(l))$ and $\forall m \in M, m \sqsubseteq_M \alpha(\gamma(m))$. A Galois connection ensures that fixed points in L can be soundly approximated by computing in M. A dynamic approximation consists in designing a so-called widening operator (noted ∇) to extrapolate the limits of chains that do not stabilize.

4.2   Polyhedra Abstract Domain

One of the most used instanciation of abstract interpretation is the interpretation over the polyhedra abstract domain, introduced in [7]. On this domain, the set of possible values of some variables is abstracted by a set of linear constraints. The solutions of the set of linear constraints define a polyhedron. Each element of the concrete set of values is a point in the polyhedron. In this abstract domain, the join operator of two polyhedra is the convex hull. Indeed, the smallest polyhedron enclosing two polyhedra is the convex hull of these two polyhedra. However, computing the convex hull of two polyhedra defined by a set of linear constraints requires an exponential time in the general case.

Recent work suggest to use a join operator that over-approximates the convex hull [15]. Figure 6 shows two polyhedra with their convex hull and weak join.

Intuitively, the weak join of two polyhedra is computed in three steps. Enlarge the first polyhedron without changing the slope of the lines until it encloses the second polyhedron. Enlarge the second polyhedron in the same way. Do the intersection of these two new polyhedra.

In many works using abstract interpretation on polyhedra, the standard widening is used. The standard widening operator over polyhedra is computed as follows: if P and Q are two polyhedra such that $P \sqsubseteq Q$. Then, the widening $P \nabla Q$
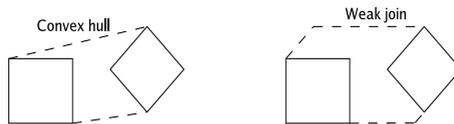

Fig. 6. Convex Hull vs Weak Join

is obtained by removing from P all constraints that are not entailed in Q. This widening is efficient but not very accurate. More accurate widening operators are given in [1].

4.3   Linear Relaxation of Constraints

Using polyhedra abstract interpretation requires us to interpret non linear constraints on the domain of polyhedra. Existing techniques aim at approximating non linear constraints with linear constraints. In our context, the only sources of non linearity are multiplications, strict inequalities and disequalities. These constraints can be linearized as follows:

Multiplications. Let $\underline{X}$ and $\overline{X}$ be the lower and upper bounds of variable X. A multiplication $Z = X * Y$ can be approximated by the conjunction of inequalities [12]:

$$(X - \underline{X})(Y - \underline{Y}) \geq 0 \wedge (X - \underline{X})(\overline{Y} - Y) \geq 0$$
$$\wedge (\overline{X} - X)(Y - \underline{Y}) \geq 0 \wedge (\overline{X} - X)(\overline{Y} - Y) \geq 0$$

This constraint is linear as the product $X * Y$ can be replaced by Z. Fig.7 shows a slice of the relaxation where $Z = 1$. The rectangle corresponds to the bounding box of variables X, Y, the dashed curve represents exactly $X * Y = 1$, while the four solid lines correspond to the four parts of the inequality.
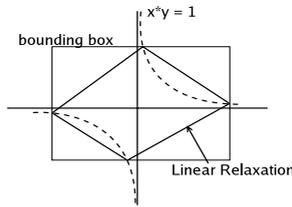

Fig. 7. Relaxation of the multiplication constraint

Strict inequalities and disequalities. Strict inequalities $X < Var$ (resp. $X > Var$) can be rewritten without approximation into $X \leq Var - 1$ (resp. $X \geq Var + 1$), as variables are integers. Disequalities are considered as disjunctions of inequalities. For example, $X \neq Y$ is rewritten into $X =< Y - 1 \vee X >= Y + 1$. Adding the bounds constraints on X and Y and computing the convex hull of the two disjuncts leads to an interesting set of constraints. For example, if X and Y are both in 0..10, the relaxation of $X \neq Y$ is $X + Y \geq 1 \wedge X + Y \leq 19$.

5   Using Abstraction in the Filtering Algorithm of w

In this section, we detail how abstract interpretation is integrated in the w filtering algorithm. Firstly, we show that solutions of w can be computed with a fixed point computation. Secondly, we explain how abstract interpretation over polyhedra allows us to compute an abstraction of these solutions. Finally, the implementation of the w^∞ function is presented.

5.1   Solutions of w as the Result of a Fixed Point Computation

Our problem is to compute the set of solutions of a w constraint:

$$Z = \{((x_1, \ldots, x_n), (x_1^f, \ldots, x_n^f)) \mid$$
$$w((x_1, \ldots, x_n), In, Out, (x_1^f, \ldots, x_n^f), Cond, Do)\}$$

Let us call S_i the possible values of the loop variables after i iterations in a loop. When $i = 0$ possible variables values are the values that satisfy the domain constraint of $Init$ variables. We call S_{init} this set of values. Thus $S_0 = S_{init}$. Let us call T the following set:

$$T = \{((x_1, \ldots, x_n), (x_1', \ldots, x_n')) \mid (x_1, \ldots, x_n) \in S_{init} \wedge \exists i (x_1', \ldots, x_n') \in S_i\}$$

T is a set of pairs of lists of values (l, m) such that initializing variables of the loops with values l and iterating the loop a finite number of times produce the values m. The following relation holds

$$Z = \{(Init, End) \mid (Init, End) \in T \wedge End \in sol(\neg Cond)\}$$

where $sol(C)$ denotes the set of solutions of a constraint C. The previous formula expresses that the solutions of the w constraint are the pairs of lists of values (l, m) such that initializing variables of the loops with values l and iterating the loop a finite number of times leads to some values m that violate the loop condition.

In fact, T is the least fixed point of the following equation:

$$T^{k+1} = T^k \cup \{(Init, Y) \mid (Init, X) \in T^k \wedge (X, Y) \in sol(Cond \wedge Do)\}) \quad (1)$$
$$T^0 = \{(Init, Init) \mid Init \in S_{init}\} \quad (2)$$

$Cond$ and Do are supposed to involve only In and Out variables. Thus, composing T^k and $sol(Cond \wedge Do)$ is possible as they both are relations between two lists of variables of length n.

Following the principles of abstract interpretation this fixed point can be computed by iterating Equation 1 starting from the set T^0 of Equation 2.

For the simple constraint: w([X],[In],[Out],[Y],In < 2,[Out = In+1]) and with the initial domain X in 0..3, the fixed point computation proceeds as follows.

$$T^0 = \{(0,0), (1,1), (2,2), (3,3)\}$$
$$T^1 = \{(0,1), (1,2)\} \cup T^0$$
$$= \{(0,0), (0,1), (1,1), (1,2), (2,2), (3,3)\}$$
$$T^2 = \{(0,1), (0,2), (1,2)\} \cup T^1$$
$$= \{(0,0), (0,1), (0,2), (1,1), (1,2), (2,2), (3,3)\}$$
$$T^3 = T^2$$

Consequently, the solutions of the w constraint are given by

$$Z = \{(X,Y) \mid (X,Y) \in T^3 \wedge Y \in sol(In \geq 2)\}$$
$$= \{(0,2), (1,2), (2,2), (3,3)\}$$

Although easy to do on the example, iterating the fixed point equation is unde-cidable because Do can contain others w constraints. Thus, Z is not computable in the general case.

5.2 Abstracting the Fixed Point Equations

We compute an approximation of T using the polyhedra abstract domain. Let P be a polyhedron that over-approximates T, which means that all elements of T are points of the polyhedron P. Each list of values in the pairs defining T has a length n thus P involves $2n$ variables. We represent P by the conjunction of linear equations that define the polyhedron.

The fixed point equations become:

$$P^{k+1}(Init, Out) = P^k \sqcup (P^k(Init, In) \wedge Relax(Cond \wedge Do))_{Init, Out} \quad (3)$$
$$P^0(Init, Out) = \alpha(S_{init}) \wedge Init = Out \quad (4)$$

Compared to equations 1 and 2, the computation of the set of solutions of constraint C is replaced by the computation of a relaxation of the constraint C. $Relax$ is a function that computes linear relaxations of a set of constraints using the relaxations presented in Section 4.3. P_{L_1, L_2} denotes the projection of the linear constraints P over the set of variables in L_1 and L_2. Projecting linear constraints on a set of variables S consists in eliminating all variables not belonging to S. Lists equality $L = M$ is a shortcut for $\forall i \in [1, n] L[i] = M[i]$, where n is the length of the lists and $L[i]$ is the ith element of L. $P_1 \sqcup P_2$ denotes the weak join of polyhedron P_1 and P_2 presented in Section 4.2.

In Equation 4, S_{init} is abstracted with the α function. This function com-putes a relaxation of the whole constraint store and projects the result on $Init$ variables.

An approximation of the set of solutions of a constraint w is given by

$$Q(Init, In) = P(Init, In) \wedge Relax(\neg Cond) \quad (5)$$

We detail the abstract fixed point computation on the same example as in the previous section. As the constraints $Cond$ and Do are almost linear their relaxation is trivial: $Relax(Cond \wedge Do) = X_{in} \leq 1, X_{out} = X_{in} + 1$. X_{in} is only constrained by its domain, thus $\alpha(S_{init}) = X_{in} \geq 0 \wedge X_{in} \leq 3$. The fixed point is computed as follows

$$P^0(X_{in}, X_{out}) = X_{in} \geq 0 \wedge X_{in} \leq 3 \wedge X_{in} = X_{out}$$
$$P^1(X_{in}, X_{out}) = (P^0(X_{in}, X_0) \wedge X_0 \leq 1 \wedge X_{out} = X_0 + 1)_{X_{in}, X_{out}}$$
$$\sqcup P^0(X_{in}, X_{out})$$
$$= (X_{in} \geq 0 \wedge X_{in} \leq 1 \wedge X_{out} = X_{in} + 1) \sqcup P^0(X_{in}, X_{out})$$
$$= X_{in} \geq 0 \wedge X_{in} \leq 3 \wedge X_{out} \leq X_{in} + 1 \wedge X_{out} \geq X_{in}$$

$$P^2(X_{in}, X_{out}) = (P^1(X_{in}, X_1) \wedge X_1 \leq 1 \wedge X_{out} = X_1 + 1)_{X_{in}, X_{out}}$$
$$\sqcup P^1(X_{in}, X_{out})$$
$$= (X_{in} \geq 0 \wedge X_{in} \leq 3 \wedge X_{in} \leq X_{out} - 1) \sqcup P^1(X_{in}, X_{out})$$
$$= X_{in} \geq 0 \wedge X_{in} \leq 3 \wedge X_{out} \leq X_{in} + 2 \wedge X_{out} \geq X_{in} \wedge X_{out} \leq 4$$
$$P^3(X_{in}, X_{out}) = (P_2(X_{in}, X_2) \wedge X_2 \leq 1 \wedge X_{out} = X_2 + 1)_{X_{in}, X_{out}}$$
$$\sqcup P^2(X_{in}, X_{out})$$
$$= (X_{in} \geq 0 \wedge X_{in} \leq 3 \wedge X_{in} \leq X_{out} - 1) \sqcup P^2(X_{in}, X_{out})$$
$$= P^2(X_{in}, X_{out})$$

Figure 8 shows the difference between the exact fixed point computed with the exact equations and the approximate fixed point. The points correspond to elements of T^3 whereas the grey zone is the polyhedron defined by P^3.
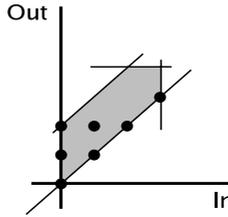

Fig. 8. Exact vs approximated fixed point

An approximation of the solutions of the w constraint is

$$Q = P^3(X_{init}, X_{end}) \wedge X_{end} \geq 2$$
$$= X_{end} \geq 2 \wedge X_{end} \leq 4 \wedge X_{in} \leq X_{end} \wedge X_{in} \leq 3 \wedge X_{in} \geq X_{end} - 2$$

On the previous example, the fixed point computation converges but it is not always the case. Widening can address this problem. The fixed point equation becomes:

$$P^{k+1}(Init, Out) = P^k(Init, Out)\nabla$$
$$(P^k \sqcup (P^k(Init, In) \wedge Relax(Cond, Do))_{Init, Out})$$

In this equation ∇ is the standard widening operator presented in Section 4.2.

5.3 w^∞: Implementing the Approximation

In Section 3, we have presented the filtering algorithm of the w operator. Here, we detail more concretely the integration of the abstract interpretation over polyhedra into the constraint combinator w via the w^∞ function.

w^∞ is an operator that performs the fixed point computation and communicates the result to the constraint store. Figure 9 describes the algorithm. All the operations on linear constraints are done with the *clpq* library [10].

Input:

$Init, In, Out, End$ vectors of variables

$Cond$ and Do the constraints defining the loop

A constraint store (X, C, B)

Output:

An updated constraint store

w^∞ :

1   $P^{i+1} := project(relax(C, B), [Init]) \wedge Init = Out$

2   **repeat**

3       $P^i := P^{i+1}$

4       $P^j := project(P^i \wedge relax(Cond \wedge Do, B), [Init, Out])$

5       $P^k := weak\_join(P^i, P^j)$

6       $P^{i+1} := widening(P^i, P^k)$

7   **until** $includes(P^i, P^{i+1})$

8   $Y := P^{i+1} \wedge relax(\neg Cond, B)$

9   $(C', B') := concretize(Y)$

10 **return** $(X, C' \wedge w(Init, In, Out, End, Cond, Do), B')$

Fig. 9. The algorithm of w^∞ operator

This algorithm summerizes all the notions previously described. Line 1 computes the initial value of P. It implements the α function introduced in Equation 4. The $relax$ function computes the linear relaxation of a constraint C given the current variables domains, B. When C contains another w combinator, the corresponding w^∞ function is called to compute an approximation of the second w. The $project(C, L)$ function is a call to the Fourier variable elimination algorithm. It eliminates all the variables of C but variables from the list of lists L. Lines 2 to 7 do the fixed point computation following Equation 3. Line 6 performs the standard widening after a given number of iterations in the repeat loop. This number is a parameter of the algorithm. At Line 7, the inclusion of P^{i+1} in P^i is tested. $includes(P^i, P^{i+1})$ is true iff each constraint of P^i is entailed by the constraints P^{i+1}.

At line 8, the approximation of the solution of w is computed following Equation 5. Line 9 concretizes the result in two ways. Firstly, the linear constraints are turned into finite domain constraints. Secondly, domains of End variables are reduced by computing the minimum and maximum values of each variable in the linear constraints Y. These bounds are obtained with the simplex algorithm.

6 Discussion

The polyhedra abstract domain is generally used differently from what we presented. Usually, a polyhedron denotes the set of linear relations that hold between variables at a given program point. As we want to approximate the solutions of a w constraint, our polyhedra describe relations between input and output values of variables and, thus, they involve twice as many variables. In abstract interpretation, the analysis is done only once whereas we do it each time a w operator is

awoken. Consequently, we cannot afford to use standard libraries to handle polyhedra, such as [2], because they use the dual representation, which is a source of exponential time computations. Our representation implies, nevertheless, doing many variables elimination with the Fourier elimination algorithm. This remains costly when the number of variables grows. However, the abstraction on polyhedra is only one among others. For example, abstraction on intervals is efficient but leads to less accurate deductions. The octagon abstract domain [13] could be an interesting alternative to polyhedra as it is considered to be a good trade-off between accuracy and efficiency.

Generalized Propagation [14] infers an over-approximation of all the answers of a CLP program. This is done by explicitly computing each answer and joining these answers on an abstract domain. Generalized Propagation may not terminate because of recursion in CLP programs. Indeed, no widening techniques are used. In the same idea, the 3r's are three principles that can be applied to speed up CLP programs execution [11]. One of these 3r's stands for *refinement*, which consists in generating redundant constraints that approximate the set of answers. Refinement uses abstract interpretation, and more specifically widenings, to compute on abstract domains that have infinite increasing chains. Hence, the analysis is guaranteed to terminate. Our approach is an instantiation of this theoretical scheme to the domain of polyhedra.

7 Conclusion

We have presented a constraint combinator, w, that allows users to make a constraint from an imperative loop. We have shown examples where this combinator is used to implement non trivial arithmetic constraints. The filtering algorithm associated to this combinator is based on case reasoning and fixed point computation. Abstract interpretation on polyhedra provides a method for approximating the result of this fixed point computation. The results of the approximation are crucial for pruning variable domains. On many examples, the deductions made by the filtering algorithm are considerable, especially as this algorithm comes for free in terms of development time.
