Abstract

The main emphasis of this chapter is a description of basic radiography of the wrist and hand with detailed description of radiographic technique and evaluation of the different projections. Static and dynamic carpal instability evaluation is vital for the assessment of ligamentous disruption. These techniques are covered in this chapter. There are a whole variety of measurement techniques which can be used in the assessment of wrist pathology. Following distal radial fracture, radial inclination, radial length and palmar tilt are important. Ulna variance is also assessed following distal radial fracture and in the context of ulnar-sided wrist pain. The scapholunate angle and capitate lunate angle are assessed when intercalated instability is suspected. Finally, the carpal height is a measurement which is applied when there is evidence of carpal collapse or loss of joint space. Arthrography still has a place in the modern assessment of the wrist. Radiocarpal and to a lesser extent midcarpal injection techniques may be employed.

1 Introduction

Plain film radiography has a fundamental role in the evaluation of the hand and wrist following trauma, in cases of suspected arthropathy, as part of an evaluation for certain systemic disorders with hand manifestations and in other miscellaneous situations such as tumour masses and pain.

2 Radiographic Projections

2.1 Radiographic Projections of the Wrist

The standard wrist projections are postero-anterior (PA) and lateral (Whitley 2005). Occasionally an oblique projection is added.

2.1.1 PA and Lateral Projections of the Wrist

Technique

The PA projection is performed with the patient seated. The shoulder is 90° abducted and the elbow is 90° flexed. The forearm is held in a neutral position with the hand flat on the table top. The tabletop should be at the same height as the forearm. The centering point is midway between the radial and ulnar styloid. The field of projection should include the distal half of the radius and ulna extending distantly to include the proximal two-thirds of the metacarpals (Fig. 1).

There are two different methods for obtaining the lateral projection of the wrist. The simplest method is to rotate the hand 90° maintaining the elbow in a flexed position. With this method, the ulna stays in a fixed position and the radius rotates through 90° along with the carpus. The second method involves rotation of both ulna and radius through 90° . This is achieved by extending the elbow and rotating the humerus

through 90° . This latter method has the benefit of enabling a second projection at 90° to the first of the ulna. The centering point for both methods is the radial styloid (Fig. 2).

Evaluation

The PA projection of the wrist is useful in the evaluation of injuries to the distal radius and ulna, carpus and proximal metacarpals. It is also helpful in the evaluation of pathology such as erosions to the distal radius and ulna and carpus. The PA wrist should profile the extensor carpi ulnaris tendon groove which should be at the level of, or radial to the base of the ulnar styloid (Fig. 1) (Goldfarb and Yin 2001).

The positioning of the lateral projection of the wrist is evaluated with reference to the palmar cortex of the pisiform (Yang and Mann 1997). A well-positioned and centered lateral projection results in the palmar cortex of the pisiform lying between the palmar cortices of the distal scaphoid and capitate (Fig. 2).

The PA view of the wrist displays the carpal anatomy (Fig. 3). The carpal bones are arranged in proximal and distal rows. The proximal row comprises the scaphoid, lunate and triquetrum, whilst the distal row is made up of the trapezium, trapezoid, capitate and hamate. The normal anatomic relationships of the wrist should demonstrate parallel opposing articular surfaces with symmetrical width of all intercarpal joints (Resnik 2000). The articular surfaces of the carpal bones should be normally aligned in three arcs (Fig. 4) (Gilula 1979). Arc I describes the outer proximal convexities of

Fig. 2 **a** Patient positioning for lateral wrist radiograph. **b** Lateral radiograph of wrist

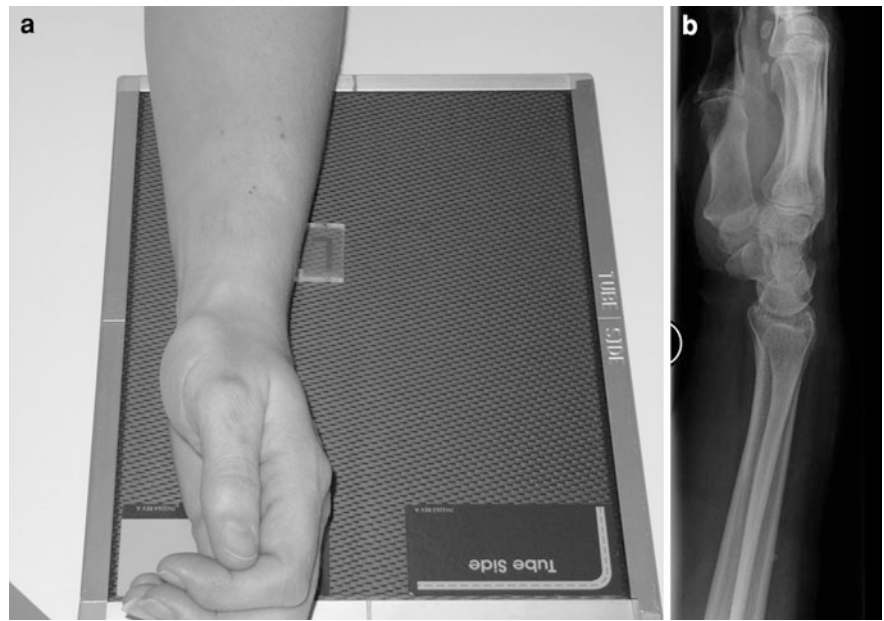

Fig. 3 Carpal anatomy

Fig. 4 Carpal arcs

scaphoid, lunate and triquetrum. Arc II describes the distal concavities of the scaphoid, lunate and triquetrum. Arc III describes the proximal convexities of the capitate and lunate. For optimal demonstration, the wrist must be imaged PA in the neutral position. Two normal anatomical variants of the arcs are recognized (Loredo and Sorge 2005). The first variant is that the triquetrum may be shorter in its proximal–distal dimension than the adjacent lunate. This gives rise to discontinuity of arc I. The second variant is that the

proximal hamate may be unusually prominent and rounded thereby creating discontinuity of arc III. Evaluation of the integrity of the arcs is important when assessing for fractures, dislocations and instability.

An important feature of the lateral wrist is the alignment of the radius, lunate and capitate (Fig. 5). These structures should be within 10° of coaxial alignment (Gilula 1979). It is noted that they are truly co-axial in only 11% of cases.

Fig. 5 Lateral wrist demonstrating axis for lateral alignment (not co-axial in this case)

2.2 Radiographic Projections of the Scaphoid Carpus

There are four standard projections for radiography of the scaphoid. They are the AP with ulnar deviation (plus or minus tube angulation), anterior oblique (pronated oblique), posterior oblique (supinated oblique) and lateral. This series is designed to provide tangential projections of the carpal bones with particular emphasis on evaluation of the scaphoid. The prime indication for these projections is the presence of trauma to the carpus particularly if there is associated tenderness in the region of the scaphoid.

2.2.1 AP with Ulnar Deviation

Technique

The patient sits to the side of the table with a flexed elbow and pronated forearm. The elbow and wrist are at the level of the tabletop. The hand is deviated in the ulnar direction (Fig. 6). The purpose of the deviation is to reduce the foreshortening of the scaphoid seen on the standard PA projection. When the wrist is in the normal neutral position the scaphoid is tilted (Gilula 1979). Additionally, the X-ray tube may be angled towards the elbow by 20° (Fig. 7) which further compensates for the normal scaphoid tilt.

The centering point is midway between the ulna and radial styloid processes. The film should include the distal radius and ulna and proximal metacarpals.

Evaluation

The PA projection should produce a good projection of the length of the scaphoid aiming at visualisation of clear joint space around the whole of the scaphoid (Fig. 6). Occasionally, there is some distal overlap. The radial styloid and ulnar styloid should be clearly seen.

2.2.2 Anterior Oblique (Pronated Oblique)

Technique

The wrist is externally rotated from the PA neutral position by 45° (Fig. 8). The radial styloid is, therefore, elevated from the tabletop. The centering point is midway between the ulnar and radial styloid. The fingers may be slightly flexed with the thumb held in front.

Evaluation

This projection (Fig. 8) gives a good demonstration of the distal scaphoid and trapezium. It is also a useful projection for evaluating the trapezoid and bases of the first and second metacarpals. The radial styloid and dorsal surface of the triquetrum is visible. Consideration may be given to applying a degree of ulnar deviation to this projection for better visualisation of the scaphoid.

2.2.3 Posterior Oblique (Supinated Oblique)

Technique

From the anterior oblique the wrist is externally rotated a further 90° (Fig. 9). The fingers are held together. The centering point is the ulnar styloid.

Evaluation

This projection demonstrates the pisiform and the piso-triquetral joint (Fig. 9). It is also useful for evaluating the hook of the hamate and bases of the fourth and fifth metacarpals. The long axis of the scaphoid lies perpendicular to the cassette.

2.2.4 Lateral

Technique

The technique is as described for the standard lateral view of the wrist (Sect. 2.1). However, a narrower field of view is generally used including only the

Fig. 6 **a** Patient positioning for AP carpus with ulna deviation. **b** AP radiograph with ulna deviation of carpus

Fig. 7 AP radiograph with ulna deviation and 20° of tube angulation

distal aspect of the radius and ulna and proximal metacarpal bases (Fig. 10).

Evaluation

The lateral projection is particularly valuable in assessing the dorsal surface of distal radius for fracture. This projection enables an evaluation of the alignment of the distal radius, lunate and capitate (Fig. 10). This projection is useful when assessing for dislocation and carpal instability.

2.3 Radiographic Projections of the Hand

There are two standard projections for the hand which are the PA and anterior oblique projections. Supplementary projections include the lateral projection and the posterior oblique projection.

2.3.1 PA Hand

Technique

The forearm is pronated and the hand rests on the cassette (Fig. 11). The ulnar styloid and radial styloid should lie equidistant from the tabletop. The centering point is the third metacarpal head. This projection should include the whole of the fingers (phalanges), metacarpals, carpus together with distal ends of the radius and ulna.

Fig. 8 **a** Patient positioning for anterior oblique of the carpus. **b** Anterior oblique radiograph of the carpus

Fig. 9 **a** Patient positioning for posterior oblique of carpus. **b** Posterior oblique radiograph of carpus

Evaluation

The PA hand projection should demonstrate all of the joints of the hand, carpus and wrist (Fig. 11). The joint spaces should be symmetrical and parallel. This projection is used in the evaluation of trauma, arthropathy and a range of miscellaneous conditions. The carpo-metacarpal joint may be evaluated with a line drawn between the distal articular surfaces of the trapezoid, capitate and hamate and the parallel articular surfaces of the second-fifth metacarpals (Fig. 12)

(Fisher and Rogers 1983). Discontinuity of this line should raise a suspicion of fracture and or dislocation.

2.3.2 PA Anterior Oblique Hand

Technique

The hand is externally rotated by 45° from the PA projection (Fig. 13). The fingers should be extended and separated. The film is centered over the third metacarpal head.

Fig. 10 Lateral radiograph of carpus

Evaluation

This projection is very useful for evaluating the shafts and necks of the metacarpals (Fig. 13). The phalanges are seen in an oblique plane. The first and second metacarpals are usually separated whilst there is an overlap of the fourth and fifth metacarpals.

2.3.3 Lateral Hand

Technique

The hand is placed in the lateral position on the cassette with the medial border of the wrist and hand resting on the cassette. The fingers are extended. The thumb is also extended and placed clear of the rest of the hand (Fig. 14). The centering point is the head of the second metacarpal.

Evaluation

This projection (Fig. 14) is useful for evaluating the carpal metacarpal region for dislocation. It is helpful in evaluating the fifth metacarpal shaft fractures. This projection is also used for foreign body assessment.

2.3.4 Posterior Oblique of Both Hands

Technique

Both hands are placed on the cassette. They should lie symmetrically. Both forearms are supinated with 45° of rotation. The radial styloid is elevated from the cassette on both sides. The centering point is midway between the hands at the level of the fifth metacarpal head.

Evaluation

The metacarpal heads should all be clearly seen and separated (Fig. 15). The purpose of this projection is to evaluate the metacarpal heads for bone erosion. This projection has also been termed the Norgaard view or 'ball catcher's' view. The obliquity of the projection enables a different part of the metacarpal head to be shown in profile. It is considered that this improves the visualisation of bone erosions from rheumatoid disease as more of the beam is tangential to the bare area of the metacarpal head, the area susceptible to erosions. This is when compared with the conventional PA projection. However, two studies have demonstrated that there is limited additional information with this projection (De Smet and Martin 1981; Edwards and Edwards 1983).

2.4 Radiographic Projections of the Phalanges

The standard projections are PA and lateral. Supplementary oblique views either of individual phalanges or as part of a PA oblique hand examination may also be undertaken. The oblique projection does not substitute for the lateral view which is an essential projection when evaluating trauma.

Fig. 11 **a** Patient positioning for PA hand. **b** Radiograph of PA hand

Fig. 12 PA hand radiograph showing level for assessment of parallelism across carpo-metacarpal joint (*white arrow*)

2.4.1 PA Phalanges

Technique

The phalanges may be X-rayed individually or in pairs. For example, the second and third phalanges are imaged together or the fourth and fifth are imaged together. The fingers are placed on the cassette with a hand in the neutral PA position (Fig. 16). The centering is over the PIP joint of the relevant finger. The X-ray should include the distal third of the metacarpal as far as the soft tissue of the fingertip.

Evaluation

The joint spaces should be uniform and parallel (Fig. 16).

2.4.2 Lateral Phalanges

Technique

The phalanges may be X-rayed individually or in pairs. Typically, the second and third are imaged together or the fourth and fifth phalanges. The phalanges are extended and separated so that both are visible on the film. The centering point is the proximal interphalangeal joint of the affected finger (Fig. 17).

Evaluation

The lateral view is especially important in the evaluation of volar plate injuries and extends or extensor avulsion injuries. The phalanx must be X-rayed in the true lateral position (Fig. 17).

2.5 Radiographic Evaluation of the Thumb

The conventional projections of the thumb are AP and lateral. They are performed separately from the examination of the hand. The PA projection may be substituted for the AP projection when there is pain or difficulty in achieving the appropriate position.

2.5.1 AP Thumb

Technique

The forearm is over-pronated such that the thumb lies on the cassette (Fig. 18). The centering point is the base of the first metacarpal.

Fig. 13 **a** Patient positioning for PA anterior oblique of hand. **b** Radiograph of PA anterior oblique of hand

Fig. 14 **a** Patient positioning for lateral radiograph of hand. **b** Lateral radiograph of hand. **c** Soft tissue lateral radiograph of hand

Evaluation

The base of the first metacarpal and the base of the proximal phalanx of the thumb are well demonstrated and can be assessed for fracture (Fig. 18).

2.5.2 Lateral Thumb

Technique

The thumb is rested on the cassette in the lateral position. The palm of the hand is slightly rotated to bring thumb into it through lateral profile. The centering point is the metacarpo-phalangeal joint (Fig. 19).

Evaluation

This projection is important for evaluation of the base of the first metacarpal for fracture (Fig. 19).

2.5.3 PA Thumb

Technique

The medial border of the hand is rested on the cassette. The hand is rotated forwards with the thumb extended until a PA view of the thumb is obtained (Fig. 20). It is important that the thumb is extended, otherwise there is overlap at the metacarpal phalangeal joint. This projection is used when it is not

Fig. 15 Posterior-oblique (ball-catcher's) radiograph of the hands

Fig. 16 **a** Patient positioning for PA second and third fingers. **b** Patient positioning for PA fourth and fifth fingers. **c** Radiograph of PA fingers

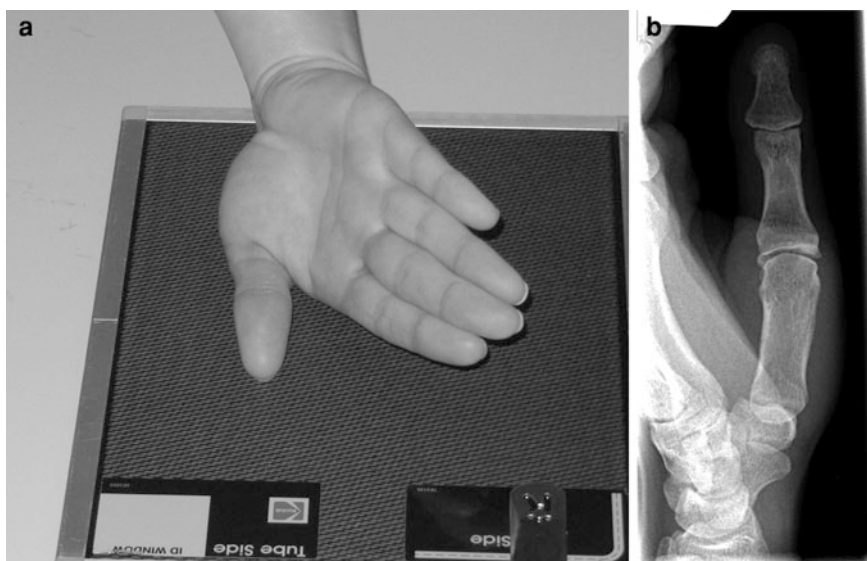

Fig. 17 a Patient positioning for lateral of second and third fingers. b Patient positioning for lateral of fourth and fifth fingers. c Lateral radiograph of fingers

Fig. 18 a Patient positioning for AP thumb. b AP radiograph of thumb

possible for the patient to achieve the over-pronation of the forearm required for the AP projection.

Evaluation

Care must be taken to obtain a good PA view and to assess for parallelism at the metacarpal–phalangeal joint.

3 Radiographic Technique

Film screen technique has been the standard methodology used for plain film radiographic examination for many years. With the advent of digital radiography

and the growth in picture archiving and storage systems, new techniques have been introduced which are replacing standard film screen radiography. Computed radiography (CR) was the first technique, introduced in the 1980s. Direct digital radiography is a more recent technique introduced in the 1990s.

Imaging may be thought of in four separate steps: generation, processing, archiving and presentation. Image generation commences when X-rays having passed through the object under examination reach the detector. In the case of film screen radiography, this will be the film. The interaction of X-ray photons with the film results in a latent image which is then processed to

Fig. 19 **a** Patient positioning for lateral thumb. **b** Lateral radiograph of thumb

Fig. 20 Patient positioning for PA thumb

produce the real image which is 'stored' on the film. In the case of film-screen radiography, all the four steps are performed on the film. In the case of digital imaging, these steps are separated. CR differs from direct radiography (DR) in the content of these steps. Modern

digital imaging produces images of the same quality as conventional film-screen radiography.

3.1 Computed Radiography (CR)

CR uses a cassette-based detector plate comprising photostimulable phosphor. Photons interacting with the phosphor elevate the energy levels of electrons within the phosphor crystals, and this comprises the latent image. The cassette is then taken to a processor. The processor (image plate reader) scans the plate with a helium–neon laser, releasing the energy from the excited electrons. Light is emitted which is converted by photomultiplier tubes into an analog signal which may then be digitised. Specific processing algorithms are then applied to this information resulting in the image for transfer and display. Images are displayed on computers or may be printed out on laser film. The plate is then exposed to intense light to completely erase the latent image and enable a further exposure with the same plate.

The processing algorithms which are used are specific to the body part and the suspected pathology. A key strength of digital imaging is its latitude and ability to display both bone and soft tissue detail with great clarity. It is necessary to optimise the image processing to the body part. Therefore, for example,

the processing algorithm for a hip X-ray will be different to the knee and different again to the hand. Also a soft tissue foreign body film will be processed differently to a skeletal film for a fracture. The raw data may be reprocessed as required. A limitation of CR is that the resolution is of the order of 2.5–5 lines per mm. This contrasts with film screen radiography of 2.5–15 lines per mm. However, 2.5 lines per mm is acceptable for standard skeletal radiography.

Whereas overexposure with film screen radiography produces a black film, the processing of an overexposed CR phosphor plate can result in an image which has a normal appearance. The risk of the overexposure is that the radiographer is less able to make a judgment regarding standard exposures. It is easy for there to be an upward creep in exposure factors over a period of time. Thus, careful quality control mechanisms are required. A useful but imperfect guide is the 'exposure index'. Underexposure results in increasing graininess of the image.

For certain applications, high-resolution CR plates have been produced. In general, they would be limited to paediatric applications but may also be used for detailed extremity skeletal work.

3.2 Direct Radiography (DR)

DR produces high-quality digital images. DR has a major impact upon workflow in the radiology department as the image is produced very quickly after exposure. An image is produced 10–40 s after exposure. This enables a rapid decision with regard to the adequacy of the image (exposure, positioning and collimation). With DR the generation and processing occur in the same device which may be placed in, or replace the standard Bucky tray. DR is based upon solid-state, flat panel, digital radiography detectors. These detectors use a very thin layer of amorphous silicon.

The typical DR detector used in skeletal work uses indirect conversion. The detector comprises a combination of a layer of X-ray fluorescent material and the amorphous silicon active matrix read-out array. X-ray photon energy interacts with thallium-activated caesium iodide releasing light photons which are detected in a 2D array of amorphous silicon diodes. An electronic signal is produced which is then digitised. The caesium thallium is applied onto the hydrogenated amorphous silicon. Each pixel in the

active matrix array comprises a light-sensitive element (photodiode) together with an associated switching component. The switching component is either in the form of a thin film diode switch or a thin film transistor switch. The charge pattern resulting from the exposure is read out amplified and digitised.

With both CR and DR, an anti-scatter grid is required. The dynamic range of DR is approaching 10,000:1. As a result of this, DR detectors have wide dose latitude. As with CR, this enables good quality images of both bone and soft tissue. DR also suffers from the potential weakness of incremental exposure drift or 'creep' as described above.

Active development of both DR and CR detectors continues with the aim of further refinements to produce improved quality images. In the case of DR, alternative manufacturing methods for large amorphous silicon active matrix arrays are a subject of research. Improvement in X-ray absorption materials for both CR and DR is an important area of development.

Digital imaging has provided the opportunity for immense workflow improvement and image storage with picture archiving and communications systems (PACS). In many centres, PACS has replaced conventional film imaging. The advantages are numerous. Importantly they include the ability to view images at multiple locations simultaneously; storage and retrieval efficiency; and image manipulation and interrogation. Advanced digital imaging techniques take advantage of the improved processing power leading to the development of tomosynthesis, dual energies subtraction and temporal subtraction imaging.

4 Additional Projections and Fluoroscopy

The radiographic evaluation of carpal instability includes a static series and dynamic fluoroscopy. The objective of these examinations is to demonstrate malalignment of the carpal bones either in a static position or alternatively as part of a dynamic examination. The dynamic examination also provides the opportunity to assess for dysynchronous movement between the carpal bones. Malalignment or dysynchronous movement is likely to be a consequence of ligament disruption. Of particular importance in this regard are the scapholunate and lunotriquetral

Fig. 21 Fluoroscopy images of PA wrist **a** ulna deviation and **b** radial deviation

ligaments. Both have strong anterior and posterior components with a thin ‘membranous’ central portion.

4.1 Carpal Instability Series—Static Evaluation

4.1.1 Technique

The standard series would include the following projections (Gilula et al. 1984). Initially, the wrist is placed in the neutral PA position. From this, the wrist is deviated in the ulnar and then radial directions (Fig. 21). Images are taken in all three positions. Following this, this series is repeated with the fist clenched. In some cases, the technique may be conducted with the fist clenched around a pencil or a tennis ball (Schmitt and Froehner 2006). Then three

further views are performed with the wrist in the lateral position: neutral, full extension and full flexion (Fig. 22). An additional view which is performed for evaluation of the piso-triquetral joint is the 30° supinated view of the wrist.

4.1.2 Evaluation

The integrity of the carpal arcs is assessed. Congruency of the intercarpal joints and the width of these joints is also assessed. Of particular importance with regard to the proximal carpal row is the relationship of the lunate relative to the radius (Schernberg 1990). The proximal surface of the lunate should not move more than half of its width on the distal surface of the radius (Fig. 21).

4.2 Dynamic Evaluation—Fluoroscopy

4.2.1 Technique

A dynamic study (Gilula et al. 1984; Braunstein and Louis 1985) provides a further opportunity to assess for carpal instability in the situation where the static views are negative. Essentially, the static series are repeated with movement. Therefore, from the PA neutral position the wrist is deviated in the ulnar direction and then back through the neutral position to the radial position. This movement is repeated. From the lateral position the wrist is fully flexed and then fully extended. This is also repeated as required. A further, non-standard part of the study follows enquiry of the patient with regard to the movement causing symptoms. The patient undertakes this movement which is recorded with fluoroscopy. This study may be recorded and therefore replayed at normal and reduced speeds.

4.2.2 Evaluation

The alignment of the carpal bones in all the positions is evaluated. In addition, careful viewing of the relative movements within each carpal row and then between carpal rows is important. For the proximal carpal joint, the movement of the lunate relative to the distal radius is important. For the metacarpal joint, the movement of the hamate relative to the lunate is important.

Fig. 22 Fluoroscopy images of lateral wrist in **a** flexion and **b** extension

Fig. 23 Measurement of ulna variance. Solid line is ulna neutral (normal). + is positive ulna variance and - represents negative ulna variance

5 Measurements

There are a number of measurements which are useful in the assessment of the wrist which can be performed on plain radiographs (Mann and Wilson 1992; Goldfarb and Yin 2001; Rosner and Zlatkin 2004; Loredo and Sorge 2005). Ulna variance is useful in a range of conditions including assessment

following fracture and ulna-sided wrist pain. Distal radial measurements include radial inclination, radial length, and palmar tilt. These are all useful in the assessment of distal radial fractures. The scapholunate and capitate–lunate angles are calculated when carpal instability is suspected. Finally, carpal height is measured when collapse of the carpus is suspected, for example, as a consequence of carpal instability or previous fracture.

5.1 Ulna Variance

Ulna variance is the difference in length between the distal radius and the distal ulna. This measurement is relevant in a number of carpal disorders including fracture assessment and abnormalities of the proximal carpal row such as chondromalacia of the lunate. The wrist is assessed in a neutral PA position. A technique for the assessment of ulna variance involves first, identifying the long axis of the radius at 2.0 and 5.0 cm from the distal radial cortex. A perpendicular running tangential to the most ulna portion of the distal radial articular cortex is then drawn to this line. Second, the line is drawn tangential to the distal ulna and parallel to the line described above (Mann and Wilson 1992; Loredo and Sorge 2005) (Fig. 23). In negative ulna variance (ulna minus), the ulna is shorter than the radius. In positive ulna variance (ulna plus), the ulna is longer than the radius. Normally, the radius and ulna are of the same length or there is mild negative ulna variance.

Fig. 24 Measurement of radial inclination. Normal inclination is 21–25°

Fig. 25 Measurement of radial length. Normal measurement is 10–13 mm

5.2 Radial Inclination

Radial inclination describes the slope of the radius between the tip of the radial styloid and the ulnar

Fig. 26 Measurement of palmar tilt (volar inclination). Normal value 0–22°

border of the radius in the frontal or PA plane. Its assessment is important following distal radial fractures (Mann and Wilson 1992; Loredo and Sorge 2005). The technique for obtaining the measurement is first to identify the long axis of the radius as described above (Sect. 5.1). Second, a line is drawn from the tip of the radial styloid to the ulnar border of the distal radius. The third line is drawn through the intersection of these lines, perpendicular to the long axis of the radius (Goldfarb and Yin 2001). The radial inclination is the angle between the perpendicular and the line running tangential to the radial styloid and ulnar border of radius (Fig. 24). The normal inclination is 23° (21–25°) (Goldfarb and Yin 2001).

5.3 Radial Length (Radial Height)

Radial length (radial height) is a method for assessing shortening of the radius, for example, following a fracture. The measurement involves identification of the

Fig. 27 Scapholunate angle. White lines represent long axis of scaphoid and lunate. Normal range is 30–60°

Fig. 28 Capitulate-lunate angle. White lines represent long axis of lunate and capitate. Normal range is 0–30°

long axis of the radius. Two lines perpendicular to this are then constructed. Firstly, tangential to the tip of the radial styloid and secondly tangential to the ulnar border of the distal radius (Fig. 25). The distance between these two lines is the radial length (Goldfarb and Yin 2001). A normal value of 10–13 mm is expected.

5.4 Palmar Tilt (Volar Tilt or Volar Inclination)

This measurement assesses the tilt of the distal radius at the radiocarpal joint. The central axis of the radius is identified in the lateral plane using points at 2 and 5 cm from the midpoint of the distal articular surface. A perpendicular is drawn to this line at the articular surface. A third line is drawn from the dorsal lip of the distal radius to the volar lip of the distal radius. The palmar tilt is the angle between the third line and the perpendicular (Fig. 26). It is normally between 0–22° (Mann and Wilson 1992; Goldfarb and Yin 2001). This is an important measurement in the assessment of distal radial fractures.

5.5 Scapholunate Angle

This angle is calculated when carpal instability is suspected (Goldfarb and Yin 2001). It is particularly pertinent in the assessment of dorsal intercalated instability (DISI). The angle is measured from the lateral view of the wrist. The angle is calculated by drawing two lines (Timins and Jahnke 1995). A line is drawn through the proximal and distal volar convexities of the scaphoid. This defines the scaphoid axis. The lunate axis is perpendicular to a line drawn between the distal poles of the lunate. The normal scapholunate angle lies between 30–60° (Fig. 27).

5.6 Capitulate–Lunate Angle

This angle is calculated when the volar instability pattern (VISI) of carpal instability is suspected. The angle is measured from the lateral view of the wrist. The long axis of the lunate is drawn as described above (Sect. 5.5). The long axis of the capitate is drawn from the centre of its distal articular surface to the centre of the proximal articular surface (Timins and Jahnke 1995). The normal capitulate–lunate angle lies between 0 and 30° (Fig. 28).

5.7 Carpal height

Carpal height provides quantification of the degree of carpal collapse e.g. in scapholunate advanced collapse

Fig. 29 Measurement of carpal height **a** method 1 and **b** method 2

(SLAC). Two methods have been described. The first method describes a ratio between the distance from the base of the third metacarpal to the proximal articular surface of the radius and the length of the third metacarpal. The line drawn extends from the long axis of the third metacarpal (Fig. 29a). With this method, the normal carpal height ratio is 0.54 (Mann and Wilson 1992).

The second method divides the carpal height (distance from base of the third metacarpal to proximal articular surface of radius) by the capitate length. The capitate length is calculated from the distal angular articular surface of the capitate (between the bases of the second and third metacarpals) and the centre of the proximal articular surface of the capitate (Fig. 29). The normal figure is 1.57 (Mann and Wilson 1992).

A carpal height index is obtained by dividing the carpal height of the diseased wrist with the

normal wrist (Loredo and Sorge 2005). This index may be followed with time as a marker of disease progression.

6 Arthrography

Arthrography of the wrist is performed in the assessment of interosseous wrist ligaments and the triangular fibrocartilage complex. Specifically, it is performed for assessment of the scapholunate and luno-triquetral ligaments in addition to the triangular fibrocartilage complex. With the advent of cross-sectional imaging techniques, it is most frequently undertaken now as part of an MRI or CT arthrographic study. The basic technique is that of a proximal row or radiocarpal injection. A more complex study will involve injection of two or three wrist compartments.

Fig. 30 Fluoroscopy images from radiocarpal arthrogram **a** needle position **b** early filling with contrast **c** mid-filling phase **d** late-filling phase (complete) **e** lateral view post exercise

Unicompartmental injection to the radiocarpal (Fransson 1993) may be undertaken by injection at two different points. The first is a dorsal approach to the junction between the scaphoid and lunate just proximal to the scapholunate ligament. The second is between the scaphoid and distal radius. The wrist is gently flexed and a 22G needle introduced under fluoroscopic guidance. Care must be taken not to damage the scapholunate ligament. Note should be taken of the normal radial inclination and allowance made for the dorsal lip of the radius when introducing the needle.

Contrast is injected into the radiocarpal space. The usual filling volume is between 2 and 4 ml. The end of the injection is signified by gentle resistance to further filling and distribution of contrast across the radiocarpal joint. Generally, contrast of 240 IU/l is sufficient for good radiographic imaging. The mixture injected will alter for CT arthrography and MRI arthrography as is described in subsequent chapters.

Contrast should be injected slowly, carefully observing the filling of the radiocarpal space and looking for contrast tracking into the scapholunate

space, lunate triquetral space, or distal radio-ulnar joint. Spot films are taken during injection (Fig. 30). At the end of the injection when there is good filling of the radiocarpal space, a further series of films is taken following gentle exercise of the wrist. A typical series of films would include PA in the neutral, ulnar deviation, and radial deviation positions followed by a lateral view. It is commonplace to have performed a static and dynamic instability series (as outlined earlier in the chapter) prior to injection of contrast.

Fluoroscopy and videotaping the procedure enabled further retrospective analysis (Gilula and Totty 1983).

The normal pattern of filling (Fig. 30) outlines the radiocarpal joint (Resnick 1995). Age-related degenerate perforations of the central portion of the scapholunate and lunate triquetral ligaments are well recognized (Linkous and Pierce 2000). Similarly age-related degenerate perforations of the radial side of the triangular fibrocartilage complex with filling of the distal radio-ulnar joint may also be observed. Small volar outpouchings (radial recesses) of the capsule are well recognized (Fig. 30). On the ulnar

Fig. 31 Fluoroscopy image from midcarpal arthrogram demonstrating needle position and filling of radiocarpal space

side there is a small pre-styloid recess above which the meniscus homologue and a further collection of contrast may be identified. Filling of the piso-triquetral space is a normal variant.

Midcarpal injection has been described by Tirman and Weber (1985). The wrist is gently flexed. The midcarpal joint is injected between the distal scaphoid and capitate (Linkous and Pierce 2000) (Fig. 31). Careful injection with fluoroscopic guidance is undertaken until good filling of the space has been obtained. Careful observation of the scapholunate and lunotriquetral spaces is undertaken, looking for evidence of filling of these spaces. Tirman regarded this as an easier method for establishing the integrity of the scapholunate and lunotriquetral ligaments. A static and dynamic instability series would be obtained.

Triple compartment arthrography (Levinsohn and Palmer 1987; Levinsohn and Rosen 1991) was introduced by Levinsohn and regarded as being of superior diagnostic quality. However, Steinbach and Palmer (2002) preferred single joint injection into the radiocarpal space. This has the advantage of single as opposed to multiple injections, whilst still providing the opportunity to evaluate the scapholunate ligament, lunotriquetral ligament, and triangular fibrocartilage complex. It also avoids the time-consuming wait

between each of the three compartment injections whilst awaiting absorption of contrast.

However, the diagnostic yield is greater with a midcarpal injection based on an analysis of unidirectional joint communications (Wilson and Gilula 1991). It was proposed that if a scapholunate or lunotriquetral ligament disruption was suspected then a midcarpal injection should be performed first. If a triangular fibrocartilage complex disruption was suspected, then a radiocarpal injection should be performed first.

Full triple compartment arthrography also involves injecting the distal radio-ulnar joint looking for communication with the proximal carpal joint.

Digital subtraction imaging was introduced to improve visualisation of scapholunate or lunotriquetral space filling when multiple compartments were injected (Quinn and Pittman 1988) without the normal three-hour delay between injections waiting for the contrast to be absorbed.

In current radiological practice, the arthrogram is usually performed in conjunction with an MRI arthrogram or CT arthrogram. Whilst 3T MR without arthrography is producing very high-quality images of the wrist (Saupe 2009) and its associated ligaments, MRI arthrography is preferred for evaluation of the ligamentous structures of the wrist (Magee 2009; Sofka and Pavlov 2009).

Abstract

The use of computed tomography (CT) in imaging has expanded radically in the last four decades since its invention. Aided by advances in computing and engineering, it has grown from being an object of curiosity in research institutions to the main modality of medical imaging across the world. Although at present, the most common use of computed tomography with respect to imaging of the hand and wrist is in trauma; easy availability, high spatial resolution and recent innovations are helping it to break new ground in assessment of soft tissue structures and dynamic imaging.

1 Introduction

Computed tomography is becoming the mainstay of medical imaging. Several studies have validated this claim including the most recent report from National Council of radiation protection (NRCPP) in the USA which stated that the number of CT studies has increased by 10 % per year from 1993 to 2006. Easy availability, very short scanning times and high spatial resolution are currently the main strengths of CT scanning. Modern advances in computing capability and digital image processing enabling instantaneous display of multi-planar reformats has helped to fuel the increase in demand in CT imaging for acute and chronic disorders. Moving on from diagnosis, CT is widely used for treatment planning and assessment of prognosis. Newer operating techniques and equipment enabling surgeons to operate on more complex injuries improving patient outcome also contributed

to increase use of CT for identification of even subtle injuries.

CT is pivotal in the imaging of hand and wrist. The unique configuration of the carpus, which involves complex articulation between multiple bones with different degrees of rotation and translation between them, makes accurate diagnosis of fractures and dislocations on two-dimensional images provided by plain radiograph problematic. For timely management of injuries and patient comfort, CT scan is the primary imaging modality of the wrist.

Modern multi detector row CT scans have the ability to produce slices that are a fraction of a millimeter thick thus providing spatial resolution capable of identifying non displaced fractures and tiny fracture fragments. CT can also be used to diagnose ligament injuries and arthritis especially in patients where MRI is difficult or contra-indicated.

2 Computed Tomography Techniques

2.1 Patient Positioning

For CT scans of the wrist and hand, the patient is asked to lie prone with the affected arm stretched out above his or her head with the hand and wrist placed with the palm facing down. This is often described as the ‘Superman’ position and it helps to reduce the dose delivered to the more radiosensitive parts of the body like cornea, breasts, mediastinum and abdominal organs. It also helps to reduce artifacts due to beam hardening that can occur if the hand is placed over the chest or by the side of the body for the scan.

2.2 Technique

Multiple rows of detectors are not essential for CT imaging of wrist trauma but they afford higher spatial and temporal resolution. Parameters like kV, mA, pitch and field of view are adjusted based on factors such as patient’s body mass index, presence or absence of cast and the indication for imaging. Radiation dose will be lower while imaging without a cast but in cases of unstable comminuted fractures or open injuries, cast and dressing can be left on. The patient is scanned in the “superman” position with

the wrist is in the middle of the gantry. The upper arm should be fully extended to counteract radial or ulnar deviation of the wrist. Excessive dorsal flexion of the wrist should also be avoided.

Technical parameters are set to achieve the highest spatial resolution but mindful of the radiation penalty. Newer dose and noise reduction techniques marketed by different manufacturers like Adaptive Statistical Iterative Reconstruction (ASiR) (GE) iDose (Philips), Adaptive Iterative dose Reduction (AIDR) (Toshiba) and Iterative Reconstruction in Image Space (IRIS) (Siemens) can be used according to local protocol.

Isotropic acquisition allows optimal reformation in multiple planes. Corrected transverse, sagittal, and coronal reformatted images are routinely obtained along the axis of the capitate bone.

Maximum bone detail is obtained by using high-resolution bone algorithms most of which involve edge enhancement.

2.3 CT Arthrogram

CT scanning of the wrist after injection of contrast is sometimes performed for better assessment of ligaments and joints in certain situations. Techniques and indications for this are discussed later in this chapter.

3 Clinical Applications

3.1 Acute Trauma

CT is now becoming the primary modality of cross sectional wrist imaging for trauma in several centres. Many centres still use MR as the preferred modality. In this chapter we shall consider the use of CT in various hand and wrist fractures.

3.1.1 Fractures of Distal Radius and Ulna

Fractures of the distal radius generate a high interest amongst orthopaedic and hand surgeons probably due to the fact that it is one of the most frequently encountered fractures in the emergency department. Treatment options have come a long way since the days of Colles’ landmark article on distal radius fractures where the main advice was to treat most patients non-operatively (Sternbach 1985). These days surgeons have more operative options and

Fig. 1 Radiograph of wrist demonstrating an intra-articular fracture at top left hand corner and clockwise images show coronal, transverse and sagittal CT reconstructions in the same patient. The degree of comminution and extent of articular depression is difficult to appreciate on the plain radiograph. Transverse section also demonstrates subluxation of the Distal radio ulnar joint (DRUJ) is difficult to appreciate on plain radiograph

expect information about fracture configuration, angulation and comminution to make decision about further management. The imaging parameters to be considered while evaluating distal radius fractures include radial inclination, radial shortening, radial tilt, articular incongruity and degree of comminution of fragments. Most of these parameters can be better identified on CT scans compared to plain radiographs. Although operative management of isolated distal ulnar fractures is less common, CT scan is occasionally indicated in badly comminuted, shortened fractures (Fig. 1).

3.2 Fractures of Carpal Bones

Wrist fractures are notoriously difficult to diagnose on initial radiographs. Various modalities including bone scintigraphy and MR imaging have been used in different institutions. There is a wide variation of

practice in the world in imaging of acute wrist injury. An international survey published in 2006 (Groves et al. 2006) of hospital practices revealed marked inconsistency in acute wrist fracture imaging protocols, which the authors believe are likely to be multifactorial but also probably reflected a deficiency in scientific evidence regarding the best practice for imaging occult wrist fractures. Moreover, practices will vary according to local expertise and availability of the different modalities operating within the constraints of individual healthcare local resources. In our institution we use CT scan to detect occult fractures if the second plain radiograph after 10–14 days of injury has been negative. Criteria for a bone fracture on CT images are the presence of a sharp lucent line within the trabecular bone, a break in the continuity of the cortex, a sharp step in the cortex, or a dislocation of bone fragments. Trabecular fractures on CT (without cortical disruption) can be difficult to differentiate from nutrient vessel. Soft tissue and

Fig. 2 Illustrates the relative frequency of fractures in the different carpal bones quoted by various sources

ligamentous injury on non-contrast CT cannot be accurately diagnosed (Adey et al. 2007). On MR imaging, one can more reliably identify trabecular fracture, and differentiation from a vessel can be done with much more confidence. In addition, bone bruising and ligamentous injuries can be more reliably identified on MRI and not CT. A recent meta-analysis (Yin et al. 2010) examined various studies performed in detecting occult scaphoid fracture comparing between bone scintigraphy, CT and MRI. MRI was shown to be more sensitive (96 %) than CT (93 %), but the specificity of both modalities remains the same (99 %). The meta-analysis also acknowledged that due to low numbers, there was lack of robust evidence to support one modality over another. (Fig. 2).

3.2.1 Scaphoid Fractures

The scaphoid is the largest bone of the proximal carpal row and provides an important link between the proximal and distal carpal row. It is also the most commonly fractured carpal bone accounting for about 70 % of wrist bone fractures (Welling et al. 2008). Waist of the scaphoid is the most common site of fracture.

Choice of imaging is dependent on local availability and as explained above, between MRI and CT, there is no clear winner. MRI is better in the diagnosis of trabecular fractures but CT is better in diagnosis of cortical fractures. MRI is more sensitive in early

Fig. 3 a Transverse CT section through scaphoid demonstrating fracture of the scaphoid waist. b Sagittal CT section through scaphoid demonstrating fracture of the scaphoid waist

diagnosis of fractures but there is no clear evidence that it is significantly better than CT (Yin et al. 2010).

The most commonly reported cause of scaphoid fracture is a fall on outstretched hand with forced dorsiflexion of the wrist. Compression or avulsion of the tuberosity is also seen occasionally. Proximal pole avulsion fractures can occur due to traction on the scapho-lunate ligament (Fig. 3).

3.2.2 Lunate Fractures

Lunate fractures account for about 4 % of all carpal fractures. Lunate occupies a central position in the proximal carpal row. Like the scaphoid, late diagnosis or non-diagnosis can result in carpal instability, nonunion and avascular necrosis. Isolated lunate fracture is often difficult to diagnose as lunate overlaps with other carpal bones on radiographs. CT imaging can demonstrate all patterns of fracture. Fracture pattern of the lunate is described according to anatomical location namely body (Fig. 4), dorsal pole and volar pole and also orientation of fracture line namely transverse and sagittal. Isolated fractures in the coronal plane are extremely rare.

3.2.3 Triquetral Fractures

Triquetral fractures are the second most common carpal fractures with a prevalence of about 20 %. Dorsal ridge fractures are the commonest and occur at the dorsal aspect due to impaction of ulnar styloid process against the dorsal surface during wrist

Fig. 4 **a** Plain radiograph that demonstrates a fracture of the lunate. **b** CT transverse section through the lunate in the same patient that demonstrates comminution that is difficult to appreciate on the plain radiograph

Fig. 5 CT transverse section through the triquetrum demonstrating a dorsal ridge fracture (*arrow*) that was occult on the initial plain radiograph

Fig. 6 CT transverse section demonstrating a minimally displaced fracture of the pisiform

hyperextension and ulnar deviation. Alternatively, dorsal ridge fractures may occur in hyperextension that results in ligamentous avulsion from the dorsal surface of the triquetrum. These fractures can be easily picked up on plain radiographs and CT is seldom indicated unless other associated injuries are present.

Fracture of the triquetral body is not very common and occurs in conjunction with perilunate dislocation and CT will be frequently indicated to assess the extent of the injury (Fig. 5).

3.2.4 Pisiform Fractures

The incidence of Pisiform fractures is about 2%. Pisiform fracture results from a direct blow. Presence of multiple ossification centres and overlap of other bones can make diagnosis of fracture on plain radiograph difficult and CT may be useful to explain the cause of symptoms (Fig. 6).

3.2.5 Trapezium and Trapezoid Fractures

The trapezium is the most mobile bone of the distal carpal row. Trapezial ridge, a vertical prominence on the volar aspect of the trapezium where ligaments and the flexor retinaculum insert, is the most commonly fractured part of trapezium. It might be due to direct blow or avulsion.

Trapezoid is the least commonly fractured carpal bone and accounts for about 0.5% of carpal fractures. Mechanism is usually high energy impact and fractures can be associated with fractures of other bones. Even though fractures cannot be visualised on plain radiographs, they are frequently picked up on CT (Fig. 7).

3.2.6 Capitate Fractures

The capitate is the largest carpal bone. Injuries are usually caused by high-energy impact. The proximal third of the capitate is almost completely covered by

Fig. 7 **a** CT transverse section through the trapezium demonstrating a flake fracture (*arrow*). **b** CT coronal section demonstrating an undisplaced fracture of the trapezoid and a lucent line through the capitate representing a nutrient artery. **c** CT transverse section demonstrating a trapezoid fracture

articular cartilage and CT is frequently used to assess the involvement of the articular surface. Due to poor vascular supply, fractures of the capitate take longer to heal and CT is used to assess healing and look for signs of avascular necrosis (Fig. 8).

3.2.7 Hamate Fractures

Hamate fractures are frequently seen in sporting injuries in individuals using clubs or racquets e.g: Golf and Tennis. These fractures are usually subtle (particularly if they are through the hook of hamate) and are caused by direct trauma from the handle of the club or racquet and can be missed on the plain radiograph. Delayed diagnosis or malunion of the fracture can lead to ulnar nerve palsy and CT is helpful in this scenario (Fig. 9).

3.3 Fractures of Metacarpals

Although metacarpal shaft fractures are easily diagnosed on plain radiographs, fractures and fracture dislocations of the bases of metacarpals can be easily missed and lead to delayed diagnoses and increased morbidity in young patients. Even with views plain

radiographs can underestimate the comminution and angulation. Hence CT is used in diagnosis and operative planning of fractures of the metacarpal bones, especially comminuted fractures and those involving the articular surface. Fractures of the base of first metacarpal, even though relatively easier to see on plain radiographs frequently warrant further imaging to assess fragmentation and articular surface. These fractures, if not treated appropriately can lead to early osteoarthritis and disability (Fig. 10).

3.4 Dislocations

Dislocations of the carpal bones can be grossly classified into lunate dislocations, perilunate dislocations or mid-carpal dislocations based on the relative positions of the distal radius articular surface and the carpal bones. (Gilula and Minnie 1979).

In lunate dislocations, the lunate is displaced relative to the distal radius but the rest of the carpal bones (localized by the capitate) are centered over the distal radius. In peri-lunate dislocation, the lunate is centered over the distal radius but the rest of the carpal bones are displaced. If both lunate and capitate

Fig. 8 CT sagittal section through the Capitate demonstrating a fracture line in an oblique plain. (*blue arrow*) Compared with Fig. 7b, note that the line passes through two cortices indicating a fracture as opposed to a nutrient artery which seldom involves two cortices

are dislocated relative to the distal radius, the term mid-carpal dislocation is used.

CT scan is frequently used to assess collateral damage caused by lunate or perilunate dislocations. As stated earlier, CT is able to identify small flake fragments representing avulsion injuries and comminution, especially of articular surfaces although MR imaging is better at assessing ligament injuries. It is not uncommon to use both imaging modalities in conjunction in cases of significant trauma.

The most common dislocation is the perilunate dislocation. These are caused by high energy impact resulting in wrist hyper-extension and ulnar deviation. They are a broad continuum of injuries ranging from minor ligament strains to complete dislocation of the carpus. Perilunate dislocations are generally associated with carpal instabilities. On application of

stress, ligamentous failure occurs from ulnar side to radius (Fig. 11).

3.5 Fracture Union

As early as 1987, Bush et al. (1987) concluded that CT was much better than plain radiographs in the assessment of fracture union. CT is better fracture gaps, bony bridges and callus. Although literature has described use of MR and Ultrasound in assessing fracture union CT remains the test of choice in assessment of fracture healing, malunion and non union. Newer techniques discussed at the end of this chapter have improved the visualisation of cortical and cancellous bone even in the presence of metal work.

3.5.1 Sequelae of Trauma (Scapho Lunate Advanced Collapse and Scaphoid Non Union Advanced Collapse)

Degenerative changes in the joint are the most common sequelae of trauma.

Scapholunate Advanced collapse (SLAC) is caused by injury to the scapho lunate (SL) ligament, especially the dorsal component which is the most critical scapholunate stabiliser. The ligament can be injured in isolation or as part of perilunate dislocation.

When the SL ligament is injured, lunate tends to dorsiflex and scaphoid tends to rotate into a palmar flexed position. Capitate tends to follow the lunate into a dorsiflexed position and also migrates proximally. These spectrum of changes lead to a dorsal intercalated segmental instability (DISI) which in turn leads to degenerative changes commonly referred to as SLAC wrist.

Similar changes can also occur with nonunion of scaphoid fracture. The scapholunate ligament is usually intact but the biomechanics are similar to that described above. The degenerative changes in this case are usually referred to as Scaphoid Nonunion Advanced Collapse (SNAC). Pattern of degenerative changes can help to diagnose these conditions. Although MR arthrography is the preferred mode of investigation in several centres for this sort of injury, CT arthrography as described in the next section is almost as sensitive and can be used in places where MR arthrography is contraindicated or difficult to access.

Fig. 9 **a** and **b** Transverse and sagittal reconstructions demonstrating a fracture of the hook of the hamate

Fig. 10 Base of metacarpal fracture

First stage involves degenerative changes in the joint between radial styloid and the scaphoid. In the second stage degenerative changes progress to the whole radio-scaphoid joint. In the third stage, changes are seen in scaphocapitate or capitolunate joints (Fig. 12).

3.6 Ligament Injury: CT Arthrography

As alluded to before the wrist joint is one of the most complex joints in the body. For simplification it can be divided into three compartments. The distal radioulnar joint, the radiocarpal joint and the midcarpal joint.

The proximal carpal row is very important in the wrist movements as it acts as the intercalated segment

Fig. 11 Lunate dislocation with multiple small avulsion fractures better appreciated on CT scan

(Kauer 1980). The carpal bones in the proximal row are held together by the scapholunate (SL) and the lunotriquetral (LT) ligaments. Both these ligaments are horseshoe shaped, with the palmar and dorsal segments thicker (more important biomechanically) than the central segment (also known as proximal or membranous segment) (Boabighi et al. 1993) (Fig. 13).

They merge anteriorly and posteriorly with the articular capsule, and seal off the radiocarpal and midcarpal compartments (Berger 1996). Another

Fig. 12 **a** Demonstration of the normal SL angle (between 30° – 60°). **b** DISI deformity with dorsal tilt of lunate and SL angle $>60^{\circ}$

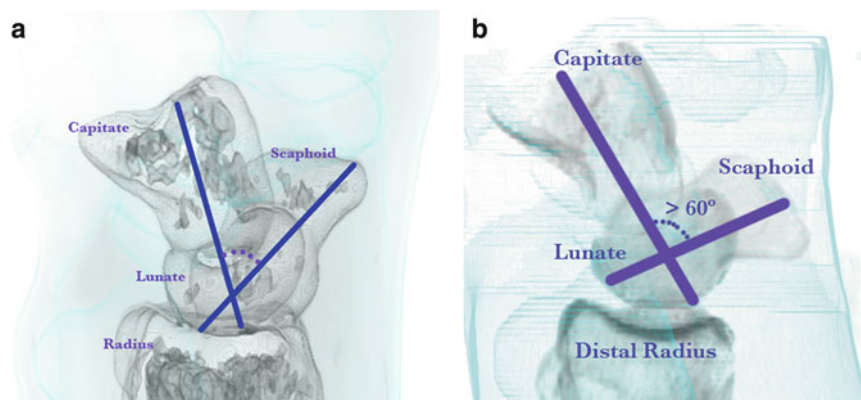

Fig. 13 Demonstration of intrinsic ligaments of the wrist. *Purple*: Volar scapho-lunate and luno triquetral ligaments. *Blue*: Proximal scapho-lunate and luno triquetral ligaments. *Yellow*: Dorsal scapho-lunate and luno triquetral ligaments

important structure is the Triangular Fibro Cartilage Complex (TFCC). It includes the extensor carpi ulnaris tendon sheath, the dorsal radioulnar ligament, the triangular fibrocartilage proper, the volar radioulnar ligament, the ulnocarpal ligaments, the ulnar collateral ligament, and the meniscus homologue. The TFCC is the key stabilizer of the DRUJ and it seals off the DRUJ from the radiocarpal joint. The capsular ligaments between the carpal bones form the secondary stabilizers of the wrist joint. These have been described in detail in literature. (Viegas 2001).

These intrinsic ligaments of the wrist can be depicted with several imaging modalities, including conventional arthrography, MR imaging (with and without intraarticular contrast agent administration),

and CT arthrography. The development of dynamic multislice CT studies allows a diagnostic approach that combines dynamic information and the accurate assessment of ligaments and the TFC complex.

Technique: Firstly the wrist is positioned horizontally under vertical fluoroscopic guidance. Then under aseptic conditions, using a 24-gauge needle, puncture is made on the dorsal aspect of the wrist (as demonstrated in Fig 14a). On average, a total of 5 mL of iodinated contrast medium is injected. The concentration should be lower than 300 mg of iodine per milliliter to avoid beam-hardening artifacts with MDCT. After the injection the patient is immediately directed to the MDCT to avoid excessive dilution of contrast medium.

Fig. 14 **a** Image representing the various joint capsules and sites for injection. *Purple*: mid carpal joint with injection site between the carpals *Blue*: Radiocarpal joint with preferred injection site being over the proximal articular surface of scaphoid. *Pink*: Distal radio-ulnar joint with preferred injection site over the distal ulna. **b** Contrast injected into radiocarpal joint was seen within the Distal radio ulnar joint (DRUJ) indicating a perforation of the Triangular fibro cartilage complex (TFCC). **c** Contrast is replacing the normal and LT ligaments indicating a full thickness tear in this young patient who had recent trauma

CT scan is then acquired as described in the previous section.

Coronal images provide a practical overview of the wrist joint. The central (proximal) parts of SL and LT ligaments are best seen on the coronal reformats and are usually meniscoid and insert onto cartilage. The transverse images are essential for appreciating the functionally important dorsal and volar portions of the SL and LT ligaments which are flat and insert onto the bones. Sagittal images provide a good analysis of the TFCC.

Ligament tears: These can be traumatic or degenerative. The traumatic tears are usually after fall on an outstretched hand and may be associated with carpal bone dislocations or fractures. Classification of ligament tears helps differentiate full-thickness (usually communicating) tears from partial-thickness (non-communicating) tears (Fig. 14b). For MDCT arthrography, a ligament tear is defined as communication of intraarticular contrast material through any segment of the ligament. TFCC tears (Fig. 14c) are

routinely classified according to the system developed by (Palmer 1989).

In the literature the sensitivity and specificity of CT arthrography has been described as high as 100 % for detecting SL ligament tears and 85 and 100 %, respectively, for LT ligament tears (Theumann et al. 2001; Schmid et al. 2005).

The advantages of CT are small field of view, excellent spatial resolution and quick scan time which virtually eliminates movement artifact.

3.7 Arthropathies

The commonest site of osteoarthritis (OA) in the hand is the first carpometacarpal (CMC) joint followed by distal interphalangeal joints. OA affecting the CMC joint is often debilitating, most commonly affecting postmenopausal women. The first CMC joint is the most commonly operated site in the hand for arthritis (Arnett et al. 1988). CT is useful in

Fig. 15 **a** Cyst within Capitate. Note the clarity of the intact cortical outline. **b** Erosion, tip of proximal phalanx. Due to the size of the erosion, it would have been difficult to illustrate on MR

operative planning and postoperative follow up if required.

Rheumatoid arthritis (RA) is a chronic inflammatory arthropathy of unknown etiology affecting a large cohort of the population. The success of disease modifying antirheumatic drugs (DMARD) and more recently the advent of biologic response-modifying drugs has increased the interest in the imaging modalities for evaluating the disease progression. These drugs are not only very expensive but are also potentially toxic necessitating their judicious use. The presence of erosions in early disease serves as a diagnostic marker for RA and is a sign of poor prognosis, signaling potentially aggressive disease (Van der Heijde et al. 1992).

Plain Radiographs, Doppler Ultrasound, Computerized Tomography (CT), Magnetic Resonance Imaging (MRI) and scintigraphy have been used for evaluation and diagnosis of the erosions. (Østergaard et al. 2003).

In CT cortical bone, being very dense, is readily visible, as is the interface with adjacent soft tissues. Thus, CT is capable of clearly delineating the borders of erosions and differentiating bone (whether edematous or not) from inflamed synovium. While plain radiography has traditionally been used as the gold standard for imaging erosions, the main disadvantage is that there are many regions such as the carpal bones where complex three-dimensional anatomy is very inadequately depicted using a two-dimensional modality. This problem is circumvented by multi-detector helical CT (MDCT), which offers the benefits of multiplanar capability, similar to MRI, with the enhanced cortical

definition intrinsic to plain radiography. Erosions on CT were defined as focal areas of loss of cortex with sharply defined margins, seen in two planes, with cortical break seen in at least one plane (Perry et al. 2005).

The main advantages of CT are that it is less expensive and faster than MR. The quick scan time is very useful in patients with concurrent shoulder disease, who have to be lying in the superman position for the scan. Another disadvantage of MR may be the conventional 3 mm slice thickness which can lead to partial volume artifacts on MR. This may lead to misinterpretation of small erosions. MDCT has the advantage of capability of acquiring images of 0.5 mm slice thickness thus reducing this artifact. Bone sclerosis can mask erosions on the MRI, but MDCT is capable of detecting erosions in the presence of extensive sclerosis. MRI does have the advantage that it allows imaging of inflammatory change within the joint, including synovitis, bone edema, and the “activity status” of erosions. None of these can be detected using CT (Perry et al. 2005). These modalities should therefore be regarded as complementary to each other in the detection of disease activity in rheumatoid patients (Fig. 15).

3.8 Tumor Imaging

Role of CT in evaluation of tumours can be complementary to MR, which is the main modality used for local tumor staging. If a lesion is suspected or discovered, the diagnostic work-up should begin with plain radiographs of the area of interest. If the tumor characterization with radiography is sufficient and in

Fig. 16 **a** Bone scintigraphy demonstrating a ‘hot spot’ which on subsequent CT. **b** was shown to be an osteoid osteoma with smooth round margins and central nidus. Contrast with **c** where

cortical break and irregularity of margins is demonstrated in keeping with a more aggressive lesion; in this case osteomyelitis

an adult metastatic disease is suspected then a bone scan to look for multiple metastatic lesions followed by a CT scan of the thorax, abdomen and pelvis is usually recommended. But if a primary bone tumor is suspected then work-up should proceed with MR imaging to evaluate the intra and extraosseous extent of tumor. Where it may be difficult to discern the pattern of bone destruction, it is recommended that CT be performed following radiography. This will help determine the pattern of bone destruction and periosteal new bone formation and to assess for the presence of matrix mineralization.

Osteoid osteoma is a benign bone tumor representing approximately 10 % of all benign bone tumors. It is more common in the lower limbs. Localization in the hand occurs with an incidence of 8 % of all reported cases (Allieu and Lussiez 1988). The phalanges are the most frequent sites in the hand (Ambrosia et al. 1987) followed by the carpal bones. Lesions in the hand may display less reactive sclerosis, a finding that can be misleading. Because of the proximity of the bones in the hands and feet, an inflammatory reaction that originates from one carpal or tarsal lesion often spreads to adjacent bones and joints. Moreover, soft-tissue swelling may be prominent in osteoid osteomas of the hands and feet, a finding that may resemble infection or inflammatory arthritis.

Many studies have shown CT is more useful than MR in illustrating the nidus. (Assoun et al. 1994) CT demonstrates the nidus as a round or oval well defined area with low attenuation. An area of high attenuation may be seen centrally, a finding that represents mineralized osteoid (Gamba et al. 1984) At radiography, it is very difficult to differentiate an intracortical abscess with a sequestrum and an osteoid osteoma with a calcified nidus. However, it is easier to differentiate between the two conditions on CT. In osteoid osteoma, the inner side of the nidus is smooth, and a round calcification is seen in the center of the nidus. In an intracortical abscess, the inner margin is irregular, and an irregularly shaped sequestrum is seen eccentrically (Chai et al. 2010) (Fig. 16).

4 Modern Advances

The limitations of CT scanning traditionally have been high radiation dose, low temporal resolution and artefacts due to metals. Another criticism has been that the anatomical images produced using a CT scanner are a ‘snapshot in time’ that do not show the dynamic interaction between the various structures which would be useful in guiding treatment. This is especially true of complex joints like the wrist.

Newer generation scanners have several features that help to overcome these limitations.

Various dose reduction techniques have been introduced by different CT manufacturers. With the increase in computing power, statistical and model based iterative reconstruction algorithms are being used for image manipulation. Research work being carried out in various hospitals including our institution have shown that extremity CT scans with good quality diagnostic images can be produced at doses comparable to plain radiography. If proven to work safely and accurately in a clinical setting, CT scans could replace plain radiography in the initial evaluation of trauma.

Modern scanners have high temporal resolution which can be utilised to perform dynamic imaging. Dynamic CT scan of the wrist has been performed in an experimental setting using cadaveric hand by Leng et al. (2011). This is possible due to the high temporal resolution offered by newer generation scanners. In the experimental setting, joint stability and relative motion of the carpal bones could be assessed. This is useful in early SLAC and SNAC wrist before the degenerative changes set in.

Artifacts due to metal can be reduced significantly by newer noise reduction techniques. Better receptors and high definition scanning modes also help to reduce metal artifacts. Another feature that is available in newer scanners is dual energy tubes. By using X-rays at two different energies (e.g 80 and 140 kV) metal prosthesis can be digitally subtracted to assess fracture healing, periprosthetic fractures and joint integrity.

Dual energy CT scanners have found application in characterisation of crystals in joints especially in patients suffering from Gout. Glazebrook et al. (2011) have demonstrated that Dual energy CT can successfully characterize uric acid crystals. Although in most clinical settings, it is difficult to justify irradiating the patient rather than aspirating easily accessible joints like the wrist, it can be used in special circumstances where aspiration is difficult or contra indicated.

5 Conclusion

In the four decades since its invention, the use of CT has rocketed. At the same time advances have placed it at the forefront of medical imaging. This progress looks set to continue and CT is more likely to become

the modality of choice in the imaging of trauma. Modern advances look promising and CT could encroach into the domain of other modalities like MR imaging and plain radiography.

Abstract

The complex anatomical nature of the hand and wrist brings about diagnostic challenges both for the Clinician and the Radiologist when considering pathology in this region. MR is a proven, widely employed imaging modality used in the detection, assessment and follow-up of disorders of both the hand and the wrist. Optimisation of both sequences and protocols are essential in order to provide good quality images which allow high sensitivity and specificity for detection of pathology. High field strength units are usually used in hand and wrist imaging alongside dedicated extremity coils. Even then, there are numerous artefacts which may be encountered including movement, pulsation, truncation, magic angle and chemical shift. These phenomena will be discussed in this chapter in addition to a brief outline of sequences and their potential uses. Pathology relating to osseous structures, tendons, TFCC and both intrinsic and extrinsic ligaments are all readily assessed on MR imaging and the optimal planes for imaging are discussed alongside common pathologies and potential pitfalls in image interpretation. MR arthrography is also discussed with particular reference to both TFCC and intrinsic ligament pathology. Recent advances in technology, including the advent of 7T units, have led to improvements in the assessment of articular cartilage at the wrist and techniques of biological imaging, which continue to evolve.

1 Introduction

The complex anatomical nature of the hand and wrist brings about diagnostic challenges both for the Clinician and the Radiologist when considering pathology in this region. However, advances in imaging techniques have allowed increasingly accurate diagnostic performance and MR imaging is a proven, widely employed imaging modality for the detection, assessment and follow-up of disorders of the hand and wrist. The radiologist requires a detailed knowledge of the anatomy and range of pathological conditions affecting the hand and wrist. However, a knowledge of the clinical information and careful consideration of the available and most appropriate imaging modalities are essential in determining the relevant technique and sequence protocols.

There are many potential pitfalls when imaging the hand and wrist, an incorrect sequence or misinterpretation of an anatomical variant may lead to inaccurate diagnosis particularly of both TFCC and intrinsic ligament pathology. This chapter will provide a review of technical considerations and MR protocols followed by discussion of the most common and most relevant clinical applications.

2 Technical Considerations

In general terms, the higher the magnetic field strength used in MR imaging the greater both the signal-to-noise ratio (SNR) and the contrast-to-noise ratio (CNR) achieved. An increased SNR allows thinner slice thickness which in turn allows greater spatial resolution and also shorter acquisition times, thereby reducing the likelihood of patient movement. Thin and contiguous slices are needed in order to accurately image the intrinsic structures of the wrist many of which are no greater than a few millimetres thick.

A high field strength magnet (1.0T or higher) is usually preferred for optimal imaging of the fine architecture of the hand and wrist; in addition a local or surface coil is necessary to ensure sufficient signal-to-noise ratio. However, for applications which rely on contrast resolution as opposed to spatial resolution—for example evaluation of radiographically occult fractures or osteonecrosis of the carpus—lower field strength extremity units (0.1–0.6T) in either

open or extremity units may suffice to answer a specific clinical question. However, in this situation cartilage lesions and subtle pathology of the tendons, ligaments and fibrocartilage will not be as readily identified. These low field strength scanners may be useful where there is limited space available within a department and for patients who are either claustrophobic or obese.

The majority of studies comparing the sensitivity and specificity of low field strength versus high field strength units in the upper limb have focussed on shoulder imaging, often with conflicting outcomes. Currently, most centres performing regular hand and wrist imaging will use at least a 1.5T unit and increasingly 3T units are becoming the norm. Thinner slices are possible with 3T imaging and CNR may be increased by a magnitude of 2.0–2.9 times that of 1.5T if all other parameters are kept constant (Saupe et al. 2005). Studies have shown the higher SNR and CNR obtained with 3T units allow significantly improved visualisation of the small anatomical structures of the hand and wrist including the scapholunate and lunotriquetral ligaments (Saupe et al. 2005). Although direct comparisons have not been undertaken, findings suggest that 3T imaging may have improved sensitivity and specificity compared to 1.5T imaging for detection of both TFCC tears and scapholunate tears (Magee 2009). Improved visualisation of the median and ulnar nerves at high field strengths imaging has also been documented (Farooki et al. 2002).

Coil selection is also vitally important in hand and wrist imaging and receiver coils with high signal-to-noise ratio capability and uniformity are needed. Surface array coils are used to provide high SNR and an extended field-of-view (Roemer et al. 1990). Studies have also shown that phased array coils and adapted birdcage head coils may be used to provide both high SNR and image uniformity (Kocharian et al. 2002). Coils continue to improve with greater numbers of elements, but the optimising coils for hand and wrist imaging remains an engineering challenge.

2.1 Positioning

In high field strength systems, there are two main options for patient positioning; the patient may lie prone within the scanner, with their symptomatic arm stretched out above the head and the wrist positioned

Fig. 1 Sagittal T2W FS image with the wrist in ulnar deviation. The lunate shows slight dorsal tilt but the long axis of the capitate remains aligned with the long axis of the radius—indicating that this appearance is due to physiological positioning

within the isocentre of the magnet, thereby allowing for homogenous fat suppression, or alternatively they may lie supine with the hand and wrist at the side of the body. The latter position may prove to be more comfortable for the patient but can lead to inhomogeneous fat suppression given the wrist and hand are not central within the magnet. Motion artefact can be a significant problem and it may be more important to optimise patient comfort and accept suboptimal positioning. Motion artefact is minimised by using restraints such as foam cushions and wedges. In order that positioning abnormalities are not incorrectly diagnosed as carpal instability syndromes it is important to eliminate significant radial or ulnar deviation at the wrist. However, even correctly positioned wrists may occasionally simulate a dorsal intercalated segment instability and correlation with both clinical findings and a lateral radiograph may be helpful in this situation. It is also useful to note that the long axis of the capitate will remain centred on the long axis of the radius when the lunate undergoes physiological extension, while in a

true DISI deformity there will be dorsal translation of the long axis of the capitate (Fig. 1).

The degree of pronation and supination of the wrist will influence the appearances of the distal radioulnar joint (DRUJ). Ideally, MRI is obtained with the wrist in a neutral position as pronation and supination can mimic dorsal and volar subluxation of the ulnar at the DRUJ. It is important to consider wrist positioning before diagnosis of DRUJ subluxation is made (Fig. 2a, b). Pronation and supination also influence the appearance of the relative length of the radius and ulnar. The ulnar appears longer relative to the radius in pronation.

For imaging of the fingers, both supine (with the arm at the side of the body) and prone (with the arm above the head) positions are described in the literature and are accepted techniques for producing good image quality (Blackband et al. 1994). As with wrist imaging positioning within the centre of the magnetic field is vitally important in imaging the fingers. Generally, the fingers are imaged when fully extended, however the flexed position (around 45 degrees), may be of value in evaluating possible pulley lesions as well as collateral ligament injury (Hauger et al. 2000).

For imaging individual finger joints a surface microscopy coil may be useful (Tan et al. 2005). If both hands or both wrists are to be imaged on the same patient then a larger extremity coil may be used to image both sides at one time thereby decreasing the scan time required. The hands and wrists can be placed palm together with the arms above the head both within the coil.

2.2 Imaging Planes

Typically protocols for the hand and wrist include images acquired in all three orthogonal planes. Imaging the thumb presents particular difficulties for alignment of planes as it does not lie in an orthogonal plain relative to the hand and wrist. In this situation, sagittal and coronal imaging is aligned relative to the thumb metacarpal from an axial image.

2.2.1 Axial

Axial imaging is usually performed first as these sequences are then used to set up the coronal and sagittal sequences. The plane should be determined as

Fig. 2 **a** and **b**—Axial imaging in the same asymptomatic patient with the wrist in **a** pronation and **b** supination. With the wrist in supination appearances suggest volar subluxation of the ulnar (*asterix*) and in pronation there is dorsal subluxation of

the ulnar (*asterix*). There is also a marked change in position of the Extensor carpi ulnaris tendon (*white arrow*) between these two wrist positions. To eliminate these apparently abnormal findings it is important to image the wrist in a neutral position

Fig. 3 The coronal plane is determined by a line bisecting the scaphoid, lunate and capitate (*yellow line*) on an axial image through the proximal carpal row

being parallel to the distal radius. For imaging of the wrist coverage should include the region between the distal radius/ulnar metaphysis proximally, extending to the proximal metacarpal shafts distally.

2.2.2 Coronal

The correct plane is crucial for coronal imaging and should be derived from an axial image through the proximal carpal row. The plane of section should bisect the scaphoid, lunate and capitate (Fig. 3). The TFCC is best demonstrated on coronal sequences, and this plane may also be used to assess both the

Fig. 4 Sagittal T2 FS image of the index finger shows both the flexor and extensor tendons as low signal structures inserting into the distal phalanx. This plane may be used to assess continuity of the tendons as well as alignment within the digit. The tendon is concave towards the proximal and middle phalanges (*black arrow*) as a result of the action of the associated pulleys at these levels. The volar plate is also demonstrated in this plane (*white arrows*)

intrinsic and extrinsic ligaments of the wrist. For imaging of the fingers the coronal plane will be determined as being parallel to the anterior volar cortex of the metacarpal heads.

2.2.3 Sagittal

The sagittal plane should be perpendicular to the coronal plane and for wrist imaging should include all soft tissues to either side of the radius and ulnar. Sagittal images are useful in determining carpal alignment and carpal instability and in the fingers the flexor and extensor tendons are best evaluated in this plane (Fig. 4).

2.3 Sequences

The exact protocols for imaging the hand and wrist will vary between institutions depending on radiologist and clinician preferences and on the scanning unit involved.

2.3.1 T1 Weighted Imaging

T1 weighted imaging is ideal for detecting marrow infiltration and is also helpful in distinguishing areas of red marrow reconversion from pathological area of change and should be included in a routine wrist protocol in at least one plane without fat saturation.

2.3.2 Fast Spin Echo

Fast Spin Echo (FSE) sequences also referred to as Turbo Spin Echo (TSE) were originally introduced in order to speed up image acquisition through the simultaneous acquisition of multiple echoes. The advantage over spin echo sequences (SE) is the reduction in acquisition time, for long TR sequences. This reduces examination time but also helps to minimise movement artefact whilst maintaining the same SNR. FSE imaging forms the basis of proton density and T2 weighted imaging widely used in clinical hand and wrist MRI. Frequency selective fat suppression will be often applied to these sequences. In addition to improving their sensitivity to water, particularly in fatty bone marrow, fat suppression will also improve contrast between bone and articular cartilage. Fat suppressed proton density FSE imaging is particularly good for imaging articular cartilage. Recently, 3D fast SE became available from some manufacturers giving the potential for thin slice contiguous images and multiplanar reconstructions. Their use is still being evaluated and evidence would suggest they are not yet suitable to replace 2D FSE imaging (Stevens et al. 2011).

2.3.3 Short T1 Inversion Recovery

Short T1 Inversion Recovery (STIR) sequences provide an alternative means to achieve fat suppression. Where a relatively short inversion time is used to null the fat signal whilst maintaining water and soft tissue signal. This technique is particularly helpful where field inhomogeneities prevent uniform fat suppression. This can be a particular problem

with hand and wrist imaging if it is not possible to position the area of interest in the isocentre of the magnet. STIR sequences are particularly useful in the detection of bone marrow abnormalities in the hand and wrist such as occult fractures. In addition the TFCC and intrinsic ligaments are often well visualised on STIR sequences. STIR images show high contrast but suffer from a low signal to noise ratio. STIR is not specific to fat and tissues with a similar T1 signal to fat will also be suppressed—this includes structures which have shown enhancement following gadolinium administration.

2.3.4 Gradient Echo

Gradient Echo images provide a high degree of spatial resolution but at the expense of relatively poor contrast resolution. In addition, 3D T1 weighted gradient echo images may be used to allow thin slice multiplanar reconstructions. These sequences show increased susceptibility artefact and therefore are of little use in the presence of metalwork, such as following surgery.

2.3.5 Typical Protocols

As already stated protocols will vary depending on preference, indication of the examination and MRI equipment. Typically, a routine wrist MRI protocol will include axial coronal and sagittal imaging using a combination of FSE proton density and T2 imaging. Fat suppressed imaging is helpful for demonstrating cartilage and improving sensitivity to fluid in bone and will usually be applied in at least two planes. It is important to include at least one non-fat suppressed T1 weighted sequence. The authors also make frequent use of thin slice 3D gradient echo sequences (GE), particularly for the evaluation of subtle bony erosions in the wrist and hand joints.

In some situations a far more limited protocol can be utilised. For instance to identify radiographically occult bone injury, particularly possible scaphoid fracture, T1 and T2 imaging in the coronal and sagittal plane may suffice.

The use of iodinated contrast may be required in some situations such as the evaluation of scaphoid non-union/avascular necrosis or for identifying synovitis (and distinguishing it from effusion) in arthritis imaging.

Fig. 5 T2 FSE axial image which shows several areas of flow artefact which manifests as ghosting of the vessels perpendicular to the blood flow in the direction of the phase-encoding gradient (*white arrows*)

Fig. 6 Chemical shift artefact—Coronal image of the wrist which shows chemical shift artefact between the capitate and hamate. This occurs in the direction of the frequency encoding gradient and manifests as a low signal intensity band adjacent to the subchondral plate of the capitate (appearing as a thickened subchondral plate) (*white arrowheads*) and a corresponding high intensity band along the subchondral bone of the opposing articular surface of the hamate (*black arrowheads*). The effect is to give an apparent asymmetry to the thickness of the articular cartilage on the two surfaces

2.4 Artefacts

2.4.1 Motion Artefact

Motion artefact will manifest as blurring or ghosting of the images. In the hand and wrist patient movement is a common cause however pulsation artefact from vessels may also occur.

2.4.2 Pulsation Artefact

Pulsation artefact results from blood flow and can be minimised by saturation bands perpendicular to blood vessels. The effect can also be minimised by planning the phase encoding direction to cast the artefact away from anatomical structures that need to be evaluated (Fig. 5).

2.4.3 Chemical Shift Phenomena

Chemical shift phenomena are usually apparent at water–fat interfaces due to a difference in resonance frequency between fat and water; fat resonates at a slightly lower frequency than water (Larmor frequency). Both SE and GE may demonstrate chemical shift artefact which appears as a hypointense band, one to several pixels in width, towards the lower part of the gradient field, and as a hyperintense band towards the higher part of the readout gradient field. This phenomenon is more pronounced at higher field strengths and lower gradient strength. In MR imaging of the wrist, chemical shift artefact is most frequently appreciated at the cartilage–bone marrow interface (Fig. 6), and may lead to over-estimation or underestimation of the cartilage thickness.

2.4.4 Susceptibility Artefact

Susceptibility artefact is related to the internal magnetisation induced in tissues by the external magnetic field and refers to the focal loss of signal intensity and distortion of the magnetic field secondary to low proton structures such as air or metal. This form of artefact is encountered frequently in musculoskeletal imaging due to the presence of surgical hardware or clips (Fig. 7). The metallic objects produce T2 and T2* shortening which results in signal loss and geometrical distortion. This effect increases exponentially with high field strength and is one of the disadvantages when imaging at 3T and higher. Approaches to reducing susceptibility artefact include: increasing the band width and/or decreasing the TE, parallel imaging, decreasing the voxel size, or lengthening the echo train length.

2.4.5 Truncation Artefacts

Truncation artefacts may occur at interfaces between high and low signal intensity structures and appear as rings at boundaries such as bone–tissue interfaces. This artefact is related to the finite number of steps used by the Fourier transform to reconstruct an image and is reduced by utilising more frequency encoding steps.

Fig. 7 Susceptibility artefact—Coronal image of the wrist joint in a patient who had previously undergone scapholunate ligament repair. A low signal area is seen in the region of the repair secondary to susceptibility artefact arising from a metallic anchor

2.4.6 Magic Angle Effect

Magic angle effect may be seen in any structure containing collagen fibres and is seen as a result of the dipole interaction between the applied external magnetic field (B_0) and the collagen fibres. This effect results in regions of artefactually increased signal intensity within the structure being imaged on short TE (T1 and proton density) sequences. The phenomenon is maximised when the relative angular orientation of the collagen fibres to the static magnetic field is approximately 55 degrees. Tendons, hyaline cartilage and menisci may all be affected by the magic angle effect which should not be misinterpreted as tendinopathic change or tearing (Fig. 8). Repositioning of the patient in a different orientation to the applied magnetic field or by using sequences with a long echo time (T2-weighted sequences) will eliminate the artefact. When magic angle effect is suspected it is useful to compare the short TE images with the same area on T2 weighted imaging.

2.4.7 Aliasing or Wraparound Artefact

Aliasing or wraparound artefact is seen where an image of tissue from outside the field-of-view (FOV) appears superimposed on images of the area of interest. This may be from a different body part positioned adjacent to the area of interest or the result of parts of the hand or wrist outside the field-of-view being superimposed on the area of interest (Fig. 9). The former is most usually seen when the hand or wrist is positioned by the side of the patient while the latter is particularly common with the small FOV imaging usually employed in hand and wrist imaging. In this case, images of adjacent body parts may be superimposed on the FOV. In both cases the resultant image resembles a double exposure photograph.

All frequency related artefacts are more pronounced at 3T imaging compared with 1.5T imaging (Barth et al. 2007). This includes metal related signal voids and other types of susceptibility artefact related to hemosiderin deposition and at air tissue interfaces as well chemical shift artefact. However, at 3T imaging the increased SNR can be employed to compensate for these artefacts more effectively whilst still maintaining a high degree of spatial resolution.

3 Imaging Findings

3.1 Osseous Structures

T1 weighted images demonstrate osseous anatomy well and are particularly useful for the detection of fracture lines and bone marrow oedema (appearing as a low signal change within the medullary cavity). However, fat suppressed T2 imaging is also sensitive to marrow signal change [seen as increased (fluid) signal] although anatomical definition may be less clearly shown. In cases of non-specific wrist pain, focal bone oedema has been shown to be present in approximately one-third of all cases on MR imaging (Alam et al. 1999); in this study, the causes demonstrated included arthritis, fracture and avascular necrosis.

MR imaging has been proven to be useful post trauma in the context of negative radiographs with particular reference to identifying occult scaphoid fractures (Breitenseher et al. 1997; Hunter et al. 1997). Early confirmation of the diagnosis is possible

Fig. 8 **a** T1 axial image of the hand distal to the carpal tunnel. There is low signal change seen within the Flexor Pollicis Longus tendon due to magic angle phenomenon (*arrow*). **b** axial

image of the same patient but with altered parameters—this sequence has a long TE value and the magic angle phenomenon is abolished (*arrow*)

Fig. 9 Wraparound artefact—Superimposed ghosting of the splinting flexor tendons is seen at the periphery of the image as a result of wraparound artefact. In addition, there is a ghost image of the thumb to the *left* of the image

with MR imaging as opposed to the previously accepted method of repeating plain radiographs 7–10 days following the initial presentation. MR imaging is also useful for demonstrating the early

stages of avascular necrosis when plain film images appear normal. This is most commonly seen following fracture to the scaphoid in association with non-union. An indicator of developing non-union is sclerosis around the fracture site without evidence of bridging bone. In the advanced stages of the condition findings also include articular surface collapse and fragmentation of the involved bone. Gadolinium sequences are used to assess for the presence of vascularity within the scaphoid where there is concern for avascular necrosis—in this case T1 weighted images show uniform low signal within a necrotic segment and there is no enhancement in a non-viable segment following administration of IV gadolinium.

3.2 Tendons

The extensor tendons situated on the volar aspect of the wrist are divided into six numbered compartments by vertical septae and the extensor retinaculum (Table 1). On the volar aspect of the wrist the eight digital flexor tendons are divided into superficial and deep groups which—along with the flexor pollicis longus tendon which inserts into the distal phalanx of the thumb, pass through the carpal tunnel. The digital flexors share a

Table 1 Extensor tendon compartments

I	Abductor pollicis longus, Extensor pollicis brevis
II	Extensor carpi radialis longus, Extensor carpi radialis brevis
III	Extensor pollicis longus
IV	Extensor digitorum longus
V	Extensor digiti minimi
VI	Extensor carpi ulnaris

common flexor tendon sheath apart from the flexor pollicis longus which has its own sheath. At the level of the carpal tunnel the flexor digitorum superficialis (FDS) tendons lie superficial to the flexor digitorum profundus (FDP) tendons. Each superficial tendon then splits at the level of the proximal phalanx passing either side of the profundus tendon to insert into the middle phalanx. The flexor digitorum profundus continues to insert onto the distal phalanx.

The flexor and extensor tendons of the hand and wrist are best evaluated in an axial plane; normal tendons should appear as homogeneously low signal structures regardless of the imaging sequence used (Fig. 10). Both proton density and T2 weighted sequences in the axial plane are usually sufficient to assess the intrinsic signal characteristics of the tendons and assess for any surrounding fluid. The tendons are susceptible to magic angle effect and the T2 sequence is helpful to rule this out where high signal is seen in tendons on the shorter TE sequence (Fig. 8). A small amount of fluid may be seen within the tendon sheath in normal asymptomatic patients and when seen warrants careful correlation with clinical findings before it is reported as abnormal. Tendinopathy is characterised by high signal change within the tendon. The tendon is frequently also thickened. Tenosynovitis is characterised by circumferential high signal fluid within the tendon sheath (Fig. 11). The tendons which are most frequently affected by tendinosis are those of the first and sixth extensor compartments, namely the abductor pollicis longus and the extensor pollicis brevis (involved in De Quervain's tenosynovitis) and the extensor carpi ulnaris respectively. The latter is particularly frequently affected in rheumatoid arthritis. De Quervain's tenosynovitis is typically associated with thickening of the tendons themselves. In the acute phase fluid may be seen in the tendon

Fig. 10 Axial normal wrist—Axial PD image of the wrist. The tendons appear as homogeneously low signal oval structures. The six extensor compartments are labelled on the volar aspect of the wrist. Lister's tubercle (*asterisk*) is a useful landmark on the distal radius which separates compartments II and III

sheath but in the chronic situation thickening of the soft tissue around the compartment (the extensor retinaculum) will be seen. Tenosynovitis of the digital flexors is commonly related to chronic injury, repetitive microtrauma and inflammatory arthropathy. Flexor tendon tenosynovitis is a common cause of carpal tunnel syndrome due to the close anatomical proximity of these tendons to the median nerve.

Coronal sequences of the flexor and extensor tendons are rarely useful owing to partial volume effects which occur in this plane. Sagittal sequences are of most value when assessing abnormalities of the finger flexor and extensor tendons.

3.3 Triangular Fibrocartilage Complex

The TFCC is a fibrocartilage ligament complex which overlies the distal ulna and is not only an important stabiliser of the distal radioulnar joint but also acts as a soft tissue cushion between the distal ulna and the carpus. This complex comprises five components: the triangular fibrocartilage, dorsal and volar radioulnar ligaments, ulnolunate and ulnotriquetral ligaments, the meniscal homologue and the extensor carpi ulnaris (ECU) tendon sheath (Fig. 12). The thickness of the TFCC varies from 2 to 5 mm and depends upon the configuration of the joint space—negative ulnar variance will lead to a thicker TFCC and conversely positive variance will lead to

Fig. 11 Tenosynovitis—Axial T1W imaging post gadolinium administration in a patient with rheumatoid arthritis shows circumferential enhancing soft tissue within the flexor tendon sheath of the little, middle and index fingers separating the deep and superficial flexor tendons and representing tenosynovitis. In addition, there is marked enhancing synovitis seen thumb MCP joint (*arrowheads*)

a thinner structure. Its radial attachment is to the articular cartilage of the sigmoid notch of the radius. There are two distinct ulnar attachments, the first to the ulnar fovea at the styloid base and the second to the styloid process of the ulnar. Separating these two areas of insertion is an area of connective tissue known as the ligamentum subcruentum (Nakamura et al. 1996). The blood supply to the TFCC comes from three sources: the ulnar artery and both the palmar and dorsal branches of the anterior interosseous artery. These vessels penetrate the peripheral aspect of the TFCC however the central and radial portions are avascular. Consequently, the peripheral portion has the potential to heal following repair whereas the central and radial portions do not.

Assessment of the integrity, thickness and signal characteristics of the TFCC is optimal in the coronal plane where the articular disc, the meniscal homologue, triangular ligament and ulnotriquetral ligament are all well visualised. The dual attachment of the TFCC to the ulnar is also best appreciated in this plane, where insertion into both the ulnar styloid tip and the fovea are seen. It is important not to mistake this bifid attachment for a tear. In addition the axial plane will better demonstrate the volar and dorsal radioulnar ligaments. The sagittal plane is also useful in visualising the ulnar foveal attachment (Amrami and Felmlee 2008).

The articular disc of the TFCC is seen on high resolution MR imaging as a low to intermediate signal

Fig. 12 Normal TFCC anatomy—coronal T2 FS image shows a normal TFCC. The bifid ulnar attachment (*white arrows*) may be seen here as well as the radial attachment. At the radial attachment hyaline cartilage is seen interposed between the TFCC and the bone (*black arrow*)—this appearance should not be misinterpreted as a TFCC tear. In this case, there is a tear of the scapholunate ligament with consequent widening of the scapho-lunate distance (*arrowheads*)

intensity band with slightly higher signal characteristics seen within the ulnar attachment on proton density and T2 star weighted images. Perforations or tears of the TFCC structure are seen as discrete areas of high signal intensity coursing through the substance of the articular disc. Degenerative change will manifest as an area of high signal intensity within the articular disc but without extension to the articular surface (Fig. 13). The radial attachment of the triangular fibrocartilage is onto hyaline cartilage and on conventional MRI this will appear as relatively high signal between the cortical bone and fibrocartilage, an important pitfall when diagnosing radial attachment tears.

Several studies have confirmed the role of MR imaging in diagnosing TFCC pathology. However, the performance of standard MRI in the diagnostic work-up of TFCC tears is highly dependent upon the location of the lesion. Studies have demonstrated that for central and radial sided TFCC tears sensitivity and specificity is in the region of 90 % when compared with arthroscopy. However, for peripheral attachment tears sensitivity and specificity are much lower. The relatively low yield of MRI for peripheral tears is primarily attributed to the false positive results induced by the high signal of the ligamentum

Fig. 13 Degenerative TFCC—PD FS coronal image shows. This case shows a patient with ulnar lunate abutment syndrome. There is bone oedema seen with the proximal aspect of the lunate (*white arrow*) and diffuse intrinsic high signal is seen within the radial central portion of the TFCC representing degenerative change within the fibrocartilage (*arrowhead*). This high signal does not extend to the articular surface and should not be misinterpreted as a tear

subcrucium on T2-weighted sequences along with the abnormal signal that may stem from degenerative changes of fibrocartilage. Tears affecting the central portion of the articular disc are generally felt to have a degenerative aetiology and are often asymptomatic. Asymptomatic perforations are a frequent finding in the triangular fibrocartilage even in young patients, one study reporting 51 % of asymptomatic wrists showing perforations (Brown et al. 1994). Peripheral tears tend to be traumatic in nature, often symptomatic and necessitate surgical intervention.

In view of the limitations of conventional MRI, MR arthrography is frequently advocated as the investigation of choice for the assessment of TFCC injury (Fig. 14). Proponents of conventional MRI suggest the use of 3D volumetric acquired gradient recalled sequences for evaluating the TFCC and have shown sensitivity of 100 %, specificity of 90 % and an accuracy of 97 % when using arthroscopy as the gold standard (Potter et al. 1997).

Fig. 14 Full thickness TFC tear. Coronal T1 fat suppressed image from MR arthrogram. Iodinated contrast injected into the radiocarpal joint at the time of the arthrogram was seen on fluoroscopy to pass into the distal radioulnar joint so only a single injection was undertaken. MRI shows the full thickness perforation through the triangular fibrocartilage (*arrow*) representing a full thickness tear and the passage through which contrast has passed between the two compartments. This is traumatic Palmer type 1A tear

3.4 Ligaments

3.4.1 The Intrinsic Ligaments

The intrinsic ligaments of the wrist are crucial to the intrinsic stability of the joint. These ligaments pass between the carpal bones without attachment to the radius or ulnar. The scapholunate ligament and the lunotriquetral ligament are clinically the most important and imaging is often integral in determining the extent of pathology related to these structures. The two ligaments are responsible for the stabilisation of the bones of the proximal carpal row and their disruption is an important component of dissociative carpal instability. Both the ligaments have three distinct components, namely the dorsal, volar and proximal. The scapholunate ligament is C shaped whereas the lunotriquetral ligament appears V shaped. The proximal portions of both these ligaments are thin fibrocartilaginous membranes with no stabilizing role. However, the fibrous volar and dorsal components act as true ligaments preventing independent flexion and extension of the proximal carpal bones so the entire unit acts as an intercalated segment (Fig. 15).

Fig. 15 Normal Intrinsic ligaments—T2 FS coronal image of the wrist shows both the scapholunate (*white arrow*) and lunate-triquetral (*black arrow*) ligaments

Fig. 16 Normal Extrinsic Ligaments. Coronal image from an arthrographic study shows part of the radioscapholunate and radioscaphocapitate extrinsic ligaments on the volar aspect of the wrist

Although scapholunate ligament injuries are usually assessed on conventional radiographic imaging in the first instance, MR imaging, and particularly MR arthrography plays an increasingly important role in diagnosing injuries of the intrinsic ligaments.

Conventional radiographs will only show abnormality where there is either an increased scapholunate gap or alteration in alignment between bones of the proximal carpal row.

Both CT and MR arthrography are more sensitive than standard MR imaging in the detection of scapholunate tears, particularly for more subtle injuries (Cerezal et al. 2005). The use of MR arthrography may allow more accurate delineation of the exact location of a tear allowing differentiation between lesions which are degenerate in nature and predominantly affecting the membranous portion of the ligament from acute injuries which involve either or both of the dorsal or volar components.

3.4.2 The Extrinsic Ligaments

The extrinsic ligaments are classified as either volar or dorsal; the volar ligaments are considered to be important stabilisers of the wrist whereas the dorsal ligaments are thought to be less crucial for stability (Theumann et al. 2003). The volar ligaments on the radial aspect of the wrist comprise the radioscaphocapitate, the radiolunatotriquetral and the radioscapholunate ligaments. On the ulnar aspect of the wrist there are two main volar ligaments which also form part of the triangulofibrocartilage (TFCC) complex, namely the ulnolunate and the ulnotriquetral ligaments. On the dorsal aspect of the wrist the extrinsic ligaments form a V shape centred over the dorsal aspect of the triquetrum. These ligaments are areas of focal thickening within the joint capsule and are often difficult to visualise with both MR and MR arthrography (Fig. 16).

Fig. 17 Ulnar collateral ligament of the thumb—**a** and **b** shows axial and coronal imaging of a normal UCL in the thumb. Both the ulnar collateral ligament (*white arrow*) itself and the overlying adductor aponeurosis are shown (*arrowheads*)

An avulsion injury of these extrinsic ligaments from their triquetral attachment is the cause of the triquetral fracture best appreciated on a lateral wrist radiograph.

3.4.3 The Ulnar Collateral Ligament of the Thumb

The Ulnar Collateral Ligament of the Thumb is also generally assessed with MRI, although ultrasound can also usefully image this frequently injured ligament. Overlying the normal ligament a thin adductor aponeurosis is identified (Fig. 17a, b). The ulnar collateral ligament stabilises the thumb metacarpophalangeal joint against radial deviation and its injury is frequently termed gamekeepers skiers thumb. When torn the adductor aponeurosis may interpose itself between the torn ends of the ligament, known as a Stener lesion, preventing healing without intervention. Failure of the torn ligament to heal results in instability and ultimately early osteoarthritis at the joint.

3.5 Hyaline Cartilage

Despite their marked clinical impact, cartilage lesions of the radiocarpal and intercarpal joints are frequently underestimated with MRI and MR arthrography possibly due to their small and subtle nature. High spatial resolution and tissue contrast is needed to detect these subtle changes. At 3T, the SNR is

sufficient but interpretation is complicated by the increased chemical shift artefact at the articular cartilage–bone interface (Fig. 6). Arthroscopy has been shown to be superior to both these imaging methods in the assessment of cartilage damage (Mutimer et al. 2008).

Much of the work regarding cartilage assessment has focussed on imaging of the knee. Various different protocols have been evaluated in this context including fat suppressed 3D spoiled GE, fast SE and direct arthrography (Gold et al. 2003). Three-dimensional GE are useful in cartilage evaluation as a high signal-to-noise ratio is afforded and allows thin slices to be produced, in addition the image may be reconstructed in different planes. These properties have not been shown to easily transfer to imaging of the cartilage within the wrist (Haims et al. 2004). This is thought in part to be due to the thickness of the cartilage at the wrist as well as the other potential difficulties with wrist imaging such as field inhomogeneity and patient movement. Therefore, an optimum method for cartilage evaluation at the wrist remains elusive at present.

4 MR Arthrography

MR arthrography is primarily indicated for the following suspected pathologies:

- Triangular fibrocartilage complex tears
- Scapho-lunate or lunate-triquetral ligament tears

- Suspected cartilage damage/intra-articular body

Communication, and therefore passage of contrast, between the radiocarpal joint and other compartments has been described in asymptomatic patients and findings therefore need to be carefully correlated with the clinical situation. A communication between the radiocarpal and midcarpal compartments has been described in 13–47 % of the population and between the radiocarpal and distal radioulnar compartments in 7–35 % of the population (Manaster 1991; Wilson et al. 1991; Cantor et al. 1994).

4.1 Protocols

As is the case with standard MR, imaging protocols for arthrographic imaging will vary between institutions. However, T1 weighted imaging will form the basis of the study showing the gadolinium arthrographic contrast as high signal. While T1 fat suppressed imaging has advantages in increasing contrast and also clarifying high signal due to contrast as opposed to fat, it is important to include at least one T1 weighted sequence without fat suppression for bony detail. It is also helpful to include a water sensitive (T2 fat suppressed) sequence to look for soft tissue pathology outside the joint itself and also for demonstrating oedematous change in bone marrow. The authors employ this sequence in the coronal plane.

4.2 Injection of Contrast

Since the first description of wrist arthrography by Kessler and Silberman (1961), many different methods, protocols and injection techniques have been described. Intra-articular injection of contrast material for the purposes of performing an MR arthrogram is usually performed under fluoroscopic guidance, although ultrasound guided injection may be used. The advantage of using fluoroscopic guidance is that a dynamic assessment for carpal instability can be made at the same time, and also fluoroscopic screening during contrast injection may demonstrate passage of contrast into adjacent compartments through ligament or fibrocartilage tears.

Single, double and triple compartment injection techniques have been described (Cerezal et al. 2005; Malfair 2008). The single compartment technique involves injection into the radiocarpal joint usually via

Fig. 18 Undersurface Flap tear of the TFCC—In this case the DRUJ was injected with contrast as well as the radiocarpal joint. This coronal image shows a partial thickness undersurface tear of the TFCC (*white arrow*) outlined by contrast injected into the DRUJ. This tear may not have been appreciated with a single radiocarpal joint injection

a dorsal approach. However, a lateral approach has also been described (Medverd et al. 2011). Because of the dorsal lip which overlies the radiocarpal joint on an AP image slight proximal angulation of the image intensifier will allow improved visualisation of the joint.

When investigating possible TFCC injury a double compartment technique is useful with a second injection into the DRUJ to outline the proximal (undersurface) of the triangular fibrocartilage (Fig. 18). This technique is useful for demonstrating partial ulnar attachment tears which are frequently non-communicating and may only be seen at the proximal attachment which may not be visible when contrast is only injected into the radiocarpal joint (Ruegger et al. 2007; Burns et al. 2011).

In the normal situation intact scapholunate and lunatetriquetral ligaments should prevent flow of contrast passage of contrast into the midcarpal joint from the radiocarpal joint and such passage will indicate a perforation or tear (which may be asymptomatic) through one of these ligaments. Conventional arthrographic studies have indicated that flow

may be one way through tears in these ligaments and there may be an advantage to injecting the midcarpal joint (Levinsohn et al. 1987, 1991; Wilson et al. 1991). However, with the direct visualisation of the intrinsic ligaments afforded by MRI it is not clear that a midcarpal joint injection offers any advantages when arthrography is combined with MRI.

4.3 Artefacts

Besides artefacts seen using conventional MRI and described in 2.4 there are additional artefacts which need to be considered in arthrography. These primarily relate to the injectate and injection technique. Injected air bubbles may mimic intra-articular bodies and care should be taken to eliminate any air bubbles from the injected system wherever possible. Injectate or local anaesthetic which has been inadvertently injected into muscle or surrounding soft tissue may be confused for oedematous change or contusion.

4.4 Indirect Arthrography

Indirect arthrography is also advocated to improve the diagnostic accuracy of standard MR sequences and is considered less invasive than direct arthrography. In this technique, intravenous contrast diffuses into the joint in a concentration high enough that an arthrographic effect may be achieved on T1 weighted images, although clearly the joint is not distended as with direct arthrography. Studies have reported the increased sensitivity in evaluation of the scapholunate ligament using indirect arthrography when compared with unenhanced MRI of the wrist but this has not been shown to be the case in evaluation of the lunatetriquetral ligament (Haims et al. 2003).

4.5 Alternative Modalities

Other imaging modalities should also of course be considered and recent studies have shown Multidetector CT (MDCT) arthrography to be more accurate than both 1.5T MR imaging and MR arthrography for the detection of partial tears of the scapholunate and lunatotriquetral ligaments (Schmid et al. 2005; Moser et al. 2007). CT arthrography offers advantages in terms of spatial resolution despite the absence of soft tissue contrast. An extremely small pilot study has shown

similar performance for direct MR arthrography and CT arthrography for the depiction of the triangular fibrocartilage although no attempt was made to evaluate the accuracy of these techniques for diagnosing tears (Omlor et al. 2009).

5 7T Imaging

7T imaging is a technique which is potentially particularly useful in the hand and wrist owing to its superior signal to noise ratio which allows higher spatial resolution; a quality which would allow even more detailed imaging of the fine anatomical structures of the hand and wrist, particularly the TFCC, intrinsic ligaments and articular cartilage. At present, this technique is limited to research purposes and presents many technical difficulties. These include the need for specialised RF coils which are currently not commercially widely available and the increasing chemical shift artefact encountered with increasing field strength. A potential future direction will be the opportunities 7T imaging offers for enhancing biological imaging techniques such as spectroscopy, sodium imaging and delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) which will benefit significantly from the signal-to-noise gains at increased field strengths with particular advantages when applied to the smaller structures of the hand and wrist.

Abstract

Nuclear medicine techniques continue to play a role in the diagnosis and management of hand, and wrist disorders, despite the advent of other cross-sectional imaging techniques such as MRI and CT. This chapter reviews the techniques available, concentrating on specific applications in the hand and wrist.

1 Introduction

Nuclear medicine techniques continue to play a role in the diagnosis and management of hand, and wrist disorders, despite the advent of other cross-sectional imaging techniques such as MRI and CT. This chapter reviews the techniques available, concentrating on specific applications in the hand and wrist.

The anatomy of the wrist is complex and the diagnosis, and management of hand and wrist injuries is difficult and challenging. In general, radiological techniques such as plain X-rays, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US) form the basis of investigations, but additional information may be provided with bone scintigraphy.

Two phase radionuclide bone scanning with ^{99m}Tc -MDP (Technetium 99 m labelled methylene diphosphonate) or ^{99m}Tc -HDP (Technetium 99 m labelled hydroxymethylene diphosphonate) is reported to be useful in imaging the hand and wrist, in both acute and chronic conditions. Bone scintigraphy is sensitive for the detection and diagnosis of occult

fractures, malunion, and osteonecrosis. In centres where the availability of MRI or CT is limited, radionuclide bone scanning has a correspondingly increased role to play. The advantage of a radionuclide bone scan is its high sensitivity; however, its specificity is relatively low (78%). A significant problem with bone scintigraphy is the accurate localization and characterization of lesions which can be difficult due to the relatively low spatial resolution of the technique (Hawkes et al. 1991; Mohamed et al. 1997). This is particularly true in the wrist where the small carpal bones lie close together, and new techniques are evolving to better localize areas of increased tracer uptake.

2 Techniques

2.1 Bone Scintigraphy

The most common nuclear medicine technique used for assessing the hand and wrist is bone scintigraphy, making use of ^{99m}Tc -MDP or similar compound. This compound binds to bone matrix by poorly understood mechanisms and emits gamma rays which can be detected by gamma cameras. A typical radiation dose following injection of 400 MBq ^{99m}Tc -MDP would be 2.3 mSv. Typical amounts of activity administered to adults undergoing bone scintigraphy are in the order of 555–750 MBq.

When imaging the hand and wrist, injection of the isotope should be undertaken in the contralateral arm to that being examined or ideally into the foot, so a direct comparison between the two upper limbs can be made.

A two-phase bone scan is generally undertaken with an early blood pool phase (at approximately 5 min) obtained to provide information relating to the vascular and extra-vascular distribution of the radiopharmaceutical. This gives an indication of vascularity. Subsequently bone uptake is assessed 3–4 h following injection. Here uptake will relate to the level of bone turnover (Fig. 1).

Generally, both hands/wrists are imaged, enabling comparison between the two sides to be made. The hand and wrists are positioned symmetrically, with the palms facing down on the gamma camera.

Fig. 1 Normal two-phase bone scintigraphy with **a** early (vascular) and **b** late phases. Note the poor spatial resolution of the study

2.2 Conventional 2 Phase Bone Scan With X-ray Registration

Wrist registration scintigraphy is used as a method to overcome the inherent low spatial resolution of the bone scan by co-registration with a radiograph (Fig. 2) (Hawkes et al. 1991; Mohamed et al. 1997). The addition of registration of the bone scan with X-ray has been shown to improve the localization of lesions to individual bones or joints (Hawkes et al. 1991; Mohamed et al. 1997; Vande Streek et al. 1998; Wraight et al. 1997). The techniques employed for X-ray registration of bone scans vary and are relatively cumbersome. This may involve the production of a custom cast with metallic markers and corresponding radioisotope markers. The hand is placed in the cast

Fig. 2 Avascular necrosis of lunate: **a** registered bone scan and **b** X-ray of the hand: The region of interest is drawn around the intense bone scan lesion, and the tracer uptake is located in the region of the metabolically active avascular necrosis of lunate bone

for conventional radiography and scintigraphy, and the two images are registered by means of the markers.

2.3 Multislice SPECT/CT

The integration of SPECT and CT provides precise localization and may enable characterization of abnormalities, identified on planar or SPECT imaging by providing additional structural information from CT.

The wrist multislice SPECT/CT offers the advantage of distinguishing individual carpal bones unlike conventional bone scans, which traditionally do not have sufficient spatial resolution to localize and characterize the site of abnormality, accurately.

The principle of SPECT/CT is to integrate/fuse SPECT and CT images accurately, and provide precise localization and characterization of metabolically active abnormalities, identified either on a planar or SPECT imaging by providing structural information from CT.

2.3.1 SPECT/CT Imaging Protocol

Dual-phase bone scans are obtained following injection of 750 MBq ^{99m}Tc -MDP, followed by CT, and finally SPECT imaging.

2.3.1.1 Two Phase Planar Wrist Scintigraphy

Following injection, both hands are positioned (palm down) on the camera face and static image for 5 min are acquired using a 256×256 matrix. Delayed imaging is performed at 3–4 h post injection with both the hands placed on the camera face, palms down, and static images in the anterior position are acquired.

2.3.1.2 Patient Positioning for SPECT/CT

The patient lies prone with one or both arms stretched out above their head towards the centre of the couch (Superman position). It is important to get the patient as comfortable, as possible. Supporting polycarbonate blocks are placed under the hands and wrists, which are taped firmly to the blocks. If needed, pillows or foam blocks are placed under the arms to provide further support. The patient's head is turned towards one side, so that they lie as flat as possible, allowing minimal distance from the gamma head.

2.3.1.3 CT Imaging

Once the patient is comfortably placed in the required position, a scout view is carried out to define the CT field. A low dose CT is used for both hands. Localization CT is then carried out with voltage settings of 120 keV, current setting of 100 mAs/slice, with slice thickness of 1.5 mm and increment of 0.75 mm. (CT imaging takes approximately 40–60 s).

For single wrist, a diagnostic CT is carried out using the following setting of 140 keV, 150 mAs/slice, slice thickness of 0.8 mm and increment of 0.4 mm. Diagnostic CT of a single wrist is performed because the single wrist is placed in the center of the couch, and hence in the center of the FOV.

2.3.1.4 SPECT Imaging

Once the CT scan is completed, a SPECT study is performed using the following parameters; Low energy high-resolution, parallel hole collimator, number of projections; 128 with 20 s time per

Fig. 3 Triquetral fracture: on dual-phase planar bone scan, there is increased blood pool (a) and increased tracer uptake (b) in the carpal bones on the ulnar side of the left hand. On the SPECT/CT images, the tracer uptake localizes to the triquetral fragment (fracture), and triquetral-Pisiform articulation (c–e)

projection and matrix size equivalent to 128×128 . The SPECT procedure is the same for both wrists, as well as for single wrist.

2.3.1.5 Image Processing

The raw data from the SPECT study is processed and transaxial slices are co-registered with the CT (Fig. 3).

2.4 Other Nuclear Medicine Techniques

Although ^{99m}Tc -MDP scintigraphy is the common nuclear medicine investigation undertaken for the hand and wrist, other techniques exist. These include the use of labelled leucocytes for the investigation of infection. ^{111}In -Chloride and ^{67}Ga -Citrate have also been used as markers for inflammation. However, not commonly used for the evaluation of the peripheral small joints (Tumeh 1996).

Labelled antibodies can be used in the investigation of arthritis. Techniques include the labelling of human polyclonal immunoglobulin G (IgG) with ^{111}In or ^{99m}Tc , or labelled anti-E-selectin monoclonal

antibody (Tumeh 1996; Jamar et al. 1995, 1997). More recently it has been shown possible to label anti-TNF monoclonal antibodies with ^{99m}Tc , demonstrating activity in synovitis in patients with rheumatoid arthritis which shows a close relationship to disease activity (Barrera et al. 2003).

Currently, increasing roles for the use of ^{18}F -fluorodeoxyglucose positron emission tomography (FDG-PET) are being found in nuclear medicine. Although specific clinical applications for the technique in the hand and wrist are yet to evolve, there is evidence that disease activity of rheumatoid arthritis can be assessed using the FDG-PET scanning of the wrist (Palmer et al. 1995).

3 Clinical Applications

3.1 Acute Fractures

Radionuclide bone scintigraphy is highly sensitive in the assessment of carpal fractures when radiographs are normal in the clinical context of trauma. Fractures of any of the carpal bones may be detected, although

scaphoid fractures are the most common (Maurer 1991; Patel et al. 1992) (Figs. 3, 4 and 5). In general, radionuclide wrist registration with X-ray combines the sensitivity of scintigraphy to detect fractures, with a rapid and inexpensive method to aid fracture localization. Such registration techniques have been shown to improve reporter confidence and influence management (Mohamed et al. 1997; Wraight et al. 1997). When assessing fractures, it is suggested that scintigraphy is more reliable if delayed at least 48 h following trauma (Rolfe et al. 1981). However, in practical terms most wrist and hand fractures are not essentially immediately. Importantly, scintigraphic uptake often precedes radiological changes in occult fractures, the latter may still be equivocal at 2–3 weeks (Dias et al. 1990). A recent study by Groves evaluated the use of 16 slice multislice CT versus skeletal scintigraphy in suspected scaphoid injuries. They recorded 23 scintigraphically positive bone scans for fracture with only 16 fractures visible on CT the same day (Groves et al. 2005a, b). In their study, all patients with discordant CT findings had significantly lower MDP uptake to background activity ratios, than those with CT proven fracture. They postulate that the scintigraphic findings of fracture may be mimicked by bone bruising (microfractures of the trabeculae) and this should be considered when reporting. Such trabecular bone injury does not have the same deleterious sequelae seen with fractures, such as avascular necrosis.

SPECT/CT may be helpful in the assessment of complicated fractures, where the injury may be relatively difficult to localize and characterize (Figs. 3 and 6). SPECT/CT scanning has a further advantage that it can be performed in a single sitting, providing early, and accurate diagnosis.

3.2 Fractures of Uncertain Age

The most common carpal fracture is that of the scaphoid. It is also the most common fracture to be misdiagnosed as a simple sprain and may become surprisingly pain free despite absence of union in the fracture. A number of such non-unions will later present with secondary degenerative arthritis. The wrist may then become symptomatic after an acute re-injury. A relatively common diagnostic problem is establishing why there is now persistent pain,

Fig. 4 Scaphoid fracture: **a** early and **b** delayed phase scanning, shows intense uptake in the scaphoid at the site of fracture. Courtesy of Dr. R. Bury, Department of Radiology, Leeds Teaching Hospitals, Leeds, UK

particularly if only the non-union is visible on the radiograph, without obvious degenerative change. In these situations, the choice may be to undertake MRI or even wrist arthroscopy, to establish whether or not there has been a loss of articular cartilage at the radio-scaphoid facet. This will help determine whether surgical treatment of the non-union is likely to improve the patient's symptoms. SPECT/CT may also clarify this in a non-invasive manner, at the same time, identifying any other carpal fracture, which may be difficult to localize on the conventional planar bone scan.

Fig. 5 Radial Fracture. This patient with normal plain films was suspected of having a scaphoid fracture. However, **a** early and **b** delayed phase scanning shows intense uptake in the distal radius representing a distal radius fracture. Courtesy of Dr. R. Bury, Department of Radiology, Leeds Teaching Hospitals, Leeds, UK

3.3 Arthritis

3.3.1 Osteoarthritis

While bone scanning alone is sensitive, its lack of resolution may prevent precise localization of arthritic change. Furthermore, its inherent lack of specificity means it has a limited role in the diagnosis and management of the disease. Bone scintigraphy is not a routine investigation in osteoarthritis (OA), but it should be recognized that the condition is a cause of increased radiopharmaceutical uptake, which may be important when interpreting studies undertaken for other indications. OA is a common condition which

may be frequently encountered either as a primary disease process, typically affecting the proximal and distal interphalangeal joints and thumb base (first carpometacarpal and scaphoid–trapezial–trapezoid (STT) joints) or as a secondary condition, such as may be seen in the wrist as a consequence of trauma. The improved localization and characterisation of SPECT/CT, pin points the site of uptake and may help in clarifying the cause of uptake by localizing the disease process (Figs. 7 and 8).

3.3.2 Inflammatory Arthritis

The inflammatory arthritides are commonly associated with synovitis and show increased uptake on both, the blood pool and delayed images of the dual-phase bone scintigraph. The appearance of increased activity is non-specific, but the distribution, for instance wrist, MCP, and PIP joint involvement in rheumatoid arthritis or DIP involvement in psoriatic arthritis may be helpful in identifying the underlying arthritis (Fig. 9). The accuracy of US and MRI in identifying synovitis and erosions, in the hand and wrist, means isolated hand and wrist scintigraphy has only a minor role to play in investigating inflammatory arthritis. However, whole-body scintigraphy may still be undertaken (to include the hands and wrists) in a technique to identify sites of inflammation throughout the body. The technique of scintigraphy may also be helpful in identifying a monoarthritis from a polyarthritis, thereby changing the differential diagnosis. As has been outlined in Sect. 2.4, other nuclear medicine techniques have become available for the assessment of inflammatory arthritis. Techniques such as scanning with ^{111}In -Chloride show good specificity for the disease, and disease activity in some joints, but uptake in the small joints of the hand is relatively weak with lower accuracy, than was seen in large joints (Sewell et al. 1993). Work using labelled IgG found the intensity of uptake, correlates well with clinical markers of inflammatory activity (de Bois et al. 1992). This study showed no correlation with radiographic measures of joint destruction.

Intraosseous cysts and erosions may be seen in combination with arthritides, or degeneration. Such processes may include intraosseous ganglion formation, typically within the lunate. Inflammatory change associated with such bony lesions may be seen as areas of increased uptake on the bone scan. The findings on the bone scan are non-specific and may

Fig. 6 Non-union scaphoid fracture: The delayed phase planar image shows, increased tracer uptake within the lateral aspect of the left wrist joint (b) with very subtle, increased blood on the early blood pool images (a). On the SPECT/CT images, the increased uptake localizes to the non-united fracture of the Scaphoid (c–e)

include multiple differentials. However, with localization techniques such as SPECT/CT the area of increased tracer uptake can be identified and characterized on the CT component of the study (Fig. 10).

3.3.3 Infection

Early differentiation of soft tissue infection from osteomyelitis is critical to ensure appropriate management. Osteomyelitis will commonly require a protracted course of antibiotics and sometimes debridement. Plain radiographic changes of osteomyelitis are often not present in early disease, and scintigraphy can be used to determine bony involvement. Typically, the bone scan is hyperaemic in the blood pool and delayed-phase within 48–72 h of onset (Maurer et al. 1981). Although an uncommon appearance, a photon deficiency may also be appreciated at a site of osteomyelitis (Barron and Dhekne 1984). The use of ^{111}In labelled white cells or ^{67}Ga -Citrate improves specificity for infection assessment, but there is a corresponding increase in radiation dose, and resolution is generally poorer. The use of SPECT/CT aids localization and characterization. SPECT/CT may be useful in differentiating soft

tissue and bone infection, and can be useful to assess the extent of disease particularly when planning debridement (Fig. 11).

3.3.4 Avascular Necrosis

Avascular necrosis is a serious and frequent complication of carpal fractures, especially of the scaphoid and lunate. Idiopathic avascular necrosis may also be seen in the carpal bones as in Keinboch's disease, affecting the lunate. Bone scintigraphy can be used to identify established AVN. In its early stages, AVN may show a photon deficiency and this may be seen at a stage where the plain radiographs are unremarkable. With time, an osteoblastic response develops in the bone leading to increased uptake of tracer on delayed scanning (Fig. 2). Typically, scintigraphy is undertaken in the subacute phase by which time the hypervascular response has occurred along with the osteoblastic response. By this stage, changes may be evident on the conventional radiographs. MRI will detect the changes at both stages. In more advanced stages of avascular necrosis, there may be involvement of other carpal bones; with degenerative changes developing in the mid-carpal joints (Bain and Begg 2006).

Fig. 7 Degenerative first carpo-metacarpal joint: Dual-phase bone scan shows increased vascularity (a) and tracer uptake (b) in the distal carpal bones of the radial side of the wrist bilaterally. On SPECT/CT images, the area of increased uptake localises to the first carpo-metacarpal joint (c–e)

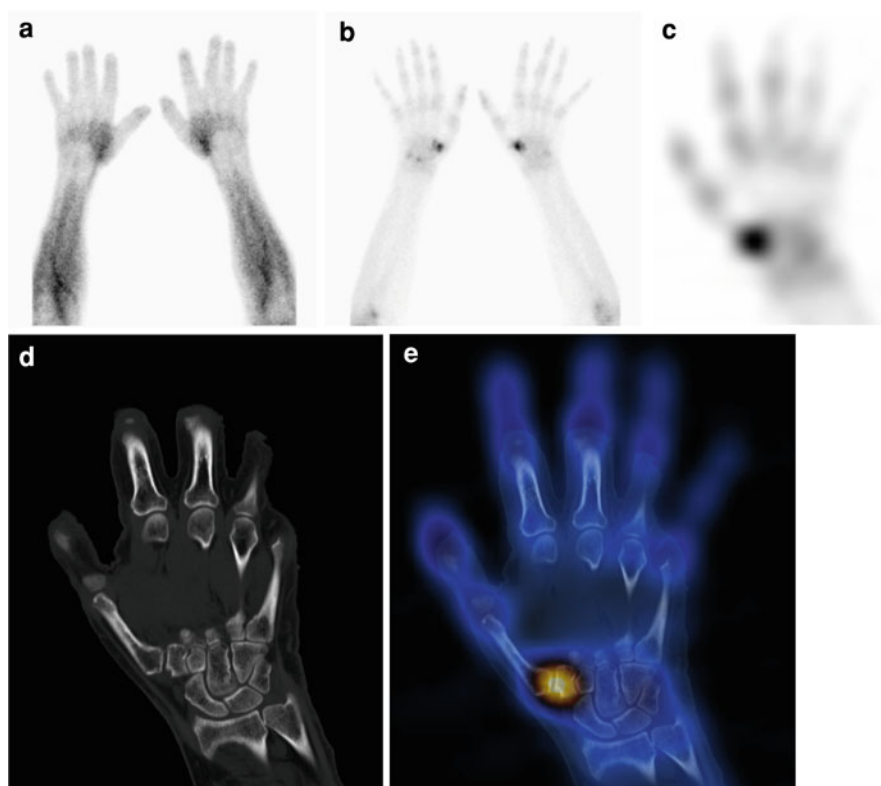

Fig. 8 Lunate-triquetral osteoarthritis: a planar scintigraphy shows increased tracer uptake associated with the proximal carpal row and b SPECT-CT identifies the site of activity as the lunate-triquetral joint. Courtesy of Drs. R. Cooper and S. Allwright, Department of Nuclear Medicine, Mater Hospital and Dee Why Nuclear Medicine, Sydney, Australia

Fig. 9 Rheumatoid arthritis. Late-phase scintigram shows uptake at the MCP joints on the right hand and both thumb interphalangeal joints. The MCP involvement is typical for rheumatoid arthritis

The improved localization using SPECT/CT may provide valuable information not only regarding vascular supply, but also the degree of surrounding

secondary OA, when evaluating avascular necrosis of the lunate, which we have found, can be used to guide the hand surgeon to the most appropriate surgery.

Fig. 10 Lunate cyst with degenerative disease. The dual-phase planar imaging shows increased tracer uptake (b) in the distal ulnar region. The early blood pool images are unremarkable (a). On the SPECT/CT image, the increased tracer uptake is localized to the lunate cyst (c–e)

3.3.5 Miscellaneous

3.3.5.1 Wrist Impaction Syndromes

There are a various causes for impaction syndromes associated with ulnar-sided wrist pain with the commonest being the ulnar impaction syndrome (Cerezal et al. 2002; Friedman and Palmer 1991). Less common causes include conditions such as ulnar impingement syndrome, ulnar styloid impaction syndrome, ulnocarpal impaction, and hamatolunate impingement syndrome. Ulnar impaction syndrome is also known as ulnar abutment, and is reported to be a degenerative condition characterized by ulnar wrist pain associated with swelling, and limitation of movement across the ulnar aspect of the wrist (Cerezal et al. 2002; Friedman and Palmer 1991; Escobedo et al. 1995; Hodge et al. 1996; Imaeda et al. 1996). MRI is a useful investigation to assess the structural abnormalities that contribute to ulnocarpal instability and pain. Scintigraphy can be useful to localize the site of intense metabolic activity and guide MRI, but localization is most accurately

achieved using registration techniques such as CT/SPECT.

3.3.5.2 Bone Tumours

Isolated peripheral skeletal metastases in the hand/wrist are relatively unusual but may occur, particularly from bronchogenic, thyroid, renal cell or malignant melanoma primaries. Hypertrophic pulmonary osteoarthropathy (HPOA) may also be detected with bone scintigraphy as increased uptake at the wrists.

Benign bone tumours include osteoid osteoma, and one study would suggest around 8% of these lesions occur in the hand and wrist (Cohen et al. 1983). When these lesions do occur in this location they seem to be most frequently seen in the proximal phalanges, and metacarpals, with a relatively low incidence in the intermediate and terminal phalanges and the carpal bones (Carroll 1953). Bone scintigraphy will classically show a double density sign with increased uptake in the surrounding sclerotic bone, but very intense uptake at the site of the nidus (Helms 1987).

Fig. 11 Septic arthritis and osteomyelitis. The planar images show increased blood pool (a) and increased tracer uptake around the distal phalanx of the middle finger (b). On the SPECT/CT images the increased tracer uptake localizes to the distal inter-phalangeal joint of the middle finger consistent with known infection at this site (c-e)

Fig. 12 Reflex sympathetic dystrophy. There is increased tracer activity in the right hand and wrist, on early phase scanning (a). Late phase scanning (b) shows increased activity in a typical periarticular distribution throughout the hand and

wrist. Courtesy of Drs R Cooper and S Allwright, Department of Nuclear Medicine, Mater Hospital and Dee Why Nuclear Medicine, Sydney, Australia

Increasingly these lesions are being treated with percutaneous ablation, but the use of an intraoperative nuclear medicine probe, following administration of radioactive tracer can be used by surgeon to help localize osteoid osteoma and ensure excision of the nidus. The most common benign bone tumour seen in the hand is an enchondroma which shows relatively low uptake on bone scanning (Vande Streek et al. 1994). Bone scintigraphy cannot reliably distinguish between benign and malignant chondroid tumours.

3.3.5.3 Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy is a poorly understood condition presenting with severe limb pain. The syndrome comprises intense pain, soft tissue swelling and discolouration, alteration in skin temperature, and limitation of movement. In many cases there is no antecedent event, but there is frequently a history of minor trauma or recent surgery. While the diagnosis may be obvious on clinical examination, it can be difficult. Bone scintigraphy typically shows abnormality on both vascular and delayed phase imaging with increased uptake, classically a periarticular distribution (Fig. 12). Clearly this pattern of uptake is not specific and must be viewed in the clinical context. Published studies show variable sensitivity and specificity for the diagnosis using Bone scintigraphy (Genant et al. 1975; Holder and Mackinnon 1984; Kozin et al. 1981).

4 Conclusion

Inevitably, newer cross-sectional imaging modalities such as MRI and CT are useful in the diagnosis of hand and wrist disorders. However, new registration techniques such as CT/SPECT have improved the ability of bone scintigraphy to accurately localize the site pathology. While bone scintigraphy has many applications it continues to play an important role in many centres for the identification of occult fractures.

Abstract

The role of ultrasound (US) in the assessment of musculoskeletal disorders is persistently increasing. Recent developments in hardware and software of US equipments and in particular use of small-size, high-frequency transducers have allowed accurate assessment of a wide variety of hand and wrist disorders.

1 Introduction

The role of ultrasound (US) in the assessment of musculoskeletal disorders is persistently increasing (Van Holsbeeck and Introcaso 2001; Mc Nally 2004; Brasseur and Tardieu 2006; Bianchi and Martinoli 2007). Recent developments in hardware and software of US equipments and in particular use of small-size, high-frequency transducers have allowed accurate assessment of a wide variety of hand and wrist disorders. The main advantages of US are its low cost, readiness, non invasivity and possibility to perform a dynamic examination. The main disadvantage is the impossibility to detect and assess deep structures, located behind bones. In addition, US is a highly operator-dependent technique and has a long learning curve. US has been used in the assessment of wrist and hand traumatic, degenerative and infective disorders, as well as in evaluating local masses (Read et al. 1996; Ferrara and Marcellis 1997; Bianchi et al. 1999, 2001, 2003; Teefey et al. 2000; Milbradt et al. 1990; Chiou et al. 2001; Moschilla and Bredahl 2002). Additional studies have stressed its role in the evaluation of inflammatory arthritis (Koski 1992; Grassi et al. 1993).

Quantification of inflammation and of structural damage is mandatory in the assessment, management and monitoring of rheumatoid arthritis (RA). Without appropriate treatment (e.g. DMARD's, biologics), RA inflammation can progress and result in joint dysfunction and deformity. An early diagnosis can lead to early instauration of a successful treatment. Standard radiographs have an important role to identify changes such as osteopenia, joint space reduction or erosions in patients with advanced arthritis. US is a useful tool in the assessment and follow-up of early to established RA (Wakefield et al. 2000, Szkudlarek et al. Szkudlarek et al. 2004a, b) and can efficiently guide local procedures such as aspiration of effusions or therapeutic injection (Karim et al. 2001). In RA US can detect different pathologic changes including synovitis, cartilage and bone changes, tenosynovitis and tendon tears, bursitis, rheumatoid nodules or secondary nerve entrapment (e.g. carpal tunnel syndrome). Clinical studies have shown that US is as effective or even more effective in detecting inflammatory changes as clinical examination. Sensitivity and specificity of US in assessment of joints changes in RA is comparable to MR imaging (Backhaus et al. 1999; Backhaus et al. 2002; Szkudlarek et al. 2004a, b; Scheel et al. 2006). Power Doppler and Colour Doppler US detects active synovial inflammation associated with hypervascularisation and neoangiogenesis. In the presence of an active synovitis, there is an increase in signal activity, which is correlated to the degree of inflammatory activity. Therefore, the use of color and power Doppler US facilitates a differentiation between active and inactive synovitis. Furthermore, numerous studies have shown a good correlation between activity of synovitis at power Doppler and inflammatory changes evident at MRI and at histopathology studies (Walther et al. 2001; Terslev et al. 2003). Echo-contrast-enhanced US has shown an improvement in the measurement of synovial thickness and activity of synovial processes in patients with rheumatoid arthritis and allows better differentiation between effusion and synovial proliferation (Goldberg et al. 1994; Blomley et al. 2001). Besides assessment of the synovium, US can evaluate pathological changes of cartilages and bones if performed using high-resolution ultrasound probes. Bone erosions are a pathophysiological hallmark of RA. US can provide a more accurate and comprehensive assessment of bone erosions than

plain radiography. The size of erosions can be monitored to evaluate disease progression.

Accurate knowledge of the normal anatomy, technique of US examination and of the US appearance of the hand and wrist are definite pre-requisites for a successful US examination. The target of this chapter is to present the technique of the US examination and the normal US anatomy of the hand and wrist.

2 Technique of Examination and Normal US Appearance

Before starting the US examination, any previous imaging studies and blood tests, if available, are reviewed. Every effort must be made to obtain a recent radiographic examination, in at least two perpendicular views, since this allows a good analysis of joints and bones and is complementary to US that permit an excellent assessment of most soft tissues. A brief clinical evaluation is always obtained since it helps in pointing the attention of the examiner to a specific area, thus shortening the time of examination and allowing a more detailed local assessment. The patient is asked for duration of symptoms, type and rhythm of pain (mechanic or inflammatory), presence of tingling, numbness or morning stiffness. If pain is the main symptom, its location and modification during muscle contraction or joint movements can often orient toward the correct diagnosis. In De Quervain tenosynovitis, for example, a sharp, acute pain located over the radial styloid and worsened by ulnar deviation of the wrist with the thumb flexed is highly suggestive of the diagnosis. The distribution of peripheral tingling can indicate the injured nerve (radial, ulnar or median). A brief regional physical examination including assessment of any local or diffuse swelling, warm or reddens follows. The joint range of motion and local tenderness are also briefly assessed.

Schematically, there are two main kinds of performing a US examination of the wrist and hand. A *focused examination* generally performed in patients suffering from disorders affecting the periarticular tissues and a *systemic examination* mostly directed to the joints. The first is a shorter examination concentrated on a specific region, selected by the sonologist according to the data available from the physician's US request, type of symptoms and results of the brief clinical examination described earlier. We perform this

type of examination in the vast majority of our patients. To give an example in a patient presenting with a painless lump at the dorsum of the wrist suspected to be a ganglion by the referring physician, the US examination can be limited to the dorsal aspect of the wrist. A time-consuming, detailed examination of all metacarpophalangeal and interphalangeal joints is not necessary and useless in such a patient. The second type of US examination is a more time-consuming, systematic examination usually obtained only in patients with a clinical suspicion or diagnosis of systemic arthritis. In both cases, a scrupulous technique of realization of the US examination, including images obtained in several planes and dynamic test, must be deployed (Creteur and Peetrons 2000; Middleton et al. 2001; Lee and Healy 2005; Tagliafico et al. 2007).

For didactic purposes, we first describe the basic anatomy of the main structures amenable to US assessment followed by description of the US technique of examination and of the normal US anatomy. We will follow an anatomic pattern, starting with the dorsal aspect of the wrist and the hand followed by the palmar aspect.

For optimal US examination of the wrist and hand, the patient sat facing the examiner with the forearm resting on the examination bed. We routinely start the examination by scanning the dorsal aspect of the wrist followed by the hand through transverse and sagittal sonograms. Then, the patient is asked to supinate the hand that now lies on its dorsal aspect, to allow examination of its palmar aspect. Again transverse sonograms are followed by longitudinal images. Color Doppler is routinely obtained. Dynamic scanning allows identification of each extensor and flexor tendon of the fingers and, most importantly, allows optimal judgement of tendons' gliding and eventual impingement inside osteofibrous tunnels. This is very useful in judging presence of tendons adhesions. Application of variable pressure with the transducer permits obtaining additional data. A firm pressure helps in eliciting local pain and thus in focalizing the examination. It also assists in judging consistency of masses facilitating for example the diagnosis of soft tissue lipoma. On the contrary, large amount of gel must be used in assessing fluid collections in order to lessen local pressure through the probe and avoid inadvertent displacement of the fluid that can result in a negative examination. In assessing presence of vessels with color Doppler, excessive pressure can

result in squeezing of vessels resulting in impossibility to accurately detect local hypervascular changes. In testing the permeability of subcutaneous veins, color Doppler is obtained during squeezing of the soft tissues distal to the site of examination performed with the contralateral hand of the examiner. This allows a temporary increase in venous blood velocity and its easier detection at color Doppler. On the contrary, blocking the venous drainage at the forearm causes dilatation of the distal vein and results in stagnation of blood inside venous masses. As previously discussed, palpation under US guidance can be realized through the transducer when a large mass is evaluated. When the mass is small, US-guided palpation is better performed by using an opened paper clip. Once placed between the transducer and the skin, this can be followed under real-time scanning thanks to its typical posterior comet tail artifact. This technique works well in cutaneous marking of soft tissue foreign bodies as well as in accurate localization of small neuromas.

3 Dorsal Aspect

US allows an accurate evaluation of the dorsal aspect of wrist and hand (Figs. 1, 2, 3, 4, 5, 6, 7, 8). Accessory muscles can be found at the dorsal face of the wrist (Muncibì et al. 2008) as anatomic variants mimicking local tumors. They show at US the typical internal muscle structure made by alternating hypoechoic (muscle fibers) and hyperechoic (fibroadipose septa) bands. Dynamic examination during resisted contraction shows contraction of the accessory muscle thus confirming the diagnosis. Located under the skin and subcutaneous tissues, a thin fascia covers the extensor tendons (ET). These tendons origin from the miotendineous junctions, located in the forearm at different level for each muscle, run distally between the joint plane and the subcutaneous tissue, to finally insert into the bone of the wrist and hand. Since all ET change their course before joining their insertion, they are prone to instability during changes of position of the wrist and hand joints. To avoid instability, the ET run inside fibrous tunnels. These are made by the surface of bones covered by periosteum (the floor) and by superficial fibrous bands named retinacula (the ceiling). To further increase tendons stability, the bone surface is not flat but made by grooves, sulci or protuberances. A synovial sheath composed by a visceral and parietal

layer, gliding one over the other, surrounds the tendons and reduces local frictions during gliding. The visceral layer is adherent to the tendon and moves with it, while the parietal layer is lax and blends with the retinacula

and other peritendineous structures. The layers are separated by a thin amount of synovial fluid. At the level of the distal radius and wrist, the twelve ET run inside six tunnels. The tunnels are numbered from the

most radial to the most ulnar. The first tunnel is located over the radial styloid while the sixth is found at the level of the cubital head. Table 1 resumes the arrangement of the tendons inside the six tunnels.

US shows the ET as hyperechoic, homogeneous structures showing a typical fibrillar structure in the longitudinal sonograms. The borders of normal tendons are regular and well defined. The normal

synovial sheath and the tiny amount of fluid contained inside it can't be detected even if high-resolution transducers are used. Retinacula are imaged at US as hyper or hypoechoic structures depending on the incidence of the US beam. They present different thickness depending of the fibroosseous tunnel examined. The retinaculum of the fourth compartment is the thicker and, since it appears mostly

hypoechoic, can simulate an effusion to unexperienced examiners (Robertson et al. 2007). The mean value or retinaculas' thickness in other tunnels is around 0.3-0.5 mm. In case of suspicion of mild thickening of retinacula, the contralateral side can be scanned to improve diagnostic confidence. In normal conditions, color Doppler does not allow detecting the normal vascularisation of tendons, sheath or retinacula. Any Doppler signals inside these structures must be retained as pathologic. Axial images allow a good analysis of details of different ET. To give an example, the APL is almost always made by multiple thin tendons rather than by a single tendon (De Maeseneer et al. 2009). This normal variation seems to facilitate impingement inside the first osteofibrous tunnel.

Deep to the ET of the third compartment, located close to the lateral aspect of the Lister's tubercle, the distal sensitive branch of the posterior interosseous nerve can be seen running from the forearm to the dorsal aspect of the wrist. At its distal portion, the

normal nerve can present a bulbous swelling (Acrel's ganglion) that must not be interpreted as a pathologic neuroma or as evidence of chronic compression. The origin of this fusiform swelling is unknown. Histologically, it is made by normal peripheral nerve structures without any neuronal cell bodies (Tubbs et al. 2007). The term pseudoganglion seems then more appropriate than that of ganglion. In younger subjects, a small artery (distal anterior interosseous artery) can be detected running close to the nerve. The distal radio-ulnar, radiocarpal, mediocarpal and carpo-metacarpal joints can be well imaged and changes related to degenerative or erosive arthropathy detected. US can efficiently guide intraarticular injections (Lohman et al. 2007) under real time control. This helps in avoiding injury to adjacent structures such as nerves and vessels and in confirming the correct site of injection. US allows detection and assessment of several extrinsic articular ligaments as well as of the scapho-lunate ligament (Griffith et al. 2001; Jacobson et al. 2002; Finlay et al. 2004; Boutry et al. 2005; Taljanovic et al. 2008; Bihan et al. 2009; Renoux et al. 2009).

At the level of the dorsum of the hand and of the fingers, the ET can be followed till their distal insertion by US. The EPB is one of the thinnest tendons and inserts into the base of the proximal phalanx of the thumb. The two extensor carpi tendons (ECRB and ECRL) can be followed till their insertion into the base of the second and third metacarpals. The EPL

has a more complex course. At the distal radius, it reflects on the medial aspect of the Lister's tubercle, a bony ridge separating the third and the second compartment of the ET. Then, it points to the base of the thumb and overlies the ECRB and ECRL tendons. Finally, it joins the EPB at the level of the head of the first metacarpal to then insert into the base of the distal phalanx of the thumb. The EPL is then subject to local friction at two levels: at the Lister tubercle and when it crosses with the two extensor carpi tendons (De Maeseneer et al. 2005). The index has two extensor tendons, the communis and the indicis proprius, which runs medial to the communis. They have similar size and course. The EIP can be harvested and used as a tendon graft in several surgical procedures. The extensor digitorum communis tendons present a high variable organization at the dorsum of the hand related to presence of the so-called tendinous junctions. These are thin tendons directed obliquely and joining adjacent ET. The dorsal interossei muscles can be seen appreciated lying among the hyperechoic metatarsals.

At the level of the metacarpophalangeal joints, the ET are retained over the dorsal aspect of the joint by the sagittal bands, thin ligaments that prevent palmar displacement of the tendons during flexion of the fingers. These bands appear as thin hyperechoic laminae covering the tendons and inserting into the periphery of the capsule. At the level of the proximal phalanx, the ET of the 2–5 fingers split into a central band and two lateral bands. The central band inserts into the base of the middle phalanx while the lateral bands join into the midline to insert into the distal phalanx. The ET are well assessed by US at the level of the MCP joint. Their distal splitting is sometimes difficult to be appreciated at transverse images. Longitudinal images allow visualization of the insertion of the central band as well as of the distal insertion into the distal phalanx. Details of the insertion of the intrinsic muscles are not detected at US. The metacarpophalangeal and interphalangeal joints can be imaged in the sagittal and axial plane. US allows an accurate assessment of erosive articular changes (McNally 2008). The cartilage of the metacarpal and phalanx head can be judged by using a dorsal and palmar approach in the extended and flexed joint while the cartilage of the bases of the phalanges are not detectable at US. US examination performed during gentle stress of the fingers' joints can help in judging the capsuloligamentous complex. This is most

often performed at the level of the MCP of the thumb in the evaluation of tears of the ulnar collateral ligament.

4 Palmar Aspect

The palmar aspect of the wrist houses several tendons, nerves, and vessels (Figs. 9, 10, 11, 12, 13, 14, 15). Abbreviations for these structures are listed in Table 2. The most superficial and thinnest tendon is the PG that runs in the midline of the wrist within the subcutaneous tissue. The PG presents a high anatomic variability. It can be absent or be replaced by a muscle (palmaris inversus). In a deeper position, the flexor tendons of the fingers (FDS, FDP, FPL) run inside the carpal tunnel (CT), a fibrous tunnel made by the carpal bones (the floor) and a palmar thick ligament, the transverse carpal ligament (TCL) (the ceiling). Inside the CT, the tendons are surrounded by a common synovial sheath enveloping the FDS and FDP of the 2–5 fingers. This common sheath generally communicates with the digital sheath of the fifth finger. The 2–4 fingers have separate digital sheaths. The FPL has a separate long sheath extending from the CT till to the proximal phalanx of the thumb. The FCR, a strong tendon surrounded by its own synovial sheath, is also located inside the CT but runs in a separate lateral channel. In its distal portion, the FCR overlies the tubercle of the scaphoid and reflects over the palmar aspect of scapho-trapezio-trapezoid joint to deepen and reach its distal insertion into the base of the 2 and 3 metacarpals. The FCU is a straight tendon located at the medial aspect of the anterior face of the wrist that inserts into the proximal pole of the pisiform. Since it has a straight course this tendon is not surrounded by a synovial sheath but by its peritenon, a thin connective tissue lamina that facilitates its gliding. Besides several tendons, the CT houses also the MN, a flat nerve located just under the TCL at the radial aspect of the tunnel. The nerve has a close relation with the FDP and FDS of the index. It innervates the muscles of the thenar eminence as well as the 1st and 2nd lumbrical muscles. The MN is responsible for sensitivity of the first three fingers and radial aspect of the fourth finger. Details of its anatomy and anatomic variations will be discussed in more details in [Nerve Entrapment Syndromes](#). The Guyon's tunnel is a small fibroosseous tunnel located superficially and medially to the CT. It is delimited by the TCL and the lateral aspect of the pisiform (the roof) and the

palmar carpal ligament (the ceiling). The tunnel houses, embedded by fat, the UN and the UAr surrounded by several UVE. The nerve is located between the artery and the pisiform. At variable level inside the tunnel or immediately distal to it, the UN splits in one motor branch and one or two sensitive branches. A more detailed description of the Guyon's anatomy will be presented in [Nerve Entrapment Syndromes](#). The UN is responsible for sensitivity of the fifth finger and medial aspect of the fourth finger. At the radial aspect of the wrist, the RAr is found running deep to the superficial fascia surrounded by satellite veins. The artery has close relation with the distal part of the sensitive branch of the RN. At the palm of the hand, the FDS and the FDP of the 2–5 fingers run together to join the base of the fingers. Their synovial sheaths are not detectable even when high-frequency transducers are used. The FDP, located just inferior to the FDS, give insertion to the lumbricals muscles. The vessels and the branches of the MN and UN run together located among the lumbricals muscles and the FDS surrounded by fat. More deeply are located the palmar interossei muscles. Utilization of high-frequency probes allows an optimal assessment of the anatomy of the flexor tendons at the

fingers. Transverse images show splitting of the FDS at the level of the proximal phalanx. The two tendinous laminae are located from proximal to distal: first superior, then lateral and medial and finally, inferior to the FDP tendon. They insert into the base of the middle phalanx. The FDP presents typically a triangular aspect with the base inferior in proximal scans and superior in more distal images. A frequent anatomic variation is bifidity of the FDP at the level of the distal part of the middle phalanx. This must not be interpreted as a posttraumatic longitudinal split. Longitudinal images are best suited to evaluate the tendons dynamically. When performed at the level of the MCP joint during flexion of the DIP joint, they show selective movements of the FDP tendon. Simultaneous flexion of the IPP joint allows concomitant movements of the FDS tendon. The insertion of the two FDS hemitendons can be imaged at the level of the intermediate phalanx by displacing the transducer medially and laterally. The insertion of the FDP into the base of the P3 is readily evident on sagittal images obtained over the distal phalanx. A variety of pulleys (annular and cruciform) retain the flexor tendons against the palmar aspect of the phalanges thus preventing palmar instability during

Fig. 12 Palmar aspect. **a, c, e** Probe positioning for longitudinal examination. **b, d, f** corresponding sonograms. **b** *Pis* pisiform, *white arrowheads* flexor carpi ulnaris tendon. **d** *Black arrowhead* median nerve, *white arrowheads* flexor digitorum tendons. **f** *Large white arrowhead* flexor carpi radialis tendon, *small white arrowhead* flexor pollicis longus tendon, *Tr* Trapezium

flexion (Bodner et al. 1999; Martinoli et al. 2000). Annular pulleys are quite rigid and are the main structures that prevent tendons bowstringing during flexion. They are numbered from 1 to 5 from proximal to, distal. The A2 and A4 pulleys located, respectively, at the base of P1 and P2 are functionally the most important. The annular pulleys are visualized as thin hyperechoic structures in longitudinal images. They show a normal thickening of their insertion in transverse images. The cruciform pulleys are more lax and located among the annular pulleys. They can be visualized at US only when a significant amount of fluid is present inside the tendon sheath.

The different joints of the fingers can be examined by sagittal and axial sonograms. The palmar plates are well depicted as hyperechoic structures, with homogeneous internal appearance, inserting into the base of the phalanges. Examination performed during gentle hyperextension of the examined joint can help in analysis of local tears or

avulsions. The palmar articular synovial recess is ready evident and must be analyzed for local effusion or synovial hypertrophy. Axial sonograms of the digital soft tissues allow assessment of the digital vessels and nerves till the level of the distal interphalangeal joint if high-frequency transducers are used.

5 Key Points

5.1 Advantages of Ultrasound in Wrist and Hand Assessment

- Ready available
- Non invasive
- Inexpensive
- Patient friendly
- Dynamic
- High resolution

5.2 Disadvantages of Ultrasound in Wrist and Hand Assessment

- Long learning curve
- Operator dependent
- Partial assessment of cartilages, ligaments and bones

5.3 Operator Requisites for US Examination in Wrist and Hand Assessment

- Perfect knowledge of the normal anatomy and anatomic variants
- Clinical knowledge of the main disorders affecting the wrist and hand
- Use of accurate and standardized technique of examination

5.4 Basic Principles of US Technique of Examination in Wrist and Hand Assessment

- Perform a basic clinical examination of the affected area and review other imaging studies before starting the US examination
- Focus the examination on the basis of clinical findings
- Analyze the structures using multiple planes of scanning
- Perform dynamic examination and color Doppler examination
- Bilateral examination if required

Abstract

Growing bone is challenging, as bone structure, shape and size change continuously until skeletal maturity. The numerous normal variants of growth which may mimic pathology have been accurately described radiographically, but little is known on the appearances on other modalities such as magnetic resonance imaging (MRI), computed tomography (CT) and ultrasound. This chapter will take you through fetal and post natal growth of the hand skeleton, and also give an overview of the assessment of bone age.

1 Introduction

The hand and wrist start developing in the early stages of foetal growth, through chondrification and ossification to finally achieve skeletal maturity at the end of adolescence. Skeletal development of the hand proceeds through a complex interplay of growth, biomechanical forces, and reciprocal development of bone shape. These bone changes have been extensively studied by radiograph, and several established methods are used in clinical practice for assessment of bone age.

The advent of magnetic resonance imaging (MRI) has shed light on the pre and post ossification changes of the areas of bone not assessed by radiography. Magnetic resonance imaging data of the hand is sparse for the neonatal period, but increasingly, more information is available for later stages of development (Ording Müller et al. 2011).

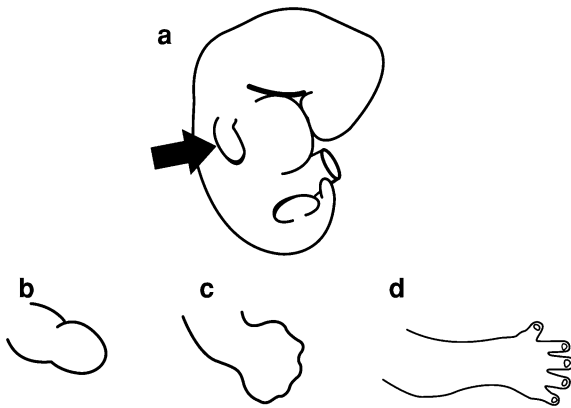

Fig. 1 Embryological development. **a** The upper limb bud appears at 5 weeks (*blackarrow*) and the limb develops, showing separation of the individual rays by 8 weeks (**b–d**)

2 Embryology of the Hand—Foetal Period

The limb buds develop at the end of the fourth gestational week, arising from the ventrolateral body wall under the influence of a thickened area of ectoderm, at the distal end of the limb bud called the apical ectodermal ridge (Fig. 1). The upper limb consists of three layers: lateral mesoderm, somatic mesoderm, and ectoderm. During the fifth week, neuronal tissue grows into the limbs and the hand plates become visible at the distal end of the upper limb. A process of programmed cell death forms the digital rays from the hand plate and individual rays are seen in the sixth week. The bones form as hyaline cartilage models of chondrified condensed mesenchyme, and in the sixth week this chondrification occurs in the distal limb skeleton including the carpal and metacarpal bones. This process continues into week seven, by the end of which all the phalanges are involved. Endochondral ossification is seen by eight weeks and progresses rapidly. Foetal ossification of the radius, ulna, and phalanges is complete by 35–40 weeks (Fig. 2). The ossification of the hand epiphyses and carpals begins in the postnatal period, in proportion with the longitudinal growth of the tubular bones.

3 Postnatal Growth of the Hand Skeleton

Until three months of age there is no ossification of the carpals and hand epiphyses. Skeletal age at this stage is best assessed by views of the lower limb

(knee and ankle) to demonstrate ossified nuclei in the proximal tibia, calcaneum, and talus in normal children. After three months of age, the left hand is used in standard assessment. Skeletal development proceeds in the same sequence in both males and females, though faster in females. This accelerated development begins to become apparent after three months of age continuing to puberty.

3.1 Carpus

Enchondral ossification of the carpal bones starts at around three months of age (Fig. 3a) and continues until skeletal maturation at 14–16 (Pyle et al. 1971). In most children, bone growth and modeling follows a specific sequential pattern with a constant ratio between carpal bone volumes (Bull et al. 1999; Canovas et al. 1997). Radiographically, the small spherical ossification centres develop into multifaceted, articulating bones with a well defined cortex. With growth, the bony surface may take a slightly more squared and irregular form, the 3 dimensional nature of which is better appreciated in MR images than radiographically (Ording Müller et al. 2011; Avenarius et al. 2012).

The carpal bones' ossification order is more variable than that seen in the other hand bones. A reliable sequence is *capitate*, *hamate*, *triquetral*, *lunate*, *trapezium*, *trapezoid*, and *pisiform*. The *scaphoid* ossification usually appears before that of the trapezium in boys and either just before or just after in girls, the ossification of both occurs by 3 years (Fig. 3b, c). The *capitate* and *hamate* begin ossification around three months of age gradually enlarging until reciprocal shaping can be seen around one year of age. These bones will begin to overlap at 8y ♂/5y ♀. The bony projection of the hamate—the hamulus—will become visible at 13y ♂/11y ♀ and growth finally completes around age 17y ♂/15y ♀. On T1 weighted MR-images, an increasing number of bony surface depressions can be seen with advancing age in both the capitate and the hamate, from at least 5 years of age until skeletal maturity (Fig. 4a–d). In the capitate, this is typically seen along the radial side. The depressions reflect normal growth, and should not be mistaken for destructive change in children with conditions such as juvenile idiopathic arthritis (JIA). Some of these depressions can be seen on ultrasound examination (Fig. 5).

Fig. 2 Embryological development. Images of the developing foetal hand at **a** 20 weeks, **b** 30 weeks and **c** 40 weeks demonstrating gradual development of the bones and thickening of the

soft tissues. At 40 weeks there is no ossification of the distal radial and ulnar epiphyses, nor of the carpals

Fig. 3 Skeletal Development to age 3. **a** Development compatible with 3 months. There is flaring of the distal radius and ulna, and flattened bases of the metacarpals. Ossification centers are present in the capitate and hamate. After 3 months differences between the sexes begin to become apparent. **b** Development

compatible with 1y 3m ♂/1y ♀. There is ossification of the capitate, hamate, and radial epiphysis. **c** Development compatible with 2y 8m ♂/3y ♀. Ossification continues in the triquetrum and 1st metacarpal epiphysis. The distal radial epiphysis has become wedge shaped toward the ulna

The *triquetrum* begins ossification around 3y ♂/2y ♀. The initial rounded shape develops its mature contour with flattening of the *hamate* and *lunate* facets seen aged 9y ♂/7y ♀. Ossification of the *pisiform* is seen at 11y ♂/9y ♀, growth is complete by 16 years of age.

Lunate ossification begins around 3y ♂/2y 6m ♀, occasionally from two ossification centres. Clear facets are seen at 10y ♂/8y ♀, especially at the *capitate* surface. Growth is complete by 16y ♂/14y ♀. *Scaphoid* ossification begins at 6y ♂/4y ♀. Its characteristic concave capitates surface is seen by 10y ♂/8y ♀. Flattening of the radial surface and alignment with the radial epiphysis can be seen at 13y ♂/11y ♀. Growth is complete by age 16y ♂/14y ♀. On MRI,

typical surface irregularities seen in the radial corners (Fig. 5b), are seen in increasing numbers with increasing age (Ording Müller et al. 2011).

The *trapezium* and *trapezoid* begin to ossify after the epiphysis of the thumb, with the trapezium becoming visible by 4y ♂/3y 6m ♀, and the trapezoid by 6y ♂/4y ♀. Overlap between the two bones is seen at 8y ♂/6y ♀ when corresponding flattening of the first and second metacarpal articular surfaces is seen. Concavity of this metacarpal surface begins to be visible by age 9y ♂/7y ♀. The *trapezium* and *trapezoid* attain their adult shapes by 15 ♂/13y ♀.

Bony depressions due to physiological development and ligamentous insertions appear in the carpus and can be occasionally mistaken for pathology

Fig. 4 Development to age 5–14 with MR correlation. **a** Development compatible with 6y ♂/5y ♀. Ongoing carpal ossification with the beginning of reciprocal shaping. MR images show pre-ossified cartilage: ulnar epiphysis and triquetral (*black arrow*) and the emerging rounded ossification center of the trapezoid (*white arrow*). **b** Development compatible with 8y ♂/9y ♀. The carpals are now ossified with reciprocal shaping. The distal phalangeal epiphyses are as wide as their shaft. MR images show developing ulnar ossification (*black arrow*) and emerging carpal and metacarpal indentations (*white*

arrow). **c** Development compatible with 11y ♂/9y ♀. The carpals have developed reciprocal contours. The distal phalangeal epiphyses begin to conform to the adjacent middle phalanx. MR images show capitate irregularities not visible on the radiograph (*black arrow*). Ligaments are clearly visible, i.e. scapho-lunate ligament (*white arrow*). **d** Development compatible with 14y ♂/12y ♀. All epiphyses are beginning to cap their shafts and the physes are narrowing. MR images show further carpal irregularities corresponding to ligamentous insertions (*arrows*)

(Ording Müller et al. 2011). The carpal intraosseous ligaments are mostly within the joint capsule, some inserting directly into bone and others attaching to articular surfaces (Schmitt and Lanz 2008). They have complex anatomical relations and a brief overview of these is necessary to understand the development of carpal depressions (Fig. 6). Proximally the scapholunate and lunotriquetral ligaments reinforce the palmar joint capsule. The radioscapolunate ligament extends from the mid-palmar aspect of the radiolunate ligament to the radius, containing neurovascular structures. Distally thick interosseous ligaments run between the carpal bones, for example the capitohamate ligament. Two groups of ligaments are present on the palmar aspect of the carpal bones: the ‘Proximal Palmar V’ comprises of the Radioulnar triquetral, Ulnolunate, and Ulnotriquetral ligaments. The ‘Distal Palmer V’ comprises of the Radioscaphocapitate ligament and the arcuate complex (triquetrocapitoscaphoid ligament). The dorsal aspect of the carpus

also has a ‘V’ complex: the ‘dorsal V’ consists of the dorsal radiotriquetral, dorsal intercarpal ligaments, and the extensor reticulum complex.

3.2 Metacarpals

The epiphysis of the first metacarpal develops in conjunction with the trapezium. At birth the proximal aspect is flattened and the adjacent trapezium is not yet ossified. Ossification of the first epiphysis starts at 2y ♂/1y 6m ♀. Enlarging transversely, the epiphysis flattens and begins to conform to the base of its shaft by 4y 6m ♂/3y ♀.

The trapezium surface becomes indented, conforming to the trapezoid by 9y ♂/8y 10m ♀. There is reciprocal shaping of the trapezium to the epiphysis, which is as wide as the shaft of the 1st metacarpal by 13y 6m ♂/11y ♀. Fusion of the first epiphysis begins by 15 years ♂/13y 6m ♀ and the fusion line may persist

Fig. 5 Ultrasound and MR of carpal depressions. **a** Carpal irregularities in the capitate and trapezium (*white arrow*). **b** Typical surface irregularities of the radial corners of the scaphoid. Further irregularities seen in the lunate and triquetrum

corresponding to ligamentous insertions. **c** Sagittal Ultrasound image from radius (*right*) to third metacarpal (*left*) demonstrating carpal irregularities

for many years. On MRI, there is a typical bony depression at the base of the 2nd metacarpal, which may easily be mistaken for an erosion (Fig. 4b).

The 2nd–5th metacarpal epiphyses develop at a slightly different rate to the first. The 2nd metacarpal epiphysis tends to lead, followed stepwise by the 3rd–5th with the 5th being the last in development. The epiphyses begin to ossify at 1 year ♂/1y 6m ♀. Their oval contour is seen to flatten, adjusting to the distal metacarpal surface by 2y ♂/1y 6m ♀. The epiphysis becomes more cuboidal and is as wide as the metacarpal shaft at 11y 6m ♂/10y ♀. Fusion of the growth plate begins by 15y 6m ♂/13y 6m ♀. On MRI, the basis of the 3rd and 4th metacarpals typically narrows dorsally.

3.3 Phalanges

The growth of the phalanges follows a similar order to the metacarpals, with the 2nd leading, and the 5th slightly behind. At birth the proximal phalanges have flat proximal surfaces and the ossification of the epiphyses appears by 1y 6m ♂/1y ♀. These epiphyses are flattened and disc like, becoming slightly concave as they develop, and are as wide as the diaphysis at 10y ♂/7y 10m ♀. At this age, the distal end of the proximal phalanx also becomes concave. The epiphysis begins to cap its shaft at 13y ♂/10y ♀, and begins fusion at 15y 6m ♂/13y 6m ♀.

The middle phalanges follow similar development to the proximal, with ossification beginning at 2y ♂/

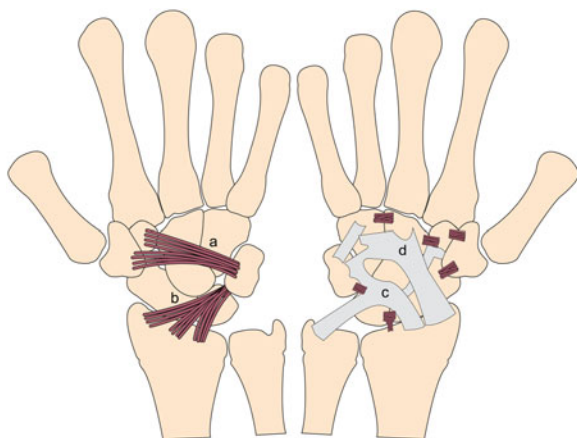

Fig. 6 Major ligamentous groups accounting for carpal depressions. *Left image:* Dorsal ligament groups. **a** dorsal intercarpal ligament, **b** dorsal radiotriquetral ligament. *right image:* Palmar ligament groups. **Red** interosseous ligaments. **Grey** c proximal v. **d** distal v

1y 6m ♀. The width of the adjacent metaphysis is obtained by 12y 6m ♂/8y 10m ♀, with capping of the shaft seen by 13y 6m ♂/11y ♀. Fusion of the epiphysis is seen by 15y 6m ♂/13y 6m ♀.

The distal phalanx epiphysis ossifies slightly later than the proximal and middle, becoming visible by 2y 8m ♂/2y ♀. Similar disc shaped growth is seen and the epiphysis is as wide as its shaft by 7y ♂/5y 9m ♀. Capping is seen at 12y 6m ♂/10y ♀, with fusion beginning at 15y ♂/13y 6m ♀. Fusion is usually complete before that of the middle phalangeal physes.

The thumb phalanges develop ahead of the 2nd–5th digits. The proximal phalanx epiphysis begins ossification by 2y 8m ♂/2y ♀. This becomes disc-like and is as wide as its diaphysis by 10y ♂/7y 10m ♀. Capping of the epiphysis is seen by 15y ♂/11y ♀, and ossification of the (smaller flexor) sesamoid is present. Fusion of the epiphysis begins at 16y ♂/14y ♀.

The distal phalanx of the thumb ossifies by 1y 6m ♂/1y 3m ♀, gradually enlarging to cap its shaft by 13y 6m ♂/11y ♀. Fusion begins shortly afterward at 14y ♂/12y ♀.

3.4 Radius and Ulna

At birth, the distal radius and ulna metaphyses are slightly flared, with the ulna slightly more proximal than the radius. The distal ulna may be slightly cupped, not to be mistaken for metabolic bone disease,

such as rickets (Fig. 2). Ossification of the distal epiphysis occurs around 15 months in the radius and 6 years in the ulna in both males and females, with both epiphyses being initially rounded and ‘pea’ like. On MRI, both epiphyses may appear very flat and nearly fragmented (Fig. 4). In the radius the ossification flattens and elongates toward the ulna. The ulnar articular facet is thinner than the styloid aspect of the radial epiphysis, giving a ‘wedge shape’ seen clearly by 4 years of age. The radial styloid process enlarges and the epiphysis is as wide as the radius by 11 ♂/10y ♀. Capping of the radial metaphysis occurs by 14 ♂/11y ♀. Fusion of the distal radial epiphysis is the last of any in the hand, beginning at around 17 ♂/15y ♀. The ulna ossification proceeds in either of two directions: flat and parallel to the ulna metaphysis or obliquely pointing toward the future site of the ulna styloid process: these patterns will be apparent by 6–7 years of age. A clear ulna styloid process with distal concavity of the adjacent mid-epiphysis should be apparent by 11y 6m ♂/9y ♀. Capping of the ulna and epiphyseal fusion is seen at 14 ♂/11y ♀.

3.5 Maturation of the Bone Marrow

In the neonate all bone marrow is haemopoietic and the conversion of red haemopoietic marrow to yellow fatty marrow takes place throughout childhood. The process begins in the extremities, progressing through the distal, then proximal long bones and finally in the axial skeleton (Laor and Jaramillo 2009) (Fig. 7). By the age of skeletal maturity, the appendicular bone marrow is almost entirely converted.

MR imaging is a very sensitive tool for the detection of changes in fat composition within bone marrow. Normal haematopoietic marrow contains approximately 40% fat, 40% water and 20% protein, whereas fatty marrow contains approximately 80% fat, 20% water and 5% protein. Due to the fat content of haemopoietic marrow, MR demonstrates apparent conversion in advance of the histological change. Marrow conversion in boys and girls is thought to proceed at the same rate (Moore and Dawson 1990).

Mature fatty bone marrow is hyperintense on spin echo sequences, with intermediate homogenous hypointense signal on fat suppressed gradient echo sequences. No enhancement is seen. Haemopoietic marrow returns a signal similar or higher than muscle

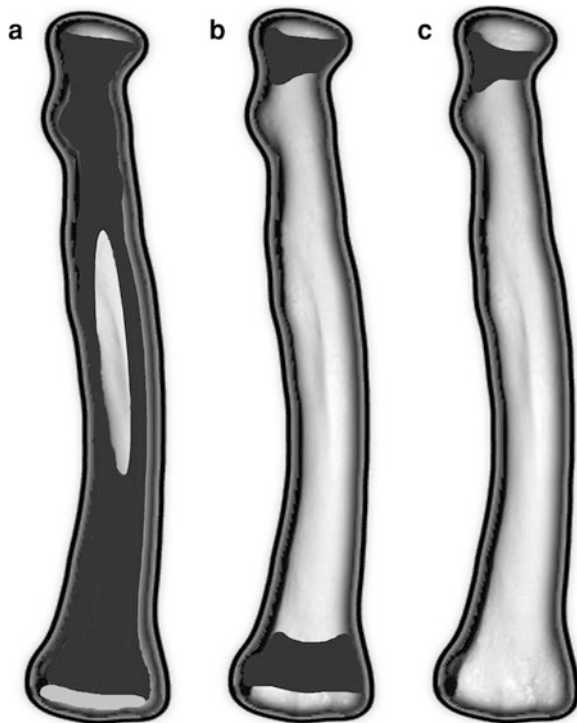

Fig. 7 Conversion of Red marrow. Red marrow conversion begins in the epiphyses (a) within 6 months of the development of the secondary ossification centre. Conversion is then seen in the diaphysis, expanding with time towards the metaphyses (b). The distal metaphysis converts followed by the proximal (c)

on T1 weighted images, due to the fat content. The higher water content results in high signal on water sensitive sequences such as STIR.

In the infant, epiphyseal cartilage is of homogenous intermediate signal intensity on T1 weighted images and of low signal intensity on water sensitive sequences. As ossification takes place, the signal returned on water sensitive sequences becomes heterogenous. Vascular channels within the cartilage can enhance, often showing a radial arrangement (Moore and Dawson 1990). As ossification begins, the ossification centre develops haemopoetic marrow and the signal intensity becomes rapidly similar to the adjacent metaphysis. Fatty conversion begins in the epiphysis and is seen within six months of the appearances of the secondary ossification centre (Moore and Dawson 1990; Jaramillo et al. 1991). Conversion then continues in the diaphysis, extending to the distal metaphysis and lastly to the proximal metaphysis.

Normal variants seen on MR include residual foci of haemopoetic marrow in otherwise converted bones.

Fig. 8 Individual bones of differing ages. 11y old, healthy male. Assessment of skeletal maturity shows a marked discrepancy between proximal and distal development, with a skeletal age of 10y based on the fingers, and 7y based on the carpal bones. Such variation can be normal, but there are known associations with central causes of growth disturbance

These areas will characteristically will have straight ‘flame’ contours and return increased signal in comparison to adjacent muscle on T1 images. Signal changes suggestive of bone marrow oedema are seen in at least one of the carpals or metacarpal bases in more than half of healthy children aged between 5 and 15 years, with no differences according to sex, age or degree of daily physical activity (Ording Müller et al. 2011). In addition bony depressions, often not appreciated on radiographs, are present in all cases (Figs. 4a–d and 5).

4 Assessment of Bone Age

Assessment of bone age is a complex task: it is prone to intraobserver and interobserver variation and can depend on experience of the method used. A hand of a given age can often contain individual bones of differing

maturity (Fig. 8). Variations in skeletal maturation between ethnic groups have been observed, however the cause is a contentious subject. Development is known to take place in a sequence which is identical for both sexes and all ethnicities (Zhang et al. 2009), however, the most robust evidence indicates that variations in the rate of skeletal development are minimally affected by ethnicity, and that socio-economic factors are of much greater significance (Schmeling et al. 2000).

Several methods of bone age assessment have been devised. Atlas methods involve comparison by age and sex matched controls with descriptions of bones, accompanying radiographs are intended primarily as illustrations. Examples include the Atlases of Greulich and Pyle, and Theimann and Nitz, which refer to North Americans of Northern European descent and Central European children of unspecified ethnicity respectively. The Greulich and Pyle age assessment is by comparison with the given reference standards within the given normal variance for age. No variance data was given in the original Theimann and Nitz method (Schmeling et al. 2006). Bone measurement methods include the Tanner and Whitehouse system. This system has gone through several refinements, the latest being the 'TW3' system (Tanner et al. 2001). The developing hand is divided into multiple regions of interest and the development of each region divided into discrete stages. A numerical score is associated with each stage and the total score allows assessment of maturity.

Studies comparing the various methods of assessment must be analysed with the understanding that, as discussed earlier, skeletal maturation is dependent on socio-economic factors. Therefore, methods based on certain populations at certain times may not be comparable with other populations.

Greulich and Pyle, and Theimann and Nitz offer close agreement in assessment, however, the Thiemann and Nitz method may be better for preventing over estimation of skeletal age in populations with high acceleration status (Schmidt et al. 2007). Atlas methods may be subject to greater interobserver variation, but are much less time consuming than measurement methods. The Tanner–Whitehouse system allows a more objective assessment, but is much more time consuming than the atlas methods. Greulich and Pyle, and Tanner and Whitehouse have been compared and found to give clinically significant differences in bone age and therefore only one method should be used in

longitudinal assessment (Bull et al. 1999; Schmidt et al. 2008).

Automated computer systems have been developed in an attempt to avoid the difficulties associated with the human mind assigning a discrete age to the essentially continuous changes of bone age. The initial aim was to automatically identify bones by means of comparison with deformable models. Identified bones are then individually assessed for age before conversion into a recognised bone age scale i.e. Greulich and Pyle or TW3. This modern approach has been validated clinically (Thodberg 2009), and future refinements may result in completely automated systems.

As has been seen, MRI shows characteristic changes to the bones of the hand and wrist with development and may provide more accurate means to assess bone age in the future without the disadvantage of exposure to ionising radiation. The technique has already been shown to have some role in assessing skeletal age of adolescent football players, where the use of ionising radiation cannot be justified (Dvorak et al. 2007).

Abstract

Congenital hand differences (CHD) have been estimated to occur in 10% of children born with congenital abnormalities. CHD can be classified according to their pre-dominant abnormality using the Swanson classification. Failure of differentiation represents the most common group. Associated (nonlimb) abnormalities are common and it is important to identify those CHD requiring systemic evaluation. Radiology is important in the diagnosis and management of CHD with plain films providing the mainstay of imaging postnatally. The management of CHD should be within a multi-disciplinary environment.

1 Introduction

Of the 1–2% of newborns born with congenital defects, 10% are born with upper limb malformations (McCarroll 2000). The incidence is higher in boys, with pre and post-term births, with multiple pregnancies and with increased maternal age (Giele et al. 2001). Congenital hand abnormalities are now commonly described as congenital hand differences (CHD). The majority (60%) of CHD has an unknown etiology but genetic factors may be attributable in 20% and environmental teratogens in 20% (Netscher and Baumholtz 2007). The embryologic limb bud can be seen at 4 weeks after fertilization, and the existing fetal limb structures continue to grow and develop for 8 weeks after fertilization. Most CHD are thought to arise during this 4-week interval (Kozin 2003).

CHD vary widely in their functional and aesthetic implications. Associated (nonlimb) abnormalities are also common, up to 26.7% in some series (De Smet 2002). It is important to identify those CHD which require further systemic evaluation and to differentiate them from isolated CHD. For example, radial deficiency occurs commonly in a number of syndromes such as the VACTERL association (vertebral abnormalities, ano-rectal and cardiac abnormalities, tracheo-oesophageal fistula, oesophageal atresia, renal defects, radial dysplasia and lower limb abnormalities).

Management must always be conducted in a multi-disciplinary environment, involving surgeons, physiotherapists, orthotists, paediatricians, prosthetists, psychologists, anaesthetists, geneticists and radiologists. The purpose of this review is to provide an illustrated classification of congenital hand differences for radiologists, which will also be of interest to the other members of the multi-disciplinary team.

2 Imaging

CHD may be demonstrated by antenatal ultrasound particularly late in the first trimester and in the middle of the second trimester of pregnancy (Rypens et al. 2006) (Fig. 1). Three-dimensional ultrasound may be helpful in defining the abnormality more clearly (Ploekinger-Ulm et al. 1996). Prenatal classification

Fig. 1 2D Ultrasound image of a fetal hand of a fetus in the second trimester with trisomy 13 and post-axial polydactyly (Image courtesy of Dr Françoise Rypens)

and characterization may help to identify fetuses that would benefit from more complete prenatal cardiac and karyotypic workup.

Postnatally, plain films provide the mainstay of imaging, with ultrasound and magnetic resonance imaging (MRI) providing useful additional characterization in a minority of cases, principally in the clarification of the nature of masses and other causes of overgrowth.

3 Classification

The most widely accepted classification of CHD was proposed by Frantz and O’Rahilly and presented by Swanson (Frantz and O’Rahilly 1961; Swanson 1976). This was subsequently modified by the International Federation of Societies for Surgery of the Hand (IFSSH) in 1983 (Swanson et al. 1983), and further modified by the Japanese Society of Surgery of the Hand (JSSH) in 2000. The major categories are listed in Table 1 and are subsequently discussed.

Table 1 Abbreviated embryologic classification of CHD (adapted from Swanson 1976)

1	Failure of formation
2	Failure of differentiation
3	Duplication
4	Overgrowth
5	Undergrowth
6	Constriction ring syndrome
7	Generalised skeletal abnormalities

The seven categories differentiate the CHD according to the predominant abnormality, and further define the abnormality according to the nature of the embryonic failure during development. Group II (failure of differentiation) represents the most common group.

4 Failure of Formation

Failure of formation of parts can be divided into transverse and longitudinal subgroups. Transverse deficiencies occur when growth stops abruptly, resulting in a “congenital amputation” and a shortened or truncated limb. Longitudinal deficiencies occur when structures are hypoplastic or absent along a longitudinal axis of the limb, resulting in abnormal formation and function biased down one ‘side’ of the limb (either the radial or ulnar sides, or ‘centrally’ between the two) (Kozin et al. 2004). In reality, most CHD within this group are mixed to some degree.

4.1 Transverse

This is defined according to the bone segment at which the growth arrest occurs (Van Heest 1996). The most common transverse deficiency occurs at the junction of the proximal and middle thirds of the forearm (Fig. 2).

These anomalies are usually unilateral, sporadic, and are rarely associated with other anomalies. Rudimentary “nubbins” or dimpling may be found at the distal end of the congenital amputation (Kozin 2003). This should not be confused with Constriction

Fig. 2 Commonest level of transverse growth arrest at proximal radius and ulna (arrow)

ring syndrome which may also manifest as an ‘amputation’ but requires the presence of a constriction ring either affecting the involved extremity or elsewhere (Wiedrich 1998).

4.2 Longitudinal

In this group the radial, central or ulnar side of the limb is abnormal. They may very rarely be characterized by absence of one or more ‘segments’ (‘forearm’ versus ‘upper arm’ versus ‘both’) of the upper limb (phocomelia), such as those defects attributed to maternal exposure to thalidomide. For example, when both segments are missing (‘complete phocomelia’), the hand is attached directly to the shoulder.

4.2.1 Radial

Radial dysplasia is the most common longitudinal deficiency and occurs when structures on the radial side of the arm fail to develop properly. It is frequently bilateral (40–60%) with a male:female ratio of 3:2 (Van Heest 1996). It has been described as “an abnormal hand joined to a poor limb by a bad wrist” (Flatt 1994) (Fig. 3).

Fig. 3 Radial dysplasia displays an array of upper limb differences, the most striking of which are usually the radially deviated wrist (*white arrow*), absent thumb (*black arrow*), shortened forearm and stiff elbow

Fig. 4 Radial dysplasia has a spectrum of abnormalities of the radius, the commonest being complete absence of the radius. In such cases the ulna (*arrow*) is relatively hypoplastic also

Radial deficiency can range from mild hypoplasia to complete absence of the radius and thumb (the commonest type) (Fig. 4). The child presents with a

hand that is radially deviated at the wrist. In the hand, the thumb is almost always affected and the fingers frequently have limited motion and function, the severity of which decreases from the radial to the ulnar side (James et al. 2004). The ulna is also usually shortened and bowed and may need later osteotomy (Fig. 5a, b).

A classification scheme has been described by Bayne and Klug for radial deficiency with proposed modifications by James et al. (Bayne and Klug 1987; James et al. 1999). For the purposes of imaging, it is useful to divide the deficiency into components and describe the characteristics of each component (James et al. 1999; Kozin 2003).

1. Thumb:
 - I. absent
 - II. hypoplastic
2. Carpal bones:
 - I. normal
 - II. absent
 - III. hypoplastic
 - IV. coalition

(Nb: Ossification centers of the carpal bones appear at a variety of ages ranging from 2 months for the capitate and hamate, to 4 years for the scaphoid, trapezium and trapezoid.)
3. Distal radius
 - I. normal
 - II. >2 mm shorter than ulna
 - III. absent physis
 - IV. absent
4. Proximal radius:
 - I. normal
 - II. radioulnar synostosis
 - III. radial head dislocation
 - IV. hypoplastic
 - V. absent

The elbows are commonly stiff, and the abnormal features frequently extend further proximally (Fig. 6). Recently Goldfarb and colleagues (Goldfarb et al. 2005) proposed a further subtype of proximal radial longitudinal deficiency, involving an abnormal glenoid, an absent proximal humerus (with the distal humerus articulating with the ulna) and radial sided hand abnormalities.

Treatment involves straightening (centralization) of the wrist, currently achieved by initial distraction (Fig. 7a) followed by centralization (Fig. 7b) (both of which require perioperative fluoroscopic

Fig. 5 **a** and **b** In radial dysplasia the ulna is frequently bowed, and may require correction as in this case which had been centralized 10 years previously. The osteotomy site (*arrow*) is secured with a large K-wire, removed at six weeks **a** pre-op **b** post op

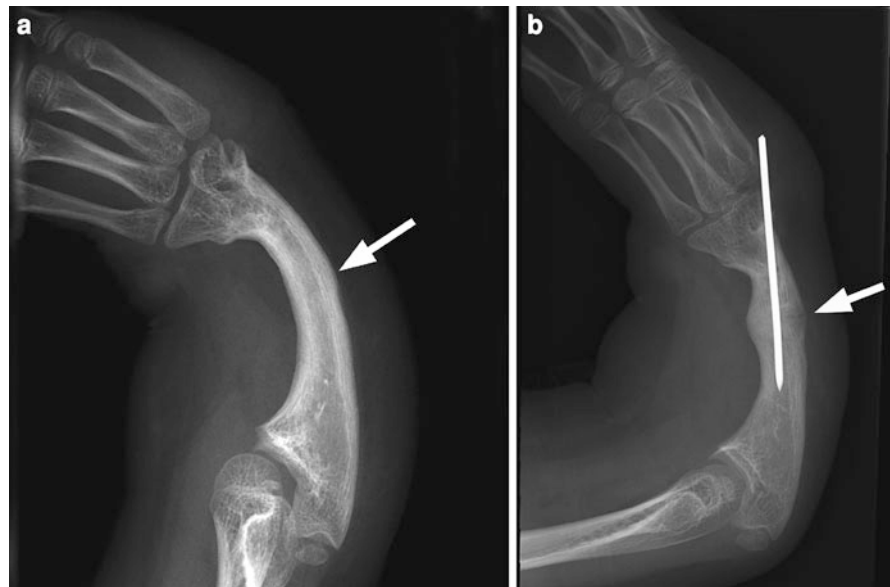

Fig. 6 Radial dysplasia with severe hypoplasia of the ulna (*black arrow*) and humerus (*white arrow*), both of which are shorter than the hand itself

screening), and later pollicisation (shortening and rotation of the index ray on its neurovascular pedicle to the position of the thumb, with tendon and intrinsic muscle rebalancing to create a ‘thumb’ from the index finger).

Importantly, radial longitudinal deficiencies often present as part of a syndrome. Associations include hematological conditions (e.g., thrombocytopenia-absent radius syndrome and Fanconi’s anaemia), cardiac anomalies (e.g., Holt Oram syndrome), the VACTERL syndrome (see Sect. 1) and craniofacial syndromes (e.g., Nager and Duane syndromes) (Lourie and Lins 1998).

Children with radial longitudinal deficiencies should therefore have a thorough multi-disciplinary evaluation at the time of presentation to exclude associated abnormalities, understanding that some of these may not be immediately apparent (e.g., Fanconi’s anaemia has a median age of onset of seven years of age) (Kozin 2003).

4.2.2 Central

This involves deficiencies of the central part of the hand and is also known descriptively as ‘cleft hand’, with traditional terms such as ‘split hand’ or ‘lobster claw hand’ having been rightly dropped because of their potentially emotive nature. Two types of cleft hand have been described, formerly known as ‘typical’ and ‘atypical’. Although they may appear similar morphologically, they both have major clinical differences and probably different embryological derivations (Miura and Suzuki 1984; Ogino 1990a).

The typical cleft hand (now known as ‘true’ cleft hand) has a deep V-shaped defect (Fig. 8a, b). Most commonly the phalanges are missing. The metacarpals may be absent or malpositioned (Fig. 9), but are

Fig. 7 Treatment of the radially deviated wrist is best achieved by (a) initial gradual lengthening of the soft tissues using an external distraction frame to bring the hand in line (*arrow*) over

the end of the ulna, followed by (b) removal of the frame and formal centralization, with tendon transfers and temporary axial K-wire fixation, requiring intraoperative fluoroscopy

Fig. 8 a True cleft hand is usually bilateral, with V-shaped clefts (*arrows*), though the severity may differ between the two hands as in this case. b True clefts are usually centered on an absent third ray (*arrow*)

rarely hypoplastic. Joints at the site of the cleft can be very complex (Fig. 10), (Barsky 1964; Ogino 1990). This type of deficiency is often bilateral, and is

usually inherited. There may be syndactyly of the ring-small or thumb-index web space, and associated foot involvement is common (Fig. 11). True central

Fig. 9 In true cleft hand a wide spectrum of severity is seen, in which transverse metacarpals can cause progressive widening of the cleft (*arrow*)

Fig. 11 Foot involvement is common in true cleft hand patients

Fig. 10 This unusual variant demonstrates the complex joints (*arrows*) which can exist in cleft hands, requiring vigilance during surgical corrections

dysplasia is also associated with cleft lip and palate but not Poland syndrome (Miura and Suzuki 1984; Ogino 1990a).

Atypical cleft hand has a shallower, U-shaped central defect that involves the central three digits (index, long and ring) (Fig. 12a), (Kozin 2003). It is a form of symbrachydactyly (shortened and webbed digits) that can vary in degree from the ‘short finger type’ (Fig. 12b), to absence of the central three digits (Fig. 12a), to a monodactylous type (thumb only, no fingers) (Fig. 12c, d), to complete absence of all digits, with only very rudimentary ‘nubbins’ (peromelic type) (Fig. 12e).

Atypical cleft hand is usually unilateral and sporadic. It is not associated with lower limb malformations or cleft lip and palate (Miura and Suzuki 1984; Ogino 1990a) but is associated with Poland syndrome (Fig. 13) (Ireland et al. 1976). The degree of hand deficiency in Poland syndrome does not correlate with that of the chest wall deformity, therefore clinical evaluation of the chest wall is required with all cases of symbrachydactyly (Kozin 2003).

4.2.3 Ulnar

This represents a spectrum of abnormalities along the ulnar surface of the upper limb. It is far less common than radial and central longitudinal deficiency (Miller et al. 1986; Schmidt and Neufeld 1988) (Figs. 14a, b; 15; 16a, b).

Fig. 12 Symbrachydactyly subtypes **a** Atypical cleft hand also known as 'U-shaped cleft hand type' with absence of the central three digits, leaving only the thumb (*arrow*) and little finger, both of which are hypoplastic in this case. **b** Short finger type, with proximal phalanges and reasonable soft tissue envelopes distally (*arrows*) of the central three digits, which could be amenable to augmentation with bone grafts. **c** Monodactylous type, in which only the thumb remains (*white arrow*), but potentially useful soft tissue envelopes to the index and little fingers (*black arrows*). **d** Monodactylous type, with only the thumb, and no distal soft tissue. Function would be greatly improved by free toe transfers, or even custom made prostheses. **e** Peromelic type, with severe attenuation at metacarpal level (*arrow* denotes proximal palmar crease)

Radial sided hand anomalies may co-exist with ulnar longitudinal deficiency and hand abnormalities are present in 68–100% of cases (Miller et al. 1986). Ulnar longitudinal deficiency may be

associated with other musculoskeletal anomalies (e.g., scoliosis), but is not associated with the visceral and haemopoetic disorders seen in radial deficiencies.

Fig. 13 Poland's syndrome with shortened digits due mostly to attenuation or absence of the middle phalanges (*arrow*), syndactylies and global hypoplasia of the hand, in association with other upper limb and chest deformities

5 Failure of Differentiation

5.1 Syndactyly

Syndactyly is one of the most common hand anomalies and results from incomplete separation of two or more adjacent digits. It has an incidence of 1:2,000 live births (Flatt 1994). The anomaly can be sporadic or familial (a family history is present in 10–40% of cases) and it may be associated with other syndromes including Poland syndrome and craniosynostoses such as Apert's syndrome (Fig. 17) (Kozin 2001).

It is classified as 'complete' if it reaches the distal interphalangeal joint (Fig. 16a), 'incomplete' if proximal to this joint, 'simple' if it involves only skin and soft tissue, and 'complex' if there is a bony fusion (usually distal) (Fig. 16b) (Van Heest 1996). Any combination of web spaces may be involved, but the commonest is an isolated third web-space involvement (between the ring and middle fingers). Syndactyly can also be classified as 'complicated' if

it occurs in association with other abnormalities in the affected area, such as duplication (Fig. 18). Syndactyly should be differentiated from 'Acrosyndactyly' (distal fusion with a proximal fenestration) which occurs in association with Constriction ring syndrome (see Sect. 9).

Radiographs may indicate that separation of syndactyly is not always appropriate (Fig. 19a, b).

5.2 Arthrogyposis

This term has been used to describe conditions that present with congenital joint contractures (Mennen et al. 2005). This clinical entity has also been described by Sheldon as amyoplasia (Sheldon 1932) and most affected children (84%) present with involvement of all four limbs (Sells et al. 1996).

The contractures are thought to be the end result of decreased intra-uterine movement by the fetus which may occur because of neuropathies, myopathies, abnormal connective tissue or decreased intra-uterine space. It is a sporadic condition with an incidence of 1 in 10,000 live births (Hall 1997) (Fig. 20a, b).

5.3 Camptodactyly

This is a painless flexion contracture of the proximal interphalangeal joint (PIPJ) that usually affects the little finger and may be progressive. It is not related to trauma and is estimated to affect just under 1% of the population to some degree (Smith and Kaplan 1968) (Fig. 21). A classification system has been described by Benson with three main types (Benson and Kaplan 1994). Type I presents in infancy and is frequently confined to one or both little fingers, with approximately equal sex incidence. Type II presents in adolescence with females being affected more commonly than males. The deformity worsens with the adolescent growth spurt. Type III is more severe and usually affects multiple digits in both hands (Koman et al. 1990), and may be associated with chromosomal disorders and skeletal abnormalities. Most structures within the finger have been implicated, although abnormalities of the intrinsic lumbrical muscles of the superficial flexor tendon are not uncommon operative findings.

◀**Fig. 14** **a** and **b** Ulnar dysplasia has deficiencies of the ulnar side of the upper limb, with partial or complete absence of the ulna, commonly with the radius providing a one-bone forearm (*short arrows*), loss of ulnar digits, ulnar deviation at the wrist, and syndactylies (*long arrows*)

Plain radiograph assessment is vital, as the presence of classical bony changes around the joint predicts a very poor surgical outcome. These bony changes include flattening of the head of the proximal phalanx, widening of the base of the middle phalanx, and an indentation at the neck of the proximal phalanx (Ty and James 2009) (Fig. 22).

5.4 Clinodactyly

This refers to an abnormal deviation of a finger in the coronal or radioulnar plane which typically affects the middle phalanx of the little finger. The finger deviation is usually directed radially. Minor angulation of <10 degrees is so common that it may be regarded as a normal variant (Ezaki 1999).

Familial clinodactyly with an autosomal dominant pattern of inheritance usually presents bilaterally, and

Fig. 15 Radiohumeral synostosis (*arrow*) can be seen in ulnar dysplasia

Fig. 16 Syndactyly **a** Simple, complete syndactyly with soft tissue union only, distal-to-distal interphalangeal joint (*arrow*). **b** Complex syndactyly with bony union which is usually at the

distal phalangeal level (*arrow*), and requires earlier release than simple syndactyly as bony deformities can occur quickly with growth

Fig. 17 Apert's hand with complex syndactyly (*short white arrow*), poorly developed or absent proximal interphalangeal joints ('symphalangism' (*black arrows*)), and a shortened thumb caused by a delta phalanx (*large white arrow*)

Fig. 18 Complicated syndactyly, with distal bony union (*large arrow*) and unusual duplication of the middle phalanx (*small arrows*)

Fig. 19 Syndactyly release is sometimes contraindicated, as X-rays may reveal that the fingers work better together than if they were separated

is not associated with genetic syndromes. Clinodactyly may also be associated with syndromic and genetic conditions, most notably Down syndrome, in which the prevalence has been estimated at 35–79% (Flatt et al 1994).

Fig. 20 Arthrogyria is frequently associated (a) with multiple camptodactylies (*arrows*), sometimes affecting all digits (b)

The deformity is caused by an abnormally shaped middle phalanx, which may be triangular (a “delta” phalanx) or trapezoidal because of a C-shaped epiphysis (Jones 1964) (Fig. 23). Serial plain radiographs can be useful for objective monitoring of the angle of deviation. If progression occurs despite non-operative treatments

Fig. 21 Camptodactyly most commonly involves the little fingers, with stretching exercises and splintage forming the mainstay of treatment, with surgery often yielding disappointing results

Fig. 23 Clinodactyly showing abnormal C-shaped epiphysis of middle phalanx (*arrow*)

Fig. 22 Bony changes in camptodactyly chisel shaped head of proximal phalanx (*long arrow*), indentation of the neck of the proximal phalanx (*short arrow*), and widening of the base of the middle phalanx augur a poor surgical result

(principally night splintage), surgery in the form of a wedge osteotomy may be required (Fig. 24a, b).

Delta phalanges can occur elsewhere in the hand and are frequently seen in the thumbs of Apert's patients, where they can cause marked deviation (Fig. 25) and often require surgery.

5.5 Congenital Thumb Flexion Deformities

Trigger and clasped thumbs are the two main causes of congenital flexion deformities of the thumb, with flexion, respectively at the interphalangeal and metacarpophalangeal joints. In trigger thumbs, a thickening in the flexor tendon may be felt at the A1 pulley level (clinically at the level of the metacarpophalangeal level).

In clasped thumbs there is a wide spectrum of differences, starting with attenuation then absence of the extensors, and progressing to flexion contractures with global thumb hypoplasias. Clinical evaluation usually suffices, though ultrasound may be useful in assessment of the tendons to aid in treatment planning. Hypoplastic extensors in a clasp thumb may respond to simple splintage whereas aplasias require tendon transfer.

Fig. 24 Clinodactyly showing (a) a delta phalanx with fused epiphysis, treated by (b) a closing wedge osteotomy (*arrow*) and temporary K-wire

Fig. 25 Apert's thumb delta phalanx (*arrow*), which usually requires surgical correction

Fig. 26 Rudimentary radial duplicate (*arrow*)

6 Duplication

This probably results from splitting of the original embryonic part rather than a true duplication (Van Heest 1996). Polydactyly may be 'preaxial' (radial i.e., thumb), postaxial (ulnar i.e., little finger) or central.

6.1 Post-Axial Polydactyly

Duplications involving the ulnar aspect of the hand are more common in patients of African descent. The incidence is reported as 1 in 1,339 live births in Caucasians and 1 in 143 live births in African Americans (Watson and Hennrikus 1997).

Fig. 27 Ulnar duplication is based on the Stelling classification. **a** *Type 1* skin bridge only (*arrow*) requiring only simple excision. **b** *Type 2* strong bony attachment, requiring

preservation and reinsertion of the ulnar collateral ligament from accessory digit to fifth finger (position of insertion marked with *arrow*). *Type 3* is complete duplication of metacarpal

Fig. 28 Triphalangeal thumb (*arrow*)

Although it is commonly an isolated finding with autosomal dominant transmission and a favorable prognosis, it may also be associated with various

syndromes. The presence of post-axial polydactyly in Caucasians is more suggestive of an underlying syndrome and merits systemic evaluation. Syndromes

Fig. 29 The Wassel classification divides radial duplication into seven subtypes. **a** *Type 2* duplicated distal phalanx. **b** *Type 3* bifid proximal phalanx. **c** *Type 4* duplicated proximal

phalanx. **d** *Type 6* duplicated metacarpal. *Type 1* is a bifid distal phalanx, *type 5* is a bifid metacarpal, and any duplication with a triphalangeal element is classified as a Wassel *type 7*

Fig. 30 Wassell 4 duplication at the metacarpophalangeal level is the commonest subtype (50%). **a** Well-matched duplicates, which would require skeletal amalgamation. **b** Post-amalgamation procedure of Wassell 4 duplication in which the radial duplicate was relatively hypoplastic, but which still requires

preservation of soft tissues (*arrow*) from radial duplicate (radial collateral ligament, thenar muscle insertions and almost all of the skin), and reinsertion into the dominant ulnar duplicate. Only the hypoplastic skeleton, pulp and nail complex has been discarded

Fig. 31 Proteus syndrome

include trisomy 13, Meckel-Gruber syndrome, Bardet-Biedl syndrome, Smith-Lemli-Opitz syndrome, short rib-polydactyly syndromes and Ellis van Creveld syndrome (Lachman 2007).

Fig. 32 Ollier's disease—multiple exostoses (*arrows*)

Accessory digits may be well developed or rudimentary (Fig. 26) (Watson and Hennrikus 1997). Commonly the digit is rudimentary and held by a soft tissue bridge requiring only a simple excision

Fig. 33 **a** Large soft tissue mass on dorsum of thumb of 18 month old boy. Rapid growth raises possibility of malignant change, meriting initial urgent radiological investigation. Plain XR revealed no bony changes or calcification. This proved to

be a benign lipoblastoma. **b** Ultrasound shows superficial heterogenous soft tissue mass. **c** Coronal T1 fat saturated sequence post contrast shows avid enhancement in the lipoblastoma adjacent to the thumb

Fig. 34 MR of right hand shows. **a** on the T1 sequence the mass in the hypothenar eminence (*large arrow*) has the same signal as fat (*small arrow*). **b** on the T2 fat saturated sequence both fat and the mass saturate out, confirming the fatty nature of the mass

(Fig. 27a), though there can be bony attachments at proximal phalangeal or metacarpal level (Fig. 27b), requiring more involved surgery.

6.2 Pre-Axial Polydactyly

Although it is less common than post-axial polydactyly, it is more common in Caucasians and particularly in Orientals. The incidence is 1 in every 3,000 live births in the white population (Ress and Graham 1998). Duplication alone is usually unilateral and sporadic, however, if one of the duplicates is a

triphalangeal thumb (Fig. 28a, b), a possible syndromic association should be considered (Rypens et al. 2006) and this can be inherited in an autosomal dominant pattern.

Thumb duplications are classified according to the level of duplication, and Wassel's classification is the most widely used and accepted (Fig. 29a, b, c, d). The most common type [Wassel type IV (Fig. 30a)] involves a duplicated proximal and distal phalanx sharing a common metacarpal articulation (Watt and Chung 2009).

Treatment usually involves creation of one good thumb out of the two duplicates, particularly if they

Fig. 35 Ollier's disease MRI. **a** T2 fat saturated coronal image shows the distribution of the high signal enchondromata **b** T1 fat saturated axial image post contrast shows a typical mottled chondroid type enhancement pattern in one lesion (*arrow*)

are of a fairly even size match, (i.e., amalgamation rather than excision) (Fig. 30b) and therefore plain radiographs are vital for surgical planning.

6.3 Central Polydactyly

This includes duplications that involve the index, middle or ring fingers and is often accompanied by syndactyly and cleft hand (Ress and Graham 1998; Tada et al. 1982).

6.4 Mirror-Hand and Mirror-Hand Spectrum

Duplication of the ulna, absence of the radius and thumb and duplication of the ring and small fingers about a common central finger characterize this exceedingly rare deformity. Only six cases of true mirror hand have been described in the literature (Watt and Chung 2009).

7 Overgrowth Conditions

These account for a small proportion of CHD and the region affected ranges from the entire limb, forearm, hand or digit. Overgrowth syndromes which may involve the hand include nerve territory orientated macrodactyly, lipomatous overgrowth, Proteus syndrome (Fig. 31), hemihypertrophy, Maffucci Syndrome, Ollier disease (Fig. 32), Parkes Weber Syndrome, Klippel-Trenaunay Syndrome and CLOVE syndrome (capillary malformations (C), lipomatous overgrowth of the trunk or extremities (LO), vascular malformations (V), epidermal naevi (E)) and generalized skeletal abnormalities) (Sapp et al. 2007).

In such cases, ultrasound and MRI can be very useful in clarifying the nature and soft tissue origin of the overgrowth (Figs. 33a, b, c; 34a, b; 35a, b). The typical MRI features of lipofibromatous hamartoma of the median nerve are illustrated (Fig. 36a, b, c).

7.1 Nerve Territory Oriented Macrodactyly and Lipomatous Macrodactyly

This is the most common overgrowth condition presenting to a hand surgeon. It is usually unilateral with a male predominance and no familial inheritance (Carty and Taghinia 2009). The lipomatous overgrowth may correspond with the ulnar or median nerve distribution within the hand (Fig. 37a, b). The affected nerves within the palm are characteristically grossly enlarged and compression neuropathies are common. The intrinsic muscles, joints, periarticular structures and skeletal parts are enlarged but blood vessels are of normal size. This latter fact is of great importance as the relative ischaemia in this condition can lead to difficulties in healing post surgery.

Fig. 36 Lipofibromatous hamartoma of the median nerve. **a** Coronal T1 shows high signal mass in the carpal tunnel (*arrows*) **b** Axial T1 sequence again shows the mass infiltrating the median nerve (*arrows*) **c** Operative photograph shows

massive enlargement (*white arrow*) of the median nerve in the distal forearm and carpal tunnel caused by extensive and diffuse fatty infiltration, with relative sparing and more normal dimensions distally (*black arrow*)

Fig. 37 **a** and **b** Nerve orientated macrodactyly following the median nerve distribution

8 Undergrowth Including Hypoplastic Thumb

This results from complete formation of the part during the embryonic period but incomplete growth and development during the fetal period (Van Heest et al 1996).

This group consists largely of the spectrum of hypoplasia of the thumb which can occur as an isolated entity, or more commonly in association with radial deficiencies. It is frequently bilateral and is

often found in association with other hand differences including multiple other short digits, duplicated thumbs and a number of syndromes (Netscher and Baumholtz 2007).

The classification of thumb hypoplasia by (Blauth 1967) is useful in treatment planning, with less severe types requiring either no surgery or augmentation procedures (such as tendon transfers, ligament reconstruction and web-space deepening), whereas more severe forms (Fig. 38) require the creation of a new thumb by pollicisation of the adjacent index finger (Fig. 39a, b).

Fig. 38 Total aplasia of the thumb (Blauth grade 5)

Plain radiographs are vital in the assessment of the hypoplastic thumb as the absence of a well-formed thumb basal joint (Fig. 40), indicates that augmentation procedures would be unlikely to produce a useful thumb, and requires a pollicisation of the index finger, with removal of the poorly-developed original thumb.

Hypoplasia of the fingers most commonly affects the index and little fingers with the middle phalanx being the most commonly affected bone (Fig. 41). This CHD is frequently inherited in an autosomal dominant pattern, and is associated with numerous congenital syndromes including Treacher Collins, Apert, Poland, Cornelia de Lange and Bloom syndromes (Flatt et al 1994).

9 Constriction Ring Syndrome

This is a rare condition where the fetus may become entangled in the amniotic membrane although the exact etiology remains controversial. It had been postulated that early amniotic rupture leads to the development of fibrous bands, which entangle the digits and limbs leading to intrauterine amputations and malformations (Torpin 1965). It has also been described as amniotic band syndrome. Prenatal risk

Fig. 39 Pollicisation of index finger for patient in Fig. 38 **a** Neo trapezium created by head of index metacarpal. **b** Pollicisation in such cases greatly upgrades the function of the hand

factors include prematurity, low birth weight, maternal drug exposure, maternal illness or trauma during pregnancy (Kawamura and Chung 2009). The reported incidence is 1 in 15,000 live births. There is no sex predilection and 60% have an abnormal antenatal history (Foulkes and Reinker 1994).

The abnormalities are characteristically asymmetric and the most common findings include distal ring constrictions (Fig. 42a, b, c), intrauterine amputations (Fig. 43a, b, c, d) and acrosyndactyly (distal fusion of digits with a proximal fenestration that communicates the dorsal side with the volar side) (Fig. 44). The fingers may be truncated, a small cleft remains at the

Fig. 40 A poorly developed basal joint in thumb hypoplasia (Blauth grade 3c) makes it very difficult to augment it into a useful thumb, though free metatarsophalangeal joint transfer from the foot has been used

Fig. 41 Little finger hypoplasia. The marked attenuation of the fifth ray makes it difficult to augment, and was therefore treated in this case by ray amputation

site of the web space, and lower limb constriction bands and talipes deformities may be seen, (Kozin 2003; Wiedrich 1998; Foulkes and Reinker 1994). These features are not typically present with syndactyly resulting from inheritable and sporadic causes.

Interpretation of plain radiographs can be difficult in the more severe forms, in which the digits can be entwined and fused (Fig. 45a, b; 46a, b).

10 Generalized Skeletal Abnormalities

This includes conditions that do not fit into the other six categories described by Swanson, and includes skeletal hand deformities that are characteristic of a generalized bone and connective tissue disorder. The “tumour” like bone dysplasias including diaphyseal aclasia, and the fibrous disorders including neurofibromatosis and fibrous dysplasia are covered in separate chapters.

More than 250 skeletal dysplasias have been described with a complex classification system involving more than 30 groups organized by genetic and radiologic similarities. A comprehensive

description of all the skeletal dysplasias involving the hand and wrist is therefore beyond the scope of this chapter, and reference should be made to a detailed text on this topic, (Lachman 2007; Spranger et al. 2002).

Antenatal ultrasound is able to diagnose many skeletal dysplasias (Dighe et al. 2008). In addition, low dose prenatal CT is starting to be used in large centers from the second trimester onward to provide further diagnostic information and aid antenatal counseling (Cassart 2010; Cassart et al. 2007). Post-delivery examination, plain film assessment, post mortem and genetic testing are, however, vital for determining a specific diagnosis for recurrence risk and counseling (Tretter et al. 1998).

A skeletal survey for the assessment of a skeletal dysplasia includes plain films of the skull, entire spine, chest, pelvis and extremities and there should be a systematic approach in the assessment of the bony skeleton.

It is important initially to determine the presence of any disproportionate shortening of the extremities and identify the presence of rhizomelia (proximal shortening of humerus or femur), mesomelia (middle segment shortening of tibia, fibula, radius and ulna) and/or acromelia (distal segment shortening of the hands and

Fig. 42 Ring constriction syndrome. **a** Tight constrictions (*arrows*) with distal lymphoedema, needs relatively urgent release. **b** Marked distal lymphoedema, with rings at two levels

on the same digit (*arrows*), plus autoamputations. **c** XR confirms involvement of all digits to varying degrees

feet). In reality, there is often a combination of shortening proximally and distally but the abnormality is categorized according to the predominant finding.

Disproportionate shortening may be present in isolation or as part of a more generalized skeletal dysplasia (Figs. 47, 48, 49, 50). The absence of hand and foot shortening in the presence of other abnormalities can suggest a diagnosis of a spondyloepiphyseal dysplasia congenita (Lachman 2008).

Secondly, assessment of the shape of the epiphyses, metaphyses and diaphyses and the appearance of epiphyseal ossification centers should be performed with particular attention to marginal irregularity, cortical thickness, flaring or flattening. Carpal bone ossification should be assessed for age and the presence of duplications, carpal fusions or accessory bones.

Findings should be organized and differential diagnosis and gamuts tables consulted in more specialist texts (Lachman 2007). Abnormalities should be differentiated from normal variants, always taking into consideration the clinical manifestations in conjunction with the radiologic findings.

This section will illustrate several more common examples with manifestations in the hand and wrist.

10.1 Achondroplasia Group

This includes three specific conditions, thanatophoric dysplasia, achondroplasia and hypochondroplasia. All have FGFR3 (fibroblast growth factor 3) mutations.

Thanatophoric dysplasia is also known as thanatophoric dwarfism and represents the second most common lethal bone dysplasia after osteogenesis type II. This condition is subdivided into types I and II, both of which are autosomal dominant mutations. In the extremities, there is generalized micromelia (shortening of all segments) and marked limb curvature (Fig. 51).

Achondroplasia is the most common, non-lethal skeletal dysplasia. It is an autosomal dominant condition with a spontaneous mutation rate of 80%. Most patients have a combination of rhizomelic, mesomelic and acromelic changes. In the hands, there is typically brachydactyly, metacarpal metaphyseal cupping and phalangeal metaphyseal widening (Lachman 2008) (Figs. 52, 53, 54).

Hypochondroplasia is also relatively very common, and shares many of same features of achondroplasia. The radiologic findings are milder and there is typically a later presentation, but there is always interpedicular widening in the lumbar spine.

10.2 Short Rib-Polydactyly Group

All conditions in this group are autosomal recessive and are similar radiologically.

Short rib-polydactyly dysplasias have the shortest ribs of all the dysplasias. In the hands, there is often severe brachydactyly with hypoplastic middle and distal phalanges. Polydactyly is commonly present.

Fig. 43 a and b Autoamputations. c and d Bilateral asymmetrical involvement

Chondroectodermal dysplasia or Ellis van Creveld syndrome is a short-limbed dwarfism with dysplastic nails, hair and teeth accompanied by post-axial polydactyly and congenital heart disease. In the hands, as well as post-axial polydactyly, there are characteristic findings of carpal fusions, extra carpal bones and cone shaped epiphyses (Lachman 2008) (Fig. 55).

Asphyxiating Thoracic Dysplasia or Jeune Syndrome has similar radiologic appearances to Ellis-van

Creveld syndrome with cone-shaped epiphyses in the hands. Uncommonly polydactyly is present.

10.3 Multiple Epiphyseal Dysplasia and Pseudoachondroplasia Group

In multiple epiphyseal dysplasia, the epiphyses of the hand are small, irregular and flattened and the carpal

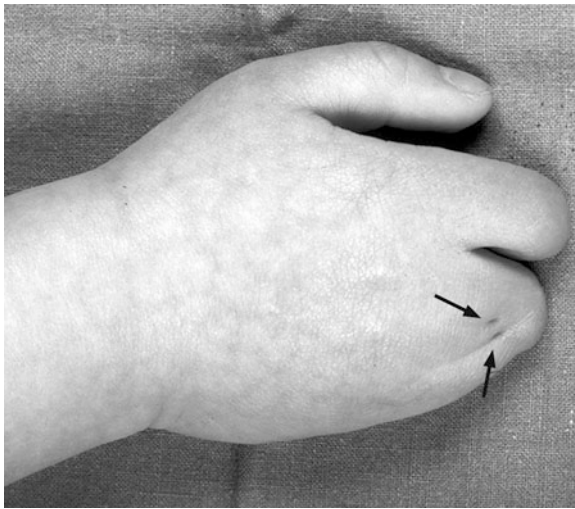

Fig. 44 Ring constriction syndrome with acrosyndactyly, and proximal fenestrations (*arrows*)

bones are small and irregular. There may be cone shaped epiphyses resulting in shortening of the short tubular bones of the hand.

Pseudoachondroplasia is a short limb, short trunk form of skeletal dysplasia. In the hands there is typically brachydactyly. The metacarpals are rounded proximally and there are mini-epiphyses in the hands with irregular carpal bones (Fig. 54).

10.4 Metaphyseal Disorders

Involvement of the hands occurs to varying degrees with the different metaphyseal dysplasias. Marked involvement of the hands is one of the main characteristics of metaphyseal chondrodysplasia McKusick Type. There is marked shortening of the hands, and flaring and cupping fragmentation of the metaphyses of the metacarpals and phalanges. The Jansen type metaphyseal chondrodysplasia demonstrates wide separation of epiphyses from metaphyses, with metaphyseal expansion and cupping. Schmid type metaphyseal chondrodysplasia, however, often has no hand involvement (Lachman 2008).

10.5 Dysostosis Multiplex Group

This group contains all the mucopolysaccharidoses, mucolipidoses and multiple storage diseases that produce a skeletal dysplasia.

Fig. 45 **a** and **b** Ring constriction with complex arrangement of acrosyndactyly, necessitating very early release to prevent intractable bony deformities

Hurler syndrome (mucopolysaccharidosis type IH) has a recessive pattern of inheritance and most cases present in late infancy or early childhood. The hands characteristically exhibit brachydactyly, proximal

Fig. 46 Difficulties of classification. **a** Elements of syndactyly (*small white arrow*), hypoplasia (*large white arrow*) and bony synostosis (*black arrow*) in same hand. **b** Central duplication

(*black arrow*), failure of formation (missing rays) and complex syndactylies (*white arrow*) in same hand

Fig. 47 Brachydactyly with absent carpal bone ossification, shortened metacarpals and shortened and dysplastic phalanges

Fig. 48 Widened diaphyses of the metacarpals, proximal and middle phalanges with "pointing" of the proximal ends of the 2nd-5th metacarpals. The epiphyses are also dysplastic

Fig. 49 Slender osteopenic bones with a metacarpal index of 10.4 in a patient with Marfans

Fig. 50 Symmetrical shortening of the metacarpals with rounded, proximal metacarpals in a patient with Morquio syndrome. The carpal centers are small with delayed bone maturation

metacarpal “pointing”, diaphyseal widening of metacarpals and proximal/middle phalanges and small irregular carpal bones with epiphyseal ossification delay (Lachman 2008) (Fig. 48).

Morquio syndrome (mucopolysaccharidosis type IVA and IVB) shows proximal metacarpal rounding, not “pointing” in the hands (Lachman 2008) (Fig. 50). The inheritance pattern is autosomal recessive (Hall 1997).

10.6 Dysplasias with Decreased Bone Density

These are represented primarily by osteogenesis imperfecta. Four main types have been described with osteogenesis imperfecta type II being the most common lethal skeletal dysplasia. In the extremities, in osteogenesis type II, there is generalized osteoporosis with or without fractures and shortened, widened long bones with thin cortices (Lachman 2008).

Fig. 51 Shortening and broadening of the tubular bones of the hand in a 20-week fetus with thanatophoric dysplasia type I

Fig. 52 Brachydactyly, metacarpal metaphyseal cupping and phalangeal metaphyseal widening in a patient with achondroplasia. In this patient, there is also flaring of the distal ulnar metaphysis

Fig. 54 Small carpals with irregular contours, shortened metacarpals and dysplastic, irregular epiphyses throughout the hand, some of which appear fragmented in a patient with pseudoachondroplasia

Fig. 53 Osteosclerosis of the bony skeleton and undertubulation of the distal radial diaphysis in a patient with osteopetrosis

10.7 Sclerosing Bone Dysplasias

This can be divided into those conditions with increased bone density without alteration of bone shape (osteopetrosis and pyknodysostosis) and the craniotubular dysplasias (craniodiaphyseal dysplasia, craniometaphyseal dysplasia and Pyle dysplasia).

The long bones in osteopetrosis demonstrate metaphyseal expansion and osteosclerosis. There may be a “bone within a bone” appearance of the short tubular bones of the hand due to variation in disease activity (Lachman 2008) (Fig. 53).

Pyknodysostosis can be differentiated by the dysplastic or absent terminal phalanges, in combination with wide-open fontanelles and hypoplasia of the clavicles (Wynne-Davies et al. 1985).

10.8 Increased Limb Length

Marfans syndrome is a connective tissue disorder with autosomal dominant inheritance caused by mutations in the extracellular matrix protein fibrillin I. Typically, the

Fig. 55 Post-axial hexadactyly, middle and distal phalangeal hypoplasia, cone-shaped epiphyses of the middle phalanges, broadening of the hamate bone and early carpal coalition in a patient with Ellis van Crevald syndrome. The metacarpal of the duplicated digit is fused proximally to the metacarpal of the fifth finger. There is broadening of the fifth finger with duplicated distal phalanges articulating with a broadened middle phalanx

patient is tall with long, slender limbs and digits. Arachnodactyly can be determined by an abnormal metacarpal index above nine (sum of the lengths of the second to fifth metacarpals divided by the sum of the widths of the same bones) (McAlister et al. 2008) (Fig. 49).

11 Summary

While the classification of CHD presented is broadly and most commonly used in clinical practice it has many limitations, not least that some differences could comfortably be placed in several groups (e.g., Fig. 46a, b).

Radiology is vital for the assessment, treatment planning and follow up of all but the mildest cases of CHD, with plain films remaining the main imaging modality. Ultrasound and MRI are reserved for specific indications. Ultrasound can be extremely helpful in the assessment of tendons, and in the clarification

of the nature of isolated swellings. MRI may provide additional information in selected cases, and is particularly important in the management of more complex overgrowth syndromes. Obstetric ultrasound now allows diagnosis of CHD earlier in fetal life, and advances in this modality will continue to raise the possibility of novel management opportunities and present new dilemmas.

Several CHD are associated with systemic syndromes and the reporting radiologist should be aware of these to highlight the need for further evaluation.

The management of CHD must be within a multidisciplinary environment with a team able to deal with all of the complex issues presented by this challenging group of patients.

Abstract

Hand injuries account for a large proportion of all injuries presenting to emergency departments. Avulsion injuries of the FDP tendons are a common sporting injury. Bowstringing of the flexor tendons are an important imaging sign of multiple annular pulley injuries. Mallet finger is the most common closed tendon injury in a sportsman. Rupture of the volar plate is a common complication of hyperextension injury. Imaging plays a crucial role in management of collateral ligament injuries. The extensor mechanism of the fingers is extremely intricate. Understanding relevant anatomy is quintessential for diagnosing and treating extensor mechanism injuries. Intra-articular metacarpal base fractures are commonly missed on initial presentation and pronated oblique radiographs help demonstrate the severity of this injury. Imaging evaluation of sports-related injuries of the hand should begin with radiographs. Ultrasound and magnetic resonance imaging play a vital role in diagnoses of soft tissue injuries. CT may be useful in understanding complex bony injuries.

1 Introduction

Traumatic hand injuries account for a large proportion of the workload of all emergency departments. Of a study of 50,272 patients, Angermann and Lohmann found that hand and wrist injuries made up 28.6 % of all injuries (Angermann and Lohmann 1993). Of these, 87 % involved the hand. Hill et al. found that the majority of isolated cases of hand and wrist

injuries arise from either a fall or sports-related injury (Hill et al. 1998).

In this chapter, we describe the most common traumatic soft tissue and bone injuries to the hand. We pay attention to the anatomy and mechanism of injury as this is fundamental to understanding and recognising patterns of injury on imaging. We also briefly mention some of the key management options that are important to be aware of whilst assessing the imaging of these injuries.

2 Volar Soft Tissue Injuries

2.1 Flexor Tendons

First described by Von Zander in 1891, avulsion injuries of the flexor tendon are common injuries in athletes. However, flexor tendon injuries are not as common as injuries to the extensor apparatus (Clavero et al. 2002).

The flexor mechanism of the digits comprises two tendons: the flexor digitorum superficialis (FDS) that inserts on the midportion of the middle phalanx, and the flexor digitorum profundus (FDP) which inserts on the volar aspect of the base of the distal phalanx. At the metacarpal head, the FDS splits and passes round the FDP tendon forming a ring aperture through which the FDP passes to become the more superficial tendon at the level of the proximal phalanx shaft (Clavero et al. 2002). These tendons run underneath the annular (A1–A5) and cruciform (C1–C3) pulleys lined by a synovial sheath that provides lubrication and nutrition. The vincula, which also provide blood supply to the tendons, connect the tendon to the synovial sheath (Hunter 1984).

Based on the mechanism of injury, these can be classified as open or closed injuries. For further discussion, we will concentrate on closed injuries. Open injuries are commonly due to lacerations. Closed injuries commonly occur when the finger is forcibly extended during maximum contraction of the profundus muscle—when a player is attempting to make a tackle and the ring finger slips off of the opposing player's shorts or jersey, hence the name "Jersey finger" (Aronovitz and Leddy 1998). Although it can occur in any finger, the ring finger is the most commonly involved finger accounting for 75 % cases

(Hong 2005). McMaster in 1933 showed that the tendon was the strongest link in the musculotendinous chain and that rupture most commonly occurs at the bony insertion (McMaster 1933). When the tendon ruptures from its insertion, it may or may not avulse a bone fragment of variable size.

The most reliable finding is a complete loss of active flexion at the Distal Interphalangeal (DIP) joint (Buscemi and Page 1987). Because pain and swelling often mask the inability to flex the DIP joint (DIPJ), it is not uncommon for this injury to be missed initially and go untreated (Aronovitz and Leddy 1998).

Treatment and prognosis are influenced by several of the following factors: the level to which the tendon retracts, the remaining blood supply to the tendon, the length of time between injury and treatment and the presence and size of a bony avulsion fragment (Aronovitz and Leddy 1998). Based on the level of retraction and presence of bony fragment, Leddy and Packer have classified this injury into three main types (Table 1).

Buscemi et al., after describing four cases of FDP tendon injuries have suggested that avulsion of the FDP tendon with a separate intra-articular fracture of the base of the distal phalanx should be classified as a Type IV injury in the Leddy and Packer classification (Buscemi and Page 1987).

Radiographs may show an avulsed bone fragment from the distal phalanx. Severe comminution of the distal phalanx precludes accurate restoration of the articular surface and is important to note as it is a contra-indication to early FDP re-insertion (Jebson 1998).

At ultrasound, normal tendons are echogenic in the hand and wrist compared to muscle. They also show a typical fibrillar echotexture, which reflects their histological structure of longitudinally oriented bundles of collagen fibres (Jeyapalan et al. 2008). In cases of tendon rupture, discontinuity with a gap in the flexor tendon may be seen. The gap may be filled with disorganised, echogenic fibrinous material (Jeyapalan et al. 2008). In the presence of tendon rupture, discontinuity of the flexor tendon is seen with the gap at the rupture site (Figs. 1 and 2). In some patients, the tendon remains in continuity but is attenuated with subtle loss of fibrillar pattern due to partial division. These tendons may show less excursion than tendons in the neighbouring fingers on dynamic ultrasound assessment (Jeyapalan et al. 2008).

Table 1 Leddy and Packer classification of closed FDP injuries (Leddy and Packer 1977)

Type I	Retraction of the tendon into the palm with disruption of the vincular system resulting in loss of blood supply to the tendon
Type II	Most common type. Tendon retracts to the level of PIP joint, being held by the intact long vinculum preserving some blood supply
Type III	Large bony fragment that gets held in place by the A4 pulley
Type IV (Buscemi and Page 1987)	Tendon rupture with attached bony fragment and concomitant separate intra-articular fracture fragment

**Fig. 1** Ultrasound of the finger using a linear probe in longitudinal plane showing empty FDP tendon sheath (arrow). DIPJ and PIPJ are on the *left* and *right* side of the image, respectively

On all magnetic resonance (MR) sequences, the flexor tendons appear as low-signal-intensity structures. In general, T1-W images provide good anatomical detail, while T2-W images are useful in assessment of inflammatory change that is associated with most pathological conditions (Clavero et al. 2002). Magnetic resonance imaging provides a non-invasive method to identify the site of tear, the degree of retraction of the torn fibres and other associated soft tissue injuries (Peterson and Bancroft 2006). In the presence of trauma, the associated oedema, haematoma and fibrosis compromise the tendon image quality and a tendon rupture is unlikely to be identified (Beltran et al. 1987).

Based on the current literature review, there is a general consensus that prompt reinsertion of an acute FDP avulsion injury is the preferred choice of treatment. In chronic injuries, the patient may be asymptomatic as they adapt by passively assisting DIPJ flexion, and do not require any further treatment (Aronovitz and Leddy 1998; Jebson 1998). If there is instability of the DIPJ with weakness of pinch or recurrent dorsal dislocations, joint arthrodesis or

**Fig. 2** Ultrasound of the ring finger using (different patient to Fig. 1) a high-frequency linear probe showing FDS rupture (Red arrow – at torn end), FDS (Green arrow) lying superficial to the FDS (Blue arrow)

tenodesis should be considered (Aronovitz and Leddy 1998).

2.2 Annular Pulleys

Normal finger flexion is a complex fine motor action that requires the integrity and orchestration of a number of delicate structures that are centred around the flexor tendon system (Hauger et al. 2000). The flexor tendon sheath pulley system is of paramount biomechanical importance in flexion, not only for accurate tracking of the tendon but also to maintain the apposition of tendon and bone across the joint and provide a fulcrum to elicit flexion and extension (Lin et al. 1989). Doyle and Blythe in 1975 originally defined a pulley system of four annular and three cruciate pulleys. In 1981, Kleinhert and Broudy defined an additional fifth pulley arising distal to the fourth annular pulley.

In recent years, the number of people involved in climbing sports has increased exponentially as a result of easy and readily available access to artificial rock-climbing walls and indoor rock climbing facilities. The annular pulley injuries are caused by climbing techniques where the entire body weight is placed on one or two fingerholds, especially in overhung wall climbs. These techniques place high forces on the proximal interphalangeal (PIP) joint and the digital pulley system, resulting in finger injuries known as climber's finger (Klauser et al. 1999). The ring and middle fingers are most commonly affected, as they are most often used in climbing and are diagnosed in up to 30 % of climbers with finger injuries (Le Viet et al. 1996). Injury to the pulley system can result in loss of strength and decreased range of motion within the affected finger, bowstringing of the FDP tendon and fixed flexion contracture of the PIP joint (PIPJ). Pain and soft tissue swelling can make clinical evaluation a difficult and limited exercise. Many studies have claimed that bowstringing of the FDP tendon across the PIPJ with resisted flexion of the fingertips is diagnostic of A2 pulley rupture. However, in a laboratory study of 21 cadaveric fingers by Marco et al. (1998), isolated or even combined rupture of A2 and A4 pulley did not result in detectable bowstringing. Rupture of at least three pulleys was required to produce obvious bowstringing in this study. Early recognition of the injury and appropriate treatment are important in avoiding complications like fixed flexion contractures (Bollen 1990).

The A2 and A4 annular pulleys, located at the proximal third of the proximal phalanx and middle phalanges, respectively, are the broader and the most functionally important annular pulleys (Lin et al. 1989). Experimental studies performed by Marco et al. (1998) showed that the A4 pulley is predisposed to rupture first when the hand is in the crimp grip. The A2 pulley usually fails from its distal to its proximal edge, whereas the A4 pulley tears from its proximal to its distal edge (Marco et al. 1998). It is important to accurately differentiate the complete from incomplete tears, as decision for operative versus non-operative management depends on this vital finding.

Various studies have been published advocating the use of ultrasound (Klauser et al. 1999, 2002; Martinoli et al. 2000; Hauger et al. 2000); computed topography (CT) (Le Viet et al. 1996) and MR

(Hauger et al. 2000, Klauser et al. 2002). An inability to directly delineate the pulleys along with the exposure to ionising radiation and relatively higher cost in comparison to ultrasound, make CT an unsuitable modality for diagnosing pulley injuries.

The magnetic resonance imaging (MRI) criteria for identifying pulley injuries include direct signs such as disrupted A2 and A4 pulleys (Hauger et al. 2000) or indirect signs like bowstringing (appreciated as increased tendon-phalangeal (TP) distance) or fluid in between the phalanx and tendon (Gabl et al. 1998). The MR has been the most accurate modality for imaging in the diagnosis of A4 lesions (Hauger et al. 2000). However, the expense, length of the examination and lack of real-time assessment are some of the drawbacks of MR examination.

Dynamic assessment gives ultrasound an advantage in the evaluation of pulley injuries. Ultrasound can demonstrate visualisation of fluid between the tendon and phalanx and allows assessment of the gliding ability of the tendons. Ultrasound demonstrated a sensitivity of 98 %, specificity of 100 %, a positive predictive value of 100 % and a negative predictive value of 97 % for the detection of finger pulley injuries (Klauser et al. 2002). Martinoli et al. (2000) demonstrated that examination in the longitudinal plane alone was sufficient as transverse sonograms added no significant information. Hauger et al. (2000) has suggested using TP distance measurements following a study performed using a cadaveric model (see Figs. 3a, b and c). A TP distance of greater than 1.0 mm was indicative of pulley system injury. An increase of the TP distance with forced flexion less than 3.0 mm was considered a sign of incomplete A2 pulley rupture, while a distance greater than 3.0 mm was considered a sign of complete rupture. Further increase in the TP distance to more than 5.0 mm was used as a sign for complete combined rupture of A2 and A3 pulley. An increase of TP distance equal to or greater than 2.5 mm was used as a sign for complete rupture of A4 pulley. Maximal active forced flexion during dynamic ultrasound examination is the most important factor for assessment of TP distance and detection of finger pulley injuries (Klauser et al. 2002).

Indications for non-operative or operative treatment are based on the clinical finding of bowstringing, functional disability, persistent pain, failure of

Fig. 3 a, b Both images taken in the same patient show increased tendophalangeal distance (*double arrow heads*) over the middle and proximal phalanges respectively, indicating rupture of the A2 and A4 pulleys. *Arrow* in b shows the ruptured A2 pulley. c Axial MR image shows increased tendophalangeal distance (*double arrow heads*) due to chronic rupture of the A2 pulley

non-operative treatment and on the amount of bowstringing of the involved flexor tendons (Gabl et al. 1998). Incomplete tears are normally treated conservatively, while complete tears are treated surgically. The treatment of complete tears with surgery has been controversial. In a study conducted by Gabl et al. (1998), complete ruptures were treated with surgery after non-operative treatment had failed. In the same study, functional outcome after non-operative and operative therapy was equal. Diagnosis and treatment at an early stage will prevent the progression of lesions and decrease the risk of long-term complications that are associated with fixed finger contracture (Hauger et al. 2000).

2.3 Volar Plate

Volar plate (VP) injury results as a consequence of hyperextension injury to the PIPJ. There may or may not be an associated intra-articular fracture (Yoong et al. 2010). Even when present, the fracture can be easily overlooked resulting in significant instability of the PIPJ (Nance Jr et al. 1979).

The VP is a multi-layered condensation of dense fibrocartilaginous tissue that lies between the flexor tendons and the PIPJ capsule. The VP attaches firmly only at the critical corner of the middle phalanx base, without strong insertion centrally. Proximally, the VP blends directly with the periosteum rather than direct insertion into the bone (Williams et al. 1998). Its important functions at the PIPJ level include providing stability against hyperextension, acting as a meniscus at the PIPJ, forming part of the intracavitary lining of the PIPJ and providing a smooth gliding surface for the flexor tendon (Williams et al. 1998).

The most common mechanism of injury is forced or sudden hyperextension at the PIPJ (Phair et al. 1989). The diagnosis of VP injury is usually made clinically, with tenderness over the volar aspect of the PIPJ, pain on passive hyperextension and instability with loss of pinch power (Nance Jr et al. 1979). The commonly used classifications are shown in Tables 2 and 3 below.

Along with AP and lateral views of the involved PIPJ, oblique views can also be helpful. In a study of 58 cases conducted by Nance Jr et al., 65 % of the fractures were best seen on the lateral view, while most of the others were best appreciated on the oblique projection (Nance Jr et al. 1979). Subtle dorsal subluxation can be identified by observing a V-shaped gap between the articular surfaces of the PIPJ joint—'V' sign. On ultrasound examination, the VP is seen as a wedge-shaped structure of intermediate echogenicity interposed between the flexor tendon and underlying PIPJ (Yoong et al. 2010). The complex three-layered collagen fibres running in different orientations (Williams et al. 1998) probably account for its mixed echogenic appearance on ultrasound. The VP is best seen in the sagittal plane and is of low signal on all MRI sequences (Fig. 4) (Yoong et al. 2010). To the best of our knowledge, there are currently no studies comparing the efficacy of ultrasound or MRI for diagnosing VP injuries.

Table 2 Eaton classification of VP injuries (Eaton 1971)

Type 1	No fracture or dislocation
Type 2	Dorsal dislocation without fracture
Type 3 stable	Fracture–dislocation with <40 % PIP joint surface
Type 3 unstable	Fracture–dislocation with >40 % PIP joint surface

Table 3 Stability-based classification (Keifhaber and Stern 1998)

Stable	<30 % articular surface
Tenuous	30–50 % articular surface
Unstable	>50 % articular surface

**Fig. 4** Sagittal T1 W MR image of the thumb showing chronic type 1 volar plate injury (White arrow)

There is a consensus that the stable injuries involving less than 30 % of articular surface are treated conservatively either by splinting with extension-block or neighbour strapping. Various studies (Phair et al. 1989; Gaine et al. 1998) have shown favourable results with early active and passive mobilisation rather than splinting. Unstable injuries

involving >50 % of articular surface are treated surgically with open reduction and internal fixation using various techniques or palmar plate arthroplasty, with later being preferred (Keifhaber and Stern 1998). The tenuous fractures involving 30–50 % of articular surface can be treated conservatively, if the articular surface congruity can be maintained with 30° flexion; if not they are best managed operatively (Keifhaber and Stern 1998).

3 Extensor Mechanism Injuries

3.1 Anatomy

The anatomy and function of the extensor mechanism of the hand comprise of a complex set of interlinked muscles, tendons and ligaments that are intricately coordinated to bring about the fine movements of the digits. The extensor mechanism of the hand can be divided into eight zones to aide in the evaluation and treatment of acute injuries (Kleinhert and Verdan 1983). The even-numbered zones are over bones, with the odd-numbered zones over the joints. Owing to the lesser number of the phalanges in the thumb, the numbering system is slightly different.

The extrinsic and intrinsic muscles of the hand make up the extensor mechanism. Zone VIII, containing the musculotendinous junctions of the extrinsic muscles is the most proximal zone. In zone VII, the extensor tendons are contained within the extensor retinaculum over the wrist joint. In zone VI, the tendons of the middle, ring and little finger are connected by juncturae tendinum. These interconnections must be considered when evaluating extensor tendon injuries (Newport 1997). In zone V, the extensor tendons are located centrally and are stabilised over the dorsum of the metacarpal head by the extensor hood. The sagittal bands (SB) are the main components of the extensor hood, which starts at the VP and has a dorsal tendinous point of insertion, gliding with the extensor system as the digit moves (Clavero et al. 2002). Distal to metacarpophalangeal (MCP) joint, the extensor mechanism becomes more complicated as the extrinsic and intrinsic muscles blend into the dorsal apparatus. The extrinsic extensor tendons divide into central and lateral slips with the central slip inserting into the dorsal aspect of the base of middle phalanx. The intrinsic muscles contribute to

form the lateral slips to form conjoint tendons, which converge distally to form the terminal tendon that inserts on the base of the distal phalanx (Kleinherb and Verdan 1983). The intrinsic tendons are directed volar to the axis of MCP joint (MCPJ), flexing this joint and directing dorsal to the axis of PIPJ and DIPJs, extending these joints (Newport 1997).

On MR images, the normal extensor apparatus appear as low-signal structures at the expected locations, axial and sagittal planes being most useful (Clavero et al. 2002).

3.2 Mallet Injury (Zone 1)

Disruption of the terminal extensor tendon at the DIPJ, caused by sudden forced flexion of the extended finger results in extension lag deformity at the DIPJ called mallet finger. Other terms like ‘baseball finger’ and ‘drop finger’ have been used to describe this. This terminal extensor tendon can rupture at or near its insertion into the distal phalanx (soft tissue mallet injury) or can avulse a bony fragment from the base of distal phalanx (bony mallet injury) (Handoll and Vaghela 2004). As a result of this injury, the DIPJ cannot be actively extended. A mallet finger may be open, but is more often a closed injury (Rockwell et al. 2000). It is the most common closed tendon injury in sports persons (Posner 1977) and can occur either after a direct blow to the DIPJ or a relatively minor trauma to the fingertip. The middle finger is most often involved, followed by the little finger (Stark et al. 1962). Doyle has classified this injury into four types as follows (Table 4).

The patient may present with swelling and bruising over the DIPJ. This being a rarely painful condition, patients frequently seek help late in the course of the event (Perron et al. 2001). Also, the extensor lag at the DIPJ may not appear for several days. Patients rarely complain of functional disability because there are relatively few activities which require full digital extension (Brzeziński and Schneider 1995). On clinical examination, apart from the fixed flexion deformity, the patient will be unable to actively extend the DIPJ. However, the deformity is correctable by passive extension.

Plain radiographs are routinely performed to exclude bony involvement (Fig. 5). Ultrasound may demonstrate: discontinuity of the extensor tendon

Table 4 Doyle classification of mallet injuries (Doyle 1999)

Type 1	Closed or blunt trauma, with or without avulsion fracture (most commonest type)
Type 2	Rupture of the tendon near or at the DIP joint
Type 3	Open, with deep abrasion of the tissues
Type 4	Trans-epiphyseal fracture in children, fractures involving a large part of the joint surface

with partial or complete tear; avulsion fracture; no real-time movements of the extensor tendon; and fluid in the region of the extensor tendon insertion (Kleinbaum et al. 2005). These findings can be used to differentiate traumatic mallet finger from others caused by fixed flexion deformity. In cases with no bone avulsion on plain film, sagittal MR images can be used to assess for terminal extensor tendon injuries and thus can be used to decide treatment (Clavero et al. 2002; Tabbal et al. 2009).

The most common type of mallet injury, closed type 1 injuries are generally managed conservatively with hyperextension splint for around 6–8 weeks. This is followed by further 4 weeks of splinting at night. Surgical treatment is usually reserved for open injuries, DIPJ instability/subluxation or a large (>30 %) displaced articular fracture fragment. A cadaveric study conducted by Hussain et al. concluded that palmar subluxation of a DIPJ without pre-existing arthritic deformity is expected when more than one half of the dorsal articular surface is injured (Hussain et al. 2008).

3.3 Boutonniere Deformity (Zone III Injury)

A boutonniere deformity occurs as a result of an injury to the central slip at or near its insertion at the base of the middle phalanx. The term *boutonniere* is derived from the French for ‘buttonhole’, as the head of the proximal phalanx can pass through the defect in the extensor mechanism (Aronowitz and Leddy 1998). Most of these are caused by an unrecognised volar lateral dislocation of the PIPJ or less commonly by a blow to the dorsal aspect of the middle phalanx that forces the PIPJ into flexion while the finger is being actively extended (Aronowitz and Leddy 1998; Perron et al. 2001). This injury can either be open or

Fig. 5 AP and Lateral radiographs of right little finger. Lateral radiograph demonstrates avulsion fracture (*white arrow*) at the site of extensor tendon insertion into the base of the terminal phalanx, usually seen in closed traumatic extensor tendon disruption with avulsion fracture (type 1)

closed, and the central slip may avulse with or without a bony fragment.

The patient usually presents with pain and swelling with maximal tenderness at the PIPJ. The classic boutonniere deformity is rarely seen in the acute phase (Aronowitz and Leddy 1998). In the early acute phase, active extension is retained by the normally orientated lateral slips; but the head of the proximal phalanx eventually goes through the central slip resulting in migration of the lateral slips palmar to the PIPJ, which flexes the PIPJ and hyperextends the DIPJ resulting in the classic boutonniere deformity (Griffin et al. 2012). The above described deformity usually occurs 1–2 weeks after the initial injury (Hart et al. 1993).

Burton has described three stages of the boutonniere deformity (Table 5).

The Elson test, which demonstrates rigidity of the DIPJ during attempted PIP extension from a flexed position, has been shown to reliably diagnose an early central slip injury. However, the drawbacks of this test are it will not demonstrate partial rupture of the central slip and may be impeded by pain (Elson 1986). Initially, plain radiographs are obtained to

evaluate for an avulsion fracture at the base of the middle phalanx (Fig. 6). In equivocal cases, where clinical evaluation is difficult owing to pain and swelling, MRI can be an effective method for detecting central slip lesions (Clavero et al. 2002). Magnetic resonance imaging can also provide valuable information about associated VP and ligamentous lesions of the PIPJ. To the best of our knowledge, there are no current studies available comparing the efficiency of clinical examination, ultrasound or MRI in diagnosing the central slip injuries.

Treatment of central slip injuries remains highly controversial. Generally these are treated closed with extension splinting of the PIPJs for 4–6 weeks followed by 2 weeks of night time splinting (Aronowitz and Leddy 1998). Surgical treatment is implemented when (1) displaced avulsion fracture, (2) axial and lateral instability of the PIPJ associated with loss of active or passive extension of the joint and (3) failed conservative treatment (Griffin et al. 2012). However, surgical reconstruction is the treatment of choice for a chronic symptomatic boutonniere deformity (Aronowitz and Leddy 1998).

Table 5 Stages of the boutonniere deformity (Burton 1982)

Stage 1	Dynamic imbalance, fully correctable passively
Stage 2	Extensor mechanism contracture, not passively correctable but does not involve the joint structure
Stage 3	Fixed contracture with joint changes involving collateral ligament, volar plate scarring and intra-articular adhesions

Fig. 6 Lateral radiograph showing a subtle avulsion fracture (*white arrow*) with associated soft tissue swelling at the base of the left middle finger intermediate phalanx

It is important to differentiate between a boutonniere and a pseudo-boutonniere deformity so that appropriate treatment plan can be implemented. Although, the appearances may be similar their aetiology is different. The pseudo-boutonniere deformity results from a PIPJ VP injury due to PIPJ hyperextension and resulting in PIPJ flexion contracture, rather than an injury to the central slip (Hong 2005). Typically, the flexion contracture of the PIPJ is fixed, and passive extension is not possible (Aronowitz and Leddy 1998). In a pseudo-boutonniere deformity, radiographs may show calcification along the volar lateral aspect of the proximal phalanx. These injuries are managed conservatively by dynamic splinting, if the flexion contracture is less than 45° and surgical release may be needed to restore extension if the PIP

flexion contracture is more than 45° (Aronowitz and Leddy 1998).

3.4 Boxer's Knuckle (Zone V Injury)

The extensor hood at the MCPJ is a retinacular system comprising the sagittal, oblique and transverse bands that stabilise the extensor tendon at the dorsal aspect of the MCPJ and keeps the tendon in place during flexion and extension. The SB is the most important structure of the extensor hood; this composes of a superficial and deep layer forming a tunnel through which the extensor tendon passes through (Kichouh et al. 2011). Sagittal band ruptures referred to as 'Boxer's Knuckle' can occur spontaneously, secondary to trauma or can be associated with synovial disorders like rheumatoid arthritis (Kichouh et al. 2011). Congenitally absent or lax SBs have been previously reported (Inoue and Tamura 1996). The most commonly injured finger is the middle finger, and the most frequently involved SB is the radial with ulnar instability (Rayan and Murray 1994). It has been thought that underlying normal ulnar inclination of the index and middle finger may predispose them to radial band disruption (Lopez-Ben et al. 2003). However, ruptures of the ulnar SB resulting in radial instability have also been reported in the literature. Patients commonly present with pain, swelling, loss of full extension and subluxation of the extensor tendon. Rayan and Murray classified SB injuries into three types as shown in Table 6.

However, the overlying soft tissue swelling and pain can make clinical assessment difficult to diagnose tendon subluxation (Lopez-Ben et al. 2003). As a result, accurate diagnosis of SB rupture may be difficult without imaging. Advantages of ultrasound over MRI include dynamic assessment, cost-effectiveness and easy availability.

Various studies have been published describing the use of ultrasound and MRI for diagnosing SB injuries. The SB is best seen in the axial plane with the MCP in slight flexion, appearing as a linear hypoechoic structure. Focal hyperechoic thickening of the SB or disappearance of the normal architecture of the SB can be demonstrated in patients with extensor hood injuries (Kichouh et al. 2011). Dynamic ultrasound

Table 6 Rayan and Murray classification of sagittal band injuries (Rayan and Murray 1994)

Type I	Mild injury with no instability
Type II	Moderate injury with extensor tendon subluxation
Type III	Severe injury with tendon dislocation

Fig. 7 Ultrasound image at MCPJ level shows subluxation of the index finger (I) extensor tendon (white arrow), secondary to extensor hood injury (not shown in this image)

with the fingers alternatively extended and then flexed in a clenched fist enables excellent visualisation of extensor tendon subluxation and dislocation at the MCPJ (Fig. 7) (Lopez-Ben et al. 2003).

On MRI, the SB is depicted as uniform low-signal intensity structure on all sequences. The T2W sequences are more accurate than T1W or post-contrast T1W sequences and post-contrast imaging does not improve the sensitivity in depicting the SB (Drape et al. 1994). The MR findings in acute injuries include morphologic and signal intensity changes, together with poor definition, focal discontinuity and focal thickening (Clavero et al. 2002). Magnetic resonance imaging of MCPJs in different kinematic positions has also been found useful in diagnosing SB injuries (Lopez-Ben et al. 2003). The role of oblique and transverse bands is not well known currently and these are also difficult to demonstrate on ultrasound and MRI (Kichouh et al. 2011).

Like other extensor mechanism injuries, the treatment of SB injuries also remains highly controversial. Ritts et al. advocate conservative treatment with splinting of the MCPJ in extension, while Hame and Melone Jr concluded that direct surgical repair with realignment of the central tendon is highly successful (Ritts et al. 1985; Hame and Melone Jr 2000). These will need to be treated as open infected injuries if the extensor mechanism or the SB injury is secondary to human bites with surgical

debridement, intravenous antibiotics and splinting (Matzon and Bozentka 2010).

4 Collateral Ligament Injuries

4.1 Ulnar Collateral Ligament of the Thumb

The ulnar and radial collateral ligaments are primary stabilisers of the thumb MCPJ against radial and ulnar stress, respectively. Injury to these structures may result in joint instability, leading to significant disability and pain (Tang 2011). A correct early diagnosis influences management decisions and treatment outcomes (Sollerman et al. 1991). The thumb MCPJ is stabilised by static and dynamic stabilisers (Tsiouri et al. 2009). The static restraints include the VP, the dorsal capsule and the ulnar and radial collateral ligaments. The extrinsic and intrinsic muscles of the thumb make up the dynamic stabilisers. The ulnar collateral ligament (UCL) comprises a proper and an accessory ligament (Tsiouri et al. 2009). In flexion, the proper collateral ligament is taut, while the accessory collateral ligament is taut in extension.

Two acronyms are commonly used to describe UCL injuries, Gamekeeper's thumb and Skier's thumb. Gamekeeper's thumb was first reported by Campbell in 1955 to describe chronic attritional attenuation of the UCL in Scottish gamekeepers, secondary to strain induced on the first Web space (Campbell 1955). The Skier's thumb is used to describe acute injuries where the thumb is forced into abduction and hyperextension against the ski pole (Gerber et al. 1981). Thumb UCL injuries are the second most common skiing-related injury, after medial collateral ligament injury of the knee (Tsiouri et al. 2009).

Injury to the UCL is caused by sudden excessive valgus stress on the thumb MCPJ. Although this was attributed to the straps of the ski pole initially, later studies have showed that the incidence of the injury remained the same even with new pole designs without a strap (Derkash et al. 1987). In approximately 90 % of cases, the thumb UCL avulses from the base of the proximal phalanx (Coyle 2003). Although less frequent, it can avulse from proximal attachment or tear in the midsubstance. In 1962, Stener described a lesion in which the distal end of

the avulsed UCL is displaced superficial to the adductor aponeurosis and is prevented from reapproximation to its anatomic insertion site (Stener 1962). Avulsion of UCL can be accompanied by more than one bony avulsion fragment with failure of the ligament bone complex at the site of the ligament–bone interface and also within the bone itself (Giele and Martin 2003).

Patients with acute injuries present with pain, swelling and reduced range of motion. Chronic presentations include deformity and loss of strength in particular pinching or grasping. On examination, tenderness to palpation will be present at the site of injury. A palpable mass on the medial side may represent the superficially displaced end of the UCL, suggestive of a Stener lesion. However, the absence of a palpable mass does not definitively rule out a Stener lesion (Heyman et al. 1993).

Evaluation of joint stability is the most important part of examination. The primary aim is to determine whether the injury is incomplete (Grade 1 or 2) or complete (Grade 3) (Tang 2011). Current consensus include testing the joint in zero degrees of extension and 30° flexion to evaluate accessory and proper collateral ligament components, respectively. Instability is defined as radial deviation of the proximal phalanx on the metacarpal head of >30–35° (Heyman et al. 1993). Stress examination demonstrating a firm end-point indicates an incomplete tear whilst opening of the MCPJ without a firm end-point indicates a complete tear (Patel et al. 2010).

Plain radiographs are routinely performed to rule out a fracture or subluxation (Fig. 8a). Previously, stress radiography, ultrasound and MR with or without arthrography have been used to assess thumb UCL injuries. In addition to the discrepancies concerning the performance and interpretation of stress radiographs, the most significant drawback is their inability to direct the treatment because they do not differentiate between a non-displaced tear and a Stener lesion (Green and Rowlan 1984). In a study conducted by Harper et al. comparing the efficacy of stress radiography versus MR examination with and without arthrography, the overall sensitivity of stress radiography was found to be only 64 % (Harper et al. 1996).

Ultrasound is useful in detecting partial and complete tears of the thumb UCL and has shown

promising results in differentiating between complete tears and Stener lesions (Schnur et al. 2002). The normal thumb UCL appears as a hyperechoic structure spanning the ulnar side of the first MCPJ. Displaced UCL tears appear as a retracted, folded-on-itself structure which is displaced proximal and superficial to the adductor aponeurosis, creating the appearance of a ‘yo–yo on a string’ on coronal MRI scans (Ebrahim et al. 2006). The positive predictive value for ultrasound in identifying UCL tears is very high (87.5 % Schnur et al. and 94 % Jones et al.). However, the specificity varies between 83 % for displaced ruptures and 91 % for non-displaced ruptures (Hergan et al. 1995). Inexpensive and easy availability along with good overall comparable results with MR make ultrasound an attractive tool for evaluation of UCL tears. The primary disadvantage of ultrasound is that it is operator dependent. Ultrasound has been recommended to be used only in the 1st week after injury, as scarring may decrease accuracy of the method (Hergan et al. 1997).

Excellent soft tissue characterisation makes MR examination a very good modality to use in UCL injuries (Fig 8b). The sensitivity and specificity have been shown to be 100 % (Harper et al. 1996; Hergan et al. 1995). Thus, MR plays a vital role in making management plans for patients with UCL tears. Cost-effectiveness and availability remain the major deterrents for using MR as the primary modality in diagnosing UCL tears. Various pitfalls as described by Hergan et al. (1997) can cause misinterpretation between displaced and non-displaced UCL tears which can have serious implications on patient recovery. Hence, MR examination has been advocated when a non-displaced UCL tear is suspected by ultrasound (Hergan et al. 1997).

Conservative versus surgical management of UCL tears has been controversial and extensively debated over the last four to five decades. Grade 1 and 2 tears are managed conservatively. Surgery is indicated in the following instances: a Stener lesion is suspected; a displaced avulsion fracture exists, where there is an acute, grossly unstable joint; in symptomatic chronic injury; and in cases of volar subluxation seen on radiographs (Smith 1977). Surgical treatment has been widely accepted as treatment of choice for Grade 3 UCL tears.

Fig. 8 a, b Plain radiograph AP view (a) and Coronal T1W MRI (b) showing bony avulsion fracture (*arrow*) at the site of UCL insertion

4.2 Radial Collateral Ligament

Injuries of radial collateral ligament (RCL) comprise 10–14 % of the collateral ligament injuries to the thumb MCPJ (Coyle Jr 2003). These have been referred to as “reverse gamekeeper’s thumb” (Cooney et al. 1990).

The RCL originates dorsally on the lateral condyle of the metacarpal head and extends in a distal and palmar direction to insert into the lateral tubercle of the proximal phalanx. (Edelstein et al. 2008). Like UCL, the RCL also consists of proper and accessory collateral ligaments which act as static restraints when MCPJ is in flexion and extension, respectively.

Injuries of the RCL result from forced and sudden adduction of the MCPJ which can occur from a fall or during sports when a ball or player strikes the thumb. Acutely, the patient presents with pain, stiffness, swelling and deformity. In the chronic situation, once the swelling and pain has subsided, patients present with persistent pain with activities that require a radial-sided force such as closing a door (Edelstein et al. 2008).

It is important to identify partial from complete RCL tears as complete tears are treated surgically, while partial tears are treated conservatively. Radial stress test and drawer tests may be used to assess for RCL injury. A recent study by Coyle Jr found proximal tears (55 %) are commoner than distal (29 %) or midsubstance tears (16 %) (Coyle 2003). This can be explained by the fact that the distal width of the RCL insertion is equal to or wider than the RCL origin at the metacarpal (Lyons et al. 1998). Complete RCL tear can result in both static and dynamic instability (Edelstein et al. 2008). Although there are several classification systems for UCL injuries, there are no specific ones for the RCL injuries. A generalised classification is used instead. Grade 1: Small incomplete tear, Grade 2: larger but still incomplete tear and Grade 3: complete tear.

Conventional radiographs are obtained to assess for avulsion fractures and subluxation. Volar subluxation of the phalanx >3 mm is much more common with RCL injury than with the UCL injury (Tang 2011) as RCL is a primary support preventing volar subluxation. Stress dynamic fluoroscopy may also aid

Fig. 9 Longitudinal ultrasound image showing rupture of radial collateral ligament

in evaluation of instability. Because of the high correlation between stress examination and operative findings, arthrography, ultrasonography (Fig. 9) or MRI are usually not needed (Edelstein et al. 2008).

On the basis of the current available literature, RCL and UCL injuries can be managed in a similar manner (Patel et al. 2010). Generally, Grade 1 and 2 injuries are treated conservatively, while treatment of Grade 3 injuries remains controversial. Various surgical methods have been described in the literature for Grade 3 injuries and no general agreement is present.

5 Fractures

Among the injuries sustained during sporting activities in the general population, it is fractures of the upper limb that predominate. The vast number of patients attending emergency department due to these injuries reflects this. In a retrospective study conducted by Aitken and Court-Brown looking at nearly 6000 fractures, 24 % of them occurred in hand and 22.4 % of these were sporting injuries. The thumb and the little fingers were most commonly involved fingers accounting for up to 57.3 % (Aitken and Court-Brown 2008). Metacarpal fractures of the thumb and little fingers are discussed below.

5.1 Thumb Fractures

The thumb provides up to 40 % of hand function (Carlsen and Moran 2009). Injuries to the thumb are predominantly fractures of the proximal phalanx or the metacarpal and ligamentous injuries around the MCPJ. Ligamentous injuries have been discussed in detail along with other soft tissue injuries of the hand. Thumb fractures are found to occur most commonly in children and the elderly (Stanton et al. 2007).

Thumb metacarpal base fractures form an important subset and will be discussed further.

5.1.1 Bennett Fracture

In 1882, Edward Hallaran Bennett first described the fracture involving the base of the thumb metacarpal. However, a Bennett fracture now refers to a two-part intra-articular fracture or dislocation involving the base of the thumb metacarpal (Rettig 2004). The mechanism of injury is classically an axial load to the flexed and adducted thumb (Hong 2005). The volar-ular fragment is held in place by its ligamentous attachment to the trapezium, known as the anterior oblique ligament, also described as the beak ligament (Bettinger et al. 1999). As a result of the injury, the remainder of the first metacarpal shaft subluxes in a dorsal, proximal and radial direction due to the pull of the abductor pollicis longus, extensor pollicis longus, extensor pollicis brevis and the adductor pollicis longus (Carlsen and Moran 2009). Gedda in 1954 has classified Bennett fractures as follows (Table 7).

Following clinical examination, a radiographic evaluation forms an integral part of the initial clinical assessment (Fig. 10). True antero-posterior and lateral views can be obtained with the Robert's and Bett's view, respectively, to look for fracture displacement and joint congruency (Carlsen and Moran 2009). These fractures are unstable and should be promptly referred to a hand surgeon for appropriate management. Closed reduction with percutaneous pin fixation is recommended if the fragment is less than 25 % of the articular surface and if the fragment is larger than 25 % of articular surface, and those irreducible by closed techniques should be opened, reduced and internally fixed (Weinstein and Hanel 2002).

5.1.2 Rolando Fracture

This was first described by Silvio Rolando in 1910, a Y-pattern fracture of the thumb metacarpal base (Fig. 11). Currently, this eponym is used widely for any comminuted intra-articular fracture of the thumb metacarpal base (Hong 2005). These are similar in location and etiology to Bennett fracture (Hong 2005). This fracture pattern is considerably more difficult to treat and has a worse prognosis than that of the Bennett fracture (Carlsen and Moran 2009). When there are two large fragments without considerable comminution, open reduction and internal fixation can

Table 7 Gedda classification of Bennett fractures (Gedda 1954, cited by (Carlsen and Moran 2009))

Type 1	Large single ulnar fragment and metacarpal base subluxation
Type 2	Impaction fracture without metacarpal base subluxation
Type 3	Small ulnar avulsion fragment with metacarpal dislocation

Fig. 10 Lateral radiograph of thumb showing fractures of the metacarpal base (Bennett fracture type 1) and proximal phalanx shaft

Fig. 11 Rolando fracture of the metacarpal base on a lateral radiograph of the thumb

be successful. For markedly comminuted fractures, distraction and reliance on ligamentous reduction of the fragments may be necessary (Carlsen and Moran 2009).

5.2 Boxer's Fracture

The most common fracture of the hand is fracture of the little finger metacarpal, accounting for up to 50 % of all metacarpal fractures and 20 % of all fractures of the hand (Lee and Jupiter 2000). A fracture to the little finger metacarpal neck is referred to as boxer's fracture. These result from incorrect technique in swinging a fist, that puts an oblique force applied to the smallest, weakest metacarpal (Walsh 2004). The fracture occurs just below the metacarpal head and is normally displaced in a volar direction (Fig. 12). It is important to assess for malrotation by examining the direction of the fingers in flexion (Hong 2005). Apex volar angulation of up to 40° is acceptable and can be treated conservatively with immobilisation in a gutter splint with ring and little finger MCPJs in a 90° flexed position (Hong 2005). Fractures that are markedly comminuted or angulated may need open reduction and internal fixation (Peterson and Bancroft 2006).

5.3 Intra-articular Fractures and Dislocations of the Carpometacarpal Joints

Intra-articular metacarpal base fractures are high-energy injuries that are often missed on initial presentation (Liaw et al. 1995). These are associated with carpometacarpal (CMC) dislocations and most commonly occur in the ring and little fingers.

The mechanism of injury involves axial load transmission through the fourth metacarpal onto the carpal bones (Cain et al. 1987). The ring and little finger CMC joints being modified saddle joints, allow considerable movement in the antero–posterior plane that predisposes these joints to dislocation (Liaw et al. 1995). At a certain stage when the ring finger metacarpal is unable to dissipate the force, a fracture occurs resulting in shortening of the ring finger metacarpal. The axial load is then transferred to the little finger metacarpal causing the little finger CMC joint injury (Liaw et al. 1995). The degree of the little finger metacarpal flexion determines the type and degree of hamate injury (Cain et al. 1987). Flexion of

Fig. 12 AP and oblique radiographs showing little finger metacarpal neck fracture (Boxer's fracture) with volar angulation

the metacarpal during impact may cause dorsal dislocation of the little finger metacarpal base, dorsal CMC ligament disruption and hamate fracture. In the little finger, the ECU, FCU and abductor digiti minimi tendon exert deforming forces on the fracture fragments (Weinstein and Hanel 2002). Cain et al. in 1987 have classified the combined ring and little finger metacarpal fracture and little finger CMC joint injury into three categories as follows (see Table 8).

The routine AP and lateral radiographs of the hand may not reveal the full extent of the ring and little finger CMC joints (Fig. 13) and a CT scan may be needed to demonstrate the full extent of the injury (Fig. 14). The 45° pronated oblique and 15° pronated oblique views are helpful in assessing the severity of this injury (Liaw et al. 1995).

The treatments of these injuries depend on the severity and stability of the CMC joints. Type 1 stable injuries treated conservatively. Closed reduction and percutaneous pinning can be used to treat unstable type 1 injuries (Cain et al. 1987). Type 2 and 3 injuries are potentially unstable and will require open reduction and internal fixation (Liaw et al. 1995).

5.4 Phalangeal Fractures

Phalangeal fractures can occur at head, neck, shaft or base of the phalanges. There are many variations of these involving various locations. Shaft fractures can

Table 8 Cain et al. classification of intra-articular fractures and dislocations of carpometacarpal joints (Cain et al. 1987)

Type	Characteristic features
1A	Subluxation or dislocation of the little finger metacarpal base without hamate fracture
1B	Type 1A + small dorsal rim hamate avulsion fracture
2	Dorsal hamate comminution is present
3	Coronal splitting of the hamate

be transverse, oblique, spiral or comminuted (Hong 2005). Displacement and angulation of phalangeal fractures result from a combination of two main factors: the mechanism of injury and the deforming nature of the fracture (Peterson and Bancroft 2006). A direct blow can result in transverse or comminuted fracture, while a twisting injury often results in an oblique or spiral fracture (Lee and Jupiter 2000).

Condylar fractures of the head of proximal phalanx are typically the result of axial loading. London described three types of Condylar fractures that influence prognosis and management: a type I stable, undisplaced unicondylar fracture; a type II unstable, displaced, unicondylar and type III comminuted bicondylar fracture (London 1971).

Along with standard AP and lateral radiographs, CT can provide further information that may assist the surgeons in management.

Fig. 13 AP, lateral and oblique radiographs of the right hand showing little finger CMC joint dislocation. Note hamate fracture (seen on CT—Fig. 14) is not visible on these plain films

Fig. 14 Sagittal CT image shows little finger CMC joint subluxation with rim fracture of the hamate (Cain et al. type 1B CMC joint injury)

Oblique or spiral fractures may be associated with malrotation. No malrotation is acceptable for phalangeal fractures, because this leads to overlap and malalignment of the digit (Peterson and Bancroft 2006). Acceptable reduction is less than 6 mm of

shortening, less than 15° of angulation and with no rotational deformity (Lee and Jupiter 2000).

Non-displaced fractures are treated conservatively, while displaced and malrotated fractures should be reduced; closed at first, but then surgically if needed (Hong 2005). For condylar fractures, London types II and III are treated surgically and stable type I injuries are managed conservatively (Stern 2005).

5.5 Interphalangeal Joint Dislocations

Interphalangeal (IP) dislocations are common injuries in athletes. These injuries usually result from significant force and may result in ligamentous injury or tear. Most IP joint dislocations involve the PIPJ (Morgan et al. 2001). The PIPJ is susceptible especially to forced abnormal motion produced in ball sports and in sports resulting in axial loading of the digit (Morgan et al. 2001). Most IP joint dislocations are dorsal, with dorsal dislocation of the middle phalanx and disruption of the VP (Fig. 15) (Hong 2005).

Fig. 15 AP, oblique and lateral radiographs of the middle, ring and little fingers showing dorsal dislocation of the proximal interphalangeal joints

6 Conclusion

This chapter has described the most common soft tissue and bone injuries to the hand. We have related the anatomy and mechanism of these injuries to the imaging assessment. We have also discussed factors that influence management decisions which enable a more thorough imaging assessment.

Acknowledgments The authors wish to sincerely thank Dr. David Moore, Dr. Steven L. J. James and Dr. Andrew J. Grainger for providing some of the images used in this chapter.

Abstract

This chapter will principally describe and illustrate acute bony injuries of the distal radius and carpus occurring as a result of trauma. Plain films form the bulk of investigations, but where indicated use of CT and MR imaging is also included. Chronic traumatic injuries principally overuse, or stress injuries will also be considered but in less detail.

1 Introduction

1.1 Radiographic Anatomy and Projections

Standard radiographic views for the evaluation of wrist are a postero-anterior (PA) and lateral. These projections are described with the relevant anatomy in [Radiography and Arthrography](#) and will not be repeated here. These 2 views will allow evaluation of injuries of the distal radius and ulna, an assessment of the carpal bones, and the carpo-metacarpal junction. Additional views may be obtained in special specific circumstance most commonly when there is clinical suspicion of a scaphoid fracture.

1.2 Analysis of Radiographs

On the PA view, inspect each bone in turn looking for cortical disruption that would indicate a fracture. It is important to consider in turn the distal radius and ulna, then the eight carpal bones and finally the bases of the metacarpals. Next, undertake scrutiny of the normal uniform spacing of 1–2 mm around each carpal bone.

Fig. 1 **a** Normal AP radiograph. Note the uniform spacing between the carpal bones including the carpo-metacarpal junction. The 3 carpal arcs are smooth. The ulnar side of the 3rd metacarpal aligns with the space between the capitate and

hamate. **b** Normal lateral radiograph. Observe the normal volar tilt of the distal radius. The dorsal cortex of the radius should be smooth with no steps or crinkles. Observe the normal alignment of the radius lunate and capitate

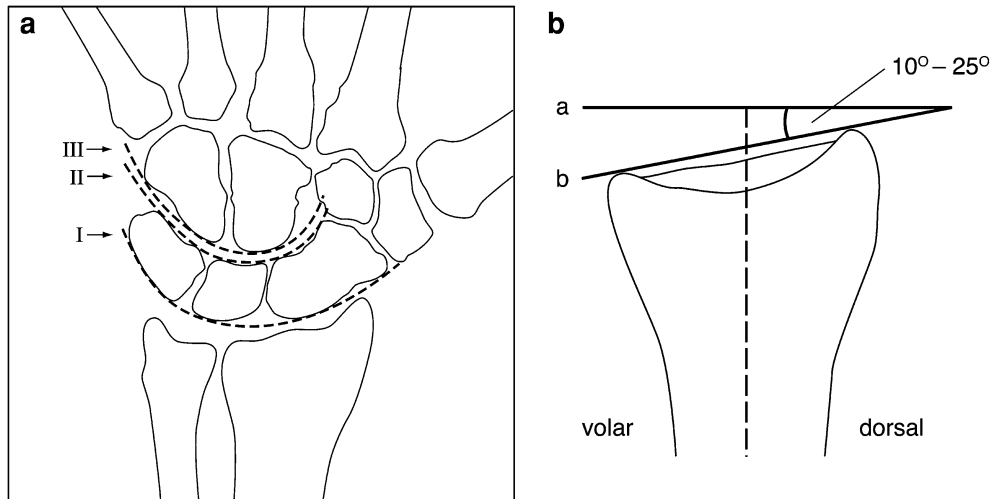

Fig. 2 **a** Line drawing indicating the position of the three carpal arcs. **b** The normal volar tilt of the distal radius

This spacing also occurs at the carpo-metacarpal junction. Loss of this spacing should lead to very careful inspection of the abnormal area, as often this will indicate significant carpal or carpo-metacarpal disruption (Fig. 1). One should also observe the arrangement of the carpal bones into smooth arcs. Three arcs have been described (Gilula 1979). The first delineates the proximal surface of the proximal row of carpal bones (scaphoid, lunate, triquetrum). The second is formed by the distal articular surface of the same bones. The third is along the proximal curvature of the capitate and hamate (Fig. 2).

These arcs should normally be smooth with no steps or disruption. Interruption of any of these

smooth arcs indicates a disruption of the normal arrangement of bony structures at the point of the step in the arc. Note should also be taken of the normal alignment of the metacarpals with the distal row of carpal bones, in particular, the relationship of the 3rd metacarpal with the distal capitate. A line drawn down the ulnar side of the metacarpal should pass through the joint between the capitate and hamate (Fig. 1). Loss of this normal alignment indicates a carpo-metacarpal disruption most commonly a dislocation. This sign is akin to the alignment of the tarsometatarsal joint in the foot.

Much important information is to be found on the lateral film. A key observation is that of the distal

radial angle. The normal distal radius has a volar tilt of approx 10° . This represents the angle between a line drawn along the long axis of the radius and a line drawn from the dorsal to the volar rim of the radius and has a normal range of 2° – 20° (Figs. 1b, 2b). Alteration of this angle occurs when there is a subtle fracture of the distal radius. Normal relationship of the distal radius and carpal bones is best assessed on the lateral view, and this is discussed further in the [Sect. 3.3](#). Displacement of the distal radial epiphysis and disruption of carpal alignment are often only evident on this view. Fractures of the triquetral bone will only be seen on the lateral radiograph.

CT is rarely used to confirm or refute the presence of a fracture. A fracture is usually evident on the plain films, but CT is helpful to define the exact anatomy in complex fractures and dislocations to aid surgical planning. This is particularly true when there is involvement of the articular surface of the radius such as a Bartons fracture dislocation and die punch injuries. The exception is when an injury of isolated carpal bones is suspected. Fractures of these, particularly hamate and capitate, may be seen only on CT. CT is of value in some carpal dislocations but is particularly of value in cases of metacarpal dislocations which can be difficult to identify on plain films. In the current era of multislice scanners, there is no longer any need to be overly prescriptive about scan planes and slice thickness. Modern scanners allow very rapid multiplanar and 3D reconstruction with isotropic voxels, so that the injured wrist can be scanned in any position and reviewed in the best plane for the injury under investigation without any loss of information or degradation of the image.

MR is not generally utilised to evaluate acute wrist trauma, but it is the investigation of choice when an occult scaphoid fracture is suspected clinically.

1.3 Ligamentous Anatomy of Wrist

The ligamentous anatomy of the wrist is extremely complex. There is disagreement between authors with considerable variation in the description of the ligament anatomy. This anatomy has been dealt with in detail elsewhere in this book and will not be reiterated here. This level of understanding is important when evaluation of the ligaments by imaging is being

undertaken. However, for the purposes of this chapter, such detail is not required. What is required is knowledge of important ligaments and their attachments. This information allows a better understanding of the patterns of bony injury and associated findings. Here, I will outline the key ligaments and indicate where in the later text this ligamentous knowledge applies. Of necessity, this is a much simplified account of the ligaments.

Ligaments are divided into extrinsic and intrinsic both dorsal and volar. The volar ligaments are stronger and more functionally significant. Extrinsic ligaments link the distal radius and ulna to the carpal bones. The intrinsic or intercarpal ligaments link carpal bones to one another.

On the dorsal aspect two ligaments are of importance in this chapter. They are the dorsal radiotriquetral (extrinsic) and the dorsal intercarpal ligament. Both attach to the triquetral bone. It is the attachment of these ligaments that account for the avulsion fracture of the triquetral (see below) (Fig. 3a).

On the volar aspect, there are 2 key ligaments. The radio scapho-capitate (RSC) and the radio lunate triquetral (RLT), both extrinsic ligaments (Fig. 3b). The position of the RSC helps understand the propensity of the scaphoid to fracture (see [Sect. 3.1](#)).

When the wrist is dorsiflexed, these two ligaments separate resulting in what is termed the space of Poirier. This space between the ligaments is an area of weakness which accounts for the carpal dislocations that occur around the lunate (see [Sect. 3.3](#)).

The attachments of the RSC and RLT to the radius account for the isolated fracture of the radial styloid which is essentially an avulsion injury. (See isolated fracture of radial styloid.)

In addition to the RSC and RLT, there are other ligaments that arise from the volar aspect of the radius to attach to carpal bones. Their names and arrangement are not important in this setting, but the multiple ligaments account for the bone fragments seen on the volar aspect of the wrist in patients with dorsal radio carpal dislocations (see [Sect. 3.3](#)).

On the ulnar aspect of the wrist lies the triangular fibrocartilage complex (TFCC). Again this has very complex anatomy, but for our purposes it is sufficient to know that there are paired ligaments on dorsal and volar aspects of the wrist. The radio-ulnar ligaments pass horizontally between the radius and the ulna styloid process. There are also two ligaments running

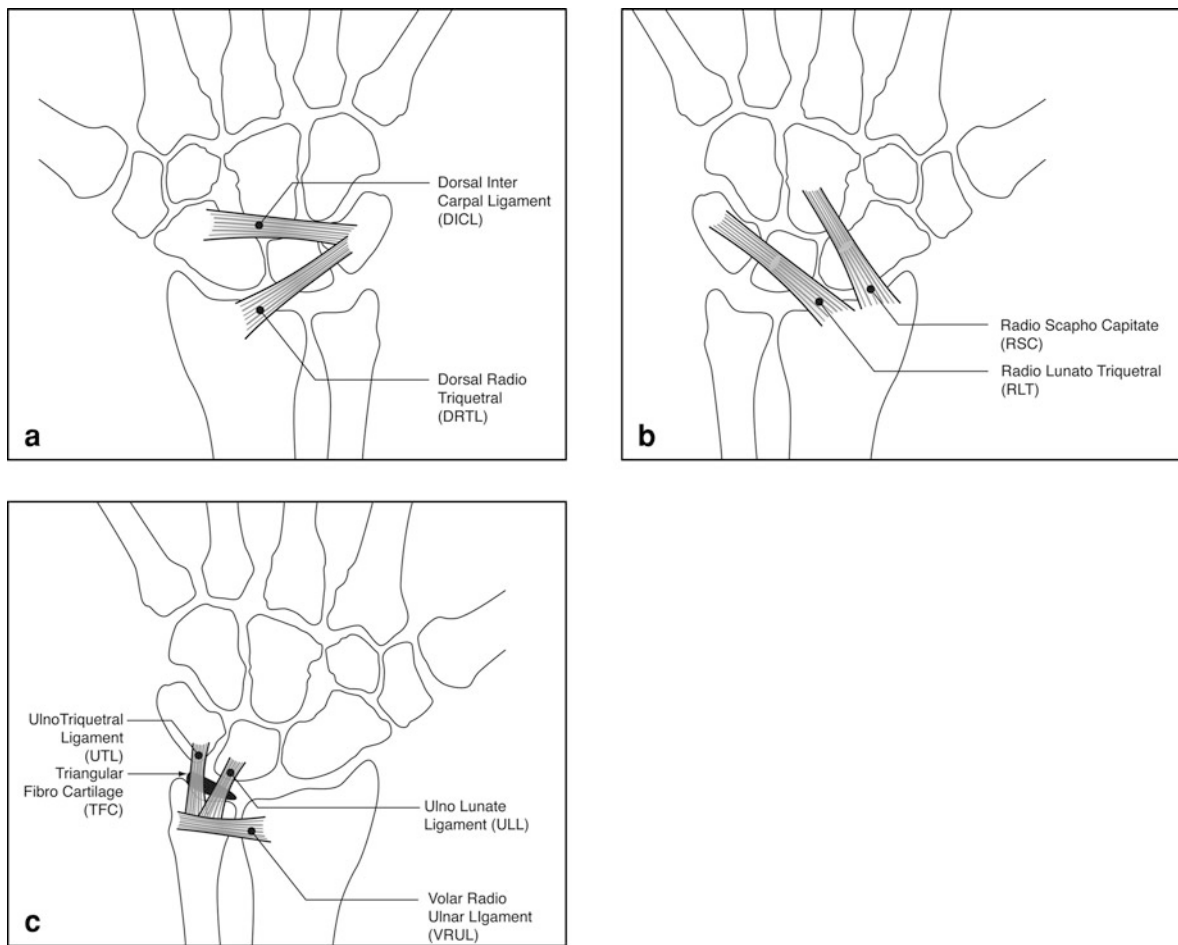

Fig. 3 a Important dorsal ligaments. b Volar ligaments radial aspect. c Volar ligaments and TFC

from the base of ulna styloid to the lunate and triquetral bone. These four ligaments account for the fractures of the ulna styloid seen in several injuries including Colles fractures and distal radio ulna joint disruption (Fig. 3c).

Of the very many intrinsic ligaments, only those connecting scaphoid, lunate and triquetral bones are of significance with respect to acute bony injuries. Thus, the scapho-lunate ligament is disrupted with scaphoid rotatory subluxation.

2 Injuries of Radius and Ulna

Most commonly injuries result from fall on the outstretched wrist. The type of injury sustained is age related.

2.1 Children

In young children, fractures of the radius proximal to the epiphyseal plate predominate in age group 6–10. These fractures often involve both radius and ulna and may be grossly displaced (Fig. 4). After this, until epiphyseal fusion injuries most commonly involve the epiphyseal plate and are thus Salter Harris fractures. Typically, there is dorsal displacement of the epiphysis with or without an associated fracture fragment from the adjacent metaphysis resulting in either a Salter-Harris type one or two injury (Fig. 5). The degree of displacement is often gross, but on occasion the anteroposterior radiograph can appear quite normal. As with adults, it is careful inspection of the lateral film which will reveal the abnormal alignment

Fig. 4 **a** and **b** AP and lateral radiographs demonstrate fracture of radius and ulna in a child. There is considerable angulation and overlap at the fracture site. The fracture is proximal to the epiphysis which is not involved. This is the typical site and appearance of wrist injuries in children under the age of 10

Fig. 5 **a** AP radiograph with no obvious abnormality. Observe however the loss of clarity of the radial epiphysal plate with increased sclerosis. **b** Lateral radiograph shows that the epiphysis is displaced dorsally. There is a small fragment of bone from the metaphysis in addition which means this is a Salter Harris type 2 injury. This is the commonest type of injury seen at the epiphysal plate

of the distal radial epiphysis. Colles type fractures do not occur in this age group. Greenstick and buckle or Torus fractures of the radius occur only in children. Torus fractures are a compression failure of bone usually at the junction of diaphysis and metaphysis. The term comes from Latin meaning a “protuberance” or “rounded swelling”. The injury is

due to compression forces resulting in a circumferential buckling of the cortex. Thus, the abnormality can be seen on both views although it may be more evident on the lateral projection (Fig. 6). It is a relatively minor injury that will heal well with only minimal immobilisation required (Davidson et al. 2001). Scaphoid fractures do not occur in children

Fig. 6 **a** and **b** There is buckling of the cortex of the radius. This is a circumferential injury and thus seen on both AP and lateral views. It is referred to as a Torus fracture and is seen exclusively in children

Fig. 7 **a** and **b** Colles fracture. There is fracture of the distal radius with dorsal angulation. The articular surface is not involved. There is some radial displacement, and there is an associated fracture of the ulnar styloid process. All of the above need to be present to fulfil the original description of a Colles fracture

under 10 and are rare in older children (Thornton and Gyll 1999).

2.2 Adults

Colles fracture is the commonest wrist injury in patients over age of 40. Increasing frequency with age suggests a relationship to osteoporosis. It was first defined by Abraham Colles professor of surgery in

Dublin in his 1814 paper “On the Fracture of the Carpal Extremity of the radius”. His definition includes the following: (1) fracture of radius within 2 cm of distal radial articular surface but not involving it, (2) dorsal angulation of distal fragment, (3) dorsal displacement of the fragment, and (4) associated fracture of ulnar styloid process. In addition, there is also often some lateral (radial) displacement of the distal radial fragment (Fig. 7). The mechanism of injury with resultant forces applied to

Fig. 8 **a** and **b** Smiths fracture. The distal radial fracture fragment is angulated and displaced in a volar direction. The articular surface not involved. There is an associated distal ulna fracture

the distal forearm bones explains these findings. With fall onto the outstretched hand in extension, impact occurs on the thenar eminence. There are compression forces transmitted along the dorsal cortex of the radius with traction forces along the volar aspect. This results in the fracture with displacement described above. The ulnar styloid fracture occurs due to radial shortening with traction on the ulnar styloid process via the triangular fibrocartilage complex principally the ligaments which attach to the process.

Smith (1847) described a variation of the above where the distal radial fragment is displaced and angled volarly and medially. This is typically caused by falling onto the wrist whilst it is flexed. Again a key feature is that the articular surface remains intact (Fig. 8). Subsequently, this fracture has been subclassified by some to include volarly displaced fractures with an intra-articular component. This injury is indistinguishable from the reversed Bartons fracture discussed below.

Barton described an injury of the distal radius (Barton 1838) as follows: “a subluxation of the wrist consequent to a fracture through the articular surface of the carpal extremity of the radius... The fragment... usually is quite small, and is broken from the end of the radius on the dorsal side” (Fig. 9). This fracture differs from Colles and Smiths fractures due to involvement of the articular surface of the radius. It is a shearing injury through the articular surface. The term is now often incorrectly ascribed to any intra-

articular fracture. Barton’s description also includes the presence of dislocation or subluxation of the radiocarpal joint. A similar injury but with the bone fragment from the volar margin is known by some as a reversed Bartons fracture. It is in fact the volar fracture with volar displacement which occurs more commonly. The fracture fragment varies in size but may involve up to 50% of the articular surface (Fig. 10). The key feature is that the articular surface of the lunate remains in contact with the displaced rim fragment of the distal radius (Fig. 9), and it is this finding that distinguishes this injury from a radio carpal dislocation.

Subtle radial fractures can be easily overlooked. The signs to look for are a subtle crinkle in the cortex of the radius usually on the dorsal aspect and seen only on the lateral film (Fig. 11). Alteration in the radial angle from the usual 10° volar angulation will provide confirmatory evidence but is not present in every case. It has been suggested that soft issue signs around the wrist such as loss of the pronator fat stripe which is normally seen as a lucent area on the volar aspect of the distal radius is a useful adjunct to identifying subtle radial fractures (MacEwan 1964). However, a recent review of the utility of this observation has shown it to be of limited value with a sensitivity of only 26% (Annamalai and Raby 2003).

Isolated fracture of the radial styloid process (Fig. 12) is also known as Hutchinsons or Chauffeurs Fracture. This refers to an intra-articular fracture that

Fig. 9 **a** There is a fracture of the distal radius with extension into the radial articular surface. **b** The distal fracture fragment is angled dorsally, the carpus is subluxed posteriorly. **c** Sagittal

CT confirms the intra-articular component of the fracture and the dorsal subluxation of the carpus

Fig. 10 **a** Lateral radiograph with a small fracture fragment of the distal radius on volar aspect. **b** Sagittal CT demonstrates the degree to which the carpus has subluxed volarly. **c** A second

case where the volar fracture and carpal displacement is clearly evident on the radiograph. It involves nearly 50% of the articular surface

runs obliquely across the distal radius from the radial cortex into the joint separating the radial styloid from the parent bone. The injury is explained by the ligamentous attachments. The strong RSL and RLT ligaments attach to the radius on the styloid side and result in this avulsion injury.

Die punch injuries occur due to impaction of the lunate on the lunate fossa of the radius which results in a depressed comminuted intra-articular fracture of the radial articular surface which may have both sagittal and coronal components (Fig. 13). The full

fracture extent may be difficult to see on plain films, but CT will demonstrate the disrupted articular surface which has both sagittal and coronal components. Depression of the fracture fragments arising in or near the lunate fossa is a key finding. There may be up to four fracture fragments. Commonly, this type of injury is seen as part of a more complex injury of the radius.

The use of eponymous names is prone to misuse. Unless all fully understand precisely what it describes, clinical confusion can result. Many

Fig. 11 **a** AP view there is some disruption of the normal trabecular pattern in the distal radius, and there is a slight step of the cortex. **b** On the lateral, there is a subtle buckling of the dorsal cortex. Note that the normal volar tilt of the distal radial articular surface has been reversed

Fig. 12 There is an isolated fracture of the distal radius running obliquely through the distal radius to reach the articular surface. This separates the radial styloid from the rest of the bone

fractures do not fall precisely into any of the exact original descriptions. It must be appreciated that descriptions of injuries that now have eponymous names attached were derived from clinical examination and cadaveric studies in the pre radiology era. The variations that can occur with all these injuries

were not appreciated at that time. For this reason, it is probably better to give a full description of the fracture lines, fragments displacement and angulation and extent of articular involvement if any. To try and improve on this situation, several classification systems have been proposed (Frykman 1967; Fernández 1993; Melone 1986; Jupiter and Fernandez 1997). These are based variously on the mechanism of injury or the anatomy of the fracture. These systems attempt to provide a framework for treatment options by the orthopaedic surgeon, but none have been universally adopted. Unless locally agreed practice is to use one of the classifications to communicate findings to your orthopaedic surgeons, they are of little practical value to the reporting radiologist on a day-to-day basis. For this reason, they have not been included in this chapter.

2.3 Distal Radio-Ulnar joint

In the acute setting, disruption of the distal radio-ulnar joint (DRUJ) is seen in association with 3 types of fracture.

By far the most common is in association with fracture of the distal radius. Any significant radial shortening may result in disruption of the distal radio ulnar joint. The incidence of this is between 11 and 19% of distal radial fractures (May et al. 2002).

A different circumstance exists with the so-called Galeazzi fracture dislocation. In this event, a fracture of the shaft of the radius occurs with angulation and/or overlap of bone at the fracture site. Unless there is a fracture of the ulna as well, there will be dislocation

Fig. 13 **a** AP radiograph shows abnormality of the distal radius with comminution of the articular surface of the radius on the ulnar side. This is the lunate fossa of the radius. **b** The lateral view demonstrates disruption of the dorsal cortex. The

lunate has been driven down onto the radius causing this injury pattern. **c** This 3D volume reconstructed CT is looking from the ulnar side of the wrist (the ulna has been removed). The lunate is seen disrupting the lunate fossa of the radial articular surface

Fig. 14 **a** AP of wrist demonstrates a wide separation and displacement of the distal radio-ulnar joint. It is impossible for this to occur in isolation. There must be a more proximal fracture of the radius with angulation or overlap at the fracture site. **b** Radiograph of forearm demonstrates such a fracture

of the DRUJ. Conversely, if a DRUJ dislocation is evident on a wrist radiograph, then a more proximal radial fracture is likely to have occurred and radiographs of the whole forearm must be obtained (Fig. 14).

The third fracture associated with distal radio ulna joint disruption is the Essex-Lopresti fracture dislocation. This occurs when a fall on the outstretched

hand results in an axial force driving the radius proximally with disruption of the DRUJ and the distal interosseous membrane finally resulting in fracture and or dislocation of the radial head. The injury is generally only sustained by a severe force.

Isolated disruption of the DRUJ is much less common and can be difficult to diagnose (Nicolaidis et al. 2000; Tsai and Paksima 2009). It is thought to

Fig. 15 **a** AP view of wrist with evidence of disruption of the carpal arcs. **b** On the lateral view, the whole carpus is displaced dorsally. The bony fragments on the volar aspect are due to avulsion by the volar ligaments attached to the volar aspect of the radius

occur with hyperpronation with fall on the outstretched hand. A fracture of the ulnar styloid process may be present, but this seen more commonly in association with a radial fracture. DRUJ disruption in turn is associated with injury of the TFCC and the associated stabilising ligaments. Thus, this tends to present more often as chronic wrist pain often with no definite acute incident.

Plain radiographs (Nakamura et al. 1995; Lo et al. 2001) and CT (Nakamura et al. 1996) have been utilised to evaluate the DRUJ, but can be difficult to assess with considerable overlap between normal and abnormal. There is an association between DRUJ disruption, ulna styloid process fracture and damage of the underlying TFCC.

Radiocarpal fracture dislocations (RCFD) are rare and occur due to high-energy injuries with both shearing and rotational components (Ilyas and Chaitanya 2008). They can occur in isolation but more commonly are associated with fracture of the distal radius. Dorsal displacement is more common than volar (Fig. 15). These injuries need to be differentiated from the Bartons fracture where a rim fracture of the radius is also present. In the Bartons fracture, the radial articular surface remains in contact with the proximal carpal row. With RCFD, the radial articular surface is no longer in alignment with the carpal row. This is best appreciated on the lateral radiograph by observing the position of the lunate relative to the radius. The dislocation may occur in

isolation, but often a dorsal dislocation is associated with a volar rim fracture of the radius. This apparent paradox is explained by the ligamentous attachments. When the carpus dislocates dorsally, the volar extrinsic ligaments attached to the volar rim of the radius may avulse a bone fragment from this site (Lozano-Calderón et al. 2006). RCFD are also associated with intra-carpal fractures and fracture dislocations (see below).

There are two classifications for these injuries. Moneim et al. (1985) classified these injuries into 2 groups depending on whether there was associated intercarpal injury or not. An alternative classification is based on the size of the radial fracture fragment (Dumontier et al. 2001). In those with no or only a small radial fragment, there is likely to be major ligamentous disruption resulting in multidirectional instability. In those with a large radial styloid fragment separated from the underlying bone, the radiocarpal ligaments are likely to be intact. Reduction of the dislocation with fixation of the fracture is likely then to restore wrist stability.

3 Carpal Injuries

3.1 Scaphoid

The scaphoid is by far the most common of the carpal bones to sustain an injury and accounts for at least

Fig. 16 In addition to the conventional AP and lateral views of wrist, if a scaphoid fracture is suspected, then additional view must be obtained. These are with **a** ulnar deviation of the wrist and **b** deviation and angulation of the tube towards the elbow

Table 1 Relative incidence of carpal bone fractures

Scaphoid	68.2%
Triquetrum	18.3%
Trapezium	4.3%
Lunate	3.9%
Capitate	1.9%
Hamate	1.7%
Pisiform	1.3%
Trapezoid	0.4%

60% of all carpal fractures (Gaebler 2006; Table 1). The propensity for this bone to fracture more often than all the other carpal bones combined is explained by its anatomy. Unique among the carpal bones the scaphoid bridges the proximal and distal carpal rows. As these two rows move to different degrees during wrist dorsiflexion, this places increased stress on the bridging scaphoid. This is compounded by the presence of the radiocapitate ligament that lies across the waist of the scaphoid. Both of these forces act to maximise the stress forces at the waist of the scaphoid thus accounting for the high incidence of injuries at this site. Furthermore, in extreme dorsiflexion, the scaphoid waist may impact upon the dorsal rim of the radius providing an additional mechanism of injury.

Radiography The scaphoid lies at about the angle of about 45° relative to the radial shaft in the sagittal plane. It is overlapped by the lunate, capitate and pisiform on the lateral view. Hence, the two conventional views of the wrist may fail to demonstrate some scaphoid fractures. With the PA view in

particular, the X-ray beam passes obliquely through the scaphoid rather than at right angles to it, so a fracture line through the waist of the scaphoid will be traversed obliquely by the beam. Therefore, unless the fracture is widely separated, it is often not detected on this view. To overcome these problems, it is essential when a scaphoid injury is suspected clinically that additional dedicated views are obtained. Typically, 2 more radiographic projections are employed with the intention of elongating the scaphoid, projecting it clear of other carpal bones and allowing the X-ray beam to pass through the scaphoid perpendicular to its long axis. The projections used vary, but in the authors department a second PA view with ulnar deviation plus one with the tube angled at 45° towards the elbow is obtained (Figs. 16, 17).

This small bone causes more diagnostic and management difficulties than almost any other due to the nature of its blood supply. Its blood supply is unusual with the blood entering the distal pole first then passing into the proximal pole. The result is that when fracture occurs through the waist of the scaphoid which is the commonest site (80% of cases) and the proximal pole (10%) the blood supply to the proximal pole is interrupted (Fig. 18). This brings with it the danger that the proximal pole loses its vascular supply and develops avascular necrosis. Fractures of the waist are associated with 30% incidence of AVN, and disruption of the proximal pole almost always leads to this complication (Fig. 19). Alternatively, the lack of blood supply hinders healing at the fracture site and non-union of the fracture occurs (Fig. 20).

Fig. 17 Effect of scaphoid views. **a** Conventional AP view does not show any definite abnormality. **b** Angled view clearly demonstrates a now obvious fracture

Classification of Scaphoid Fractures by Location

Fig. 18 The sites of scaphoid fracture with frequency of occurrence. Fractures of the waist account for the great majority

Historically, extreme care has been taken in managing patients with suspected scaphoid injuries. Because of the difficulties that may occur in identifying scaphoid fractures on radiographs, a combined clinical and radiological approach has been adopted to minimise the possibility that a fracture has been overlooked. In patients with an appropriate history and clinical findings suggestive of scaphoid fracture, an initial scaphoid series of radiographs is obtained. If a fracture is identified, the wrist is immobilised and

Fig. 19 Initial radiograph taken at time of injury demonstrated a fracture of the waist of the scaphoid. This radiograph taken 18 months later shows that the fracture line remains well demarcated with sclerotic edges. This represents established non-union of the fracture

managed accordingly. If no fracture identified, it is recognised that this does not completely exclude a fracture due to the difficulties described above. Accordingly, because of the possible long-term complications that may arise after suboptimal treatment of a fracture the patient is managed as if a fracture is present and the wrist is immobilised. The patient is then reviewed at about 10 days when further radiographs are obtained. It is stated that resorption

Fig. 20 The proximal pole of the scaphoid is sclerotic and shrunken. This is the appearance of established avascular necrosis some 5 years after initial injury

will occur around a fracture site rendering it visible on delayed radiographs. This process may need to be repeated on several occasions until either a fracture is clearly identified or the patient's symptoms resolve. "We overtreat a lot of patient to avoid undertreating a few" (Barton 1992).

This practice or similar modifications remain in common use (Brookes-Fazakerley et al. 2009); however, it has been questioned in the era of more sophisticated imaging options. To understand the validity of the management rationale, some basic background information is required.

How many fractures are present but not visible at the time of the initial radiographs?

Most studies have shown that in fact a great majority of fractures (85% or more) are visible on the initial films (Leslie and Dickson 1981; Brøndum et al. 1992). Some even consider that all fractures can be identified (Duncan and Thurston 1985).

How many patients develop non-union or avascular necrosis?

The same authors independently found that these complications occurred in 5% of patients with a scaphoid fracture.

How often are fractures identified on follow-up films?

In a recent study using MR as the gold standard, it was found that detection of occult fractures on follow-up films was extremely inaccurate, with sensitivity as low as 9% and very poor interobserver reliability (Low and Raby 2005). This confirmed observations

Fig. 21 Multislice CT with coronal reconstruction demonstrates a fracture of the scaphoid. No abnormality was evident on the plain radiographs

by others (Tiel-Van Buul et al. 1992a, b). It is apparent that clinicians rely on clinical findings rather than radiographs to guide management.

To improve on this situation, for many years other imaging modalities have been utilised including isotope bone scan CT and MRI. A recent international survey (Groves et al. 2006) however has shown that despite the extensive evidence base the majority of departments still undertake repeat radiographs when no fracture is seen. Alternative imaging modalities are employed only as a secondary investigation and in order of frequency these are MR CT and isotope scan.

Isotope bone scans are sensitive but non-specific. Whilst almost all fractures will show evidence of increased isotope uptake if scanned 3 or more days after the acute event, approximately 35% of increased isotope up take in the carpus is due to abnormality other than a scaphoid fracture, and additional imaging may be needed to resolve this issue (Tiel-Van Buul et al. 1992a, b; Tiel-Van Buul et al. 1993; Waizenegger et al. 1994; Beeres et al. 2007).

CT is utilised more than isotope scans (Groves et al. 2006). Whilst CT can undoubtedly identify some occult fractures (Fig. 21), there is still an error rate (Adey et al. 2007), and it has been shown that trabecular bone injury will not be detected although the relevance of this is debatable (Memarsadeghi et al. 2006; La Hei et al. 2007).

MRI is now the investigation of choice (Foex et al. 2005), but use remains limited due to perceptions that

Fig. 22 **a** Radiographs are normal. No scaphoid fracture identified on any view. **b** and **c** Coronal T1-weighted and STIR MR demonstrates a fracture across the scaphoid waist

seen as a low signal linear line on the T1-weighted and high signal line on the STIR sequence

its availability is restricted. There is extensive literature regarding the use of MR in patients with suspected scaphoid fracture not evident on plain film (Fig. 22) (Raby 2001; Brydie and Raby 2003). This consistently indicates that MR accurately identifies scaphoid fractures, and other carpal or radial fractures that may be responsible for the patient's symptoms. Just as importantly a normal MR will exclude bony injury allowing early discharge of the patient from hospital care, and it is this fact that renders it cost effective (Kumar et al. 2005). Several studies have confirmed this to be the case. The ability to be able to reliably discharge patients without need for immobilisation, further hospital attendance or repeat radiographs is the most important benefit of this strategy (Dorsay et al. 2001).

Despite the best efforts of all concerned in the management of patients with scaphoid fractures, non-union or AVN still occurs in a small proportion of patients. Attention has thus been directed to imaging techniques that may indicate that a recognised fracture is either failing to unite or developing AVN in the hope that early detection of these complications would allow early intervention (Figs 23, 24). To date, evidence of ability to reliably detect these complications is limited. The major focus has been on the use of MRI with contrast enhancement. The theory is that as fracture of the scaphoid waist may interrupt the blood supply to the proximal pole, then on contrast enhanced scans lack of enhancement of the proximal pole will indicate lack of blood supply and thus poor prognosis with non-union or avascular necrosis as a

long-term result (Dawson et al. 2001). Studies have had conflicting results, and the numbers in the studies have been small (Singh et al. 2004; Cerezal et al. 2000). There is no good evidence that contrast-enhanced MR can accurately predict either of these complications. However, whether or not these complications are detectable earlier by imaging is of little consequence if the final outcome remains unaltered. To date, there is no robust evidence that there is any improvement in outcome as a result of contrast-enhanced MR, and one study has shown no outcome benefit in a group of patients who underwent MR prior to surgery (Singh et al. 2004). Further studies with accumulation of large data sets are required to confirm or refute its value.

CT also has its advocates (Smith et al. 2009) with a recent paper suggesting benefit in the detection of AVN and non-union with improved outcome after surgery. Confirmatory evidence from other sources is awaited. CT however is undoubtedly of value in detecting certain other complications of scaphoid fracture. Some scaphoid fractures unite satisfactorily but may develop the so-called hump back deformity (Fig. 25). This occurs when the distal fracture fragment flexes in a palmar direction with the distal carpal row whilst the proximal fragment rotates dorsally with the proximal carpal row. This results in angulation occurring at the fracture site with a prominent dorsal bony protrusion and is best appreciated on CT. It is associated with persisting pain, restriction of movement and development of arthritic changes. CT can also assist in confirming that a fracture has united

Fig. 23 **a** Radiograph shows scaphoid waist fracture with cystic bone resorption 5 months after initial injury. **b** Coronal T1-weighted image. There is loss of normal marrow signal in the proximal pole. **c** STIR sequence shows diffuse high signal

indicating marrow oedema. **d** Post-contrast T1 weighting with fat saturation shows enhancement of the proximal pole suggesting it retains a vascular supply

when plain films suggest that a fracture line persists (Fig. 26).

3.2 Other Carpal Fractures

After the scaphoid, the triquetral bone is most commonly injured accounting for 18–20% of injuries (Table 1). This injury is usually due to a bony avulsion of the insertion of the radio and ulno triquetral ligaments. Typically, the fracture is not evident on the PA view but can be seen on the lateral as a bone fragment seen on the dorsal aspect of the wrist (Fig. 27). Transverse fracture can also occur due to extreme dorsiflexion with compression of the triquetrum between the ulna and hamate. These fractures may be seen in association with Perilunate dislocation (see below).

Other carpal bone injuries are all relatively rare, each of the other carpal bone accounting each for only 2–3% of injuries. CT or MR may have a useful role to

play in these injuries that are often difficult to detect on plain films.

Fractures of the hamate can involve the hook in isolation or the body. Hook fractures are often associated with sporting activities since the handle of a bat or racquet abuts the hook. Conventional radiographs will often fail to demonstrate such injuries that may therefore be diagnosed as soft tissue injuries or “wrist sprain” only (De Schrijver and De Smet 2001). Additional views have been shown to demonstrate these fractures such as the so-called carpal tunnel view. However, if such a fracture is strongly suspected clinically, then CT will demonstrate them most clearly (Fig. 28) (Kato et al. 2000). Fracture of the body can occur in isolation but more often are associated with other carpal fractures or with fracture dislocation of the 5th metacarpal base. These injuries are usually evident on conventional radiographs (Fig. 29).

Capitate fractures in isolation are uncommon. Typically, fractures occur through the waist of the

Fig. 24 **a** Fracture of scaphoid proximal pole now 6 months old. **b** There is complete loss of normal marrow signal in the proximal pole on T1-weighted image. **c** PD fat-saturated image

shows diffuse marrow oedema. **d** Post-contrast T1-weighted with fat saturation. There is no enhancement of proximal pole suggesting loss of blood supply

Fig. 25 **a** Radiograph shows a fracture across the proximal third of the scaphoid. Resorption at fracture site has resulted in cystic change at the fracture line. **b** CT undertaken to confirm non-union. There is no evidence of any bony continuity at the

fracture site. **c** Sagittal reconstruction demonstrates displacement at the fracture site resulting in the so-called hump back deformity

Fig. 26 **a** Radiograph of scaphoid fracture after 6 months. The fracture line persists suggesting possible non-union. **b** Coronal reformatted CT. The scaphoid is sclerotic with a linear lucency across the waist suggesting non-union. **c** Sagittal reformatted CT shows that in fact there is bony union across the majority of the fracture site. A step in the cortex is the cause of the linear lucency seen on the previous images mimicking a persistent fracture line

capitate. These can be seen on the AP view of the wrist (Fig. 30). More commonly capitate fractures occur in association with perilunate dislocation. Fractures occur as a result of wrist dorsiflexion. With more severe injury, the proximal pole of the capitate can be displaced and rotated through either 90° or 180° (Fig. 31). These findings are seen along with other fractures of the greater arc or zone of vulnerability.

Lunate fractures are uncommon and typically are small chip or avulsion fractures. Only occasionally do the fractures extend through the bone. The principal complication is that of avascular necrosis (Keinbock's disease). Pisiform and trapezoid fractures are rare and are not considered further.

3.3 Carpal Dislocations

The proximal carpal row (scaphoid, lunate and triquetral) act as a functional unit and is referred to as an

intercalated (inserted in between) segment. That is a functional row of bone inserted between the distal radius and the distal carpal row. These three bones act as a keystone coordinating wrist motion and transmitting force between wrist and hand. The proximal row of carpal bone has no tendons attached and relies on complex ligamentous attachments as well as bony configuration for stability. The pisiform although it lies proximally is not functionally associated with these bones. It is a sesamoid bone within the tendon of flexor carpi ulnaris.

The distal row of trapezium, trapezoid, capitate and hamate is more stable and forms a transverse arch supporting the metacarpal bones. The distal row of carpal bones are rarely disrupted unless associated with other injuries (see below). The scaphoid that lies at an angle bridges the proximal and distal carpal row and normally contributes to stability of the carpus. Fractures of the waist of the scaphoid break this bony linkage between the two rows. Most carpal fractures and dislocations occur due to falling on the

Fig. 27 This lateral radiograph shows several bone fragments on the dorsal aspect at mid-carpal level. This finding almost invariably indicates a triquetrum fracture although the AP view will usually be normal. Further investigation by cross-sectional imaging to prove the origin of the bone fragments is generally not required or indicated

outstretched wrist with the wrist forced into a hyperextended position. Evaluation of these injuries is aided by the evaluation of lines or arcs drawn through the carpus. Somewhat confusingly this nomenclature does not relate to the same arcs used to describe

Fig. 29 **a** AP radiograph of wrist is normal. **b** Oblique view demonstrates a vertical fracture of the hamate

Fig. 28 Sagittal CT demonstrating a fracture of the hook of the hamate. This was not visible on conventional radiographs

normal carpal alignment (Yeager and Dalinka 1985). In this terminology, the lesser arc separates the lunate from the adjacent carpal bones (Fig. 32). The greater arc passes through the scaphoid, capitate, hamate, triquetrum (and in some modifications the distal radius and ulna). Injury through the lesser arc represents a lunate dislocation. Injuries of the greater arc indicate a perilunate injury. This may be an isolated perilunate dislocation or with associated fracture(s) of bones along this arc. Virtually, all combinations of fracture can occur along this zone. This is best referred to as the “Zone of Vulnerability” (Johnson 1980). An abnormality anywhere along this arc should prompt a thorough search of all points to identify associated fractures. Injuries of the greater arc are twice as common as those of the lesser arc.

Carpal dislocations thus most commonly involve the proximal row of bones, and the lunate is most often involved. Understanding the lateral radiograph

Fig. 30 There is fracture through the proximal third of the capitate. This is unusual in isolation

is key to detect these injuries although valuable information is also available on the PA view. On a normal lateral view of the wrist, there should be alignment of the lunate with the distal radius and the capitate. That is to say that a line drawn through the centre of the lunate should inferiorly pass through the radial articular surface and superiorly should pass through the centre of the capitate (Fig. 33). If this rule is broken, a carpal dislocation is certain. We (Raby et al. 2005) have likened this to a saucer (the radial articular surface) with a cup (the lunate) sitting on it. Within the cup, there should sit an apple (the capitate). Lunate dislocation occurs with hyperextension injuries. On a PA radiograph, the normal intercarpal

Fig. 32 Carpal fracture dislocations occur along the greater arc or zone of vulnerability

distances are disrupted with bony overlap evident. The lunate appears to have a triangular shape where normally it has a trapezoid appearance. It is on the lateral film however where the diagnosis is most easily detected. Here, a dislocated lunate will be seen displaced to the volar aspect. It is rotated so that it has the appearance of a new moon (Fig. 34). The alignment of the radius and capitate is preserved, but the lunate (the cup) lies palmar to the line drawn through the radius and capitate. Lunate dislocation is most

Fig. 31 **a** Complex mid carpal fracture dislocation. There are fractures of the scaphoid and proximal third of the capitate. **b** On the lateral view, the proximal capitate articular surface can be seen rotated through 90° lying dorsal to the lunate. There

is perilunate dislocation of the carpus. Capitate fractures are more commonly seen in association with these mid-carpal injuries

Fig. 33 The normal alignment of the three key bones on the lateral view. The capitate sits on the lunate which sits on the radius. A line drawn through the capitate should pass through the approximate centre of the lunate and distal radial articular surface

commonly an isolated finding with additional fractures found only uncommonly. The maxim “the cup should never be empty” is a simplistic but effective way of detecting these injuries.

Perilunate dislocation is also a hyperextension injury and is often associated with other carpal

injuries (see above) most commonly a fracture of the scaphoid. It is more common than lunate dislocation. In this injury, the lunate remains aligned with the radius, but the capitate and the rest of the distal carpal row are displaced in a volar direction (Fig. 35). For this to occur, there must be disruption of some of the intra-carpal ligaments. The injury is often not apparent on the PA views, but on the lateral film the lunate (cup) remains on the saucer (distal radius). The capitate (apple) does not sit in the cup but lies posterior (volarly). As already seen perilunate dislocation is typically associated with other fractures along the greater arc zone of vulnerability (Fig. 36). When there are both fractures and perilunate dislocation present, the convention is to describe first the fractures then the dislocation. In this case, the description should be of a trans-scaphoid, trans-triquetral and perilunate dislocation.

Scapho-lunate disassociation is also known as rotatory subluxation of the scaphoid. It is a ligamentous injury occurring with forced wrist extension. Several ligaments are disrupted in this injury. In sequence, the radioscaphoid, the volar radiocapitate and finally the scapho-lunate ligament fail. This allows the distal scaphoid pole to rotate in a volar direction. On plain radiographs, the injury can be identified by noting a widening of the intercarpal distance between scaphoid and lunate. This is the so-called Terry Thomas sign. The rotation of the

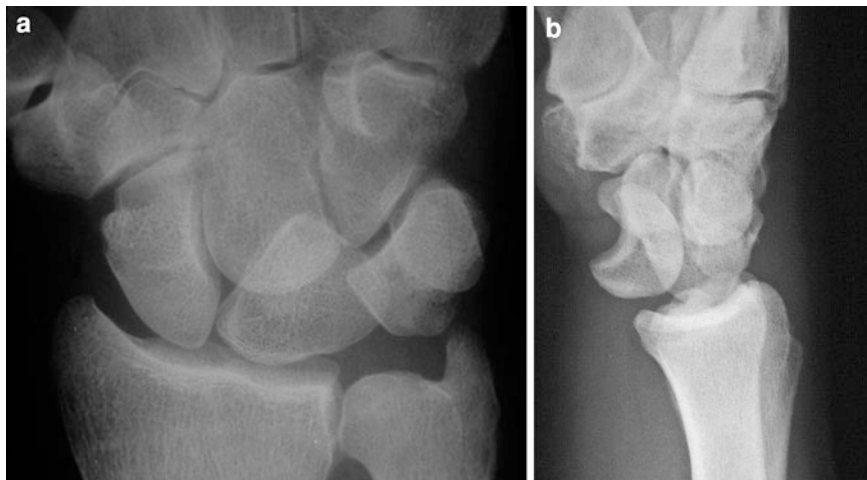

Fig. 34 **a** There is disruption of the proximal carpal arc with interruptions at the junctions of lunate with the scaphoid and triquetral. The lunate has a triangular configuration compared with the normal quadrilateral shape. **b** Lateral view

demonstrates loss of the normal alignment of the radius, lunate and capitate with the lunate rotated and displaced volarly. These are all signs of lunate dislocation

Fig. 35 **a** There is little to see on the AP view of the wrist apart from the wrist apart from the triangular configuration of the lunate. The arcs are maintained. **b** On the lateral view, however, there is loss of the normal carpal alignment. The lunate sits normally on the radius, but the capitate now lies dorsal to the lunate indicating a perilunate dislocation. The cup of the lunate is empty

Fig. 36 **a** AP radiograph demonstrates fractures of the waist of the scaphoid and triquetrum bones. There is disruption of the second carpal arc with loss of the normal intercarpal spacing. There is marked overlap of both scaphoid and lunate with the

capitate. The lunate has an abnormal triangular appearance. **b** The lateral view demonstrates the capitate does not sit on the lunate but lies dorsal to it. This is a trans-scaphoid trans-triquetrum perilunate dislocation

scaphoid causes it to be foreshortened, and the distal pole seen end on has a ring-like appearance (Fig. 37) (Hudson et al. 1976). On occasion, the radioscaphoid ligament avulses a bone fragment from the radial styloid attachment, but more often there is no fracture evident so that this is injury that can be easily overlooked.

4 Carpo-Metacarpal Injuries

There is normally little movement at the carpo-metacarpal joints. Strong ligaments bind the distal carpal row to the base of the metacarpals, and there is little movement possible either on palmar or

Fig. 37 There is widening of the gap between lunate and scaphoid. The scaphoid has rotated and appears foreshortened. There is a ring-like appearance of the distal pole due to the pole now being seen end on. This indicates disruption of the scapho-lunate ligament. Known correctly as rotatory subluxation of the scaphoid, it has been known as the “Terry Thomas sign” in the UK after an actor who had a large gap between his front teeth

dorsiflexion. Dislocations at this site only rarely occur in isolation and are more commonly associated with fractures of the metacarpal bases or the adjacent carpal bones, most commonly the hamate and capitate. These injuries are rare and result from high-energy axial loading of the metacarpals such as occurs when delivering a punch. The site of injury often leads to request from the referring clinician for radiographs of the hand rather than the wrist. An AP and oblique view will be obtained.

Disruption of the carpo-metacarpal joint may occur in isolation or may be associated with fracture of either the proximal metacarpal or the adjacent carpal bone. Isolated dislocations without associated fracture are difficult to identify. These injuries can be detected by observation of the loss of the normal gaps between the distal carpal row and the base of the metacarpals and/or by identifying areas of increased bone density due to the resultant bone overlap (Fig. 38). Fisher et al. (1983) described the appearance of the carpo-metacarpal joint from the second to fifth metacarpal as having an elongated M shape. The articular surfaces of the metacarpals and adjacent carpal bones form two parallel lines with this M shape. Loss of this normal configuration should alert the viewer to a

Fig. 38 AP radiograph of wrist. There is loss of the carpo-metacarpal spaces with increased bone density at the base of the 2nd and 3rd metacarpals due to bone overlap indicating dislocation at this site

possible metacarpal dislocation. All of these findings are best seen on the AP view. Where there is suspicion on the standard radiograph series, a lateral of the hand may add further useful information. The displaced metacarpal will then be visible as almost all are dislocated dorsally (Fig. 39). Metacarpal fractures when present aid identification of the injury. Carpal fractures may be impossible to see on plain films and may only be evident on subsequent CT (Fig. 40) (Kaewlai et al. 2008; You et al. 2007). A common injury is that of fracture dislocation of the 5th metacarpal, and this accounts for 50% of single ray dislocations. It is likely that this is due to the attachment of the extensor and flexor carpi ulnaris tendons to the 5th metacarpal base which draw the dislocated bone proximally resulting in bony overlap. The second metacarpal accounts for 25% of solitary dislocations. Multiple dislocations are more common. Dislocation of the 5th metacarpal plus one or more of the other metacarpals accounts for 80% of injuries at this level (Rodgers 2001).

5 Acute Soft Tissue Injuries

In acute trauma, soft tissue injuries are common but are usually overshadowed by the presence of bony fractures and dislocations. Thus, injuries of the

Fig. 39 **a** AP and oblique radiographs of wrist and hand. There is loss of the normal carpal-metacarpal spacing at the base of the 3rd to 5th metacarpals. Increased sclerosis is also

evident, meaning there must either be bone impaction or overlap. **b** An additional lateral view demonstrates dorsal dislocation of the metacarpals

Fig. 40 **a** Loss of carpo-metacarpal space at 5th metacarpal. Note also there is loss of alignment of the third metacarpal with the capitate. **b** Sagittal CT image demonstrates dorsal dislocation of a metacarpal with fractures of the capitate. **c** Axial CT image shows fractures of capitate and hamate. CT will often identify additional fractures in this type of injury

Table 2 Palmer classification of TFCC tear

Traumatic injury	Comments
A. Central perforation	
B. Ulnar avulsion	May have avulsion of ulna styloid Associated with injury to palmar and dorsal radio-ulnar ligaments. May result in instability
C. Distal avulsion	Distal avulsion of ulna lunate or ulna triquetral ligaments
D. Radial avulsion	Avulsion of insertion into radius, may be associated with a fracture

Fig. 41 Twenty-one-year male with pain persisting after a fall on the wrist some 6 weeks previously. Coronal T2* GE MR of wrist. There is a central perforation of the articular disc of the TFCC

intercarpal ligaments which occur in most carpal dislocations are not specifically identified and treated. Isolated soft tissue injuries do occur as a result of trauma. Rupture of the scapho-lunate ligament with rotary subluxation of the scaphoid has already been considered. The triangular fibrocartilage complex is another soft tissue structure which can be injured acutely. Bony injuries may be present, but in many cases it is an isolated soft tissue injury. Palmer (1989) classified injuries of the TFCC into acute traumatic (Palmer class 1) and chronic degenerative (Palmer class 2). It is only the former that will be considered

here. Palmer further subclassified these acute TFCC injuries into 4 groups depending on the site of perforation (Table 2). MR has proven to be accurate in the assessment of TFCC injuries (Fig. 41) (Oneson et al. 1996), but MR arthrography may be required to detect these injuries (Zanetti et al. 2007). Imaging at higher field strength (3T) has been shown recently to improve identification of the injuries without the use of intra-articular contrast (Magee 2009).

6 Chronic/Overuse Injuries

Chronic stress injuries of the upper limb are far less common than in the lower limb. This is self-evident as in normal circumstances the upper limb is not weight bearing rendering it much less likely to come under repetitive stress during normal daily activities. Stress injuries of the upper limb are thus almost exclusively found in those who undertake activities outwith the norm. Principally, this involves athletes' or those with unusual jobs that require use of the upper limb in an unusual activity.

In a review of 44 cases of upper limb stress injuries in athletes, SINHA et al. (1999) found only 17 occurred in the wrist. The only stress fractures reported involve the distal radius, the distal ulna and the scaphoid. Stress injuries in athletes may occur as a result of repetitive stresses applied at the site of muscular attachments to bone such as may occur with weight lifters. Alternatively, repeated weight bearing especially if there is impact loading can also result in a bony stress response. This has been described most often in gymnasts usually females as their routines include many activities (Webb and Rettig 2008), which involve weight bearing on the upper limb often with impact forces in addition. The radiology findings on plain films have been described (Carter et al. 1988). In a series of 8 gymnasts aged 14–16, radiographs of the wrist demonstrated irregularity and widening of the radial epiphyseal growth plate bilaterally but asymmetrically. The irregularity of the growth plate was largely marked on the metaphyseal side (Fig. 42). Some of the cases also showed an ill-defined cystic appearance. In 5 cases, the ulna growth plate was also affected but to a lesser extent. The findings have likened to the appearances seen in rickets (Liebling et al. 1995). The MR appearances have been described (Shih et al. 1995). In an

Fig. 42 AP radiograph of wrist of a young gymnast. There is widening of the epiphyseal plate with irregularity on the metaphyseal side

examination of 93 wrists in 47 gymnasts. The authors described several findings including widening of the growth plate, extension of the physal cartilage into the metaphysis and or epiphysis. Also noted in some cases were vertical or horizontal fractures of the metaphysis. MR was more sensitive than plain films in the detection of most of these abnormalities. This has been confirmed in a recent paper (Dwek et al. 2009).

In addition to the metaphyseal stress injuries described above, the scaphoid has been reported to undergo stress fracture. Seven of Sinha's 44 cases had scaphoid stress fractures. These are seen in gymnasts but also in weight lifters. Weight bearing with the wrist in extension is the mechanism of injury which places repeated stress across the scaphoid waist. Stress fractures of the other carpal bones are exceptionally rare (Anderson 2006).

There are two further areas worth brief consideration. The first is the bone changes that may be seen within the wrist and carpus as a result of chronic vibration. Use of vibrating power tools such as pneumatic drills and chain saws may result in a spectrum of clinical disorders including white finger syndrome and carpal tunnel syndrome representing respectively vascular and neural changes as a result of exposure to repeated vibration over a long period of

time. Furthermore, cystic changes visible on radiographs within the carpal bones particularly have been reported to occur in these workers. These changes in cysts measuring between 2 and 5 mm occur most commonly in the lunate and scaphoid. The association of these findings with occupational exposure is however inconsistent with some finding these changes almost as frequently within age-matched controls (Malchaire et al. 1986). There seems little evidence that those at risk should have regular screening radiographs of the wrists and in those with symptoms radiographic findings need to be treated with caution as cause and effect have not been proven (Gemne and Saraste 1987).

Finally, there are a few reports of instances of cysts developing at the site of healing fractures (Fig. 43). This is seen particularly in children with greenstick fractures, and the distal radius is the commonest site. The cystic change is seen initially at or close to the fracture site but persists and appears to migrate proximally into the diaphysis with time. On cross sectional imaging, the lesion is seen to lie not within the medullary cavity but in a juxtacortical or subperiosteal position (Roach et al. 2002). The pathogenesis is debated (Phillips and Keats 1986) with subperiosteal fat (Papadimitriou et al. 2005) subperiosteal (Durr et al. 1997) and intra-osseous haemorrhage all mooted as possible causes. The presence of a lucent lesion of bone away from the fracture site some time after the injury which may have healed can lead to diagnostic confusion with a tumour (Houshian et al. 2007) being considered as a possible cause. Thus, recognition of this entity with the typical cross-sectional appearance will prevent this erroneous diagnosis being entertained for too long.

7 Summary/Key Points

Careful evaluation of both AP and lateral radiographs is essential to avoid overlooking significant injury of the wrist and carpus. Understanding of ligamentous anatomy aids understanding of the injury patterns that occur.

Identification of one injury should alert one to the possibility of other associated injuries. Knowledge of the pattern of these injuries allows a systematic directed search to be undertaken.

Fig. 43 **a** Lateral radiograph at time of injury demonstrating a Salter-Harris type 2 injury (left image) Later radiograph with fracture healed but cystic change evident on volar cortex (right image). **b** CT of lesion shows cystic area lies within cortex.

c Axial T1- and **d** T2-weighted MR confirms fatty marrow content of lesion. Case reproduced with permission from reference 71

Lateral radiograph contains much vital information. It is essential to become familiar with its appearances and understand the normal anatomical relationships.

MR is a technique of choice for detecting occult scaphoid fractures.

Describe fractures and dislocations systematically rather than using eponymous names.

Abstract

The painful clunking, unstable wrist has been an area of specific interest for clinicians and radiologists for many years. This chapter aims to focus on the unstable wrist, reviewing the clinical problem, exploring current hypotheses, critically evaluating radiological tools in aiding the clinician, and illustrating the integrative views of the authors based on their fundamental research and clinical practice. This chapter cannot provide a complete overview as this is a controversial area with an extremely extensive literature.

1 Introduction

Carpal instability is a problem of unknown extent, of which sparse literature suggests an incidence of 2.6 % in adults (Mink van der Molen 1997). The lack of reliable data relating to incidence is partly due to the lack of consensus relating to diagnosis and terminology and also the result of differences between ways in which carpal instability is classified (Kobayashi et al. 1997). The wrist has a complex anatomy involving 15 bones comprising the radius and ulna, carpal bones, and metacarpal bases. However the biomechanical principles governing carpal kinematics and instability remain poorly understood.

2 Anatomy

With the exception of flexor carpi ulnaris on the pisiform, none of the tendons that move the wrist insert onto carpal bones. This means stabilization of

Fig. 1 Diagram showing the major extrinsic ligaments of the wrist. **a** Volar showing 1 = ulnotriquetralcapitate, 2 = radioscaphoidcapitate, 3 = radiolunatetriquetral, 4 = ulnolunate, 5 = radiolunate. **b** Dorsal showing the radiotriquetral ligament which also has an attachment to the lunate

the carpal bones is almost entirely passive, movements being dependent on the shapes of the articulations between bones and their passive stabilization by a complicated series of intrinsic ligaments.

Wrist ligaments fall into two groups: the extrinsic ligaments linking the radius or ulna to the carpal bones and the intrinsic ligaments running between carpal bones. The two most important intrinsic ligaments lie in the proximal carpal row, between the scaphoid and lunate (scapholunate) and between the lunate and triquetrum (lunatetriquetral) bones.

The scapholunate (SL) and lunatetriquetral (LT) ligaments have a complex structure with strong fibrous volar and dorsal components and a thinner membranous central portion. The membranous portion has no stabilizing function and only the volar and dorsal components act as true ligaments. Small perforations in the membranous portion of the ligaments may exist in the normal population. The dorsal component of the SL and the volar component of the LT ligaments are the thickest and most important components for stabilization (Cerezal et al. 2012). The lunate attachments of the two ligaments are stronger than the scaphoid and triquetrum attachments which means injury will tend to occur at the scaphoid attachment of the SL ligament and at the triquetrum attachment of the LT ligament.

The extrinsic ligaments lie on the volar and dorsal aspects of the wrist. On the volar aspect of the wrist the ligaments tend to course from the radius and ulna toward the capitate (radioscaphocapitate and ulnotriquetralcapitate ligaments) or toward the lunate

(radiolunate and ulnolunate ligaments). On the dorsal aspect of the wrist the most important extrinsic ligament is the dorsal radiotriquetral ligament which also sometimes has attachments to the lunate which it stabilizes against volar flexion (Viegas et al. 1999) (Fig. 1).

3 The Clinical Problem

The classical presentation of carpal instability is a patient presenting with reduced range of motion and wrist pain and mechanical symptoms, usually a clunk. Such a presentation requires the clinician to establish the cause of the mechanical symptoms by identifying the site of instability.

A clunk is described as a low-pitched dull sound, caused by sudden subluxation or reduction of a partially dislocated carpal bone (Gilula et al. 2002). Various types are described (Garcia-Elias 2008). The origin may be from a particular carpal row with disruption of the SL ligament within the proximal carpal row the most frequently described entity (Amadio 1991). LT instability is a less frequently encountered pattern of proximal carpal row instability. In the authors' experience midcarpal laxity or instability (MCI) is the most frequently encountered cause of the clunking wrist in daily practice.

The most frequently used and widely recognized system for the classification of carpal instability is the MAYO classification. This system identifies four categories of instability (Dobyns 1998).

- Type I: Carpal instability dissociative (CID), representing instability occurring within a carpal row with S-L or L-T intercarpal ligament disruption as examples.
- Type II: Carpal instability non-dissociative (CIND), described as carpal instability between rows. This falls into three broad groups: instability between the radius and proximal carpal row, instability between the proximal and distal carpal rows, or a combination of the two.
- Type III: Carpal instability complex (CIC), a combination of types I and II.
- Type IV: Adaptive carpal instability (CIA), in which abnormal carpal kinematics result from trauma such as a distal radial malunion, or congenital dysplasia.

The reality is frequently more complex than this apparently simple classification suggests and the clinical situation is rarely clear. Because of this imaging assessment is commonly required.

4 Imaging

4.1 Conventional Radiography

The primary imaging modality for wrist problems in general and specifically for patients with an unstable wrist is conventional radiography. It is recommended that both wrists are imaged enabling comparison; this can only be done if standardized techniques are used. Although this standardized technique is well described in the literature (Gilula et al. 2002; Peh and Gilula 1994; Weiss et al. 2007), awareness of such standardization among radiographers and clinicians is often lacking. Training of radiology technicians and radiographers in how to achieve optimal and reproducible images should be part of the clinical responsibility of the supervising radiologist. The measurement of specific angles that are extensively described in the literature with respect to carpal instabilities can only be done reliably on these standardized images (Gilula et al. 2002). Ideally, the technician should be part of the team dealing with wrist pathologies.

Although the use of conventional PA and lateral radiographs is widely adopted, the value of additional views is questionable and debated in the literature and

among clinicians. Several additional views (instability series and/or stress views) are described; PA views with maximal ulnar and maximal radial deviation, and AP clenched fist views are among the ones most commonly used (Gilula et al. 2002; Peh and Gilula 1994; Weiss et al. 2007; De Filippo et al 2006; Metz et al. 1997; Pliefke et al. 2008). In some cases up to 15 different additional views to analyze the wrist of a single patient are described (Metz et al. 1997). However, the literature on standardization of technique and reproducibility of these additional views is very limited. Although these views are described as being advantageous for analyzing wrist instability in the authors' opinion they hold significant limitations. Too many variables are introduced, for instance the maximum ulnar or radial deviation differs enormously between patients and within the same patient at different time points. Furthermore, these views have not been tested in a healthy population with no established normal parameters (Toms et al. 2011). An additional problem is that views with maximal ulnar and radial deviation only provide information on the end points of deviation and lack information on the whole pathway of the movement (see section on 4D imaging). One also has to be aware of the normal movement patterns of the carpals and their projection on the radiographs in normal situations. In maximal radial deviation the projection of the scaphoid and lunate is completely different compared to views in maximal ulnar deviation. If the radiologist is unaware of this phenomenon, adequate interpretation of these views is difficult.

4.2 Signs and Angles

The classic signs described on PA and lateral radiographs of the wrist are the dorsal intercalated segmental instability (DISI) and volar intercalated segmental instability (VISI) pattern (Gilula et al. 2002). It must be remembered that these are not diagnoses as such; they are merely signs reflecting underlying pathology although they are also seen in healthy individuals (then sometimes referred to as DISI or VISI configuration (Metz et al 1997)).

A DISI deformity is characterized by dorsal tilting of the lunate compared to the scaphoid. This will result in an increased scapho-lunate (SL) angle, generally above 60–80 degrees (there is some variation in the normal values given in the literature). A DISI pattern is

Fig. 2 DISI deformity on lateral wrist radiograph. There is an increase in the scapholunate angle (see “[Radiography and Arthrography](#)”) (dotted line) between the axis of the scaphoid (red line) and the axis of the lunate (blue line)

classically described in patients with lesions of the SL ligament (Fig. 2) while a VISI pattern is classically described in patients with lesions of the LT ligament however this is actually infrequently seen in LT ligament lesions. A VISI stance is much more frequently encountered in midcarpal instability or a general lax wrist. However, it is important to realize that both are also seen in patients with intact SL and LT ligaments who have other injured ligaments (Dobyns 1998). A VISI deformity is identified when there is volar tilting of the lunate compared to the scaphoid resulting in a decreased scapho-lunate angle. Generally, this is described as below 30 degrees although again numbers vary in the literature. For details of methods of measuring these angles see “[Radiography and Arthrography](#)” in the chapter by Davies, this volume.

4.3 Type I Instabilities

Lesions of the scapholunate ligament are the most common lesions encountered in daily clinical practice. They usually present after a fall on an outstretched hand. Initial radiographs are frequently normal. Although the natural course of an undetected SL ligament injury is unknown, the DISI pattern will usually take some time to develop. Initially carpal stabilization is maintained, predominantly by other intrinsic

Fig. 3 Scapholunate dissociation. There is widening of the scapholunate interval (arrowhead) and the resulting flexion of the scaphoid results in overlapping of the body and distal pole of the scaphoid giving the signet-ring sign

ligaments (for example the STT ligaments. Extrinsic ligaments play no role in maintaining carpal stability in a neutral position, but come under tension in extreme flexion, extension and deviation. It is in the later stages, when other ligaments begin to fail that the DISI deformity starts to develop (Theumann et al. 2006). Other classic signs of a lesion of the SL ligament are widening of the SL distance (traditionally called “Terry Thomas” sign) (Fig. 3). An increase in distance between the scaphoid and lunate bone on a PA wrist radiograph of more than 2 mm can be regarded as suspicious for injury to the ligament, while a gap of greater than 4 mm is considered abnormal. Because of intra-observer differences in measurements it is helpful to recognize that the distance between the individual carpal bones is approximately equal given the cartilage thickness over the carpal bones shows little variation. It may be helpful to image the contralateral wrist as not infrequently the patient has the same SL configuration on each side which may be indicative of a preexisting condition such as congenital laxity of the SL ligament (Vitello and Gordon 2005). Dissociation of the scaphoid and lunate bones as a result of SL ligament disruption results in the scaphoid tending to move into volar flexion. When the normal constraints are removed, the lunotriquetral block has the tendency to move into dorsiflexion. This will result in the DISI pattern and consequently increased SL angle. Another sign on the PA wrist view will be foreshortening of the

Fig. 4 Scapholunate advanced collapse (SLAC). Long-standing scapholunate dissociation has resulted in osteoarthritis with joint space loss and sclerosis at the midcarpal and radioscaphoid joints

scaphoid leading to overlapping of the distal pole of the scaphoid and the body of the scaphoid resulting in the so-called signet-ring sign (Weiss et al. 2007) (Fig. 3). However, this is also seen in a substantial number of normal wrists and will also be seen on inadequate PA views in which there is (even mild) radial deviation (Pliefke et al. 2008). It has to be noted that the flexed position of the scaphoid and the extended position of the lunate is much more easily recognized on the lateral view. In long-standing, often missed, SL lesions a Scapho-Lunate-Advanced-Collapse (SLAC) wrist will develop, although it is unknown how fast this may occur. Depending on the stage of the disease the radiograph will show the SL dissociation combined with osteoarthritis typically at the radioscaphoid and/or the midcarpal joints (Fig. 4). Radiologists need to detect and recognize early SL ligament lesions, in order to prevent this often devastating condition.

If an SL lesion is obvious on a plain radiograph together with the appropriate clinical picture, the diagnosis of a static instability is made (Taleisnik 1984). If the patient is clinically suspected of an SL instability pattern with a normal radiograph then additional imaging has to be performed to rule out a dynamic instability pattern. Several imaging modalities can be used for this purpose although in the authors' opinion cineradiography is extremely valuable (see Other Imaging Modalities/Cineradiography).

Lesions of the Luno-Triquetral (LT) ligament are, in our opinion, probably under diagnosed, but there is no

data about the incidence or prevalence. The pattern of instability is the opposite to that seen in a SL lesion. Since the lunate is separated from the triquetrum but still firmly attached to the scaphoid, it will follow the scaphoid into volar flexion while the triquetrum will dorsiflex which can result in a VISI deformity. The distance between the lunate and triquetrum may be increased.

4.4 Type II Instabilities

Type II instability is instability occurring between carpal rows and/or the distal radius/ulna, at the level of the radiocarpal or midcarpal joint. It is often found in patients with increased laxity of the ligaments resulting in hypermobility. In these patients, there is no history of trauma present and the patient is completely asymptomatic. Nevertheless, extrinsic ligament injury can lead to painful instability. There is an ongoing confusing debate about the terminology, etiology, classification, treatment, and imaging of these conditions in the literature. The most common distinction is between palmar (Lichtman et al. 1993) and dorsal midcarpal instability (Louis et al 1984). The former is more commonly recognized as a clinical entity. The radiographic findings are diverse. All the abnormalities described earlier in SL or LT dissociations are found, although the VISI pattern is described as being the most common abnormality especially in the palmar instability subtype (Toms et al. 2011; Lichtman and Wroten 2006). Again several additional views are described as being helpful. Garcia-Elias describes the forced ulnar and radial deviation and the anterior and posterior drawing views to determine ligament laxity (Garcia-Elias 2008). The absence of normal values for these views and the degrees of laxity in healthy subjects without wrist pain make the use of these views in general practice debatable.

Although no scapholunate ligament tear is identified in mid carpal instability, scapholunate widening may be seen as a sign of general ligament laxity (Garcia-Elias 2008).

4.5 Other Imaging Modalities

4.5.1 MR Imaging and CT

The aim with cross-sectional imaging modalities is to identify the nature and extent of ligamentous

Fig. 5 Coronal 3T images (2mm, dedicated wrist coil) On T1 FS (a), PD (b) and T2 FS (c) the dorsal, functionally most important, component of the scapho-lunate intrinsic ligament (SLIL) is seen. The separate fibers are well delineated (arrowheads)

disruption and to identify any associated abnormality such as articular cartilage damage. As discussed above, the conventional radiographic signs only develop later after injury and direct visualization of the ligaments is required to diagnose their disruption. If primary ligament repair is planned this has to be undertaken early or there is a high risk of nonhealing (Garcia-Elias and Geissler 2005; Lindau 2010).

The sensitivity of MRI for SL ligament tear detection is reported as between 37 and 95 % (Johnstone et al. 1997; Manton et al 2001; Zlatkin et al. 1989). Using non-arthrographic 3T MRI the sensitivity is better for complete tears than for partial tears and the sensitivity and specificity for SL lesions is higher than for LT lesions. Sensitivity is considerably improved by the use of MR arthrography but this turns a non-invasive investigation into one with intra-articular injections in at least 1 or 2 compartments (radiocarpal and midcarpal joints). Sensitivity is reported as between 62 and 100 % (Braun et al. 2003; Meier et al 2002; Schmitt et al. 2003). It is not uncommon to have normal degenerative perforations in the membranous component of the intrinsic ligaments which means that the passage of contrast on MR arthrography between the radiocarpal and midcarpal joints is not in itself evidence of a symptomatic or significant ligament injury. Although 3T conventional MRI shows good sensitivity to intrinsic ligament disruption,

arthrographic contrast still seems to improve sensitivity (Magee 2009). There are no comparative studies between 1.5 and 3T regarding lesions of the SL and/or LT ligament (Saupe 2009; Schmid et al. 2005; Stehling et al 2009). In the authors' experience 3T non-arthrographic studies provide adequate demonstration of the morphology of the important intrinsic wrist ligaments (Figs. 5, 6). When this is combined with functional assessment using videofluoroscopy MR arthrography is rarely needed.

Coronal and axial imaging provides the best means of assessing the intrinsic wrist ligaments. Full-thickness ligament disruption is seen as nonvisualization, or a full-thickness defect in the ligament (Figs. 7, 8). Partial ligament disruption may be appreciated as a focal discontinuity in a component of the ligament (Fig. 9). High signal intensity can be seen in the ligament of fat-saturated images. However, it should be noted that discontinuities in the membranous portion of the ligament may not be significant if the volar and dorsal components of the ligament are intact (Fig. 10).

MRI is the imaging modality of choice for the evaluation of the extrinsic ligaments of the wrist. The palmar scapho-capitate and triquetro-hamo-capitate ligaments, together often called the arcuate ligament are the most important ones to identify in patients with palmar midcarpal instability. The visualization of the arcuate ligament is described in cadavers using

Fig. 6 Coronal 3T images (2mm, dedicated wrist coil) On T1 FS (a), PD (b) and T2 FS (c) the functionally most important volar component of the luno-triquetral intrinsic ligament (LTIL) is seen and separate fibers are well delineated (*arrowheads*)

Fig. 7 Full-thickness tear of scapholunate ligament. **a** Coronal T1 fat suppressed image from MR arthrogram. Only the radial carpal joint was injected with gadolinium, but contrast passes freely through the scapholunate interval into the midcarpal joint as a result of a scapholunate ligament tear (*arrowhead*). Note also contrast is seen in the distal radioulnar joint as a result of a triangular fibrocartilage complex tear. This coronal section only shows the tear in the membranous portion of the ligament. **b** Axial T1 image from MR arthrogram. conventional MR imaging as well as with MR arthrography (Theumann et al. 2003, 2006; Chang et al. 2007); however clinical descriptions of its use are rare (Toms et al. 2011; Theumann et al. 2006).

CT on its own is of less value in the diagnosis of carpal instability. However, combined with an arthrographic injection demonstration of the intrinsic ligaments can be achieved and there is literature comparing MR imaging and MR arthrography versus

Fig. 8 Tear of lunate-triquetral ligament. Coronal T1 fat suppressed MR arthrographic image. There is diastasis of the lunate-triquetral joint with disruption of the lunate-triquetral ligament (*arrow*)

CT arthrography in which the latter is more sensitive especially for partial injuries to the intrinsic ligaments (Schmid et al. 2005; Moser et al. 2007). CT can be useful to assess the later stages of the disease (SLAC wrist), especially to determine the amount of cartilage

Fig. 9 Incomplete tear of scapholunate ligament. **a** Coronal T1 fat suppressed MR arthrographic image through the volar aspect of the scapholunate joint shows disruption of the scapholunate ligament. **b** An adjacent coronal section from the same series showing the scapholunate ligament is intact more dorsally. **c** Axial T1MR arthrographic image through the

proximal scapholunate joint (S = Scaphoid, L = Lunate) confirms the volar scapholunate ligament disruption with an intact dorsal component (*arrowhead*). damage. In the preoperative planning of salvage procedures, such as proximal row carpectomy or four corner fusion, Lunate-Capitate-Triquetrum-Hamate (LCTH) arthrodesis, CT scanning provides essential additional information for the hand surgeon.

4.5.2 Cineradiography

The drawback of cross-sectional imaging (as with radiographs) is the static nature of these modalities. Since instability is essentially a dynamic problem,

dynamic imaging modalities such as cineradiography and fluoroscopy are particularly suited for its investigation (Protas and Jackson 1980). Both wrists can easily be examined, at relatively little cost and in a minimum amount of time compared to an MRI study. Examining both wrists offers the advantage that the examiner has a good idea of the movement pattern of the non-injured wrist and this can be compared with the injured wrist. The images obtained can be easily stored in PACS for reviewing and for demonstration

Fig. 11 Undertaking a cineradiographic examination of the wrist. The patient is seated at the end of the fluoroscopy table at the left side of the examiner. Both wear lead protection. The examiner wears protective lead gloves. The monitors are right in front of the examiner to evaluate the movement patterns in close detail

to the clinician. A standardized protocol has to be performed which should be developed after discussion with the hand surgeon. Different stress tests can be performed, although the Watson test (clinical test for scapho-lunate instability) is difficult to perform due to technical reasons (lead gloves worn by the examiner). In order to perform a fluoroscopic examination one has to understand the normal kinematic movements of the wrist. Normal kinematics are extensively described in several (experimental) studies (Arimitsu et al. 2008; Kaufmann et al. 2006). A routine assessment of the non-injured wrist also helps understanding these normal kinematic patterns.

It is important to position the patient well during fluoroscopy (Fig. 11). The arm rests with the elbow on the fluoroscopy table to eliminate as much muscle action of the upper and lower arm on the hand (Fig. 12). Our protocol consists of: PA and lateral view with radial and ulnar deviation (Fig. 13), lateral view with palmar and dorsal flexion (Fig. 14), lateral view with anterior and posterior drawer test (Fig. 15), and finally the Lichtman test (Fig. 16).

There are surprisingly few studies that deal with the diagnostic accuracy of cineradiography for SL lesions. A study by Pliefke et al. (2008) mentioned a sensitivity of 86 % with a specificity of 95 %. A study by Kwon and Baek 2008, using a cutoff point of a 2 mm scapho-lunate gap at fluoroscopy, mentioned a

Fig. 12 Arm positioning. The elbow of the patient rests on the fluoroscopy table to eliminate forces exerted on the hand

maximum sensitivity of 95 % (Kwon and Baek 2008). In an unpublished study by the authors a sensitivity of 95 % was found. In the authors opinion the most appropriate imaging modality after plain films in cases of SL instability should be a fluoroscopic examination of the wrist because of the aforementioned advantages.

In midcarpal instability the Lichtman test is, in our opinion the most important stress test to perform, both clinically as well as using cineradiography (Lichtman et al. 1981, 1993). In this test the thumb of the investigator is placed over the distal carpal row. With

Fig. 13 The movements of the hand during the beginning of the examination. **a** PA view with radial deviation; **b** PA view with ulnar deviation; **c** lateral view with radial deviation; **d** lateral view with ulnar deviation

palmar translation of the carpus the proximal carpal row will move in flexion and with axial loading the wrist is moved from radial to ulnar deviation (Fig. 16). In midcarpal instability the proximal row will initially fail to translocate radially and extend but will then suddenly snap into position, the so-called “catch-up clunk”. If this is painful the test is called positive and is considered a diagnostic indicator of a symptomatic midcarpal instability. The anterior and posterior drawer tests as described by Garcia-Elias (2008) are also important. The anterior drawing test is aimed at demonstrating laxity of the palmar ligaments especially the scaphotrapezial ligament; the posterior drawer test, in which the hand is translated dorsally compared to the wrist stresses the dorsal ligaments, especially the dorsal scaphotriquetral ligament. It is this test which is felt to be the most important test to demonstrate dorsal midcarpal instability.

5 Understanding of Wrist Biomechanics by 4D Imaging

As discussed above, analysis of motion patterns of the carpal bones is often useful in diagnosis of instability patterns. Analysis of the complete motion trajectory of the carpal bones has been shown to be particularly beneficial when no diagnostic signs are found in radiographs and stress views at maximal radial or ulnar deviation also show no abnormalities (Protas and Jackson 1980; Braunstein et al. 1985; Obermann 1996; Schmitt et al. 2006).

For the past 30 years cineradiography has been the instrument to image these instability patterns. New developments in detecting motion patterns of carpal bones are devoted to 4D imaging of carpal kinematics. Four-dimensional imaging provides for visualization

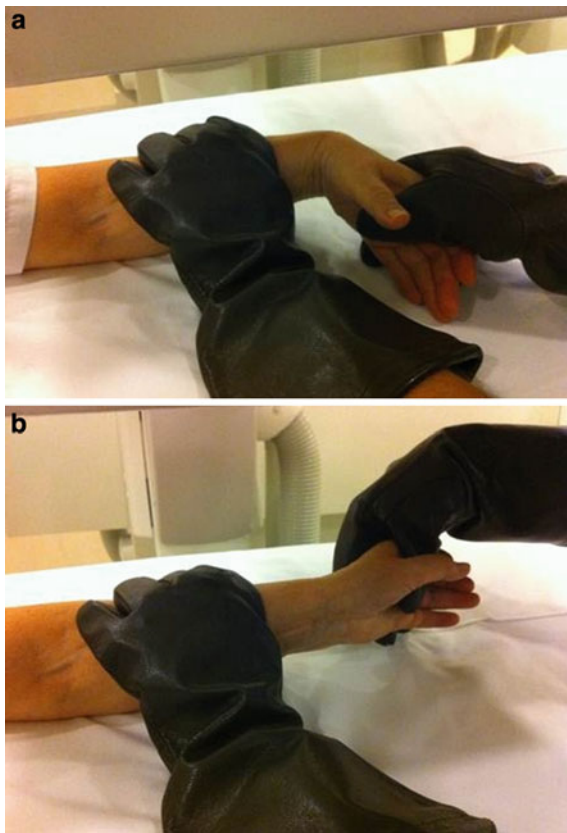

Fig. 14 Additional movements. **a** Lateral view with palmar flexion; **b** lateral view with dorsal flexion (extension)

and quantification of motion patterns of each individual carpal bone in 3D space (Carelsen et al. 2009; Crisco et al. 1999; Snel et al. 2000). Four-dimensional imaging methods are divided into quasi dynamic CT-imaging of the wrist using multiple static poses of the hand (Crisco et al. 1999; Snel et al. 2000) and also true dynamic 4D imaging of carpal bones during movement of the hand (Carelsen et al. 2009). These methods have advantage that they are potentially easier to interpret than cineradiography that uses 2D projections of the bone anatomy for each time frame. In 4D imaging the full 3D geometry of each carpal bone is available in each time frame. This also allows quantitative analysis of motion patterns in terms of translations and rotations of each individual bone as a function of time.

Currently, 4D imaging of the wrist joint is primarily used for basic research on joint biomechanics (Foumani et al. 2010a, b; Moojen et al. 2002, 2003; Moore et al. 2007; Streekstra et al. 2010) but has the

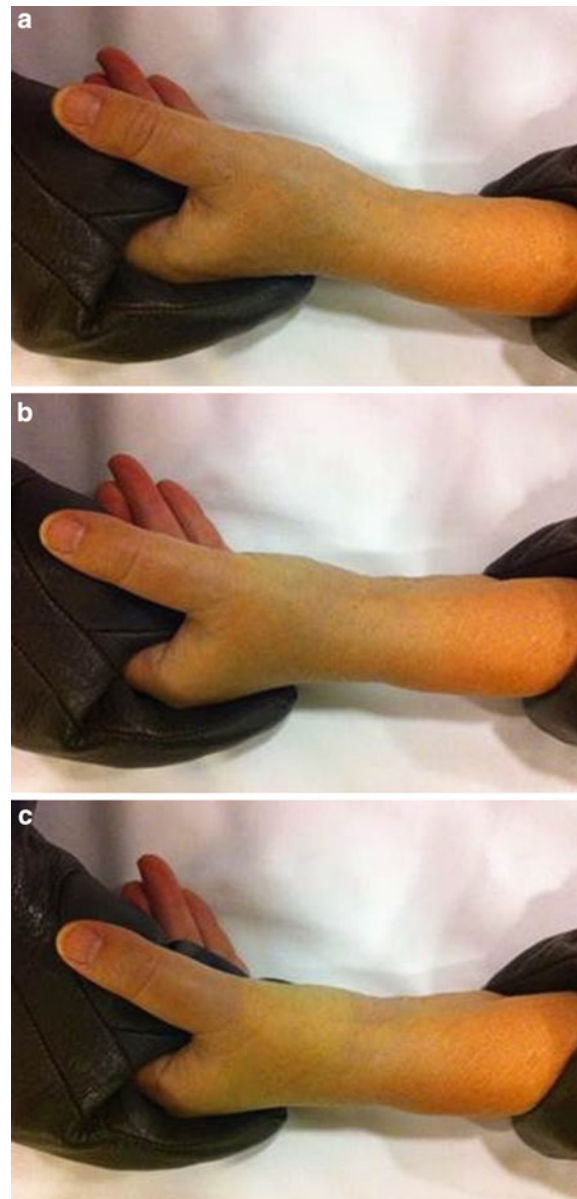

Fig. 15 Additional movements-drawer test. **a** Anterior drawer test is performed by applying pressure at the dorsal side of the hand. **b** The hand is then brought back into neutral. **c** The posterior drawer test is performed by applying pressure on the palmar side of the hand

potential to be used for clinical evaluation true 3D carpal instability patterns. An example of this potential is the detection of 3D motion pattern in a patient with SL dissociation. The motion pattern demonstrated reveals that widening of the bone gap between the scaphoid and lunate is not observed at maximal radial or ulnar deviation but at an intermediate of the

Fig. 16 The Lichtman or midcarpal shift test. **a** Initially the hand is in neutral position. **b** Dorsal pressure is applied. **c–e** Axial loading is then given and the hand is moved from radial to ulnar deviation

hand during the range of motion (Fig. 9). This is in agreement with qualitative cineradiographic observations of carpal motion through radial-ulnar deviation (Snel et al. 2000). The added value of 4D imaging is the quantitative nature of the observation in terms of translations and rotations of carpal bones that may help to develop more objective parameters to diagnose instability patterns of joints (Fig. 17).

Another example of the possible usefulness of the 4D approach in diagnosing wrist problems is the detection of joint space width as a representation of cartilage thickness over the entire joint surface area as a function of hand position (Fig. 18). In patients with SL-dissociation the joint space seems to be reduced

over the entire joint surface compared to healthy volunteers (Foumani et al. 2010a, b).

6 Treatment and Clinical Perspective

One of the key purposes of non-invasive diagnostics is the triage between a conservative or invasive (arthroscopy or arthrotomy) therapeutic approach. In our setting cineradiography aids in tailoring the appropriate treatment for the specific patient with chronic undiagnosed wrist pain (CUWP), making the choice between surgical and physical therapy easier.

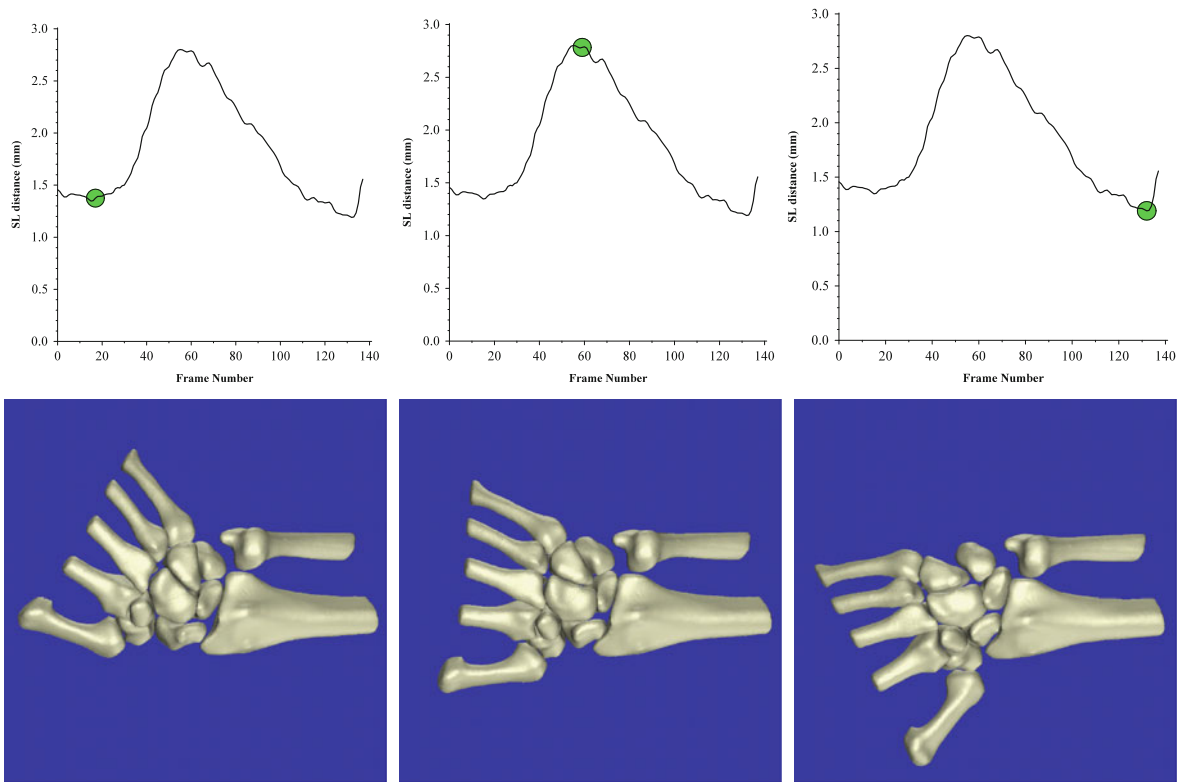

Fig. 17 Three time frames of a 4D image sequence of moving wrist bones in a patient with SL-dissociation. The image sequence shows widening and narrowing of the gap between the scaphoid and lunate (SL-distance) as a function of the hand position

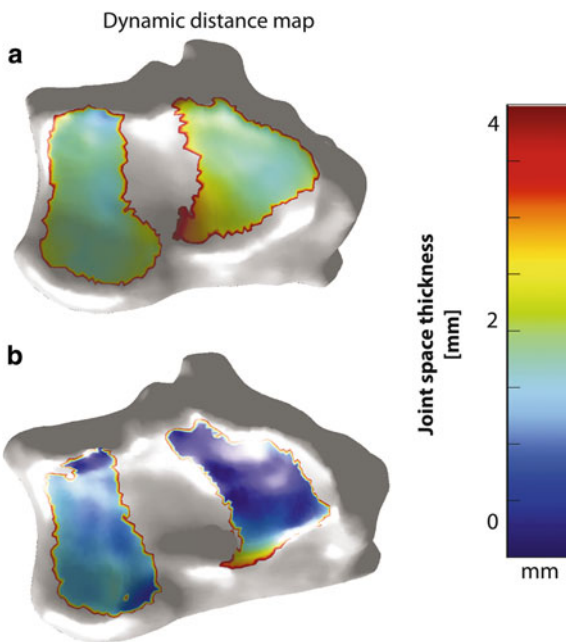

Fig. 18 Dynamic distance maps showing reduced minimal distance between adjacent joint surfaces in a follow up acquisition of patients and healthy volunteers. **a** Healthy Volunteers. **b** Patients with scapholunate dissociation

Fundamental research has shown that chronic wrist pain, without any morphological anatomical substrate detected by state-of-the-art diagnostic tools, could be controlled by non-surgical therapeutic strategies, such as adaptations in motor control (Smeulders et al. 2001). In a comparative study, Smeulders et al. 2001 found a significant difference in fluency of motion between patients and controls. They concluded that disturbance of fine motor control in CUWP may be a contributing factor to chronic wrist pain. A second case control study in patients with CUWP compared to healthy volunteers described a significant difference in fluency of movement between the two groups (Smeulders et al. 2002). This difference was strikingly found in the unaffected wrist, in which the authors hypothesized that chronic wrist pain is maintained by persistent abnormal cerebral motor function.

Since instability of the wrist is a possible cause for unilateral wrist pain, undiagnosed with standard radiography, MRI or CT, the cause of this may also be due to persistent abnormal motor function. This has led to the development of a specialized training regime for this CUWP patient group (Videler et al.

1998). This exercise program tackles unstable wrists combining central cerebral focused motor re-education and muscle strengthen coordination. The use of cine radiography as a triage modality may be a beneficial, cost-effective manner of managing patients with pain in the chronic unstable wrist. In excluding other causes of wrist pain, and a positive finding of midcarpal instability, cineradiography can play a pivotal role.

Acknowledgments We would like to thank M. Foumani MD and Mrs. M.R.W. Evers-van Bavel for their help in preparing the manuscript.

Abstract

Compressive neuropathies (CN) occur when peripheral nerves (PN) are exposed to long-standing excessive pressure (Bard and Lioté 2007; Blancher and Kubis 2007; Graif et al. 1991; Hobson-Webb et al. 2008; Silvestri et al. 1995; Stewart 1993). The chronic compression is responsible for local internal changes in the nerve leading to impaired nerve function and clinical findings reflecting on the nerve affected as well as the duration of compression.

1 Introduction

Compressive neuropathies (CN) occur when peripheral nerves (PN) are exposed to long-standing excessive pressure (Bard and Lioté 2007; Blancher and Kubis 2007; Graif et al. 1991; Hobson-Webb et al. 2008; Silvestri et al. 1995; Stewart 1993). The chronic compression is responsible for local internal changes in the nerve leading to impaired nerve function and clinical findings reflecting on the nerve affected as well as the duration of compression.

The recent increasing interest on CN of the wrist can be explained by their growing frequency, often related to sport or occupational activities, financial consequences due to work absence and increased diagnostic possibilities related to new development in imaging techniques (Aagaard et al. 1998; Beekman and Visser 2004; Spratt et al. 2002). CN are quite common in the routine outpatient practice and can mimic, especially in the early stages, other musculo-skeletal disorders. A carefully taken patient history and a well-performed accurate clinical examination

are the mainstays of a correct diagnosis (El Miedany et al. 2008). Nevertheless, instrumental examinations allow the confirmation of the clinical findings, identification of the level and degree of nerve compression and in most cases permit the assessment of the cause of the compression. There are two main types of clinical examinations obtained in PN assessment: electrodiagnostic and imaging studies. The first excel in the exquisite assessment of nerve function while imaging modalities such as magnetic resonance imaging (MRI) and ultrasound (US) permits a superb evaluation of the morphology of the affected nerves and of most compressive causes (Beekman and Visser 2002; Graif et al. 1991; Martinoli et al. 1996, 2000a, b; 2005; 2008; Padua et al. 2008; Valle and Zamorani 2007). MRI allows an optimal tissue contrast and an accurate assessment of all anatomic structures surrounding the nerves. Because of its multiplanar capability and large field of view, it is the most used imaging technique in local neoplastic disorders. Nevertheless, accurate assessment of thin nerves of the distal arm requires high field equipments and collaborative patients to avoid arm movements even in uncomfortable positions. Patients' claustrophobia limits the possibility of MRI. Presence of a cardiac pacemaker is well-known absolute contraindications to the examination. The advances in US technology have lead to an improvement in the assessment of the musculoskeletal system (Bianchi and Martinoli 2007; van Holsbeeck and Introcaso 2001). Nowadays, US is considered an optimal imaging technique to evaluate the normal anatomy and disorders of PN (Fornage 1988; Peer and Bodner 2008). Examination of the hand and wrist nerves is accurately performed by using high-frequency transducers with exquisite superficial focusing capability and very high definition (Bianchi et al. 1999, 2001). Advantages of US include the ability to assess long segments of nerve quickly and perform dynamic examinations. US is inexpensive, well tolerated by patients, has no contraindications and is currently considered by several authors to be the primary technique for imaging PN pathology.

Because of the high ability of US in assessing PN of the hand and wrist as well as of its low cost, we will focus this chapter on US. First, a review of the normal anatomy of the PN and of the basic pathologic physiology of CN is presented and then follows a description of the normal anatomy of the carpal and

Guyon's tunnels, together with a description of the technique of US examination and US anatomy. Finally, we will present the US appearance of the main conditions causing wrist CN.

2 Normal Anatomy and US Anatomy of PN

Nerve axons, invested by a thin layer of connective tissue (endoneurium), packed together compose the nerve fascicles that are surrounded by the perineurium. The size and number of fascicles that form a nerve depend on the individual nerve, distance from site of origin and amount of pressure the nerve is subjected to. Fascicles are separated by connective tissue (interfascicular epineurium) housing vessels. The nerve trunk is finally surrounded by the superficial epineurium, a thick sheath containing loose connective with elastic fibers and vessels (Kaymak et al. 2008).

High-resolution US can accurately assess the echo texture of normal PN both in vitro and in vivo (Martinoli et al. 2000a, b; Silvestri et al. 1995) (Fig. 1). Longitudinal sonograms image them as composed of multiple hypoechoic parallel but discontinuous linear areas separated by hyperechoic bands. On transverse scans, the hypoechoic areas correspond to oval or rounded images, encircled by a hyperechoic background. Histological correlation demonstrated that the hypoechoic bands correspond to the fascicles that run longitudinally within the body of the nerve, while the hyperechoic background reflects the interfascicular epineurium. The overall number of fascicles detected by US is smaller than their actual number and their number diminishes with the frequency of the US transducers utilized (Silvestri et al. 1995).

3 Pathological Physiology of CN

PN are elastic structures that can adapt and deform secondary to external forces. They run in the extremities surrounded by fat and connective tissue that lessen frictions against adjacent rigid anatomic structures. When crossing joints, PN are usually contained in osteofibrous tunnels that prevent their dislocation during articular movements. A variety of

Fig. 1 Normal ultrasound anatomy of a peripheral nerve. Longitudinal and transverse sonograms. Longitudinal (a) and transverse (b) sonograms obtained on the median nerve at the carpal tunnel show the nerve (arrows) as a well-delimited

structure made by multiple anechoic nerve fascicles (arrowheads). The fascicles are surrounded by the hyperechoic perineurium. In (a), note the different appearance (fibrillar pattern) of the flexor tendons (FT) compared to the median nerve

pathomechanism can be involved in the development of CN. The most common mechanism is a direct extrinsic compression of nerves in anatomic locations in which they are retained in a relatively fixed position and cannot displace on the action of the compressive cause. A typical example is that of a nerve running inside an inextensible osteofibrous tunnel subject to extrinsic compression by a mass. Another mechanism is hypermobility of nerve. In these cases, the nerves are too mobile and are subject to compression or stretching against bony protuberance or fibrous ligaments during displacements.

In EN, nerve changes and clinical symptoms are dependent both on the degree of compression and on its duration. Low pressure applied for short time is relatively well tolerated, and complete recovery can be expected after withdrawal of external compression. On the other side, high pressure for long periods of time can severely alter the morphology and function of nerves and eventually can result in its irreversible damage. Long-standing external compression on a PN results in internal structural changes. First, impaired vein flow leads to increased intraneural interstitial pressure that results in reversible intraneural edema, mainly found at the level of connective tissue. In more prolonged compressions, ischemia due to damage of the vasa nervorum, the small vessels that are responsible for the vascularization of the nerve trunk, leads to irreversible internal fibrosis. This results lastly in myelin sheath and axonal degeneration. Such

morphological changes alter nerve conduction with subsequent sensitive or motor impairment depending on the type of nerve affected.

Wrist CN are mainly observed as a consequence of nerve compression inside inextensible fibrous tunnels. The most frequent is the carpal tunnel syndrome (CTS), which follows the entrapment of the median nerve (MN) inside the carpal tunnel (CT) (Ashraf et al. 2009; Bianchi et al. 2007; Boutte et al. 2009; Buchberger et al. 1991, 1992; Duncan et al. 1999; Pinilla et al. 2008; Sernik et al. 2008). Entrapment of the ulnar nerve (UN) at the Guyon's tunnel (GT) is less frequent (Ashraf et al. 2009; Bianchi et al. 2004; Patel et al.).

4 Anatomy of the Nerves of the Wrist and Hand

The main nerves found in the wrist region are the MN, radial nerve (RN) and UN. The MN descends inside the anterior compartment of the forearm in a median position to enter the hand through the CT, a fibrous canal located at the volar aspect of the wrist (Bianchi et al. 2007). The CT is an inextensible structure delimited posteriorly by the carpal bones and anteriorly by the transverse carpal ligament (TCL). The TCL is a thick fibrous structure that is continuous with the anterior superficial fascia of the forearm proximally and blends distally with the

palmar aponeurosis of the hand. From an anatomic point of view, two layers compose the TCL. The superficial layer is formed by the distal expansion of the palmaris gracilis tendon that prolongs into the palmar aponeurosis. The deep layer is made by thick transverse fibers forming a rectangular ligament of nearly 3–4 cm of craniocaudal size. The radial aspect of the TCL inserts into the tuberosity of the scaphoid and into the tubercle of the trapezium, while the ulnar attachments are into the pisiform and the hook of the hamate. A vertical septum originates from the inferior radial aspect of the TCL and delimitates a small lateral fibrous tunnel that houses the flexor carpi radialis tendon. The CT is larger proximally at the level of the pisiform and smaller distally at the level of the hook of the hamate. The TCL is thicker and more rigid distally. The CT contains nine tendons, four tendons of the flexor digitorum superficialis and four tendons of the flexor digitorum profundus for the 2nd–5th fingers and the tendon of the flexor pollicis longus. To facilitate tendons gliding inside the tunnel during flexion and extension of the fingers, synovial sheaths, formed by a visceral and a parietal layer, surround them. The visceral layer attaches firmly to the tendons, while the parietal layer adheres to the peritendinous structures. A small amount of synovial fluid retained between the two layers allows their gliding during tendon movements and their smooth gliding. Although a great variability exists in the arrangement of synovial tendon sheaths, they are usually two in number. The lateral surrounds the flexor pollicis longus tendon, while the larger medial one envelops the remaining tendons. Several anatomic variants of the CT can be encountered and can predispose to CTS. A variety of anomalous muscles can be found inside the CT (Touborg-Jensen 1970). They are mainly the result of cranial extension of lubricates muscles or distal extension of a flexor digitorum anomalous bellies. Other variants are less common.

At approximately 5 cm from the proximal wrist crease, the MN leaves the palmar cutaneous branch that supplies the proximal portion of the palm of the hand (Taleisnik 1973). The branch initially runs close to the main nerve trunk. Then, it leaves it to direct laterally and run between the palmaris and flexor carpi radialis tendon. The small sensitive branch then reaches the hand region either running superficially to the TCL or between its two layers. Knowledge of the anatomy and course of the superficial branch is

important since it can be inadvertently injured during TCL section in CT release.

After having released the sensitive branch, the MN enters the tunnel along with the flexor tendons. Inside the CT, it lies just inferior to the TCL, superficial and parallel to the flexor tendons of the index and middle fingers and medial to the flexor pollicis longus tendon. The second branch of the nerve at this level is a thenar motor branch. The branch can detach from the trunk either proximal, inside or distal by rapport to the CT. The different types must be recognized by the surgeon to avoid their inadvertent surgical section. It supplies the thenar muscles. More distally, the MN splits into several sensory branches to the first, second and third digits and the radial half of the fourth digit. Some anatomic variations in the MN must be known since they can facilitate CTS. The most frequent is the so-called bifid MN (Iannicelli et al. 2000, 2001; Propeck et al. 2000). It is due to proximal division of the nerve into two separate nerves that run close one to the other inside the CT. A bifid NM can be seldom associated with persistence of the median artery, another common anatomic variant (Gassner et al. 2002; Kele et al. 2002). In these cases, the artery lies in between the two nerves and runs with them inside the CT. Thrombosis of this anomalous artery can be associated with CTS either because of its enlargement or because of secondary ischemia of the vasa nervorum (Kele et al. 2002). These variations can be easily detected by US. The bifid median nerve appears as a split of the nerve in two trunks that usually have a different size. The nerve can be separated by a variable distance, and usually, they are more easily detected at the level of the pronator quadratus on transverse sonograms. When they run inside the CT, they run closer and are more difficult to be distinguished. The persistent median artery can be easily followed by US since it originates from the ulnar artery at the level of the proximal forearm to descend close to the MN along the anterior aspect of the forearm. Since the artery has approximately the same diameter of the MN fascicles, an accurate technique of examination must be deployed to detect it. In case of doubt, gentle pressure with the transducer results in augmentation of its pulsatility. Color Doppler can be also used to assess the internal blood flow.

The small GT is located palmar and medial to the CT. It is formed by the palmar carpal ligament, which forms the roof, and by the TCL, the pisiform

and the hook of the hamate that constitute the remaining walls. The tunnel houses the UN, and the ulnar artery and veins surrounded by loose connective tissue and fat. As for the CT, accessory muscles can be found running inside the GT (Patel et al.). The most common is the accessory abductor digiti minimi. This muscle takes origin from the antebrachial fascia of palmaris longus tendon at the distal aspect of the forearm. It then directs distally to enter the Guyon's tunnel. Inside the tunnel, it is mostly found running superficially to the UN and UA. Nevertheless, some muscles run in between the two. It then enters the palm of the hand to insert into the base of the proximal phalanx of the small fingers together with the abductor digiti minimi muscles.

5 Technique of US Examination and Normal US Anatomy

US can easily detect the MN and UN at the level of the distal forearm (Aleman et al. 2008; Bianchi et al. 2004, 2007; Jamadar et al. 2001). As for every anatomic district, knowledge of the normal anatomy and of the peculiar nerve echo texture is a definite prerequisite for the detection of PN and differentiation from other surrounding structures such as tendons. The MN can be easily detected since it runs between the tendons of the flexor digitorum superficialis and profundus muscles. The UN runs close to the UA that is readily detected at US because of its pulsatility. The nerve lies just medial to the artery. Detection of the smaller nerves such as the superficial branch of the RN is also possible but necessitates the use of high-frequency transducers and a good experience in PN evaluation.

US accurately depicts both tunnels and their contents (Bianchi and Martinoli 2007; Buchberger et al. 1991, 1992; Peer and Bodner 2008; van Holsbeeck and Introcaso 2001) (Fig. 2). The CT is visualized by transverse and sagittal sonograms. Transverse images are obtained first since they are more panoramic. If obtained with adequate transducers, i.e., larger than 4–5 cm, transverse sonograms allow the simultaneous visualization of all intracanal structures. They are obtained first proximal to the CT, at the level of the pronator quadratus muscle, to localize the different anatomic structures

Fig. 2 In vivo normal ultrasound appearance of the carpal tunnel. Transverse images obtained from cranial (a) to distal (b). At the level of the proximal CT (a), the median nerve (arrow) lies inside the tunnel in a superficial location, between the transverse carpal ligament (arrowheads) and the flexor tendons (FT). *Sc* scaphoid; *Pis* pisiform. The Guyon's tunnel (void arrow) houses the ulnar artery and nerve. At the distal tunnel (b), the transverse carpal ligament appears rectilinear and the median nerve more flattened. *TZ* trapezium; *H* hamate hook

before they enter the canal. Moreover, it is important to explore the cranial portion of the MN since in CTS the MN is larger at this level. More distally, identification of different bone landmarks of the CT is essential in order to perform a correct US examination. At the proximal tunnel, the landmarks are the rounded appearances of the pisiform medially and of the scaphoid laterally. Both bones are covered by a flexor tendon: the flexor carpi radialis lies on the scaphoid, while the flexor carpi ulnaris inserts into the pisiform and, by its more superficial fibers, continues distally as the pisohamate ligament. The TCL appears as a curved linear hyperechoic band connecting the lower face of the pisiform to the scaphoid. Beneath the ligament are imaged the flexor tendons and the MN. Since these run obliquely, the transducer must be tilted toward cranial to correctly depict them and avoid anisotropy. Each tendon can be localized by its anatomic position and behavior at dynamic scan during the

Fig. 3 Carpal tunnel. Anatomic variations: anomalous muscle. Longitudinal and transverse sonograms obtained with fingers in extension (**a, b**) and flexion (**c, d**). Images obtained in extension show a low-lying accessory bundle (*arrows*) of the flexor

digitorum superficialis muscle. Transverse image shows the displacement of the median nerve (*arrowhead*) by the muscle. Note how the accessory muscle moves cranially to the carpal tunnel in fingers' flexion and is no more evident

movement of the fingers (Chen et al. 1997). No muscles can be found in normal condition inside the CT. In cases of accessory muscles, realization of dynamic examination during flexion and extension of the fingers is mandatory to detect them (Fig. 3). The MN appears as an oval hyperechoic structure containing several rounded hypoechoic fascicles. It lies just deep to the TCL. Bone landmarks of the distal tunnel are the pointed hook of the hamate medially and the flat volar surface of the trapezium laterally. Compared to the proximal tunnel, the distal tunnel is smaller. As a consequence, the flexor tendons appear crowded and hardly distinguishable and the MN more flattened. The distal TCL is thicker and more rectilinear. Sagittal images are then obtained over the flexor tendons and the MN that presents the characteristic fascicular internal appearance (Bianchi et al. 2007; Bianchi and Martinoli 2007). The occurrence of a bifid MN, found in as many as 2.8% of normal subjects, appears at US as a splitting of the nerve at the proximal level (Fig. 4). In the distal canal, the two nerves are found closer and are difficult to distinguish. Bifid MN can be also involved in CTS

(Bayrak et al. 2008). The occurrence of an accessory median artery located close to a normal or bifid MN inside the CT is a well-known anatomic variation (Fig. 4). Its internal flow is readily assessed by color Doppler imaging. US findings of the anomalous artery correlate well with MRI appearance (Fig. 5).

As for the carpal tunnel, transverse images of the Guyon's tunnel are obtained at a proximal and distal level (Fig. 6) (Bianchi et al. 1999, 2004). Proximal sonograms, acquired at the pisiform level, show the thin palmar carpal ligament overlying the pulsatile UA. Once detected the artery, inclination of the transducer helps in depicting the UN that is located between it and the medial aspect of the pisiform. Distal sonograms show the superficial branches of the UA and UN overlying the tip of the hook of the hamate. Tilting the transducer in a way to study the medial aspect of the hypothenar muscles allows the visualization of the medial aspect of the hamate bone and detection of the deep ulnar artery branch and of the deep (motor) branch of the UN surrounded by the hypothenar muscles. Longitudinal sonograms of the branches of the UN are technically

Fig. 4 Carpal tunnel. Anatomic variations: bifid median nerve with persistent median artery. Transverse (a) and transverse color Doppler (b) sonograms. Images show a median nerve made by two separate trunk of different size (white arrowheads). A persistent median artery runs between the two nerves (black arrowheads). The artery shows normal internal flow signal at color Doppler

more difficult to be obtained and are of limited help in the assessment of the GT.

Although injections of steroid inside the carpal tunnel are realized by clinical guidance in the vast majority of patients, US can seldom be used to avoid inadvertent MN injury (Smith et al. 2008).

6 CTS

Several articles have demonstrated a good correlation between US data and electrophysiologic measurements in CTS (Kaymak et al. 2008; Kwon et al. 2008; Mondelli et al. 2008). US findings have been extensively described (Bard and Lioté 2007; Bianchi et al. 2007; Buchberger et al. 1992; Hobson-Webb et al. 2008; Klauser et al. 2009; Padua et al. 2008). They can be arbitrary divided into alterations in MN and CT appearance and findings related to the compressive causes.

Fig. 5 Carpal tunnel. Anatomic variations: MRI appearance of persistent median artery. Transverse PD fat sat (a) and PD (b) MR images show the anomalous artery (black arrowheads) located close to the normal MN (white arrowheads)

6.1 Changes in MN Appearance

In long-standing compression inside the CT, the MN shows the alteration in its size as well as morphologic changes. Regardless of the cause of local compression, the nerve presents typically a swollen appearance at the proximal tunnel and decrease in the size in the distal tunnel (Fig. 7). To objective these morphologic changes, two measures have been proposed. The first is the nerve cross-sectional area that is obtained at the proximal level. Two techniques of measurements have been proposed: the ellipse formula and direct tracing of the axial surface of the nerve that has been shown to be more accurate. A surface greater than 0.10 cm^2 has been reported to be a valuable criterion for the diagnosis. Different authors have defined different values with threshold suggested for MN abnormality between 9 and 14 mm^2 . Klauser reported better results by comparing

Fig. 6 In vivo normal ultrasound appearance of the Guyon's tunnel. Transverse images obtained from cranial (a) to distal (b). At the proximal level (a), the ulnar nerve (white arrowhead) lies inside the tunnel between the ulnar artery (black arrowhead) and the pisiform (Pis). At the distal tunnel (b), note the deep branch of the UN (small white arrowhead) located close to the hook of the hamate (H) and surrounded by muscles (M). The superficial branch of the UA runs in a more superficial location (small black arrowhead)

cross-sectional area measurements of the MN obtained at the level of the carpal tunnel with those obtained at the level of the pronator quadratus muscle (Klauser et al. 2009). The authors found that the difference between the two measurements (Delta CSA) allowed more specific and sensitive results. Use of a Delta CSA threshold of 2 mm^2 yielded the greatest sensitivity (99%) and specificity (100%) for the diagnosis of CTS (Klauser et al. 2009). The second measure is the so-called fattening ratio that is obtained at the distal level and is calculated by dividing the latero-lateral diameter of the nerve for its thickness. A value greater of 4 is associated with CTS.

High-resolution transducers can also show intra-neural changes, i.e., reduced echogenicity and a disorganized internal fascicular pattern due to edema and

Fig. 7 Carpal tunnel syndrome. Morphologic changes in the median nerve. Transverse sonograms obtained in a patient with carpal tunnel syndrome proximal (a) and at the level of the tunnel (b). In (a), the nerve (white arrowhead) presents a regular internal aspect with the hypoechoic nerves fascicules well differentiated from the internal connective tissue. In (b), the nerve (black arrowhead) is swollen with a surface area evaluated at 22.8 mm^2 . It presents a homogenous hypoechoic appearance due to internal edema or fibrosis

fibrosis. Color Doppler techniques can show increased flow signals in the perineural plexus and among the nerve fascicules due to acute neuritis (Fig. 8).

6.2 Changes in CT Appearance

In the wide majority of patients, because of the increased intracanal pressure, the TCL presents a more pronounced convex appearance. This sign, the so-called bulging of TCL, is found either at proximal or at distal tunnel (Buchberger et al. 1991, 1992). Objective assessment of bulging has been reported at the distal tunnel and can be obtained by measuring the distance from the most superficial point of the TCL to a line connecting the tips of the hook of the hamate and the tubercle of the trapezium. A distance equal or greater than 4 mm is considered abnormal and

Fig. 8 Carpal tunnel syndrome. Color Doppler changes in the median nerve. Longitudinal (**a**) and transverse (**b**) sonograms obtained in a patient with carpal tunnel syndrome. In both

images vascular signals inside the nerve (*arrowheads*) are evident due to hyperemia secondary to nerve compression

Fig. 9 Carpal tunnel syndrome. Causes of nerve compression. Tenosynovitis. **a** transverse color Doppler sonogram in a patient with carpal tunnel syndrome due to aspecific tenosynovitis. Images show the tendons (*black arrows*) surrounded by hypoechoic thickened synovium (*white arrow*). Note displacement of the median nerve (*arrowhead*). No hypervascular changes are noted inside the synovium. **b** serous tenosynovitis of the flexor tendons revealed by an anechoic effusion (*asterisk*) located inside the tendon sheath

significantly associated with CTS. Sometimes increased thickness of the TCL can be noted together with focal calcifications.

6.3 Demonstration of Compressive Causes

The vast majority of CTS is due to aspecific tenosynovitis of the flexor tendons. US demonstrates tenosynovitis as a hypoechoic halo surrounding the

Fig. 11 Carpal tunnel syndrome. Post-surgical appearance. Normal findings at transverse sonograms obtained at the proximal (a) and distal (b) tunnel. Both images show a palmar

displacement of the median nerve because of correct release of the transverse carpal ligament. *FT* flexor tendons; *Sc* scaphoid; *Tr* trapezium; *HH* hook of the hamate; *arrowheads* median nerve

Fig. 12 Carpal tunnel syndrome. Post-surgical complications. Thickening of the transverse carpal ligament. Longitudinal sonogram. Image shows an irregular hypoechoic thickening of the transverse carpal ligament (*black arrowheads*) compressing the median nerve (*white arrows*). *FT* flexor tendons

Fig. 13 Carpal tunnel syndrome. Post-surgical complications. Partial release of the transverse carpal ligament. Longitudinal sonogram. Image shows the release of the distal transverse carpal ligament that appears hypoechoic (*black arrowhead*). The proximal ligament was not sectioned at surgery and still compresses the median nerve. Note swelling and hypoechoic- enicity of the proximal to the compression site (*white arrow*). *FT* flexor tendons

Fig. 14 Carpal tunnel syndrome. Post-surgical complications. Trauma of a bifid median nerve at transverse sonograms. Images obtained proximal to (a) and inside (b) the tunnel shows a hypoechoic traumatic neuroma of a trunk of the bifid median nerve secondary to local trauma during arthroscopy. *FT* flexor tendons; *arrowheads* bifid median nerve

tendons due to fluid effusion and thickening of the tendon synovial sheaths (Fig. 9). Typically, tenosynovitis facilitates the visualization and differentiation of the tendons running within the tunnel because of the increased contrast between the hypoechoic synovium and the hyperechoic tendons. Color Doppler can detect hyperemic changes within the inflamed synovium or more rarely inside the tendons. Sometimes a

definite fluid effusion can be detected inside the tendons sheath as a hypoechoic collection located at the proximal cul-de-sac of the tendon sheath (Fig. 9). Unfortunately, the US appearance of tenosynovitis is aspecific, and US does not allow the differentiation among inflammation secondary to systemic arthropathies such as rheumatoid arthritis or infections and other possible etiologies.

Fig. 15 Carpal tunnel syndrome. Post-surgical complications. Section of a branch of the median nerve. Longitudinal sonogram. Image obtained at the palm of the hand shows complete interruption of one of the distal branch of the median nerve (callipers) secondary to local trauma during arthroscopy. *Black arrowheads* proximal and distal stump neuroma; *white arrowheads* normal nerve portions

Focal masses inside the tunnel are easily detected by US. US can detect accessory muscles as well-delimited hypoechoic masses that exhibit the same internal echo texture of normal peripheral muscles (Fig. 3). Dynamic examination is particularly useful in their detection since it shows the muscle entering/leaving the CT during flexion/extension of the fingers. Transverse images are best suited to show the displacement and compression of the nerve during movements of the fingers. Ganglia are the most common masses found inside the CT. They are cystic lesions with fibrous wall, filled by tick mucinous fluid, that are depicted by US as polilobulated, hypoanechoic structures with well-defined borders and internal septa. Older ganglia show thickening of the peripheral wall and of the internal septa. No internal flow signals are depicted by color Doppler in uncomplicated ganglia, while discrete hyperemia can be detected in recent rupture. Amyloid deposits are rare causes of CTS and can be seen in long-standing renal failure. US images them as solid hypoechoic ill-defined lesions. Knowledge of the underlying systemic disorder is obviously a prerequisite for the US diagnosis. A hypertrophied callus secondary to a

Transverse sonograms obtained from proximal to distal (a-d). **a** In the more proximal image, the branch is normal (*white arrowhead*). *Arrow* median nerve. **b** More distally, the branch

is swollen and hypoechoic due to traumatic neuroma (**c**) at the level of the section of the transverse carpal ligament, US shows an irregular area of fibrosis (*arrow*). The branch is not visible. **d** More distally, the branch presents a normal appearance. *FCR* flexor carpi radialis tendon

Fig. 17 Guyon's tunnel. Anatomic variations: anomalous muscle. Transverse sonograms obtained on the distal forearm (a) and at the level of the Guyon's tunnel (b). Proximal image (a) shows an accessory abductor digiti minimi muscle (*asterisk*) originating from the antebrachial fascia. In (b), the muscle runs within the Guyon's tunnel. It displaces anteriorly the ulnar artery (*black arrowhead*) and nerve (*white arrowhead*). FCU flexor carpi ulnaris; Pis pisiform

fracture of the distal radius or palmar displacement of bone fragments can cause compression of the MN. They are best evaluated by standard radiographs or CT. Nevertheless, they can also be assessed by US (Fig. 10). In chondrocalcinosis, calcified deposits in the volar capsule of the wrist joint can also result in a mass effect with secondary displacement of the MN (Fig. 10). A volar subluxed or dislocated semilunar is rapidly detected by US inside the CT by its characteristic outline. Neurogenic tumors located inside the CT are a rare cause of CTS. They appear as hypo-echoic masses with well-defined borders located close to the MN. A definite differential diagnosis between Schwannomas and neurofibromas can be difficult, if not impossible, at US. Schwannomas are usually eccentric to the nerve and can show high internal vascular signals at color Doppler, while in neurofibromas nerve fascicle enter the relatively avascular tumor. Lipofibromatous is a fibrofatty mass that densely infiltrates and encases most commonly the MN. The enlarged nerve can be easily detected by either US or MRI (Toms et al. 2006).

Fig. 18 Guyon's tunnel. Anatomic variations: anomalous muscle. Transverse sonograms obtained at the level of the Guyon's tunnel at rest (a) and during active abduction of the little finger (b). Images show an accessory abductor digiti minimi muscle (*asterisk*) located between the ulnar artery (*black arrowhead*) and nerve (*white arrowhead*). In (b), note the increase in the size of the accessory muscle (*asterisk*) during contraction and secondary displacement of the ulnar artery and nerve. Pis pisiform

US is useful in the assessment of post-operative PN lesions (Peer et al. 2001) and also has a role in recurrent symptoms or complications (Tagliafico et al. 2008) after CTS release and in the post-surgical follow-up (Smith et al. 2008). In well-performed surgical release of the TCL, the MN can be seen displaced anteriorly. Transverse images are best suited to assess the absence of persistent compression (Fig. 11). Recurrences are mainly related to thickening of the TCL due to local fibrosis (Fig. 12) or incomplete surgical section of the TCL. Incomplete sections of the proximal portion of the TCL are mostly seen in patients operated by an endoscopic approach. In these patients, US usually detects the swollen, interrupted distal TCL; while in a more proximal location, the ligament appear continuous (Fig. 13). The most common complications of endoscopic release are

Fig. 19 Guyon's tunnel. Intracanal ganglion cyst. Transverse sonograms obtained at the level of the Guyon's tunnel. **a** note the ganglion (*asterisk*) appearing as an anechoic cystic lesion located inside the tunnel. **b** US-guided needle puncture.

Note the needle (*white arrowhead*) located in the center of the ganglion. **c** After aspiration of the mucoid content, the injected steroid presents as hyperechoic foci (*black arrowhead*). *Pis* pisiform

section of the MN. They are more commonly encountered in patients with bifid MN (Fig. 14). They appear as partial or complete interruption of the nerve that can show focal swelling due to amputation neuromas. Inadvertent section of distal branches of the MN at the palm of the hand can be also detected (Fig. 15). Cut of the palmar sensitive branch of the MN during sectioning of the TCL can be seen in open release of CTS (Tagliafico et al. 2008). In addition, the small branch can be injured in the post-operative course due to the development of local fibrosis of the perineural tissues (Fig. 16).

7 Guyon's Tunnel Syndrome

Compared to the common CTS, ulnar neuropathies at the Guyon's canal are rare. Depending on the site of compression (cranial or distal to nerve bifurcation),

various syndromes due to the involvement of either the main nerve trunk or its motor and sensitive branches have been described.

Chronic external pressure caused by repetitive utilization of tools during manual work or sport activities (such as biking), in which chronic stress is applied on the ulnar aspect of the volar wrist, can cause a nerve entrapment. Focal masses are easily detected on transverse US scans. As mentioned before, anomalous muscles inside the GT are well depicted by US (Fig. 17). Since there are no muscles inside the tunnel in normal conditions, the diagnosis is straightforward in case of a mass located inside the tunnel, which presents the typical internal muscle architecture. Color Doppler does not show any internal flow signals. Contrasted abduction of the small finger during dynamic US examination reveals shortening and increase in the axial diameters of the muscle due to its contraction (Fig. 18). These muscles

Fig. 20 Post-traumatic neuroma of the superficial branch of the radial nerve. Transverse images (a) A proximal image shows a normal branch (*white arrowhead*). More distally (b), the nerve is swollen and hypoechoic (*black arrowhead*) because of a post-traumatic neuroma

are however normally well tolerated. When hypertrophied, they can compress the UN (Patel et al.). Ganglion cysts usually related to the pisotriquetrum joint space can develop inside the GT. They present at US as anechoic cystic lesion with sharp borders (Fig. 19). US can effectively guide a real-time cystic puncture, thus avoiding inadvertent injury to the UA and UN. Steroid injection can also be guided by US (Fig. 19).

8 Disorders of the Superficial Branch of the RN

The superficial branch of the RN is rarely affected by CN at the wrist or hand. This small sensitive nerve can be compressed by local fibrosis of the tissues surrounding the retinaculum of the first extensor compartment in patients affected by De Quervain's tenosynovitis (Lanzetta and Foucher 1993). US shows aspecific thickening of the nerve associated

with the typical findings of De Quervain's stenosing tenosynovitis. In rare cases, the superficial branch can be unintentionally injured during surgery (Fig. 20).

9 Key Points

US bone landmarks of the carpal tunnel

- Radial side proximal: tubercle of the scaphoid (rounded)
- Ulnar side proximal: pisiform (rounded)
- Radial side distal: trapezium (flat)
- Ulnar side distal: hook of the hamate (pointed)

US appearance in peripheral nerves entrapment

- Nerve swollen and hypoechoic proximal to the entrapment site
- Nerve thinned at the level of the entrapment
- Nerve swollen and hypoechoic distal to the entrapment site (less common)
- Internal vascular signals proximal to the entrapment site (less common)

Clinical utility of US in CTS

- Confirm the clinical diagnosis by showing changes in the MN
- Assess the cause of nerve compression
- Illustrate normal anatomic variants that can modify the surgical approach

Most common complication after CT release

- Incomplete resection of the transverse carpal ligament (endoscopic approach)
- Local fibrosis with thickening of the transverse carpal ligament
- Nerve injuries (bifid median nerve) (endoscopic approach)

Abstract

This succinct chapter on osteonecrosis and osteochondrosis in the wrist and hand describes the aetiology and typical bones involved in these conditions. A description of the available of imaging modalities including plain radiographs, computed tomography, scintigraphy and Magnetic resonance imaging are described with their strengths and weaknesses. Detailed individual description and classification of carpal bone osteonecrosis and osteochondrosis including Kienbock's disease of the lunate and the rarer Preiser's disease of the scaphoid are included.

1 Introduction

Osteonecrosis or avascular necrosis of the carpal bones is a common cause for chronic wrist pain, limiting movement and weakening grip strength. In the wrist osteonecrosis most frequently occurs as a result of disruption to the osseous blood supply as a result of trauma. While the scaphoid is the most frequently affected bone in the wrist, osteonecrosis of any of the carpal bones can occur and multiple carpal bone involvement is described (De Smet et al. 1993; Humphrey et al. 2006; Telfer et al. 1994; Zafra et al. 2004; Garcia and Vaca 2006).

The osteochondroses refer to a heterogenous group of conditions with a tendency to affect the immature skeleton. A variety of possible mechanisms have been proposed for these conditions, but those affecting the wrist and hand are characterized by features of osteonecrosis thought to occur through a process of microtrauma.

The most well recognized of these conditions in the hand and wrist is Kienböch's disease affecting the lunate.

Osteonecrosis from any cause can result in late complications, most commonly osteoarthritis and although surgical options meet with varied success, early diagnosis may limit these complications. Conventional radiographs are often the first line imaging investigation but it should be appreciated that the changes seen are relatively late in the disease process. MR imaging is extremely well suited to the detection of the early phases of avascular necrosis, permitting diagnosis before collapse of the carpal bones has occurred (Golimbu et al. 1995).

2 Aetiology

The term osteonecrosis by definition implies bone necrosis or bone death. Originally infection was thought to be the underlying cause but histopathological studies showed that the bone is aseptic and also avascular, implicating vascular insufficiency as the underlying aetiology. A variety of insults may lead to osseous vascular impairment and carpal bones are particularly vulnerable to such insults as they have a poor collateral circulation. Notably osteonecrosis occurs most often in the scaphoid, lunate and capitate bones which have particularly tenuous vascularity (Botte et al. 2004; Gelberman and Gross 1986).

Vascular impairment and therefore osteonecrosis may result from a variety of underlying causes including radiation, vascular, metabolic and systemic conditions. In the wrist the most common cause is trauma, with the scaphoid and capitate most frequently affected. A clear cause for osteonecrosis is not always established. This situation most commonly arises in the lunate where it is termed Kienböch's disease. Despite the absence of a history of trauma it is generally believed that the aetiology of these conditions is traumatic in nature, rather than relating to a primary vascular event (Resnick 2002). Other osteochondroses described in the hand and wrist are Preiser's disease (scaphoid), Thiemann's disease (phalanges) and Dieterich's disease (metacarpal head) (Botte et al. 2004; de Smet 2000; Ferlic and Morin 1989; Herbert and Lanzetta 1994; Tashjian et al. 2004).

The different cellular elements within bone (including osteocytes, osteoblasts and osteoclasts) differ in their susceptibilities to anoxia. After physical

disruption of blood flow, the haemopoietic elements are generally acknowledged to be the first to undergo anoxic death followed by bone cells and subsequently bone marrow fat cells (Crues 1986; Glimcher and Kenzora 1979a, b, c). This means that temporary anoxia can result in varying degrees of cell death potentially affecting the haemopoietic elements without necessarily involving the other bone cells. It is generally recognised that once marrow fat cell death occurs the involved segment of bone can be labelled as infarcted. Marrow involvement is critical to the detection of bone infarction on MRI examination.

3 Imaging Techniques

3.1 Radiography

In most cases the X-ray findings lag behind the clinical manifestations, hence the initial radiographs may appear normal. The onset of fat necrosis brings with it vasodilation in the still vascularised surrounding bone resulting in an influx of inflammatory cells. Dead bone starts to undergo removal by osteoclasts and this means that potentially viable bone will become relatively osteopaenic. This comparatively radiolucent bone will be adjacent to non-viable necrotic bone which becomes relatively sclerotic (Fig. 1). As the process progresses increasing sclerosis followed by collapse and fragmentation of the avascular bone occurs.

3.2 Computed Tomography

Computerised tomography is rarely used in the primary assessment of carpal bone osteonecrosis. However the complex 3-D anatomy of the carpal bones means it can be useful for providing information relating to the extent of volume reduction of the affected bone and the detection of early subchondral collapse, along with the detection of secondary changes such as osteoarthritis. It can also prove more sensitive to the detection of an associated un-united fracture and sclerosis in the avascular bone.

The base of the hook of hamate is at a relatively high risk for avascular necrosis following fracture (Telfer et al. 1994). The complex anatomy of this bone means avascular necrosis is often best detected at CT.

Fig. 1 Early avascular necrosis 8 weeks following a scaphoid fracture. **a** Ulnar deviated PA film with tube angulation and **b** Anterior Oblique shows a fracture line. The difference in

density can be appreciated between the increased density of the proximal pole, accentuated by the relative osteopaenia of the distal pole

CT changes seen in osteonecrotic bone reflect the plain film findings of sclerosis, appreciated as increased attenuation and subsequent collapse and fragmentation (Fig. 2). Cystic change may be seen along the margins of an un-united fracture (Bush et al. 1987).

3.3 Magnetic Resonance Imaging

Magnetic resonance is the imaging modality of choice for the early detection of osteonecrosis, depicting marrow signal changes before changes are apparent using plain films and CT (Imhof et al. 1997). Although scintigraphy may offer similar sensitivity it shows less specificity when compared with MRI. The signal abnormality on MRI depends on alteration of the fat cells in the bone marrow, initially seen as oedema-like change within the marrow, appreciated as a reduction in the normal fat signal on T1 weighted imaging and increased signal on water sensitive sequences (Imhof et al. 1997; Mitchell et al. 1989) (Fig. 3). As the process progresses areas of reduced signal intensity on T2 weighted imaging emerge, surrounded by areas of increased signal intensity representing the interface between non-viable bone and reparative granulation tissue. At this stage MRI may show a characteristic serpiginous double line at

Fig. 2 Scaphoid fracture with early avascular necrosis. The sagittal CT reformat shows increased attenuation to the proximal pole of the scaphoid reflecting osteonecrotic bone with relative osteopaenia in the distal pole

the interface between the necrotic area and the fibrovascular granulation tissue. The double line represents the granulation tissue adjacent to reactive

Fig. 3 **a** Coronal T1 and **b** Coronal Oblique T2 (fat sat) MR images obtained 18 days following scaphoid fracture. On the T1 the fracture line interrupts the marrow signal with patchy signal reduction around the fracture line seen as increased T2 signal (oedema) on the T2 image. Note the normal marrow

signal at the proximal pole. Five weeks later (**c**) Coronal T1 MR image shows diffuse low signal and (**d**) Coronal T2 (fat sat) image shows diffuse increased signal in the proximal pole with normal signal in the distal pole. The appearances represent early AVN

bone formation (Imhof et al. 1997; Mitchell et al. 1989). While the two lines may not always be distinguished a sharp line of demarcation is still a typical and helpful feature (Fig. 4). Contrast-enhanced imaging can be performed and may help distinguish viable from non-viable bone but should be interpreted with caution. See Sect. 4.1.

3.4 Bone Scintigraphy

The relative insensitivity of radiographs for detecting the early stages of avascular necrosis has led to the increased use of MRI for this role. Bone scintigraphy is also very sensitive to the early detection of osteonecrosis although it is relatively non-specific and

Fig. 4 **a** Coronal T1 W shows abnormal low signal within the proximal scaphoid bone **b** PD (fat sat) image also shows abnormal low signal delineated by a high signal serpiginous line. There is surrounding abnormal low signal within the

proximal scaphoid bone demarcating the dead bone within the proximal pole and representing granulation tissue. There was no history of trauma in this case, which represents the partial form of Preiser's disease

should always be interpreted alongside conventional radiographic findings. In the early stages of avascular necrosis increased metabolic activity in the bone is seen as higher uptake in bone scintigraphy on early and late phase scanning. Later bone scintigraphy typically indicates an area of decreased radio-tracer uptake; a cold spot or photopenic region. This in isolation is not diagnostic of osteonecrosis as other conditions including myeloma, some skeletal metastases, irradiation, haemangiomas and infection can also result in reduced or impaired tracer uptake.

4 Scaphoid

The scaphoid is the most common site for osteonecrosis to occur in the wrist. This is because of its high susceptibility to trauma and precarious blood supply. The proximal pole of the scaphoid receives its blood supply in a retrograde fashion from small dorsal ridge vessels entering the waist of the scaphoid from the radial artery. These vessels provide around 70–80% of the internal vascularity of the bone, in particular to the proximal pole. A separate vascular supply from the palmar aspect supplies the remaining internal vascularity, all to the region of the distal pole (Botte et al. 2004). The consequent tenuous blood

supply to the proximal pole makes it vulnerable to osteonecrosis following fracture. There is a reported frequency of proximal pole osteonecrosis of between 11 and 65% following scaphoid fracture (Mazet and Hohl 1963). However this varies according to the site of the fracture, with fractures of the proximal third having the highest incidence of osteonecrosis and a reducing incidence with more distally located fractures. Osteonecrosis has been reported as occurring in the distal pole of the scaphoid following fracture, but this is extremely rare (Sherman et al. 1983).

Plain radiographs of established cases show an increased bone density in the affected scaphoid seen at between 4 and 8 weeks and associated with non-union (Fig. 1). Later reduction in size, fragmentation and secondary degenerative changes can be seen (Fig. 5).

MR imaging is now the modality of choice for the detection of early avascular necrosis. Typically, MR will show low signal intensity within the bone marrow of the proximal pole on both the T1 and T2 weighted images. It has been suggested that high signal on T2 implies viability of bone but this is not the case (Cerezal et al. 2000) (Fig. 6a). Contrast enhancement significantly increases the detection of non-viable bone but the use of dynamic enhancement studies does not appear to improve sensitivity (Cerezal et al. 2000; Megerle et al. 2011; Donati et al.

Fig. 5 Established proximal pole scaphoid osteonecrosis 6 months following fracture. There is fracture non-union with dense sclerosis and volume loss in the proximal pole. Cystic change is also seen about the fracture line

2011) (Fig. 6b). While studies do indicate that MRI provides a good assessment of the vascularity of the bone as assessed with punctate bleeding at the time of surgery; the general picture that is emerging suggests that MRI, even with gadolinium enhancement, is less good at predicting outcome of surgery in terms of union and revascularization (Cerezal et al. 2000; Megerle et al. 2011; Schmitt et al. 2011; Singh et al. 2004; Dawson et al. 2001).

4.1 Preiser's Disease

Preiser's disease is a rare condition which results in ischaemia of the scaphoid bone without a history of trauma. Rarely it can occur bilaterally and has also been described with Kienböck's disease (de Smet 2000; Ferlic and Morin 1989; Herbert and Lanzetta 1994) (Fig. 7). Risk factors may include excessive alcohol intake, corticosteroid administration, chemotherapy and other disease processes.

Histologically, there are empty bony lacunae, necrotic marrow and partly degenerated articular cartilage. Clinically, pain along the dorsal and radial aspects of the wrist is typical.

Conventional radiographic images and CT show the expected sclerosis, volume loss and cystic change which, with time progresses to collapse and fragmentation (Fig. 7 and 8). Using MRI two patterns can be identified, a partial or focal form with ischaemia of the proximal half of the scaphoid (Fig. 4) and a diffuse form with complete ischaemia and necrosis (Fig. 7) (Kalainov et al. 2003). The former, partial type has a better prognosis. Isolated non-traumatic osteonecrosis of the distal pole of the scaphoid has also been described (Garg et al. 2011).

Treatment protocols for Preiser's disease include wrist immobilization and cortisone injections. Surgical options include partial excision with replacement by non-vascularised or vascularised bone graft, proximal row carpectomy, scaphoid excision with midcarpal fusion and total wrist fusion.

5 Lunate

5.1 Kienböck's Disease

Kienböck's disease is most commonly observed in patients between the ages of 20 and 40 years, with a predilection for the right hand in persons engaged in manual labour. Some patients have an antecedent history of trauma but the majority of cases are idiopathic. There is a strong association between ulna minus variance and Kienböck's disease, which has led to the suggestion that abnormality in loading is an important aspect in the aetiology, although 40% of cases are seen in neutral ulna variance. Additionally, negative ulnar variance is usually bilateral and Kienböck's disease is rarely bilateral. Other theories that have been postulated include medialisation of the lunate, horizontalisation of the radial epiphysis or abnormal morphology of the lunate. In some individuals there is a variation in the blood supply of the lunate; a single dominant branch (8%) rather than a dual supply from volar and dorsal branches with an anastomosis potentially increasing the risk of osteonecrosis (Gelberman and Gross 1986).

5.1.1 Imaging

The appearances of established lunate osteonecrosis on conventional radiographs is initially sclerosis followed by progressive collapse of the lunate and fragmentation (Figs. 9 and 10). Associated findings such as ulnar negative variance may also be seen and in the later stages degenerative change may occur.

Fig. 6 **a** Coronal T2 W (fat sat) shows scaphoid fracture non-union. High signal oedema is seen in the marrow in both the proximal and distal fracture fragments. **b** Coronal T1 W (fat sat) post intravenous gadolinium shows oedema-induced

enhancement in the distal pole with absent enhancement of the oedematous but avascular proximal pole despite the presence of oedematous change on T2 W imaging

Fig. 7 Bilateral Preiser's disease. **a** Reformatted CT. There is sclerosis, fracturing and fragmentation with volume loss in the scaphoid of this patient without trauma. **b** T1 weighted and **c** T2 weighted (fat sat) MR images from the contralateral wrist

show the condition is bilateral, with diffuse signal abnormality throughout the scaphoid with a serpiginous boundary between representing the interface between necrotic bone and granulation tissue Courtesy of Dr Phillip Tirman

Radiographs are important in differentiating osteonecrosis from other causes of wrist pain such as ulna-lunate abutment, fractures, carpal malalignment, instability and arthritis.

CT of the wrist is more sensitive than plain films for demonstrating structural change including sclerosis, compression and fractures of the lunate. Fractures are more common in Kienböck's disease than previously reported (Fig. 11). Earlier detection of fractures by CT, before collapse of the lunate occurs, may allow treatment to prevent the collapse (Friedman et al. 1991).

As with osteonecrosis at other sites, MRI and scintigraphy provide earlier evidence of Kienböck's disease and can help establish the diagnosis in the presence of normal conventional radiographs. Two patterns of abnormality have been defined on MRI, one involving only focal involvement of the radial half of the lunate, the second being a diffused reduction in T1 signal throughout the bone marrow (Sowa et al. 1989 Nov) (Fig. 12). In common with osteonecrosis elsewhere, marrow signal appears low on T2 imaging in the later stages of the disease, but initially high signal may

Fig. 8 Preiser's disease. The scaphoid shows sclerosis and volume loss due to osteonecrosis. There was no history of trauma in this 25-year-old male presenting with wrist pain and successfully treated with a vascularised graft Courtesy of Kimberly K. Amrami MD. Mayo Clinic, Rochester Minnesota, USA

be seen, which may be focal or patchy in distribution. Cystic change and collapse/fragmentation may be seen in the later stages of the disease (Fig. 13).

5.1.2 Staging of Kienböck's Disease

Although many classifications have been proposed they are quite similar, four stages are recognised in the commonly used Lichtman classification (Lichtman et al. 1977).

Stage I: Pre-radiological disease.

The plain radiograph is normal except for possible predisposing factors such as negative ulnar variance. Detection of stage 1 disease is by MRI where there is typically internal bone marrow signal change with low signal on T1 W and low or patchy high signal on T2 W imaging. Stage 1 disease can also be detected by bone scintigraphy.

Stage II: Sclerosis of the lunate bone without collapse (Fig. 9).

Stage III: Lunate fragmentation and collapse.

As a consequence of collapse there may be associated scapholunate dissociation and rotatory subluxation of the scaphoid. This has led to subdivision of stage III into stage IIIA: no rotatory subluxation and IIIB: associated scapholunate dissociation and rotatory subluxation.

Fig. 9 Plain radiograph showing sclerosis of the lunate typical features of Kienböck's disease. Note the presence of ulnar negative variance, a typical but not exclusive association with Kienböck's disease

Stage IV: Arthritis of the radiocarpal and mid carpal joints.

Although there is no difficulty in establishing the diagnosis of Kienböck's disease with MRI, many therapeutic options exist. Along with conservative management there are surgical options, including revascularisation of the lunate and lunate unloading by ulnar lengthening or radial shortening. However there is no strong consensus on the indications and results are variable (Kristensen et al. 1986; Weiss et al. 1991).

6 Capitae

Osteonecrosis of the capitae is recognised following fracture or more commonly following midcarpal fracture dislocations (scaphocapitate syndrome) (Tashjian et al. 2004). Although idiopathic osteonecrosis without a history of antecedent trauma is described it is rare (Kutty and Curtin 1995; Lapinsky and Mack 1992). The vascular anatomy of the capitae shares similar features

Fig. 10 Kienböck's disease at a more advanced stage than shown in Fig. 8, with subchondral fracturing and collapse at the proximal pole, again with ulnar minus variance

Fig. 12 Kienböck's Disease. Coronal T1 W image shows diffuse low signal change in the lunate, but there are focal regions of increased and intermediate signal intensity which are often observed in bone necrosis. Courtesy of Dr Muhammed Mubashar, University Hospital South Manchester, UK

Fig. 11 Sagittal CT reformat shows advanced Kienböck's disease with sclerosis, fracture and fragmentation. Early secondary degenerative change at the radioulnar joint can be appreciated as irregular joint space loss and cystic change in the subchondral bone of the radius

to those of the scaphoid with a retrograde internal flow pattern which explains the predominant proximal pole pattern of necrosis.

The changes described on X-ray are of initial proximal pole osteopaenia followed by sclerosis. This may progress to complete fragmentation and collapse. MRI will show typical features of osteonecrosis as previously described.

Treatment often involves excision of the capitate bone with carpal fusion, revascularisation has also been successfully achieved (Murakami et al. 2002).

7 Hamate

Avascular necrosis of the hamate is relatively uncommon and in the cases reported follows trauma. Post-traumatic osteonecrosis of both the hook of hamate and body have been described (Telfer et al.

Fig. 13 Coronal T2 W image showing advanced Kienboch's disease. High signal change is seen associated with cystic change and volume loss

1994; Failla 1993). It has been noted that like the scaphoid and capitate the proximal pole is vascularised via a retrograde circulation and, as would be expected, the proximal pole seems to be more vulnerable (Botte et al. 2004; Tashjian et al. 2004).

8 The Hand

Osteonecrosis has been reported in a variety of bones in the hand, most commonly in the metacarpal heads and about the proximal interphalangeal (PIP) joints of the phalanges. Thiemann's disease is reported as a rare autosomal-dominant form of avascular necrosis affecting the PIP joint (Tashjian et al. 2004). The condition has also been termed juvenile osteochondropathy of the fingers and multiple phalangeal epiphysitis. It usually presents as progressive enlargement of the PIP joints, frequently starting with the middle finger before involving the index and ring fingers. There is often sparing of the little PIP and thumb IP joints. The condition is usually painless, but contractures, finger shortening and deformity are said to be features (Rubinstein 1975). As expected, radiographic features include flattening, sclerosis and fragmentation of the epiphyses.

Osteonecrosis of the metacarpal heads (Dieterich's disease) has been described in association with trauma, systemic lupus erythematosus and steroid use. Radiographs show sclerosis and fragmentation of the metacarpal head which may show features resembling periarticular erosion (Tashjian et al. 2004).

Abstract

Hand and wrist are well recognized as a mirror of disease for various metabolic and endocrine pathologic conditions. Among them, osteoporosis is the most common metabolic bone disorder. It is defined as “a skeletal disease, characterized by decreased bone mineral density (BMD) and micro-architectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture”. As a disease of the elderly, its prevalence will increase as the population ages leading to a need to intensify and optimize the diagnostic techniques for its assessment. BMD is a measurement of bone mass and a reflection of the amount of calcium in bone. Currently, the *gold standard* for measuring BMD is Dual-energy X-ray Absorptiometry (DXA).

1 Introduction

Hand and wrist are well recognized as a mirror of disease for various metabolic and endocrine pathologic conditions (Theodorou et al. 2001). Among them, osteoporosis is the most common metabolic bone disorder. It is defined as “a skeletal disease, characterized by decreased bone mineral density (BMD) and micro-architectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture” (Anonymous 2003). As a disease of the elderly, its prevalence will increase as the population ages leading to a need to intensify and optimize the diagnostic techniques for its assessment. BMD is a measurement of bone mass

and a reflection of the amount of calcium in bone. Currently, the *gold standard* for measuring BMD is Dual-energy X-ray Absorptiometry (DXA). On the basis of the T-score (the difference between the BMD of the patient under examination and the BMD of a standard young adult population) The World Health Organization (WHO) has defined as:

- *normal* T-score values of -1.0 or higher;
- *osteopenia* T-score values of less than -1.0 but higher than -2.5 ;
- *osteoporosis* T-score values of -2.5 or less;
- *severe osteoporosis* T-score values of -2.5 or less with a fragility fracture (Kanis JA, on behalf of the World Health Organization Scientific Group 2007).

Osteoporotic fractures may affect any part of the skeleton except the skull. Most commonly, fractures occur in the distal forearm (Colles' fracture), thoracic and lumbar vertebrae, and proximal femur (hip fracture). Fractures usually have substantial clinical and social impact. Following a fragility fracture, significant pain, disability, and deformity can ensue, compromising life quality and shorten life expectancy (Cockerill et al. 2004; Center et al. 1999). Moreover, if fracture union is not achieved, the patient may suffer long-term disability due also to degenerative joint disease distal to the fracture and to reflex sympathetic dystrophy (Cosman 2005). A prior fracture increases the risk of future fractures (Cummings et al. 1995). Moreover, fractures are often under-recognized and patients who sustain a fragility fracture often do not receive adequate or appropriate medical treatment for the underlying osteoporosis. Given the substantial impact of osteoporosis on both patients and the medical community, it is imperative that physicians improve awareness and knowledge of osteoporosis in the setting of low-energy fractures.

2 Classification of Osteoporosis

Osteoporosis is generally characterized into primary and secondary causes. Primary osteoporosis is divided into type I, postmenopausal osteoporosis, and type II, senile or age-related osteoporosis. Type I represents a high turnover state that occurs after menopause. Type II is largely a failure of osteoblastic bone to form (Lane et al. 2006). In "postmenopausal" osteoporosis there is an apparent excess loss of cancellous bone with relative sparing of cortical bone, and the clinical

syndrome involves Colle's fracture and vertebral fracture. In "senile" osteoporosis there is a more simultaneous loss of both cortical and cancellous bone. The pathogenesis of senile osteoporosis is uncertain, but it is postulated to result from an age-related decline in renal production of 1,25-dihydroxyvitamin D and calcium malabsorption, with subsequent secondary hyperparathyroidism. Fracture syndrome often seen in the patient with senile osteoporosis characteristically involves the hip and pelvis (Ross 1998). Besides the above mentioned, other risk factors like presence of dementia, susceptibility to falling, history of fractures in adulthood, history of fractures in a first-degree relative, frailty, impaired eyesight, insufficient physical activity and low body weight can partly contribute to the development of osteoporosis and its complications (Guglielmi et al. 2008).

Secondary osteoporosis is caused by a multitude of factors, including endocrine disorders, hematopoietic diseases, immobilization, gastric disorders, medications (long-term oral glucocorticoid therapy), increased alcohol intake and smoking (Seeman et al. 1983).

3 Diagnosis of Osteoporosis

3.1 Conventional Radiography

Indications of bone loss on radiographs are generally a reduction in density and changes in morphology. It has been estimated that in most cases osteopenia becomes detectable on conventional radiographs only after a loss of at least 20–40% of the skeletal bone mass (Virtama 1960; Grampp et al. 1993). Nevertheless, conventional radiography is widely available, and it remains useful for the detection of specific alterations in certain instances (e.g., subperiosteal resorption in hyperparathyroidism). Alone and in conjunction with modern, computed-aided, imaging techniques, conventional radiography is widely used for the detection of fractures, for the differential diagnosis of osteopenia, or for follow-up examinations in specific clinical settings (Genant et al. 1996; Guglielmi et al. 1994). Moreover, conventional radiographies are predominantly performed at sites of the peripheral skeleton (calcaneus and distal radius) as surrounding soft tissue does not compromise image

quality and standardization (Caligiuri et al. 1994; Vokes et al. 2006).

In osteoporosis a decrease in the mineralized bone volume results in a decrease of the total bone calcium and a decreased absorption of the X-ray beam. This phenomenon is then referred to as *increased radiolucency*. As bone mass is lost, changes in the bone structure occur. Bone is composed of two compartments: cortical bone and trabecular bone. The structural canes seen in the cortical bone represent bone resorption at different sites (e.g., the inner and outer surfaces of the cortex, or within the cortex in the Haversian and Volkmann channels). These three sites (endosteal, intracortical, and periosteal) may react differently to distinct metabolic stimuli. Cortical bone remodeling typically occurs in the endosteal “envelop”, and the interpretation of subtle changes in this layer may be difficult. With increasing age there is a widening of the marrow canal due to an imbalance of endosteal bone formation and resorption that leads to a “trabeculization” of the inner surface of the cortex. Endosteal scalloping due to resorption of the inner bone surface can be seen in high-bone turnover states like reflex sympathetic dystrophy. Intracortical bone resorption may cause longitudinal striation or tunneling. These changes are seen in various high-turnover metabolic diseases affecting the bone like hyperparathyroidism, osteomalacia, renal osteodystrophy, and acute osteoporoses from disuse or reflex sympathetic dystrophy syndrome, but also rapidly evolving postmenopausal osteoporosis. It is usually not apparent in disease states with relatively low turnover like senile osteoporosis.

Accelerated endosteal and intracortical resorption, with intracortical tunneling and indistinct border of the inner cortical surface, is best depicted with high-resolution radiographic techniques with optical magnification.

Subperiosteal bone resorption is associated with an irregular definition of the outer bone surface. This finding is pronounced in diseases with high bone turn-over, principally primary and secondary hyperparathyroidism (Guglielmi et al. 2001, 2003).

In the appendicular skeleton, changes in the trabecular and cortical bone are first apparent at the ends of long and tubular bones due to the predominance of cancellous bone in these regions.

Radiologic imaging of the hand is a fundamental step in evaluating grade and type of osteoporosis,

Fig. 1 Radiographs of the hand showing a detailed evaluation of II, III, and IV metacarpal bones. Spongy and cortical compartments are separately evaluated

thanks to anatomic peculiarities of this anatomic region that allow a best detailed evaluation through high-resolution systems (e.g., industrial films).

Metacarpal bones (usually II, III, and IV) are investigated. Spongy and cortical compartments are separately evaluated (Fig. 1). The cortico-medullar index, based on the evaluation of the cortical thickness at II metacarpal bone, represented in the past a good semi-quantitative measure for grading osteoporosis at this site (Link et al. 1994).

3.2 Peripheral Dual-Energy X-Ray Absorptiometry

Bone mineral density is an important factor influencing bone strength and a key predictor of fracture risk in patients with osteoporosis and other metabolic bone diseases (Cummings et al. 2002; Grampp et al. 1997). DXA is the most widely used technique for diagnosis of osteoporosis (Cauley et al. 2005;

Fig. 2 DXA of the distal (87% cortical bone) and ultradistal (65% trabecular bone) forearm

Damilakis et al. 2006; Guglielmi et al. 2003). This technique determines an aerial density and BMD is therefore given as g/cm^2 . It has a limited ability to evaluate bone geometry and cannot provide separate cortical and trabecular bone evaluations (Seeman and Delmas 2006).

An increasing number of small, portable DXA scanners are becoming available for application to peripheral sites (distal radius and calcaneus). Scanning of the forearm takes about 5 min to perform. The position of the forearm is standardized by the patient gripping a vertical rod. DXA allows an evaluation of weight-bearing and not weight-bearing bones. The scan is performed in a rectilinear fashion at a distal (87% cortical bone) and ultradistal (predominantly 65% trabecular bone) site (Fig. 2). Accuracy is 3%, precision is better than 1% and radiation dose is $0.1 \mu Sv$. Due to its composition, the forearm site is not a sensitive site for monitoring changes in BMD with respect to the calcaneus that is 95% trabecular bone and offers more potential for this purpose. The WHO criterion for the diagnosis of osteoporosis (T-score of -2.5 or less) is applicable to the forearm

but the definitive threshold for diagnosis has still to be determined (Pacheco et al. 2002). By consequence, BMD changes in peripheral bones such as phalanx and forearm must be very carefully interpreted. In fact, screening individuals using peripheral sites and technologies is not completely supported by current evidences. Picard and collaborators (Picard et al. 2004) compared results of BMD obtained at the forearm and phalanges with those obtained at lumbar spine and femoral neck evaluated by DXA: even though the negative predictive value reached more than 95% of the true negatives, the positive predictive value was only ranged from 40 to 43% what is, again, distant from the ideal situation. In general, it is recognized that the elder the subject is, the more likely to have agreement between a peripheral and a central measurement (Deng et al. 1998).

Monitoring treatment could be a very specific applicability but, even in this case, distal sites are not completely accepted due, mainly, to the fact that the changes expected with the available therapies are also smaller than at central sites. As reviewed by the ORAG group (Guyatt et al. 2002), if the forearm was used for monitoring treatment, only the treatment with Hormonal Therapy and Alendronate for 2–4 years could be adequately monitored.

3.3 Peripheral Quantitative Computed Tomography

Bone strength and fracture risk are also influenced by parameters of bone quality such as micro-architecture and tissue properties, evaluable by developing techniques other than DXA. Peripheral Quantitative Computed Tomography (pQCT) has been proposed as a relatively inexpensive method to assess trabecular BMD in single-slice mode (Rüeggsegger et al. 1976; Schneider and Börner 1991; Guglielmi and Lang 2002; Guglielmi et al. 1997). Dedicated peripheral CT scanners are available for assessing BMD in the radius and tibia. They are smaller, more mobile and less expensive than whole body CT scanners. pQCT measures the apparent volumetric BMD (mg/cm^3), in contrast to projection techniques such as DXA of the radius, and allows separate assessments of trabecular and cortical bone (Ito et al. 1997; Schneider and Reiners 1998) (Fig. 3). Peripheral QCT is most commonly applied to the non-dominant forearm.

Fig. 3 Peripheral QCT of the distal radius allows separate measurement of trabecular bone, cortical bone, total and cortical area and marrow cross-sectional area

Initially the forearm length is measured as the distance between the tip of the ulnar styloid and the olecranon. The patient's forearm is placed pronated in the pQCT gantry with the elbow resting on a block and the hand gripping the hand fixture. The arm is secured with Velcro straps to prevent movement. A coronal scout scan is performed and a reference line is placed to bisect the medial border of the end of the distal radius. Accurate and consistent positioning of this reference line is essential in any longitudinal or multi-center studies for comparable results. The sites generally scanned in the radius are the 4% (distal), 50% (mid) and between 60 and 66% (proximal) shaft, but other sites (e.g., 38% distal) are also used. The parameters measured at the 4% site include total and trabecular bone mineral content (BMC), BMD and cross-sectional area (CSA); in the shaft cortical BMC and BMD are measured with many geometric parameters including total and cortical area (mm^2), cortical thickness (mm), marrow cross-sectional area (mm^2), periosteal and endosteal circumference (mm),

(Adams 2009). The definition of osteoporosis given by the WHO (T-score of -2.5 or less), is applicable only to DXA of the lumbar spine, femoral neck, total hip and distal 33% radius. The definition does not apply to other anatomical sites (e.g., calcaneus) or to other densitometric techniques, such as Quantitative Ultrasound (QUS) or QCT, in either a central or peripheral QCT in the spine, and in distal radius and tibial sites.

Measurements of either total or trabecular BMD of the ultra-distal radius, by pQCT, predict fractures of the hip in post-menopausal women (Engelke et al. 2008). pQCT performs as well as, if not better than, DXA spine or QCT spine for prediction of wrist and hip fractures (Engelke et al. 2008).

Advantages of pQCT over axial QCT are that pQCT generates a lower radiation dose ($1-2 \mu\text{Sv}$ in pQCT compared with $50 \mu\text{Sv}$ in spinal QCT), and that it provides substantially higher reproducibility (Guglielmi et al. 1997). Advantages of pQCT over DXA are high accuracy, separate measurement of

cortical and trabecular bone, and cross-sectional bone imaging to offer additional information.

Recent advancements in another novel technology, volumetric QCT (vQCT), offers three-dimensional (3D) information, and cortical and trabecular bone can be separately analyzed. A particular challenge of volumetric BMD (vBMD) is the reproducible location of a given analysis volume of interest (VOI) in longitudinal scans. Most analysis software is experimental and only a few commercial programs are available. The overall advantages of this vQCT technique include high precision, on the order of 1–2% for BMD of the spine, hip and radius; nearly instant availability of data, in a matter of seconds to minutes; widespread access, with many thousands of systems available worldwide; and minimal user interaction. The major disadvantage for vBMD is the use of modest radiation exposure, which for the radius requires an effective dose <10 μ Sv (Genant et al. 2008). Guglielmi et al. found that pQCT of the ultradistal radius is a precise method for measuring the true volumetric BMD and for detecting age-related bone loss in the trabecular and total bone of female subjects encompassing the adult age range and menopausal status (Guglielmi et al. 2000).

Another area of active research is high-resolution peripheral QCT (HR-pQCT), that allows accurate and precise 3D evaluation of vBMD, quantitative trabecular structure analysis of the distal radius and also a separate assessment of cortical and trabecular BMD, although with longer scan times and increased likelihood of motion artifacts (Boutroy et al. 2008; Sornay-Rendu et al. 2009). The advancement of techniques allowing assessments of cortical bone is important. Indeed, non-vertebral fractures are a significant cause of morbidity and mortality in osteoporosis, and cortical bone can account for a significant amount of the likelihood for fracture in the peripheral skeleton. On the other hand, occurrence of a forearm fracture increases the risk of future hip, spine, and forearm fractures (Cuddihy et al. 1999). This is of particular importance if one thinks that although they are accepted as a major fracture type, forearm fractures remain under-recognized and under-treated as osteoporosis-related fractures (Endres et al. 2007). Spadaro et al. (1994) evaluated the contributions of the cortical and trabecular compartments to bone strength at the radius and found

that the cortical shell contributes substantially to bone strength.

The structure or spatial arrangement of bone at the macroscopic and microscopic levels is thought to provide additional, independent information on mechanical properties and may help to better predict fracture risk and assess response to drug intervention. Boutroy and colleagues (Boutroy et al. 2005) gave the first indication that peripheral trabecular structure assessment is indeed useful to differentiate women with an osteoporotic fracture history from controls better than DXA at hip or spine. Khosla and colleagues (Khosla et al. 2006a; Khosla et al. 2006b) examined age- and sex-related bone loss cross-sectionally and speculated as to the different patterns of bone loss in men and women.

3.4 Quantitative Ultrasound

Quantitative sonography methods have been introduced in recent years for the assessment of skeletal status in osteoporosis (Guglielmi et al. 2009). QUS involves generating ultrasound impulses that are transmitted (transversally or longitudinally) through the bone under study. The frequency range employed in QUS of bone lies between 200 kHz and 1.5 MHz. The ultrasound wave is produced in the form of a sinusoid impulse by special piezoelectric probes, and is detected once it has passed through the medium; there are two distinct probes, emitting and receiving, and the skeletal segment for evaluation is placed between them (Guglielmi and de Terlizzi 2009).

The first ultrasound parameters employed for characterizing bone tissue were: Speed of Sound (SoS) and Broadband Ultrasound Attenuation (BUA). More complex parameters have been developed from combination of SoS and BUA: Amplitude Dependent Speed of Sound (AD-SoS), stiffness, Quantitative Ultrasound Index (QUI) (Gluer and the International Quantitative Ultrasound Consensus Group 1997; Guglielmi et al. 2003). The technique is usually applied at the calcaneus, tibia, and phalanges, but has also been used at the patella and distal radius (Gnudi et al. 2000). The phalanx is a long bone consisting of a trabecular component and a cortical component, the principal determinant of the mechanical resistance of the bone. The phalanx is measured by QUS at the metaphyseal site,

Fig. 4 Quantitative ultrasound at hand phalanges showing the different graphic traces in a normal subject and osteoporotic patient

where both trabecular (at about 40%) and cortical bones are present. The metaphysis of the phalanx is, moreover, characterized by a high bone turnover and, therefore, extremely sensitive to changes in skeletal status due to natural causes (growth and aging), metabolic diseases (e.g., hyperparathyroidism), or drug-induced effects (treatment with glucocorticoids). When measurements are performed at the radius site, propagation occurs mainly along the external surface of the bone, and thus provides information mostly of cortical bone.

The European multi-center study (PhOS) (Wüster et al. 2000), performed on over 10,000 women, provided clinical validation of QUS at the phalanx. In this study the method could identify osteoporotic subjects with vertebral or hip fractures. Guglielmi

et al. (1999) found no significant differences between phalangeal QUS and X-ray densitometric BMD methods (DXA and central QCT) in separating normal from osteoporotic subjects when using ROC analysis (Fig. 4). Hartl et al. (Hartl et al. 2002) showed that the diagnostic performance of QUS at the calcaneus and the phalanx were comparable with central DXA in assessing subjects with osteoporotic vertebral fractures. Krieg et al. (2003) studied an elderly (70–80 years) Swiss population, to assess the ability of QUS at the calcaneus and phalanx in discriminating subjects with, and without, hip fracture. An interesting Italian study demonstrated that QUS at the phalanx is more sensitive in discriminating subjects with, and without, vertebral fractures immediately post-menopause, prior to the age of

70 years, whereas QUS at the calcaneus is more sensitive in the subsequent period, at the age of 70 years and older (Camozzi et al. 2007).

Even if clinical studies demonstrated positive and statistically significant correlations between results from QUS and photon bone densitometric method, this is not sufficient to predict central BMD from QUS (Wüster et al. 2000; Guglielmi et al. 1999; Schott et al. 1995). These observations demonstrate that QUS cannot replace photon absorptiometric bone densitometry, but the two techniques can provide complementary information to improve estimates of vertebral fracture risk: low QUS values must be considered as a factor in fracture risk assessment which is independent of BMD and, therefore, emphasizes the clinical importance of QUS in appropriate clinical situations. Anyway, it is important to note that the WHO definition of osteoporosis based on densitometry terms (T-score of -2.5 or less) is not applicable to QUS. On the other hand, QUS for the study of post-menopausal osteoporosis is now completely validated: scientific societies of several European countries have included bone QUS in their national guidelines for the diagnosis and management of osteoporosis, particularly for the evaluation of fracture risk in post-menopausal women (National Osteoporosis Society 2002; Schattauer GmbH 2006). Ultrasound velocity has also been applied to monitor changes and response to treatment in women with osteoporosis. In particular, some studies show that treatment with alendronate (Ingle et al. 2005), raloxifene (Agostinelli and de Terlizzi 2007), and teriparatide (Gonnelli et al. 2006) can be monitored using phalanx QUS.

3.5 Magnetic Resonance

Magnetic resonance (MR) offers alternative ways of assessing skeletal properties. Trabecular bone is not visualized at MR imaging so that a trabecula appears as a signal void, surrounded by high-intensity fatty bone marrow. This signal void is due to the very short T2 relaxation time of bone and to the bone marrow interface (Link et al. 1999; Guglielmi et al. 2003). Due to technical advances, like optimized coil design, fast gradients and high field strength, clinical MR scanners provide an in vivo spatial resolution close to the diameter of a single trabecula (Sell et al. 2005;

Fig. 5 High-resolution MR of the radius allows quantification of the trabecular bone architecture (scale, shape, orientation, connectivity and finite element models of the trabeculae)

Wehrli 2007). Moreover, with the advent of parallel imaging, motion correction techniques and new sequences, the limits of spatial resolution and scan time can be further overcome (Banerjee et al. 2006; Techawiboonwong et al. 2005). Most in vivo studies focused on peripheral skeleton because the distal radius, distal tibia and the calcaneus are easily accessible with small coils, contain a high number of trabeculae and the bone marrow consists of fat, resulting in high bone–bone marrow contrast. Each stage needs to be standardized to ensure a high degree of reproducibility (Newitt et al. 2002). On the other hand, the processing of high-resolution MR (HR–MR) images generally consists of several stages (registration, segmentation, resolution enhancement and normalization or binarization), before measures of the trabecular architecture can be evaluated (Wehrli 2007; Newitt et al. 2002) (Fig. 5). The efficiency of these techniques was evaluated in terms of reproducibility (2–4%), (Gomberg et al. 2004) and different approaches have been applied successfully in several cross-sectional, and recently in longitudinal, studies (Wehrli et al. 2001; Majumdar et al. 1999; Cortet et al. 2000). MR imaging aims to quantification of the trabecular bone architecture through five types of measures (describing scale; shape and orientation of the trabeculae; connectivity or complexity of the trabecular network and finite element models—FEM) directly characterizing mechanical properties.

Many Authors studied performances of MR in studying trabecular structure at distal radius and phalanges. Stampa et al. (2002) used phalanges, a convenient anatomic site particularly suitable for

obtaining high signal-to-noise and high-spatial resolution images, to derive quantitative three-dimensional parameters based on an algorithm and model for defining trabecular rods and plates. To date the quantification of trabecular bone architecture by HR-MR imaging at distal radius aimed to assess the prevalence and incidence of osteoporotic fractures (Majumdar et al. 1999; Cortet et al. 2000; Majumdar et al. 1997). Early studies suggested that MR-based parameters of the trabecular architecture better separate patients with, and without, osteoporotic fractures compared to BMD (Cortet et al. 2000; Majumdar et al. 1997). Link et al. (1998), Majumdar et al. (Majumdar et al. 1997), and Wehrli et al. (Wehrli et al. 1998; Wehrli et al. 2001; Wehrli et al. 2002) have shown the ability to discriminate spine and/or hip fractures using trabecular structure or textural parameters from *in vivo* MR images of the radius. In measuring the effect of pharmacological therapies for osteoporosis, some studies shows that parameters of trabecular micro-architecture derived by MR could better monitor changes due to anti-resorptive treatment than BMD (Chesnut et al. 2005). One of the early longitudinal studies showed that salmon calcitonin had therapeutic benefit compared with placebo in maintaining trabecular micro-architecture at multiple skeletal sites (Chesnut et al. 2005).

4 Other Metabolic and Endocrine Disorders

4.1 Acromegaly and Gigantism

These conditions are characterized by excess production of growth hormone (GH) due to acidophilic adenomas of the anterior lobe of the pituitary gland or from diffuse hyperplasia of the acidophilic cells. GH excess, which can arise in children (gigantism) or in adult (acromegaly), leads to an overgrowth of bone in the skeleton. In the immature skeleton the disease is associated with extreme height and a large skeleton with normal bone age. In the mature skeleton, after physal closure, excessive GH production causes an increase in width of bone and soft tissue enlargement manifested particularly in the acral parts of the skeleton.

Fig. 6 Acromegaly showing bony overgrowth, joint widening, metacarpal hooking, and arrow-head terminal tufts

Radiographic manifestations of the hand in patients with acromegaly include soft tissue thickening of the digits, osseous enlargement and increased width by means of thickening and squaring of the phalanges and metacarpal bones, overconstrictions or overtubulation of the shafts of the phalanges with normal or increased cortical thickness, widening of the articular spaces due to thickening of the articular cartilage, bone proliferation at tendon and ligament attachment site (enthesopathy) (Fig. 6).

In diagnosing early acromegalic changes some indexes have been proposed. Among them the sesamoid index, proposed by Kleinberg et al. (1966). According to this method, the size of the medial sesamoid at the first metacarpophalangeal joint is measured. This index has, however, a limited reliability because of the significant overlap in measurements in acromegalic patients and controls. Besides bone proliferation, bone resorption can associate (Resnick 1995), leading to a decreased bone density, particularly in the late stages of disease (Sartoris 1971). In addition, osteoarthritis usually complicates the disease (Resnick 1995).

4.2 Hypopituitarism

Hypopituitarism can arise from many causative factors (neoplasms, surgery, irradiation, injury, vascular insult, infection, and granulomas of the pituitary gland or the hypothalamus). Familial pituitary deficiency is reported in 10% cases. Isolated GH deficiency during the period of skeletal growth leads to abnormality of osseous development as a delay in appearance and growth of ossification centers and a similar delay in their fusion and disappearance (Resnick 1995). Radiographic manifestations in the hand include shortening and broadening of the metacarpal bones and distal phalanges or, less commonly, a hypoplastic appearance of the distal phalanges, metaphyseal irregularity, flattening and absence of closure of the physes, and severe osteoporosis. Open epiphyses may be observed in the distal portions of the radius and ulna (Resnick 1995).

4.3 Thyroid Disorders

Thyroid hormone increases bone remodeling (Mosekilde et al. 1990). In cases of excessive thyroid hormone, osteoclastic activity predominates on osteoblastic one, with resultant bone resorption. In the hand, hyperthyroid osteopathy leads to bone loss that is manifested as a lattice-like appearance in the phalanges, and “flaky” cortices due to radiolucent intracortical striations (Resnick 1995). In hypothyroidism, bone abnormalities are more evident in neonates, children, and young adults, and result in retardation of skeletal maturation with subsequent retardation in growth. Delayed appearance and growth of epiphyseal ossification centers, and abnormality of physal development accompanied by delayed physal closure are observed. In the hand, arrest in growth is manifested as shortening and widening of the metacarpal bones, which present endosteal cortical thickening (Fig. 7) (Steinbach et al. 1975). Hypoplastic phalanges of fifth finger may be seen (Sartoris 1996). In affected epiphyses, ossification proceeds from multiple centers rather than from a single site (pseudoepiphyses). Abnormal epiphyseal ossification results in a characteristic irregular and fragmented epiphyseal appearance recognized as epiphyseal dysgenesis (Borg et al. 1975; Parker 1981).

Fig. 7 Hypothyroidism (cretinism) in a child. There is retarded skeletal maturation with shortening of the metacarpals and squaring of the epiphyses

4.4 Hyperparathyroidism

Hyperparathyroidism, a clinical condition characterized by an elevation of serum parathyroid hormone concentration, may be primary, secondary, or tertiary. In primary hyperparathyroidism, hypersecretion of parathyroid hormone is due to abnormality in the parathyroid glands (single or multiple adenomas, diffuse hyperplasia, and carcinoma). Secondary hyperparathyroidism usually is secondary to chronic renal disease, or occasionally, malabsorption states. Tertiary hyperparathyroidism occurs in patients with chronic renal disease and secondary hyperparathyroidism who develop autonomous parathyroid function.

The hand is almost always involved in hyperparathyroidism. Subperiosteal bone resorption is most frequently observed along the radial aspect of the phalanges, particularly in the middle phalanges of the index and middle fingers (Fig. 8) (Resnick 1995).

Fig. 8 Hyperparathyroidism. There is subperiosteal resorption along the middle phalanges with terminal phalangeal resorption (acro-osteolysis)

Subperiosteal bone resorption involves the phalangeal tufts as well, where loss of the cortical “white line” represents the earliest sign of the disease progressing to acro-osteolysis (Sundaram et al. 1979). Intracortical resorption always associates (Meema and Meema 1972) leading to development of pseudoperiostitis (Resnick 1995). Owing to rapid or severe bone loss multiple intracortical, radiolucent areas, in the form of linear striations or tunneling, may be observed in the metacarpal bone and appear more evident in the cortex of the second metacarpal bone (Meema and Meema 1972). In the hand, osteoclastic resorption occurs along the endosteal surface of bone causing localized scalloped or pocket-like defects along the endosteal margin of the cortex. In children with primary or secondary hyperparathyroidism, irregular radiolucent areas may be apparent in the metaphysis adjacent to the growth plate of tubular bones of the hand (Resnick 1995). In the hyperparathyroid state, osseous resorption may occur at sites of tendon and ligament attachment to bone also at the hand and the wrist (Resnick 1995). Trabecular resorption within medullary bone, particularly in the advanced stages of the disease, may involve the tubular bones of the hand that assume a characteristic granular appearance, with loss of distinct trabecular detail, and subsequent osseous deformities that may simulate the changes of osteomalacia (Resnick 1995). Brown tumors are also

Fig. 9 Secondary hyperparathyroidism in an adult with chronic renal disease. **a** There is subperiosteal resorption along the phalanges, terminal phalangeal resorption with soft tissue and vascular calcification. **b** After successful renal transplantation the resorption has resolved as has the soft tissue but not the vascular calcification. The terminal phalanges remain stunted

included among the radiographic manifestations of hyperparathyroidism and represent localized accumulations of osteoclasts, fibrous tissue, and giant cells, which can replace bone and occasionally produce osseous expansion. They appear as single or multiple well or poorly demarcated osteolytic lesions with an eccentric or cortical location (Resnick 1995). A prominent radiographic feature of hyperparathyroidism is generalized osteopenia. Nevertheless, as hyperparathyroidism may induce either bone resorption or formation, increased radiodensity of bones may become a prominent radiographic feature. There is a meaningful association between primary hyperparathyroidism and CPPD crystal deposition that may lead to the pseudogout syndrome. Renal osteodystrophy is the clinical term indicating bone disease in patients with chronic renal failure. The radiographic manifestations of renal osteodystrophy reflect hyperparathyroidism and deficiency of 1,25-dihydroxyvitamin D, rickets and osteomalacia, osteoporosis, soft tissue and vascular calcifications, and miscellaneous changes (Fig. 9) (gout arthritis due to hyperuricemia). Lytic, expansile lesions, the so-called brown tumor may occur in the long bones of the hand and will

mimic a giant cell tumor both radiographically and histologically (Fig. 10). They are commoner in patients with chronic renal disease because of the larger numbers of patients surviving on dialysis and that most cases of primary hyperparathyroidism are now detected on serum biochemistry.

4.5 Rickets and Osteomalacia

The terms rickets and osteomalacia refer to the same condition manifesting in the child and adult, respectively. The commonest cause worldwide is inadequate dietary intake of vitamin D. Other causes include inadequate sunshine, malabsorption states, anti-epileptic drug therapy, renal disease and rarely tumor related. This results in inadequate or delayed mineralization of osteoid in mature cortical and spongy bone (osteomalacia) and from an interruption in orderly development and mineralization of the growth plate (rickets) (Resnick 1995). As rachitic changes are more evident in regions of the most active bone growth, target sites of rickets include the distal ends of ulna and radius (Park 1932). General radiographic features of rickets include retardation in bone growth and osteopenia. Slight axial widening of the physis represents the earliest specific radiographic finding (Steinbach and Noetzi 1964). Disorganization and “fraying” of the spongy bone occur in the metaphyseal region, which eventually demonstrates widening and cupping (Fig. 11) (Resnick 1995). In the hand of the rachitic children, irregularities and widening of the physes seen in the metacarpals and phalanges also may be associated with bone resorption. In osteomalacia medullary bone shows a decrease in the total number of trabeculae, owing to a loss of secondary trabeculae. The remaining bone trabeculae are prominent and present a “coarsened” pattern with unsharp margins reflecting deposition of inadequately mineralized osteoid. Looser’s zones, typical of osteomalacia elsewhere in the skeleton, are uncommon in the hands.

4.6 Hypoparathyroidism

Hypoparathyroidism is a general term describing a clinical state of parathyroid hormone deficiency, which results in hypocalcemia and neuromuscular

Fig. 10 Brown tumor in a patient with chronic renal disease. There is a pathological fracture developing through a lytic expansile lesion in the distal end of the metacarpal. There are features of hyperparathyroidism affecting the phalanges

Fig. 11 Rickets. **a** In a young child there is generalized osteopenia with cupping, splaying, and fraying of the distal radial and ulnar metaphyses. **b** In an adolescent the only

abnormalities are generalized osteopenia and relative demineralization of the distal radial and ulnar metaphyses

dysfunction. It can have many causes like surgery, congenital absence or atrophy of the parathyroid glands, and parathyroid gland destruction after radiation. The major radiographic manifestations of hypoparathyroidism are osteosclerosis, which may be generalized or localized, and soft tissue calcification. In the hand, radiographic findings of hypoparathyroidism are usually subtle and represented by subcutaneous, ligamentous and tendinous calcifications, premature fusion of the physes, entropathy, and osteoporosis (Resnick 1995).

Pseudohypoparathyroidism (PHP) or Albright's hereditary osteodystrophy, is a congenital disorder characterized by hypocalcemia and hyperphosphatemia. Pseudopseudohypoparathyroidism (PPHP) is the normocalcemic form of PHP and is also caused by

failure and end-organ response to parathyroid hormone. In the hand, radiographic findings of PHP and PPHT include shortening of the metacarpal bone and phalanges secondary to premature physal closure, widening and shortening of the phalanges with presence of cone-shaped and pseudo-epiphyses, soft tissue calcification, and small diaphyseal exostoses that extend perpendicularly from the surface of the bone (Fig. 12). In most cases of PHP and PPHP, metacarpal shortening shows predilection for the first, fourth, and fifth rays and may lead to a positive metacarpal sign (the line drawn tangential to the heads of the fourth and fifth metacarpal bones intersects the end of the third metacarpal bone, indicating disproportionate shortening of the fourth and fifth metacarpal bones).

Fig. 12 Pseudohypoparathyroidism. There is shortening of the metacarpals with soft tissue calcifications

4.7 Scurvy

Scurvy is due to a deficiency, typically dietary, of vitamin C (ascorbic acid) which leads to a reduction in collagen formation in bone. The radiographic features include generalized osteopenia, thinned cortices with sparse trabeculae, dense metaphyseal line with an adjacent lucent line, metaphyseal spurs (Pelkan spurs) and finely pencilled dense epiphyseal margins (Wimburger's sign). Capillary fragility may lead to subperiosteal hemorrhage that in time may heal with exuberant periosteal ossification. All these features are more commonly seen in the lower limbs than the hand or wrist.

5 Conclusions

Several metabolic and endocrine disorders cause skeletal involvement of hand and wrist. Among them osteoporosis is the most common metabolic bone disease. Besides traditional methods (conventional radiographs), new interesting techniques are developing and appear promising in the evaluation

of peripheral osteoporosis. Many studies evaluate DXA application at distal radius; pQCT demonstrates promising results in studying bone microarchitecture thanks to new technologies like vQCT and HR-QCT; QUS are proving to be very useful in the evaluation of bone properties and showed good performances with respect to DXA; finally, HR-MR, on the basis of sophisticated software, is becoming a new challenging technique in the assessment of trabecular structure. Other metabolic and endocrine conditions may manifest with radiographic abnormalities in the hands including rickets and hyperparathyroidism.

6 Key Points

- Osteoporosis and other several metabolic and endocrine disorders cause skeletal involvement of hand and wrist.
- DXA is the *gold standard* for measuring BMD in the axial skeleton, as defined by WHO.
- pDXA as well as pQCT are the methods of choice in the evaluation of peripheral osteoporosis.
- QUS is a useful tool in the evaluation of bone properties.
- vQCT, HR-QCT, and HR-MR, on the basis of sophisticated software, are challenging techniques in the assessment of trabecular structure.

Abstract

Joint involvement in the hand and wrist is a feature of many forms of arthritis and because multiple joints are included, a view of both hands and wrists can provide important diagnostic information based on the pattern of disease involvement, even before the actual appearances of the changes are considered. Although for the most part this chapter focuses on plain film appearances, advanced imaging modalities, particularly ultrasound (US) and MRI, are increasingly finding applications in the mainstream clinical imaging of hand arthritis and are discussed in the appropriate sections.

1 Introduction

Joint involvement in the hand and wrist is a feature of many forms of arthritis and because multiple joints are included, a view of both hands and wrists can provide important diagnostic information based on the pattern of disease involvement, even before the actual appearances of the changes are considered. Although for the most part this chapter focuses on plain film appearances, advanced imaging modalities, particularly ultrasound (US) and MRI, are increasingly finding applications in the mainstream clinical imaging of hand arthritis and are discussed in the appropriate sections.

2 The Inflammatory Arthritides

The inflammatory arthritides include rheumatoid arthritis (RA), the seronegative arthritides and juvenile inflammatory arthritis (JIA). While it is recognised that

osteoarthritis (OA) has an inflammatory variant, the features of this condition will be discussed separately.

The management of inflammatory arthritis has changed dramatically in recent years with the advent of powerful biological therapies which, if instigated early, can prevent the severe joint destruction that used to be commonly seen. The use of such drugs means that imaging plays an increasingly important role in the management of these diseases. While CR shows characteristic features of inflammatory arthritis, these represent late findings in the disease process and the use of advanced imaging techniques is becoming more common as they allow early diagnosis before irreversible joint damage has occurred. Nevertheless CR continues to play an important role in the diagnosis and characterisation of hand and wrist arthritis and usually forms the initial imaging study.

2.1 Plain Film General Principles

The subtle changes seen in early inflammatory arthritis require high quality radiographs reviewed in optimal lighting conditions. The use of digital radiographic techniques is now prevalent and has been shown to provide similar accuracy to film-screen techniques in the diagnosis of arthritis (van der Jagt et al. 2000; Jonsson et al. 1994). Additional advantages over conventional films exist for the reader such as on-screen magnification and windowing (Paskins and Rai 2006).

A systematic approach to the review of the hand and wrist radiograph for arthritis is required. Important features to identify are:

- soft tissue swelling
- joint space loss
- bone changes
 - erosion
 - osteopaenia
 - enthesitis
- bone alignment.

Finally the distribution of joint disease provides important information when forming a differential diagnosis.

2.1.1 Soft Tissue Swelling

Soft tissue swelling is usually the earliest sign on CR of an inflammatory arthritis. It represents synovial hypertrophy, oedema in the adjacent soft tissues and

joint effusion. When seen at the interphalangeal joints the swelling has a symmetrical spindle shape about the joint. This pattern of soft tissue swelling contrasts with that seen in gout which tends to show a more irregular asymmetrical ‘lumpy’ appearance. At the metacarpophalangeal (MCP) and wrist joints the soft tissue contour may not be significantly displaced and it is often the appreciation of an increased density to the periarticular soft tissues and effacement of the fat planes that suggests the presence of joint disease. At the MCP joints soft tissue swelling can be extremely subtle and it is useful to look for loss of the fat planes normally seen between the joints (Fig. 1). In the wrist the normal fat planes adjacent to the scaphoid and ulnar styloid are sensitive sites for the detection of soft tissue swelling.

2.1.2 Alteration in Joint Space

Loss of joint space as a result of cartilage destruction is a characteristic feature of many joint diseases. In inflammatory arthritis joint space loss is typically uniform, across the joint. In many joints this is helpful in distinguishing inflammatory from OA, which typically shows non-uniform joint space loss. However, it is less useful in the hands where the interphalangeal and MCP joints in both forms of arthritis can show uniform joint space loss.

As with soft tissue swelling joint space loss is an early plain film feature of inflammatory arthritis, but while soft tissue swelling can be subtle, the recognition of joint space loss is generally more straightforward (Fig. 1). It is important to recognise that once joint space loss is identified irreversible damage has occurred to the joint. So while it is an early plain film feature, it still represents a relatively late stage in the whole disease process.

Detection of joint space loss in the hands and wrists is usually straightforward because joint space can be easily compared to other similar joints on the radiograph. It is important to recognise that the joints between the carpal bones normally all show similar spaces. The observation of preserved joint space, in a joint which otherwise shows evidence of significant arthropathic change, is an important one and may help with the differential diagnosis. In particular gout characteristically preserves joint space until late in the disease.

In severe arthritic change bony ankylosis may occur. This is most commonly seen in the seronegative arthritides and in juvenile arthritis and represents end stage disease. Ankylosis may be bony or fibrous.

Fig. 1 Rheumatoid arthritis: there is joint space loss demonstrated at the middle, ring and little MCP joints. This is made more apparent by the relative preservation of joint space at the thumb and index MCP joints. There is also soft tissue swelling which is best appreciated at the index and little MCP joints

(*arrowheads*). The joint space swelling at the MCP joints can also be appreciated by the loss of the normal fat plane between the joints. There is also malalignment of the MCP joints with ulnar deviation

Occasionally widening of the joint space may be seen in arthritis. This is rare and is usually the result of a tense effusion distending the joint and separating the bones.

2.1.3 Bone Changes

Osteopaenia

Periarticular osteopaenia is a well-recognised feature of some inflammatory arthritides but is perhaps the most difficult to reliably identify. It may be more obvious in cases of mono or pauciarticular joint involvement, where other joints are clearly normal for comparison, but can be more difficult to appreciate when there is polyarticular disease as is often the case in the inflammatory arthritides. Appearances can also be difficult to interpret if there is an element of generalised disuse osteoporosis. Often it is easier to identify that there is no evidence of osteopaenia, and this in itself is a useful observation when forming a differential diagnosis.

Erosion

Bone erosion is a hallmark of inflammatory arthritis and a sign of significant joint damage. Erosions can be subdivided into proliferative and non-proliferative erosions. Proliferative erosions are associated with new bone formation and are classically a feature of enthesal disease as discussed below. Non-proliferative

erosions are a feature of seropositive (rheumatoid) arthritis. The distinction between these two types of erosion is an important one in the differentiation of seropositive and seronegative arthritis.

Erosions can be described by their relationship to the joint and can be categorised as central, marginal or juxta-articular. Marginal erosions occur at the edge of the joint line and involve the exposed bone between the edge of the articular cartilage and the joint capsule. They are a classical feature of RA. Central erosions occur, as their name suggests, into bone normally covered by the articular cartilage. They are less common and are classically seen in inflammatory (erosive) OA. Juxta-articular erosions occur further away from the joint and are typically seen in gout. They have characteristic features that are discussed later (see [Sect. 3.1.1](#)).

Erosions are seen as a discontinuity in the cortex of a bone. However, this is only the case when the eroded cortex is seen in profile on the radiograph. While this is frequently the case in the finger joints, wrist erosions are often seen en-face if they lie on the palmar or dorsal aspect of the carpal bones. En-face erosions are seen as focal lucencies within the bone without associated cortical breach and may be indistinguishable from cysts. The improved detection of these erosions, particularly when small, is one of the reasons cross-sectional imaging techniques such as US and MRI have a much greater sensitivity to erosive change than CR.

Enthesal Disease

Enthesitis is a characteristic feature of the seronegative arthritides. Enteses represent the bony attachment sites of ligaments, tendons and capsule. On plain film imaging the important bone changes that can be visualised in enthesitis are enthesophyte formation and erosion. Entesophytes, which develop at, or immediately adjacent to the site of an enthesitis are seen as bone proliferation. They may have a coarse appearance, with both cortical and medullary bone being apparent, or may have a finer 'whisker' like appearance.

MRI demonstrates intra-osseous bone changes, in enthesitis in the form of high T2 (oedema like) signal in the bone adjacent to the enthesitis. MRI and US also show changes in the soft tissues about the enthesitis including bursitis and alteration in the appearance of the ligament or tendon inserting at the affected enthesitis. These will only be detected on plain films if there are adjacent fat planes that become effaced by a thickened tendon, or enlarged bursa.

2.1.4 Bone Alignment

Joint malalignment is a feature of many arthropathic processes and results from a variety of causes (Fig. 1). These include ligament degeneration or disruption, tendon rupture or subluxation, cartilage loss and bone attrition or erosion. In most cases the malalignment will be apparent clinically and may even be less apparent on the radiograph in the case of reversible subluxations, such as are seen with SLE, as the act of positioning the patient for the radiograph reduces the subluxation.

2.2 Rheumatoid Arthritis

The aetiology of RA remains unknown, but it is recognised that it is a chronic autoimmune disorder with the potential to affect multiple systems and has an incidence of approximately 1%. Women are more frequently affected than men and the joint disease is characterised by a polyarticular synovitis. The synovitis is initiated by cytokines including interleukin-1 and tumour necrosis factor (TNF) and occurs early in the disease process (Arend 2001). The later stages of the disease involve joint destruction as a result of bone erosion and cartilage loss. Synovitis is considered to be a strong predictor of bone erosion (McGonagle et al.

1999; McQueen et al. 1999). The majority of patients have polyarticular involvement at presentation although occasionally patients may present with single joint involvement. The hands and wrists are commonly affected and radiographs of the hand and wrist provide a valuable tool in being able to assess multiple joints in a single examination. In addition to joint involvement, synovitis may involve the tendon sheaths and rheumatoid nodules may occasionally be seen in the hands.

The clinical, and consequently radiological, picture of RA has changed over recent years due to dramatic advances in the way RA is treated clinically. Management now involves the use of powerful biologic agents, which can arrest joint damage early in the disease process preventing the development of the severely mutilated joints that were seen previously on CR (Villeneuve and Emery 2009). However, the effective use of these new treatments requires the early diagnosis of the disease, before plain film changes are evident. Increasingly US and MRI are finding roles in routine clinical practice for this purpose. Despite this plain films of the hands and wrists remain widely used in the diagnosis and management of the disease; and the need to detect early and subtle changes of RA is greater than ever. The hallmarks of RA on plain film imaging are soft tissue swelling, periarticular osteopaenia, joint space loss, erosion and malalignment. The classical plain film appearance of RA in the hands and wrists is of a symmetrical polyarthritides with a proximal distribution typically involving the wrists, MCP and proximal interphalangeal (PIP) joints. Characteristically the distal interphalangeal (DIP) joints are spared providing an important distinguishing feature from OA and psoriatic arthritis.

2.2.1 Soft Tissue Changes and Bone Density

The earliest plain film changes are soft tissue swelling and periarticular osteopaenia. At the MCP and PIP joints the soft tissue swelling is appreciated as spindle shaped thickening of the soft tissues developing symmetrically about the joint (Fig. 1). In the wrists, early changes of soft tissue swelling are best appreciated along the ulnar border of the joint and medial to the ulnar styloid and can be detected early by the loss of the normal fat planes (Fig. 2). As discussed above periarticular osteopaenia can be a difficult sign to evaluate, particularly with the polyarticular involvement seen in RA.

Fig. 2 Rheumatoid arthritis: there is soft tissue swelling about the distal ulnar seen as deviation of the fat planes (*arrowheads*). Note also the erosive change seen for example in the ulnar styloid, radial styloid and 2nd metacarpal base

2.2.2 Joint Space Loss

As the disease progresses symmetrical joint space loss at involved joints becomes apparent (Fig. 1). In the wrist, the radiocarpal joint is usually the site where this is appreciated first, but with time the whole wrist becomes involved (Fig. 3). This is in contrast to OA with its classical isolated involvement of the thumb base in a trapeziocentric distribution.

2.2.3 Erosion

The earliest ‘pre-erosive’ changes of RA are typically seen on the radial aspect of the index and middle metacarpal heads (Fig. 4). Initially, cortical thinning develops, which then progresses to a ‘skip’ pattern or a ‘dot-dash’ type of deossification associated with localised osteopaenia. Subsequently, frank bone erosion is seen. Erosions in the finger joints are usually marginal in location, being seen in the first instance at sites within the joint that are unprotected by overlying articular cartilage (Fig. 5). In the wrist the earliest sites for erosion are typically along the ulnar aspect of the joint, on the ulnar styloid, trapezium and hamate (Figs. 3, 6). While erosion occurs at this site as a result of synovial proliferation on the ulnar aspect of the wrist joint, an important factor is also tenosynovitis of the extensor carpi ulnaris, an early site of soft tissue disease.

Fig. 3 Rheumatoid arthritis: there is joint space narrowing between the carpal bones and at the radiocarpal joint. The lucency in the distal radius represents an erosion seen en-face despite cystic appearance. There is also erosion of the ulnar styloid with soft tissue swelling. Note the radial deviation of the wrist typical of the malalignment pattern seen with rheumatoid arthritis

Cystic forms of RA have been described where cystic change develops, generally in the carpal bones, without radiographic or MRI evidence of erosion (Gubler et al. 1990). A form of the disease featuring large cystic areas, typically occurring in active men has been termed ‘rheumatoid arthritis of the robust reaction type’ (Fig. 7) (De Haas et al. 1974). Using CR it is not possible to reliably distinguish between cysts and en-face erosions, which also commonly occur in the carpal bones.

It is important to appreciate that erosive change is a dynamic process and involves healing as well as bone destruction. This can be appreciated on serial films where healing of erosions may be seen (Fig. 8). It also means that the morphology of erosions changes with the disease progress. In the later chronic stages of the disease, erosions become more clearly delineated with the development of sclerotic borders at the interface between the sites of bone destruction and healing (Fig. 9).

2.2.4 Malalignment and Ankylosis

Tendon and ligamentous dysfunction along with bone erosion results in deformity and malalignment in the later stages of the disease. ‘Boutonniere’ deformity describes a

Fig. 4 Rheumatoid arthritis: early erosive change is seen along the radial border of this index metacarpal head. There is localised osteopaenia with a 'dot-dash' pattern of deossification (*arrows*). Note also the soft tissue swelling

Fig. 5 Rheumatoid arthritis: marginal erosions are seen at the middle MCP joint (*arrows*). Note also the joint space loss compared with the adjacent MCP joints

pattern of malalignment produced by flexion of the PIP joint and extension of the DIP joint. This results from detachment of the extensor tendon from the middle

Fig. 6 Rheumatoid arthritis: erosive change is shown in the bones along the ulnar aspect of the wrist. In addition to erosions seen in the ulnar styloid, erosion is also seen in the triquetrum, hamate and base of 5th metacarpal. These represent early sites for the detection of erosions

phalanx, volar displacement and its subsequent action as a flexor. An opposite deformity referred to as the 'swan neck' deformity is seen as hyperextension of the PIP joint and flexion of the DIP joint. The cause is thought to be flexor tenosynovitis and/or synovitis in the PIP joint with resultant dysfunction of the stabilising effect of the volar plate. Mallet finger is a less common deformity resulting from disruption or dysfunction of the extensor tendon's action on the terminal phalanx. Ulnar deviation of the fingers and the radial deviation of the wrist giving a 'zigzag' deformity to the hand is typical for RA (Resnick 1976) (Figs. 1, 3, 10). This subluxation of the MCP and carpometacarpal joints seen in RA is irreversible.

In advanced disease, arthritis mutilans may develop where bony destruction leads to severe displacement with 'telescoping' of the phalanges. Ankylosis may also occur in the later stages of the disease. Typically this involves the wrist with intercarpal and carpometacarpal fusions but less commonly fusion may be seen at MCP and PIP joints, between the bases of the metacarpals or between the radius and ulna.

2.2.5 Secondary OA

As a result of the dysfunction of the joints, it is not uncommon for mechanical OA to develop in the later stages of the disease. Consequently a combination of

Fig. 7 ‘Robust’ pattern of rheumatoid arthritis: this male patient shows severe bilateral wrist arthropathy with involvement also seen at the index and middle MCP joints on the right. Note the cystic changes seen in the wrist and MCP joints typical of the pattern of disease, which has been termed rheumatoid arthritis of robust reaction type

Fig. 8 Rheumatoid arthritis: **a** there are erosions seen at the MCP joint in both the metacarpal head and proximal phalangeal base. Two years later **b** there is evidence of healing of the erosions on both proximal and distal side of the joint. Despite this there is progressive joint space loss

both rheumatoid and OA may be seen in the hands and wrists, with typical subchondral sclerosis and marginal osteophyte formation being present alongside the RA changes described. However, the OA change does not usually overshadow the features of RA.

2.2.6 Other Soft Tissue Changes

The changes of RA are not confined to the joints and other synovial tissues may be affected. In the hand and wrist this is usually the flexor and extensor tendon sheaths, and the changes here contribute to the disability and deformities seen with the condition. Subcutaneous nodules are another common feature of the disease, seen in around 20% of patients. Nodules may also be seen within tendons and along with the tenosynovitis may be a cause of triggering. While soft tissue findings may be manifest as thickening or swelling on CR, they are better evaluated using US or MRI and will be discussed in [Sect. 2.5](#) (el-Noueam et al. 1997; Fornage 1989; Gibbon and Wakefield 1999).

2.3 Seronegative Arthritis

The seronegative arthropathies comprise a group of multisystem inflammatory arthritides sharing common features. Chief among these is the characteristic involvement of the entheses with inflammation classically seen at the bony insertions of tendons and ligaments. Other important features are:

(a) an absence of rheumatoid factors,

Fig. 9 Rheumatoid arthritis: this patient has long-standing RA with erosive involvement of multiple joints. Note the sclerotic margins of many of the erosions which is typical in the chronic stages of the disease

Fig. 10 Rheumatoid arthritis: the patient has severe polyarthritis and shows typical malalignment with radial deviation at the wrist and ulnar deviation at the MCP joints

- (b) a strong association with the HLA-B27 histocompatibility antigen (although it is important to realise this is not necessary for the development of these diseases, or required for the diagnosis),
- (c) a tendency for axial skeletal involvement.

The CR hallmark of these conditions as they affect the hand and wrist is the presence of proliferative erosive change representing erosive enthesal disease.

2.3.1 Psoriatic Arthritis

Hand involvement in the seronegative arthritides occurs most frequently and characteristically in psoriatic arthritis. The condition occurs in association with cutaneous psoriasis and there has often been a long history of skin psoriasis prior to development of the arthritis. However, in some cases (reports suggest up to 20%) the arthropathic changes may occur prior to the onset of the cutaneous disease (Scarpa et al. 1984). There is considerable variation in the reported incidence of psoriatic arthritis in patients with cutaneous psoriasis. One study has suggested psoriatic arthritis is

seen in around 7% of patients with cutaneous psoriasis (Leczinsky 1948), while a more recent British study has suggested the figure may be as high as 40% (Green et al. 1981). Sacroiliac involvement is seen in 20–40% of patients and peripheral joint involvement is reported in around 15% of patients with psoriasis (Green et al. 1981; El-Khoury et al. 1996).

Five clinical subgroups of psoriatic arthritis are recognised:

1. Involvement of the DIP joints, usually asymmetrically often associated with dactylitis.
2. Arthritis mutilans.
3. A pattern of arthritis indistinguishable from RA but usually with a more benign course.
4. Oligo- (or mono-) arthritis distributed asymmetrically and involving any synovial joint.
5. A pattern of disease the same as ankylosing spondylitis (which may be associated with any of the above groups).

It is important to realise that patients with cutaneous psoriasis are susceptible to other arthropathies including RA and OA.

Fig. 11 Dactylitis in psoriatic arthritis: there is diffuse soft tissue swelling of the index finger with associated arthropathic change

Fig. 12 Early psoriatic arthritis: marginal erosive changes are seen at the bases of the index and little distal phalanges, but note also the early enthesophyte formation adjacent to the erosions

In common with the other seronegative arthropathies the disease classically involves enthesis sites. It is suggested that inflammation in the multiple closely related enthesal sites in a digit is the cause of dactylitis seen in psoriatic arthritis (Benjamin and McGonagle 2001). The presence of

Fig. 13 Psoriatic arthritis: there is prominent fluffy enthesophyte formation seen both proximal and distal to the distal interphalangeal joints

nail dystrophy among psoriasis sufferers is a significant risk factor for the development of psoriatic arthritis and evidence suggests this may be because of the intimate relationship between the nail bed and the enthesis sites of the DIP joint (Wilson et al. 2009; McGonagle et al. 2009).

The most significant pattern of joint disease seen in the hands is an erosive arthritis, which has a predominantly distal distribution with predilection for the DIP joints. The distal distribution helps distinguish it from RA, with its typically more proximal joint involvement. Joint involvement in RA tends to be symmetrical (similar joints involved in the two hands) while psoriatic arthritis tends to show a more asymmetrical distribution.

Soft Tissue Changes and Bone Density

Soft tissue joint swelling is seen as an early but non-specific radiographic feature of psoriatic arthritis. When seen global swelling of the digit in the form of dactylitis 'sausage digit', is virtually pathognomonic of the disease (Fig. 11). Periarticular osteopaenia is not a feature of psoriatic arthritis and can be useful in distinguishing it from RA.

Erosion, Bone Proliferation and Resorption

Bone erosion is seen most commonly at the joint margin and shows an enthesal pattern as discussed in "Enthesal Disease", with fluffy new bone formation at and adjacent to the erosion site (Figs. 12, 13). As the erosions develop they lose their initial marginal location and tend to coalesce. Classically, erosions on

Fig. 14 Psoriatic arthritis: there is a severe mutilating polyarthritis with multiple subluxations and extensive erosive change. Note the ‘pencil-in-cup’ pattern of erosive change seen at the thumb interphalangeal joints. There has been extensive bone resorption, e.g. the right, little proximal and intermediate phalanges and there is bony ankylosis at the left little distal interphalangeal joint

the distal side of the joint merge together centrally to produce a concavity, which extends laterally as a result of enthesophyte formation, while the proximal erosions lead to a tapering of the bone. The effect is to produce the characteristic ‘pencil in cup’ appearance considered by some to be pathognomonic of the disease (Arnett 1987) (Fig. 14).

New bone formation is not confined to the enthesis sites and periosteal new bone may be seen relatively early in the disease occurring along the shaft of the phalanges (Fig. 15). This is frequently associated with a soft tissue swelling, and is probably related to tenosynovitis (El-Khoury et al. 1996; Olivieri et al. 1996).

A further feature of the enthesal disease seen on hand/wrist imaging can be noted at the sesamoid bones. Sesamoid bones lie within tendons and so a considerable portion of their surface area represents enthesis site. It has been noted that the sesamoid bone of the thumb may enlarge in patients with psoriatic arthritis giving an increased sesamoid index (length \times width of the sesamoid) (Whitehouse et al. 2005).

Bone loss is not limited to periarticular erosion in psoriatic arthritis and acro-osteolysis (distal tuft resorption) is a well-recognised feature (Martel et al. 1980; Miller et al. 1971). It can help distinguish psoriatic arthritis from erosive OA, which may also

cause erosive change at the DIP joints. Progressive osteolysis of the terminal phalanges may give them a ‘peg like’ appearance, although osteolysis may progress to involve the majority of the phalanx (Figs. 14, 16). When osteolysis is seen there is usually associated nail involvement. Acro-osteolysis may be seen in cases of psoriasis without arthritis (Miller et al. 1971).

Ankylosis

Bony ankylosis is a feature of psoriatic arthritis occurring later in the disease process (Fig. 14). The process commences as a result of fibrous tissue forming within the joint and this can give the impression of a widened joint space.

2.3.2 Other Seronegative Arthritides

Although hand and wrist involvement is seen in the other seronegative arthritides it is not as common or typical as the involvement of the hands in psoriatic arthritis.

Ankylosing Spondylitis

Ankylosing spondylitis primarily affects the axial skeleton but peripheral joint involvement is seen and this may involve hands and wrists (Resnick 1974; Vinje et al. 1985). Around 30% of patients with severe disease are reported to show hand and wrist

Fig. 15 Psoriatic arthritis: there is fluffy periostitis seen along the shafts of the proximal phalanges typical of psoriatic arthritis

involvement (Resnick 1974). An asymmetrical distribution is usually seen and features include periarticular osteoporosis, along with joint space narrowing, proliferative erosions and soft tissue swelling. Enthesophyte formation may be seen as part of the enthesitis (Fig. 17). Involvement may be seen in all compartments of the wrist and any of the small joints of the hands. Bony ankylosis may be seen and may have a relatively rapid onset.

Reactive Arthritis (previously Reiter's Syndrome)

Classically reactive arthritis involves the small and large joints of the lower limb, upper limb involvement is unusual. However, clinical and radiographic changes do occur in the hands and wrists with radiographic changes in the wrists being more common than changes in the hands (Lin et al. 1995; Mason et al. 1959). As with psoriatic arthritis, joint involvement tends to be asymmetrical. The changes seen in the hands are similar to those seen in psoriatic arthritis, with soft tissue swelling, joint space narrowing and proliferative marginal erosions. There may also be

Fig. 16 Psoriatic arthritis: note the extensive bone destruction that has occurred about the distal interphalangeal joints. The cupped appearance to the bases of the distal phalanges is typical

sesamoid enlargement as a result of the periostitis (Stadlnik and Dublin 1975). In contrast to psoriatic arthritis, where DIP joint involvement is most common, the PIP joints are more frequently involved in reactive arthritis than the DIP or MCP joints (Lin et al. 1995). While periarticular osteopaenia is not a typical feature of psoriatic arthritis, it is more widely recognised as occurring in the acute phases of reactive arthritis.

Wrist involvement may occasionally be severe in reactive arthritis. It can involve any of the wrist compartments and is typically asymmetrically distributed (Mason et al. 1959). Periosteal new bone formation is seen with erosions, osteopaenia and soft tissue swelling. Although the new bone formation has a fluffy configuration, more linear new bone may be seen, particularly alongside the radius and ulnar (Mason et al. 1959).

Arthritis Associated with Enteropathic Disease

Arthritis associated with inflammatory bowel disease is generally classified with the seronegative arthritides because the pattern of arthritis is very similar to that seen in ankylosing spondylitis. While axial involvement

Fig. 17 Ankylosing spondylitis: there is exuberant enthesophyte formation at the insertion of the flexor carpi ulnaris tendon onto the pisiform (*arrowhead*). This represents an enthesitis, a typical feature of ankylosing spondylitis

predominates, 15–20% of patients with inflammatory bowel disease exhibit a peripheral arthritis, more frequently seen with Crohn's disease than ulcerative colitis (Gravallese and Kantowitz 1988). Commonly this involves the wrists (along with the knees, ankles and elbows) and the condition occurs as transient arthritis. This is frequently asymmetric and occurrences tend to parallel flares of the inflammatory bowel disease. The arthritis is characteristically non-destructive and while CR may show soft tissue swelling and periarticular osteopaenia, erosions and joint space loss are not usually seen.

Destructive changes have been reported at peripheral joints in association with inflammatory bowel disease, but in this situation the findings are very similar to RA and distinction may not be possible. Indeed the two conditions may coexist.

Hypertrophic osteoarthropathy has a well-recognised association with pulmonary disease, but there is also a rare association with inflammatory bowel disease. HPOA is typically seen as linear periosteal new bone formation at the wrist, involving the radius and ulna, but may also involve the metacarpals. There is some evidence that the periosteal new bone may fluctuate with the disease activity (Arlart et al. 1982).

Although not generally considered alongside the other spondyloarthropathies, an asymmetric erosive arthritis of the hands and wrists with predominantly distal distribution is recognised as occurring in

association with primary biliary cirrhosis (Mills et al. 1981). Hypertrophic osteoarthropathy is also described with this condition.

2.4 Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is the term given to a heterogeneous group of conditions beginning in childhood and involving inflammation in one or more joints. By definition the term encompasses all forms of arthritis beginning before the age of 16 and persisting for more than 6 weeks when other known conditions have been excluded. The most recent classification has been determined by the International League of Associations for Rheumatology (ILAR) and unifies different classifications which previously existed in North America and Europe (Petty et al. 2004). Seven categories of JIA are recognised in the current classification (Table 1) (Petty et al. 2004; Ravelli and Martini 2007). The classification system is not without controversies and further developments may well occur (Ravelli and Martini 2007).

Early in the disease soft tissue swelling and osteopaenia may be seen in the hands and wrists of affected children. However, joint space loss is less frequently seen and often represents a later feature particularly in the oligoarthritis form of the disease. Erosion is also a relatively late radiographic finding in JIA. In patients with seropositive juvenile idiopathic polyarthritis more rapid joint space loss and erosion may be seen, a process similar to that seen in adult onset RA. Deformities may develop including boutonniere, flexion and swan neck deformities in the fingers. Radial deviation of the MCP joints in association with ulnar deviation of the wrist is recognised in JIA, and Resnick has noted the contrast between this pattern and the opposite finding of ulnar deviation of the MCP joints and radial deviation of the wrist commonly seen in adult onset RA (Granberry and Mangum 1980; Resnick 2002a).

Some radiographic findings are more specific to juvenile arthritis. In the late stages of the disease bony ankylosis is a common finding particularly at the wrist where radiographs may demonstrate union of the carpal bones to the metacarpals creating a solid ossific mass (Fig. 18). Periosteal new bone formation is also a common finding in the hands in JIA, typically

Table 1 Classification of Juvenile Idiopathic Arthritis (Petty et al. 2004; Ravelli and Martini 2007)

Category	Clinical features
Systemic arthritis	Arthritis in one or more joints associated with, or preceded by fever and accompanied by one or more of the following: <ul style="list-style-type: none"> • rash • lymphadenopathy • hepatomegaly and/or splenomegaly • serositis
Oligoarthritis	Arthritis in 1–4 joints during the first 6 months of disease This typically occurs in early childhood and is more common in females. The oligoarthritis is usually asymmetric and predominantly affects the lower limbs
Rheumatoid-factor: positive polyarthritis	Arthritis affecting five or more joints during the first 6 months of disease with positive rheumatoid factor The disease typically affects the hands with a symmetric polyarthritis
Rheumatoid-factor: negative polyarthritis	Arthritis affecting five or more joints during the first 6 months of disease without rheumatoid factor
Enthesitis related arthritis	More common in male patients and characterised by the association of enthesitis and arthritis. The disease belongs to the group of spondyloarthropathies
Psoriatic arthritis	
Undifferentiated arthritis	

Fig. 18 JIA: this patient demonstrates many of the late features of JIA. Note the fusion of the carpal bones, cupping and deformity of the proximal phalangeal bases and epiphyseal deformities resulting from growth disturbance

occurring along the metacarpal and phalangeal shafts. Growth disturbances involving the epiphyses of long bones are a further feature of juvenile arthritis (Figs. 18, 19). In the wrists, abnormalities of bone growth are seen in the form of irregular or multiple ossification centres in the carpal bones. In the hands, short, widened phalanges and metacarpals may develop in the later stages of the disease as a result of

growth disturbance and periosteal new bone formation (Fig. 19).

The osteoporotic bone seen in JIA may lead to epiphyseal collapse and deformity as a result of compression fractures due to abnormal stresses on the bone. Cupping of the proximal phalangeal bases as a result of compression by the metacarpals on the osteoporotic bone is described (Resnick 2002a) (Fig. 18).

Fig. 19 JIA: there is epiphyseal deformity at the bases of the intermediate phalanges. There is corresponding deformity to the proximal phalangeal articular surface. Soft tissue swelling is also seen. Also note the widened intermediate phalanges typical of the disease

In common with adult onset RA, tenosynovitis is seen in JIA and may be observed as soft tissue swelling on plain radiographs. Rheumatoid nodules are also seen in JIA; these occur almost exclusively in the rheumatoid-factor-positive polyarthritis subcategory of the disease where they are seen in around one third of patients in the first year of disease (Ravelli and Martini 2007). Again on CR these may be seen as focal soft tissue lumps.

As with adult inflammatory arthritis, the majority of plain film findings represent late stages of the disease. While CR remains important in the assessment of the disease the role of more advanced imaging techniques, such as US and MRI, is increasing. In addition to allowing the visualisation of soft tissue changes such as synovitis, effusion and tenosynovitis; the cartilaginous bone ends of the immature skeleton, where early damage occurs are also demonstrated (Johnson and Gardner-Medwin 2002).

2.5 Advanced Imaging Techniques in Inflammatory Arthritis

Many of the features of inflammatory arthritis seen on CR represent late changes, which are often irreversible. Current guidelines in the management of these conditions emphasise the early and aggressive treatment of inflammatory

arthritis to alter the long-term disease process, minimise joint damage and induce long-term remission.

2.5.1 Synovitis and Effusion

Synovitis is an early feature of many arthritic processes including the inflammatory arthritides and connective tissue disorders. Using plain films the earliest manifestation of synovitis is soft tissue swelling, which may be associated with periarticular osteopaenia. The soft tissue swelling is usually detectable clinically by the time it can be seen on CR. Both US and MRI are readily able to detect synovitis and effusion before changes are visible on CR or detectable at the clinical examination (Farrant et al. 2007a; Peterfy 2001).

Normally synovium is not visualised at US, but when it becomes thickened it is seen as abnormal intra articular soft tissue (Fig. 20a) (Wakefield et al. 2005). The echogenicity of synovitis varies depending on the extent of extracellular oedema, the more fluid present the darker the synovium appears. Generally it appears of low reflectivity when compared with adjacent subcutaneous fat, but it may appear anechoic or brightly hyperechoic. Vascularity will frequently be demonstrated in the synovium using colour or power Doppler (Fig. 20b). When anechoic or hypoechoic, synovitis may be difficult to distinguish from joint fluid, which may have similar echo characteristics. However, with probe pressure fluid will normally be displaced while synovium is non-displaceable and only poorly compressible. Effusion will also show no Doppler signal. The morphology of the inflamed synovium varies, but typically in the low capacity joints of the hand and wrist it appears as thickening of the joint lining or as a solid mass.

On MRI synovitis has been defined as an area in the synovial compartment that shows above normal, post gadolinium enhancement of a thickness greater than the width of normal synovium (Ostergaard et al. 2003). This definition emphasises the importance of post-gadolinium imaging in the detection of synovitis which readily enhances and is otherwise very difficult to distinguish from effusion using conventional T1, proton density and T2 weighted imaging (Fig. 21).

2.5.2 Bone Erosion and Marrow Oedema

US and MRI will demonstrate erosive change resulting from inflammatory arthritis. A defect in the cortical

Fig. 20 Wrist synovitis shown on ultrasound in rheumatoid arthritis: **a** the synovitis is seen as a low reflective soft tissue mass lesion (*S*), in this case on the ulnar aspect of the wrist. Part of the extensor carpi ulnaris tendon can be appreciated just superficial to the synovitis (*arrowhead*). **b** Using power Doppler vascular flow can be demonstrated in the synovitis. *Uln Styloid* ulnar styloid process, *Tri* triquetrum

surface is identified which may contain synovium (Figs. 21, 22). With both techniques the erosion must be identified in two planes to avoid confusion with normal bone surface contours. It is also important to be aware of the normal shape of the bones and in particular the sites of ligament attachments and vascular channels both of which can be confused with erosions. US and MRI are both more sensitive than CR for erosion detection. While US will only show the surface defect of an erosion, MRI shows changes within the substance of the bone marrow at the erosion site in the form of high T2 signal consistent with increased water content and often described as bone marrow oedema (Fig. 21b, c) (Ostergaard et al. 2003). Bone marrow oedema is a common finding in RA reported in 39% of cases of less than 3 years duration and 68% of cases of longer established RA (Savnik et al. 2001).

Marrow oedema may be seen in the absence of erosion and is potentially reversible; it is closely related to the extent of synovitis and may represent pre-erosive change, being strongly predictive of future erosion (McQueen et al. 2003; Haavardsholm et al. 2008; Hetland et al. 2009; Savnik et al. 2002).

2.5.3 Enthesitis

Enthesitis is a characteristic feature of the seronegative arthropathies and is seen in the hand and wrist as a common feature of psoriatic arthritis. MRI demonstrates changes within the bone, in the form of marrow oedema, erosion and enthesophyte, and within the inserting tendon or ligament and surrounding soft tissues in the form of high T2 signal change and thickening of the inserting structure. The changes seen in the inserting tendon or ligament are

Fig. 21 Rheumatoid arthritis shown on coronal MRI: **a** T1 weighted, **b** T2 weighted with fat saturation. Extensive synovitis is seen at the wrist as intermediate signal soft tissue on T1 and high signal soft tissue on T2 weighted imaging. It is best appreciated on the ulnar aspects of the wrist (*arrow*) where

it is seen eroding the triquetrum. **c** T1 fat saturated post i.v. gadolinium. Synovial enhancement is demonstrated. The T2 weighted and post gadolinium imaging demonstrates marrow oedema in the hamate (*asterisk*) and on T1 weighted imaging this is seen to be associated with bone erosion (*arrowhead*)

Fig. 22 Rheumatoid arthritis erosion on US: the index MCP joint is demonstrated in longitudinal section. There is synovitis within the joint (*asterisk*) and an erosion is seen in the metacarpal head (*arrow*). The erosion contains hypochoic synovium. *M* metacarpal head, *P* proximal phalanx

similar to those seen in tendinopathic change. The fingers are sites of multiple entheses all in close proximity and a feature of psoriatic arthritis is dactylitis where widespread inflammatory changes seen throughout the digit which may reflect inflammation at the multiple entheses sites (Fig. 23) (Benjamin and McGonagle 2001). The extensive high T2 signal soft tissue changes seen beyond the joints in psoriatic arthritis are an important distinguishing feature from RA (Jevtic et al. 1995). US will also detect changes at the entheses sites in seronegative arthropathy, but

Fig. 23 Psoriatic arthritis: coronal T2 weighted fat saturated image showing dactylitis. Extensive soft tissue oedema is shown in the digits. Enthesitis is demonstrated as foci of marrow oedema associated with capsular and ligamentous insertion sites (*arrows*) such as the insertion of the collateral ligament of the proximal interphalangeal joint highlighted (*arrowhead*) (Image courtesy of Dr PJ O'Connor and Dr A Radjenovic)

will not show the associated marrow changes. Fine enthesophyte formation is particularly well shown at tendon and ligament insertions using US.

Fig. 24 Rheumatoid arthritis: a transverse ultrasound through the extensor digitorum compartment at the wrist shows tenosynovitis. The extensor tendons (*arrowheads*) are surrounded by fluid (*F*) and synovitis (*S*)

2.5.4 Tendon and Soft Tissue Disease

Tendon disease and tenosynovitis are both features of the inflammatory arthritides. Both US and MRI will demonstrate fluid in synovial sheaths and associated synovitis (Fig. 24). As in the case of joint disease gadolinium enhancement is helpful in distinguishing synovitis from fluid in tendon sheaths. Tendon rupture is a recognised complication of RA and may be due to tendon attrition resulting from adjacent osseous deformities or disease involvement of the tendon itself. Again US and MRI can demonstrate tendon rupture. The dynamic assessment of tendons that can be undertaken with US may help in identifying which tendons are torn and in establishing the location of the torn ends.

Rheumatoid nodules are a feature of RA. They most frequently occur in pressure bearing areas such as the elbow or heel, but are occasionally seen in the hand and wrist. They may occur in the subcutaneous soft tissues or adjacent or within tendons. Nodules typically appear on US as ovoid homogenous low reflective masses (Nalbant et al. 2003). On MRI nodules may have a solid appearance with a homogenous enhancement following gadolinium, but a cystic pattern may also be seen (el-Noueam et al. 1997). When nodules are seen adjacent to bone there may be associated cortical remodelling. The differential diagnosis for a rheumatoid nodule includes a gouty tophus. Bone remodelling is less frequently seen with rheumatoid nodules than with tophi, and tophi generally show increased density resulting in shadowing behind the lesion on US.

2.5.5 Application to Clinical Practice

Increasingly, US and MRI are being used in the early detection of inflammatory arthritis. US has clear advantages in being able to screen multiple joints in both hands and wrists rapidly and inexpensively while MRI is more time-consuming and requires intra-articular injection for the reliable assessment of synovitis. MRI has the advantage of being able to detect the early bone changes of bone marrow oedema along with synovitis and there is evidence to suggest that marrow oedema is the strongest predictor of future erosive damage (McQueen et al. 2003; Savnik et al. 2002). Most studies would suggest that US and MRI are of comparable sensitivity for the detection of synovitis and erosions, although US is limited around some joints, such as the MCP joints and in the wrist, by its inability to fully examine all bone surfaces (Farrant et al. 2007a, b).

2.5.6 Other Imaging Modalities

CT will demonstrate erosive change in bones, but at this time has not found routine clinical application in the investigation of the inflammatory arthritides. Scintigraphy will show increased uptake at inflamed joints using a variety of tracers including conventional ^{99m}Tc -MDP. Inflammatory arthritis will produce increased tracer activity on all three phases of the bone scan. The technique provides a means of observing disease distribution, which may help in indicating the type of arthropathy. It is also sensitive to early changes in the disease process and may give information about disease activity, but bone scintigraphy is not part of the routine investigation of inflammatory arthritis and generally MRI and US can provide similar information.

2.6 Monitoring Disease Progression

The monitoring of disease progression and response to treatment in inflammatory arthritis is currently a subject of intensive research. Plain film scoring methods exist such as those developed by Larsen and Sharp based on erosions, joint space loss and soft tissue changes (Larsen et al. 1977; Sharp 1996). However, in recent years attention has turned to the use of MRI and US for monitoring disease status.

The use of MRI and US to monitor disease progression has concentrated on the scoring of erosive change and synovitis and, on MRI, marrow oedema.

Techniques for monitoring synovitis fall into two broad groups, detection of change in synovial volume and detection of change in synovial vascularity. Both volume and vascularity are predictive of disease activity. Volume can be reliably assessed with MRI but there is considerable technical difficulty in producing reliable measurements of volume on US other than with the use of semiquantitative scores. Vascularity is assessed on MRI using dynamic scanning during gadolinium enhancement and evaluating the shape of the contrast uptake curve which is more rapid in more active disease. Doppler US imaging can be used to assess the vascularity of synovitis, which in RA is shown to increase with disease activity. At this time these techniques remain in the research environment and have not found their way into mainstream clinical practice.

3 The Crystal Arthritides

The crystal arthropathies all involve crystal deposition either in, or adjacent to an affected joint. This is a heterogeneous group of diseases resulting in a variety of radiographic findings. Common crystals implicated are monosodium urate (producing gout), calcium pyrophosphate dihydrate and hydroxyapatite (HA).

3.1 Gout

Although the radiological features of gout are well recognised, the pathophysiology of the disease is more complicated and remains the subject of research and controversy. Fundamental to the disease process is hyperuricaemia resulting either from decreased renal excretion or excess production of uric acid. The condition is frequently described as having four clinical phases (Monu and Pope 2004):

1. Asymptomatic hyperuricaemia: hyperuricaemia may exist in asymptomatic, but susceptible individuals, for years before the onset of clinical and radiographic findings.
2. Acute gouty arthritis: presentation with acute joint inflammation as a result of precipitation of urate crystals into the joint typifies this stage of the disease. While polyarticular disease is recognised, the acute inflammatory attacks are usually monoarticular and involve peripheral joints, usually in the lower limb and most commonly in the foot. Without treatment, progressive attacks result in more joints becoming involved and more chronic disease, which may affect any joint in the body.
3. Intercritical gout: this refers to the period without symptoms between acute attacks. It may last months or even years.
4. Chronic tophaceous gout: in this stage of the disease tophi develop in multiple tissues in the body as a result of urate crystal deposition with associated foreign body giant cell reaction. With the advent of effective antihyperuricaemic therapy this stage of the disease is becoming less common. Tophaceous deposits occur in a wide variety of tissues including tendons and ligaments, cartilage, bone and other soft tissues. Deposition in tendons and ligaments may lead to rupture (Moore and Weiland 1985) while mass effect may produce neural compression and gouty deposits are a recognised cause for carpal tunnel syndrome (Chen et al. 2000; Ogilvie and Kay 1988).

3.1.1 Imaging Findings

Gout arthritis may involve any of the joints in the hand and wrist, but the DIP and PIP joints are most frequently affected. In the acute stages of the disease the radiographic findings are often non-specific, soft tissue swelling may be evident. If US and MRI are undertaken an effusion may be evident. The bone and soft tissue changes become more characteristic and apparent in the chronic phase of the disease where soft tissue tophi develop. These are appreciated as asymmetrical soft tissue swellings and the hands are frequently involved. Although calcification of the soft tissue swellings may occur it is said to be an unusual finding, and is likely to reflect a disorder of calcium metabolism such as associated renal impairment (Fig. 25) (Watt and Middlemiss 1975).

Joint space usually remains well preserved until late in the disease despite extensive erosive change, and this is one of the key features of the disease helping to distinguish it from other arthritides (Fig. 26). Erosions

Fig. 25 Gout in patient with chronic renal failure: This patient has gout with large asymmetric soft tissue tophaceous masses about the distal interphalangeal joint which shows erosive change best appreciated in the terminal phalanx. The tophi are heavily calcified, a feature that is seen particularly in patients with renal impairment

result from tophi and may occur within joints, but are often seen some distance from the joint. The erosions have a characteristic circular or ovoid configuration and may have a sclerotic margin. Overhanging margins giving a ‘punched out’ appearance to the erosion are typical (Fig. 26) (Watt and Middlemiss 1975). Joint disease in the hand most commonly involves the interphalangeal joints in an asymmetrical distribution. All compartments in the wrist may be involved and extensive osseous erosion in the wrist is not uncommon.

US may detect crystal deposition on the articular cartilage and this has been reported in 92% of joints affected by gout (Thiele and Schlesinger 2007). The crystal deposition on the cartilage surface gives a double contour appearance to the joints. Both MRI and US will detect erosions due to gout and show tophaceous material associated with them. The tophi are seen as low reflective structures that are highly attenuating with shadowing behind the lesion. Crystal material within their substance varies from hypo- to hyperechoic. Lesions are clearly defined and may demonstrate marked hyperaemia. MRI shows tophi as structures of intermediate to low signal intensity on

Fig. 26 Gout: this radiograph shows the typical ‘punched-out’ erosions with overhanging edges seen in gout. Note the marked soft tissue swelling and relative preservation of joint space, both features of this disease (Image courtesy of Dr PJ O’Connor)

short TE imaging but with variable intensity on T2 weighted imaging, most frequently heterogenous intermediate to low signal. It has been postulated that the variation in T2 intensity may relate to differences in calcium concentration (Yu et al. 1997). Bone erosion by soft tissue tophi is more commonly seen in the feet than the hands. Tophaceous involvement of tendons in the hand may also be seen on US and MRI.

3.2 Calcium Pyrophosphate Crystal Deposition Disease (CPPD)

Calcium pyrophosphate dihydrate (CPPD) deposition disease may be a primary abnormality or may occur in association with other conditions. Given how common CPPD deposition disease is it has been pointed out that many of the suggested associations that have been described in the past may be simple chance occurrence of two disorders (Resnick 2002b).

The nomenclature of CPPD deposition disease is confusing and controversial. The following guidelines on terminology have been put forward and are helpful for the radiologist (Resnick 2002b; Steinbach 2004; Steinbach and Resnick 1996):

Chondrocalcinosis Refers to the presence of cartilage calcification identified radiologically or pathologically.

It can be due to a variety or combination of calcium crystals including calcium pyrophosphate dihydrate.

CPPD deposition disease A specific term indicating a disorder characterised by CPPD crystals in or around joints.

Pseudo-gout This is a clinical syndrome produced by CPPD crystals resulting in acute attacks of gout like symptoms. The diagnosis is clinical and cannot be made radiologically.

Pyrophosphate arthropathy This term describes a pattern of joint damage occurring in CPPD deposition disease. It resembles OA but has some distinct features. Chondrocalcinosis may or may not be present on radiographs demonstrating pyrophosphate arthropathy.

One of the reasons for the confusion is the highly variable presentation of the disease. Calcium pyrophosphate deposition may be completely asymptomatic or result in severe destructive arthropathy, its ability to mimic other arthritides has been emphasised (Steinbach 2004; Martel et al. 1970). Patients with symptomatic CPPD deposition disease generally present with an OA like arthropathy although an acute inflammatory component may be seen. Intermittent attacks of pseudogout are said to occur in 10–20% of symptomatic patients and result from the shedding of pyrophosphate crystals into the joint (Steinbach 2004). The wrist is a frequent site for attacks of pseudogout. Synovitis associated with CPPD crystal deposition disease is a recognised cause of carpal tunnel syndrome.

3.2.1 Imaging Findings

The hallmark of CPPD deposition disease is the presence of CPPD crystals in or around a joint. This is most commonly seen in the form of chondrocalcinosis, but crystal deposition may also occur within synovium or capsular tissues. It is important to realise that the presence of these findings alone does not infer pyrophosphate arthropathy and pyrophosphate arthropathy does not require radiographic evidence of CPPD crystals. In the wrist chondrocalcinosis is frequently identified in the triangular fibrocartilage, although it has been shown that crystal deposition in the lunate-triquetral ligament is more common (Fig. 27) (Yang et al. 1995). Hyaline cartilage deposition may also be seen. Pyrophosphate arthropathy shows similar changes to OA with joint space narrowing along with subchondral sclerosis and cyst

Fig. 27 Calcium pyrophosphate deposition: there is calcium crystal deposition in the triangular fibrocartilage (*arrowhead*). In addition crystal deposition is also seen in the lunotriquetral ligament (*white arrow*) and in the synovium of the distal radial the joint (*black arrow*)

formation. However, the distribution of the changes in the wrist contrasts with the classic trapeziocentric distribution of OA with a strong predilection for the radiocarpal wrist compartment (Fig. 28a). Associated with crystal deposition there may be disruption of the triangular fibrocartilage and ligamentous dysfunction resulting in rotatory subluxation of the scaphoid and scapholunate disassociation; this gives rise to a pattern of dorsal intercalated segment instability (DISI) similar to that seen following trauma. This pattern of scapholunate advanced collapse of the wrist (SLAC wrist) was originally described as a feature of OA but studies indicate that CPPD deposition disease is also a major cause of SLAC wrist (Chen et al. 1990).

The pattern of joint disease in the hands is also different to that seen with generalised OA with relative sparing of the interphalangeal joints and involvement predominantly of the MCP joints, most frequently those of the index and middle fingers (Fig. 28b). Another typical feature of the disease is the presence of hook like osteophytes generally seen on the radial aspect of the metacarpal head; this pattern of osteophytosis is particularly seen in patients with haemochromatosis and pyrophosphate arthropathy, a recognised association. As with idiopathic pyrophosphate arthropathy, involvement of the index and middle MCPs is commonly seen with

Fig. 28 Pyrophosphate arthropathy: **a** calcium pyrophosphate crystal deposition can be seen in the synovium about the triangular fibrocartilage and in the distal radial on the joint. There is also crystal deposition in the lunotriquetral ligament. This is associated with arthropathy. The distribution of arthritis in the wrist is not typical for osteoarthritis. There is involvement

of the radiosaphoid and midcarpal joints, but note the preservation of the scaphotrapezial and thumb carpometacarpal joints. **b** In the same patient there is arthropathy involving the middle MCP joint with subchondral cyst formation, joint loss and early osteophyte formation (*arrow*)

Fig. 29 Haemochromatosis arthropathy: there is joint space loss at the index and middle MCP joints with subchondral sclerosis. Involvement of the ring and little MCP joints and the little PIP joint can also be appreciated. Note the typical hook like osteophytes (*arrows*)

haemochromatosis; however, it has been observed that involvement of the ring and little finger MCP joints is also seen and is more common in patients with haemochromatosis than in those presenting with idiopathic pyrophosphate arthropathy (Fig. 29) (Steinbach 2004; Adamson et al. 1983).

Crystal deposition in cartilage and synovium and soft tissues including tendon is readily detected using US (Ciapetti et al. 2009). The position of crystals within the substance of cartilage is helpful in

distinguishing pyrophosphate arthropathy from gout, where the crystals lie on the surface of the cartilage forming the double contour appearance.

3.3 Calcium Hydroxyapatite Crystal Deposition Disease

Hydroxyapatite (HA) deposition disease is the best characterised of a group of crystal deposition diseases

Fig. 30 Hydroxyapatite deposition: a large hydroxyapatite deposit is seen in the soft tissues adjacent to the middle MCP joint. Note the amorphous appearance. In this case the crystal deposition has a relatively well-defined margin

that may cause acute or chronic joint symptoms. The pathophysiology of the disease remains poorly understood. Crystal deposition may occur both in the periarticular tissues, most commonly tendons and ligaments, and within the joint itself and the disease can be usefully considered in two forms, periarticular disease and intra-articular disease (Uri and Dalinka 1996).

3.3.1 Periarticular HA Deposition Disease

The wrist and hand are common sites for HA crystal deposition and patients present with pain and swelling in the acute situation. When this occurs the pain may be particularly severe although in the more chronic situation the pain and tenderness is usually mild. Wrist involvement is more common than hand involvement, and crystal deposition usually occurs in tendons or ligaments, a particularly common site is in the flexor carpi ulnaris tendon on the ulnar aspect of the wrist (Gandee et al. 1979). In the hand the soft tissues around the MCP joints and the fingers are relatively common sites (Fig. 30). The calcification is seen on plain films and generally has an amorphous appearance without internal trabeculation. Deposits may have ill-defined borders or have a more well circumscribed appearance. While HA deposits may remain static on sequential radiographs, a notable

feature is that the calcification may change in size becoming larger, smaller or even disappearing completely; and such changes may occur over a relatively short period of time. A definite history of trauma is rarely given, but there is some suggestion that HA deposition in soft tissues may be related to repetitive low grade trauma such as may occur with certain occupations and activities (Gandee et al. 1979).

3.3.2 Intra-Articular HA Deposition Disease

Intra-articular HA deposition can occur without visible changes on the radiograph. However, crystal deposition in the synovium or capsule may be seen and occasionally chondrocalcinosis is identified (Uri and Dalinka 1996). The hands and wrists are more frequently involved than the larger joints. A destructive arthropathy resembling OA may be seen with joint space loss and osteophyte formation.

4 Osteoarthritis (OA)

Despite its ubiquitous nature and increasing prevalence as a result of an ageing population, the pathophysiology of OA remains poorly understood and the subject of considerable research. The advent of advanced imaging modalities such as MRI and US has started to reveal that OA should be considered a disease of the whole joint and not just one of articular cartilage and bone, which is often the impression given by the plain film. Synovitis, effusion, marrow oedema and ligamentous and fibrocartilage abnormalities are now recognised imaging features of the disease and may play an important role in the pathogenesis of pain.

It is recognised that certain risk factors exist for the development of OA, including intrinsic problems with the joint such as previous trauma, laxity or bone deformity. However, other factors are also important, including gender and genetic susceptibility, along with extrinsic factors acting upon the joint such as obesity or joint overuse as a result of sporting or occupational activity (Felson 2004). OA may occur in one or more joints as a direct result of acute or chronic repetitive trauma; but the hand and wrist is an important site for the development of idiopathic OA. In this case, there is usually involvement of other larger joints such as the knees, hips and spine.

Fig. 31 Osteoarthritis: The typical ‘saw-tooth’ appearance of interphalangeal joint OA is seen. Note also the subchondral cyst formation and sclerosis

4.1 Plain Film Findings

The characteristic features of OA seen on CR are well recognised and reflect changes in the articular cartilage and subchondral bone along with osteophyte formation. Cartilage thinning and degradation is recognised as joint space narrowing. Subchondral bone change includes eburnation, sclerosis and cyst formation. Periarticular osteoporosis is not a feature of the disease.

In the hand the most commonly affected joints are the interphalangeal joints of the fingers and the thumb. Changes in both the PIP and DIP finger joints are frequently seen, but isolated involvement of the DIP joints may occur. Involvement of the PIP joints without DIP joint involvement is relatively unusual. Wrist involvement is almost always confined to the thumb base in a trapeziocentric distribution.

4.2 Findings at Specific Joints

4.2.1 Interphalangeal Joints

The classical features of OA described above are all seen at the interphalangeal joints. Subchondral cyst formation may be particularly prominent. In many joints cartilage loss in OA, seen as joint space narrowing, occurs asymmetrically within the joint favouring areas where the joint experiences particular pressure. In interphalangeal joints, joint space loss frequently occurs across the whole joint. Areas of eburnation and subchondral collapse may produce a characteristic ‘saw-tooth’ appearance to the articular surfaces (Fig. 31).

Osteophytes are often seen on the dorsal aspect of the interphalangeal joints where they may track proximally. The hands are usually evaluated radiographically with a

dorsal-palmar view and on this single view the extent of such osteophytosis may not be appreciated. Osteophytes account in part for the palpable swellings appreciated at the DIP and PIP joints and termed Heberden’s and Bouchard’s nodes, respectively. However, it is also recognised that cystic distension of the joint capsule with gelatinous material and synovium is also seen, particularly at the DIP joints, and in some cases this may account for the nodes. Such cysts appear to extrude through points of weakness in the capsule, typically either side of the central extensor tendon (McGonagle et al. 2008; Tan et al. 2005).

4.2.2 Metacarpophalangeal Joints

Involvement of the MCP joints is not uncommon but usually only occurs in the presence of more distal disease involving the interphalangeal joints of the hand (Martel et al. 1973). In contrast, pyrophosphate arthropathy characteristically affects the MCP joints proving a useful distinguishing feature where otherwise, in the absence of any visible crystal deposition, it shows features similar to OA. In many cases joint space loss is the only finding and the presence of OA elsewhere and the absence of erosions and periarticular osteopaenia must be used to distinguish OA from inflammatory arthritis. Osteophytes when present are usually small, in comparison to the larger osteophytes seen in CPPD deposition disease.

4.2.3 The Wrist

Trapeziocentric Joints

The usual pattern of wrist OA involves the thumb base, occurring at the thumb carpometacarpal joint (trapeziometacarpal) and scaphotrapezotrapezoidal (STT) joint (between the scaphoid, trapezium and trapezoid). In the absence of trauma causing secondary OA, involvement of the other joint spaces in the wrist is uncommon and when seen, should suggest the possibility of an alternative diagnosis such as pyrophosphate arthropathy.

It is often helpful to think of the articulations between the scaphoid, trapezium, trapezoid and thumb metacarpal as a single unit and disease here can be summarised as trapeziocentric or pantrapezial. While either the STT joint or thumb carpometacarpal joint may show isolated OA changes, involvement in the two joints together is common (Fig. 32) (North and Eaton 1983). There is evidence that CR overestimates the

Fig. 32 Osteoarthritis: this example shows the typical appearances of thumb base OA involving the CMC joint. There is radial subluxation of the metacarpal base. In this case the STT joint is preserved. Also note the preservation of the remaining wrist joints typical of OA

extent of disease involving this unit. North and Eaton showed that while trapeziocentric OA was seen in 73% of cases radiographically it was found to be present in only 46% at anatomical dissection (North and Eaton 1983). Characteristic changes of sclerosis, osteophytosis, joint space loss and subchondral cyst formation are seen. Osteophytosis is particularly common at the thumb carpometacarpal joint where bony fragmentation may also be seen. It is thought that the pathogenesis of OA at the thumb carpometacarpal joint may result from abnormal joint laxity and radial subluxation of the metacarpal base at the carpometacarpal joint is a feature of advanced disease (Fig. 32) (Sicre et al. 1997). It has been noted that the saddle-shaped articulation between the trapezium and thumb metacarpal is generally flatter in women than men, and therefore inherently less stable (North and Rutledge 1983).

Other Wrist Joint Involvement

Injury to the wrist may result in secondary OA involving wrist joints other than those at the thumb base. Classically radiocarpal or midcarpal OA may be seen following scaphoid injury. If fracture occurs, secondary OA may develop, generally between the radial styloid and distal fragment of the scaphoid. This situation is known as scaphoid non-union advanced collapse (SNAC) and, in the later stages of the disease, involvement of the radio-scaphoid joint and subsequently the midcarpal joint is seen (Krimmer et al. 1997). Radioscaphoid disease progressing to midcarpal

Fig. 33 SLAC wrist: osteoarthritis has developed following an injury with disruption of the scapholunate ligament (note widening of the scapholunate interval). Changes of OA are seen at the radioscaphoid joint, typical with this pattern of disease

disease is also seen as a consequence of scapholunate disassociation and has been termed scapholunate advanced collapse (SLAC) (Fig. 33) (Watson and Ballet 1984). This pattern of joint disease is also seen as a consequence of pyrophosphate arthropathy and the distinction can only be reliably made if there is evidence of CPPD deposition disease (Chen et al. 1990).

A further pattern of wrist OA may be seen in association with positive ulnar variance leading to impingement across the ulna-lunate and ulna-triquetral joints. This has been termed the ulnocarpal impaction syndrome and results in findings typical of OA involving the ulna-lunate and ulna-triquetral joints. Dissociation of the lunate and triquetrum may be seen on CR as a consequence of lunate-triquetrum ligament disruption. MRI will also show this feature along with perforation of the triangular fibrocartilage, which is commonly associated.

4.3 Inflammatory OA

While OA is not generally viewed as an inflammatory arthritis, a subgroup of patients is recognised as having an inflammatory variant of the disease, which has been termed inflammatory OA (Ehrlich 1972a; Utsinger et al. 1978). Since these patients may show erosions the term erosive OA has also been used.

Fig. 34 Erosive OA: there is central (subchondral) erosion typical of erosive osteoarthritis

Although large joint involvement has been recognised, inflammatory OA characteristically affects the small joints of the hands. The relationship between conventional OA and erosive OA is unclear and authors have suggested on the one hand that the two arthropathies may constitute separate disease entities (Peter et al. 1966), while others suggest it may belong at one end of a disease spectrum (Grainger et al. 2007; Cobby et al. 1990). It has also been postulated that inflammatory OA represents a disease entity at an interface between OA and RA (Ehrlich 1972b). With the advent of more advanced imaging modalities it is apparent that cases not considered erosive using plain film criteria may show erosions with MRI (Tan et al. 2005; Grainger et al. 2007). These findings suggest that the division of OA into erosive and non-erosive forms on the basis of CR may be artificial.

4.3.1 Radiographic Features

The radiographic hallmark of erosive OA is the presence of erosive change alongside the expected findings in OA of joint space narrowing and proliferative change. Sites of involvement in the hand and wrist are the same as those seen in generalised primary OA although erosive change at the thumb base is rarely seen even in the presence of interphalangeal joint erosions. Erosions in inflammatory OA are typically central in location, which contrasts with the marginal erosions seen in rheumatoid and psoriatic arthropathy (Fig. 34). Nevertheless marginal erosions, indistinguishable from those seen in RA, may be demonstrated, particularly using MRI (Grainger et al. 2007; Kidd and Peter 1966). The central pattern of erosion may be due to synovial inflammation but it is

also suggested it relates to collapse or pressure atrophy of the subchondral bone. Central erosions may lead to the characteristic ‘seagull wing’ appearance. Periosteal new bone formation may be seen although it is not usually as florid as that found in psoriatic arthritis. Bony ankylosis is a relatively frequent occurrence in inflammatory OA (Martel et al. 1980).

Distinguishing erosive OA from inflammatory arthropathy can be difficult. OA typically affects the PIP and DIP joints, which is useful in distinguishing it from RA with its generally more proximal distribution. The bone proliferation and sclerosis seen in OA also contrasts with the appearances of RA where osteopaenia is the typical finding. When seen in the wrist, erosive OA will usually show the characteristic thumb base distribution of OA while the inflammatory arthritides will show involvement in all wrist compartments. The distinction between erosive OA and psoriatic arthritis can be more difficult as the latter also shows bony proliferation in the form of enthesophyte formation and a distal distribution. The central pattern of erosion helps in distinguishing the two conditions, as does the more florid periosteal new bone seen in psoriatic arthritis. The presence of OA elsewhere such as the thumb base may also give clues, but it is important to remember that OA is a common condition and may coexist with seronegative arthritis or RA. This occurrence may account for some cases diagnosed as erosive OA.

4.4 Advanced Imaging Techniques

MRI has been used in a research capacity to look at OA in the hand and this has given valuable information on the potential aetiology of the disease (Tan et al. 2005, 2006a, b). However, as yet there are no mainstream applications for the routine use of MRI in hand and wrist OA. Similarly US is readily able to detect changes of OA, particularly synovitis, osteophyte and effusion (Keen et al. 2008a, b). While US appears to be more sensitive to the detection of osteophyte and joint space narrowing in hand and wrist OA than CR, its use as a diagnostic tool remains confined to the research environment (Keen et al. 2008b). US is useful as a technique for guiding therapeutic injection to the carpometacarpal joint in cases of trapeziocentric OA (Gregory et al. 2008).

Fig. 35 Scleroderma: the study demonstrates extensive soft tissue calcification seen in subcutaneous tissues. Note also the soft tissue loss from the tips of the fingers

5 Connective Tissue Disease

5.1 Scleroderma

Scleroderma is a connective tissue disorder with characteristic radiographic abnormalities seen in the bones and soft tissues and frequently affecting the hands and wrists. Raynaud's syndrome (paroxysmal vasospasm of the digital arteries) is associated with the disease and may be the presenting feature. Joint involvement is an important component of the disease.

Radiographic features of scleroderma in the hands include:

- Soft tissue resorption at the fingertips: this is a common finding which may be visible on CR if the tissues overlying the distal tip of the terminal phalanx are examined (Fig. 35).
- Soft tissue calcification: The hand is the most common site for calcinosis seen in scleroderma and calcification may be seen in both of the subcutaneous tissues and periarticular capsular tissues. The calcification has an amorphous appearance (Fig. 35).
- Bone erosion and articular involvement: the most frequent pattern of bone loss in scleroderma involves resorption of the terminal tuft, which can result in

complete destruction of the terminal phalanx. Patients may go on to develop an erosive arthropathy which generally favours the distal and PIP joints with sparing of the wrist; although it has been noted that involvement of the first carpometacarpal joint may be seen (Resnick et al. 1978). A pattern of erosive arthropathy has been reported in patients with scleroderma that much more closely resembles RA with a deforming arthropathy involving the hands and wrists (Armstrong and Gibson 1982; Baron et al. 1982). However, it has been emphasised that when these findings are seen they may represent part of an 'overlap syndrome' with features of both diseases, or indeed the coexistence of the two diseases (Armstrong and Gibson 1982).

5.2 Dermatomyositis and Polymyositis

Dermatomyositis and polymyositis are connective tissue disorders both characterised by muscle inflammation and weakness, and in the case of dermatomyositis, skin involvement. Both conditions may give rise to soft tissue calcification. Characteristically intramuscular calcification involves the proximal limb muscles, but subcutaneous calcification similar to that seen in scleroderma

may be seen in the hands, as may distal phalangeal resorption. Joint involvement may also occur clinically although radiographs are normally unremarkable or show subtle changes such as periarticular osteopaenia and soft tissue swelling. Occasional reports of destructive joint changes exist (Bunch et al. 1976).

5.3 Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a connective tissue disorder predominantly affecting women during childbearing years. Early clinical manifestations include systemic malaise and fever, skin rash and articular symptoms. In the later stages of the disease more severe multisystem involvement may be seen. Articular symptoms are common and have been reported in 76% of patients (Labowitz and Schumacher 1971), although the figure may be as high as 90% (Resnick 2002c). Symmetrical, bilateral involvement of the small joints of the hands is common. The most frequent finding is synovitis, and radiographs may show soft tissue swelling and osteopaenia (Weissman et al. 1978). At this stage MRI and US will demonstrate the effusion and synovial thickening. Erosive change is not typical of the disease and has only occasionally been reported (Weissman et al. 1978). This provides an important distinguishing feature from RA. It remains unclear whether those cases showing erosions in fact represent a group of patients with both SLE and RA.

A distinctive feature of SLE is a deforming non-erosive arthropathy, which may develop early in the disease course, but is more common later in the disease (Fig. 36) (Resnick 2002c; Weissman et al. 1978). Involvement is usually symmetrical involving multiple digits with a combination of deformities and subluxations that are commonly reducible. Swan-neck and Boutonniere deformities typical of those seen in RA are seen, but joint space loss and erosion are rarely seen even with severe deformities. Hyperextension at the thumb interphalangeal joint is said to be characteristic. It has been noted that the deformity may disappear when the hand is positioned for radiography (Resnick 2002c). These changes may also be seen in children where they may mimic JIA (Martini et al. 1987).

Some patients may demonstrate soft tissue calcification, and terminal phalangeal sclerosis has also been reported. The latter can occur in the absence of

Fig. 36 SLE: subluxations, which were reversible, are seen at the MCP joints. However, note the absence of erosions and the preservation of joint spaces

associated Raynaud's phenomenon (Weissman et al. 1978). Osteonecrosis is a well-recognised feature in SLE and may occur in the hands where its presence (typically in the MCP heads) should raise the question of possible SLE (Weissman et al. 1978; Fishel et al. 1987). Other features that have been reported include subchondral cyst formation, typically in the metacarpal heads and carpal bones, and occasionally 'hook erosions' seen as bony defects usually on the radial aspect of the metacarpal heads (Resnick 2002c).

5.4 Rheumatic Fever (Jaccoud's Arthropathy)

A deforming hand arthropathy associated with rheumatic fever is well recognised and is radiologically indistinguishable from the deforming non-erosive arthropathy of SLE. It has been termed Jaccoud's arthropathy. This usually occurs after repeated attacks of rheumatic arthritis.

Joint involvement is commonly seen in the course of an acute attack of rheumatic fever where multiple joints may be involved either simultaneously or successively. This joint inflammation may be seen as soft tissue swelling on CR. US and MRI may detect small joint effusions and occasionally tenosynovitis.

5.5 Mixed Connective Tissue Disease

Mixed connective tissue disease, as its name suggests, combines overlapping features of the connective tissue diseases and RA. A wide range of articular and soft tissue abnormalities may be seen on hand and wrist radiographs including osseous erosions, bone deformity, soft tissue calcification and atrophy and resorption of the terminal phalanges. Articular changes are most commonly seen in a proximal distribution similar to that seen in RA, involving PIP and MCP joints and the wrist.

Abstract

Penetrating injuries and staphylococcal pathogens are the most frequent causes of infections at the hand, with the soft tissues involved in about 95%, and the bones and joints in 5%, only. In soft tissue infections, MRI is mostly necessary for depicting infections of the deep palmar spaces, whereas finger infections are prone to clinical examination. Typically, bone and joint infections are first visible in radiograms two weeks after clinical onset. MRI is powerful in early detection and in the assessment of spreading of both osteomyelitis and infectious arthritis, the adjacent soft tissues included. CT imaging is the modality of choice in the search of sequestra and cloaca when the superficial soft tissues and the skin are involved in chronic osteomyelitis. At the hands, rare infections are of tuberculous, syphilitic, leprous, viral, fungal, and parasitic origin.

1 General Aspects

1.1 Introduction

Infectious diseases of the hand affect the soft tissues, the bones, and the joints solely or in combination. In the past, the final diagnosis was made by clinical, laboratory findings, and radiographic survey views (Hausman and Lissner 1992). However, the approach toward dedicated diagnostic imaging has changed for several reasons in the last decade (Pineda et al. 2009; Santiago-Restrepo et al. 2003): First, imaging accuracy has significantly improved with the introduction of the high-resolution techniques of ultrasound, CT,

Fig. 1 Synopsis of the infectious pathways at the hand skeleton. **a** Direct pathways of infection with implantation or hematogenous spread of pathogens into the soft tissue (1), the joint (2), and the bone (3). Stars are used for symbolizing both the direct and hematogenous infection routes. **b** Indirect pathways comprising spreads of an infection from the soft tissues into the bone (4) or into the joint (5), and finally from the bone marrow into the adjacent joint and vice versa (6).

and MRI. Second, the advance of refined surgical and medical treatment options has increased the pre-tension according to detailed wrist and hand imaging. Third, the spectrum of hand infections has changed over the years with the expansion of the worldwide travel and the increasing number of surviving individuals suffering from immunodeficiency diseases.

Early diagnosis of hand infections is essential to prevent functional impairment or even destruction disease which usually remains secondary to delayed or insufficient treatment.

1.2 Routes of Infection

The soft tissues, bones, and joints of the hand can be contaminated by different routes (Fig. 1) (Tsai and Failla 1999; Resnick 1976):

- *Direct implantation of pathogens:* The infection arises directly after penetrating injuries with disruption of the overlying skin. This route is by far

c Marked thickening of the palmar digital bulb in the presence of a felon. The bony terminal phalanx is not involved. **d** In another case, infectious spread of a felon from the palmar soft tissues to the terminal phalanx is evident and has caused infectious bone destruction. **e** Subacute bacterial arthritis of the proximal interphalangeal joint immediately following a penetrating stab injury. There are deep erosions of the subchondral plates aside onset of sclerosing bone reaction

most frequent at the hands. In a similar pathway, pathogens can be incidentally inoculated during arthrography and arthroscopy, in open surgery as well as in transcutaneous insertion of pins.

- *Spread from a neighbored source of infection:* An infectious focus extends from one tissue layer to another, e.g. from the subcutis to the bones or joints, or from the bone marrow to an adjacent joint and the surrounding soft tissues, or from one to another communicating tendon sheath.
- *Hematogenous spread of infection:* Pathogens are inoculated via the blood circulation. Common sources of transient bacteremia are the respiratory, genitourinary, and gastrointestinal systems besides others and equivocal cases. This pathway is infrequent at the hands.

1.3 Imaging Techniques

Conventional radiograms (CR) complimented by fluoroscopic spot views in equivocal cases are

exposed to exclude or confirm inflammatory involvement of the hand skeleton. Eight to ten days usually pass before signs of osteomyelitis are visible. Early signs of acute osteomyelitis include subtle periosteal reaction and focal subperiosteal osteopenia (Capitanio and Kirkpatrick 1970). Osteolyses follow within the next weeks, and osteosclerosis appears in the chronic stage. Obliteration and swelling of the periarticular soft-tissue planes (“soft-tissue sign of arthritis”), periarticular osteopenia (“collateral sign of arthritis”) as well as articular destruction (“direct signs of arthritis”) appear in acute pyogenic arthritis and will progress in days to weeks. Soft-tissue calcifications are sometimes seen in tuberculosis of the tendon sheath.

Nuclear scintigraphy (NUC) with ^{99m}Tc phosphonates provides information about local hyperemia when using the three-phase technique (angiographic, blood pool, and delayed phases). For early detection of an infectious source, this technique is useful days and weeks before abnormalities become visible in radiograms (Gold et al. 1991). If scintigraphic results are unremarkable, an acute infection of the hand skeleton can be excluded. Soft-tissue infections lead to regional hyperemia with a diffuse nuclide uptake in the area involved and the contiguous bone skeleton. If soft-tissue infection directly spreads to the adjacent bones and joints, a marked nuclide uptake indicating hyperemic bone metabolism is mostly evident in three-phase scintigrams. However, positive scintigraphy does not allow differentiation between posttraumatic bone remodeling and infection, because an increased formation of fibrous bone, and therefore, an increased binding of ^{99m}Tc phosphonates is seen in both disease entities (Schauwecker 1989). This is also the case in chronic osteomyelitis. Differentiation can be tried with gallium scintigraphy which is sensitive to active bone disease (Pineda et al. 2009; Gold et al. 1991).

Scintigraphy with ^{99m}Tc -HMPAO-labeled leukocytes and ^{99m}Tc -nanocolloids as well as immunoscintigraphy with ^{99m}Tc -labeled monoclonal granulocytes or human unspecific immunoglobulin selectively demonstrates acute granulocyte-induced inflammations (Schauwecker 1989). There are some limitations: First, in the early months after an injury, leukocytic scintigraphy cannot differentiate between reparative remodeling and inflammatory processes. Second, in aseptic arthritis such as rheumatoid

arthritis and chronic infections such as tuberculous or leprous arthritis, uptake of labeled granulocytes can simulate findings of active osteomyelitis and pyogenic arthritis.

Ultrasonography (US) is the first-line imaging method when a fluid or abscess collection is assumed in the soft tissues and joint spaces (Kothari et al. 2001). For high-resolution US of the hands, probes of 10 MHz or more must be used. An important indication of US is the search for foreign bodies that are invisible in radiograms (Peterson et al. 2002). In the presence of osteomyelitis, involvement of the contiguous soft tissues can be screened with US.

Computed tomography (CT) is well suited to delineate the destructive bone processes in osteomyelitis, i.e. the sequestrum, the surrounding granulation tissue, and the involucrum. A sequestrum can be reliably detected in CT imaging by means of its dense eburnization and its location within the granulation tissue (Pineda et al. 2009; Santiago-Restrepo et al. 2003; Gold et al. 1991). Due to less sensitivity in comparison with MRI, CT is applied in the evaluation of soft-tissue inflammation in equivocal cases only for the search of foreign bodies and intraosseous or intraarticular air collections. Because osteomyelitis is often associated with soft-tissue infection, intravenous administration of a contrast agent is recommended for proper detection. The imaging features of an abscess are the peripheral enhancement and the semi-liquid abscess center (Kothari et al. 2001). Retrograde contrast-filling of a sinus tract (sinography) can be combined with CT scanning to depict the course of a sinus tract from the cutaneous orifice back to its medullary origin (Santiago-Restrepo et al. 2003). Finally, CT imaging—and also ultrasonography—is used for guiding percutaneous punctures of soft tissues, bones, and joints to obtain fluid for bacteriologic evaluation.

Magnetic resonance imaging (MRI) is very sensitive in detecting infections of the soft tissues, the bones, and joints and in depicting the extension of the inflammation (Pineda et al. 2009; Gold et al. 1991; Hopkins et al. 1995; Towers 1997; Morrison et al. 1993). The use of a dedicated surface coils or phased-array multi-channel coils is premise for MRI of the hand to obtain high-resolution images. In literature, the necessity of intravenous gadolinium is controversially discussed. According to the authors' experience, the administration of gadolinium is mandatory

for further characterizing infectious bone, joint, and soft-tissue edema. Differentiation between vascularized inflammatory tissue and central abscess colligation zone is facilitated with the use of gadolinium (Hopkins et al. 1995; Towers 1997; Morrison et al. 1993). However, it must be mentioned that MRI is inferior to CT imaging in detecting sequestra (Pineda et al. 2009; Gold et al. 1991). The T2-weighted fat-saturated FSE sequence (alternatively, the STIR-FSE sequence) and the T1-weighted fat-saturated SE sequence after gadolinium—both acquired in the transaxial plane—are most suitable to determine extra- and intraosseous inflammatory processes. The other imaging planes are crucial to determine the extent of the infection in the longitudinal direction.

2 Soft-Tissue Infections

In about 95% of all infections of the hand, exclusively the soft tissues are involved, namely the cutaneous, subcutaneous, fascial, tendinous, ligamentous, muscular, and synovial structures, whereas bones and/or joints are affected in only about 5% (Hausman and Lisser 1992; Tsai and Failla 1999). The heterogeneous spectrum comprises paronychia, felons, suppurative tenosynovitis, deep space infections, and gangrenous infections. The most common cause in etiology is a penetrating injury, while hematogenous spread is less frequent (Tsai and Failla 1999; Resnick 1976). Even the tiniest injury, such as a paronychial tear during nail care, is sufficient to inoculate pathogenic organisms. Individuals with a compromised immune system and/or sensory deficiency (e.g. patients suffering from diabetes mellitus or severe carpal tunnel syndrome) are predisposed to infections. In initial stages, infections mostly remain at the site of origin, since there are a number of anatomically defined compartments, like the subcutaneous space, the deep palmar spaces, the tendon sheaths, and the joint compartments. Clinical symptoms are local redness, hyperthermia, swelling, pain, and functional impairment.

Physical examination is usually sufficient for final diagnosis. However, when clinical uncertainty exists, diagnostic imaging can provide essential information for treatment decision, e.g. if an abscess in the deep spaces must be excluded or localized precisely (Beltran 1995). Furthermore, the pathogens can be

identified with ultrasound-guided aspiration to specifically initiate antibiotic medication.

2.1 Soft-Tissue Infections at the Fingers and Midcarpus

The following types of soft-tissue infection can be differentiated by location:

A *paronychia* is an acute infection of the space surrounding the eponychial fold, mostly caused by *Staphylococcus aureus*, less frequently by anaerobic or fungal pathogens (Jebson 1998a). Paronychial infections often begin after nail care and immediately spread around the eponychium to develop a purulent drainage. Lymphadenitis can be present. Chronic courses of paronychia caused by *Candida albicans* are seen in diabetic individuals.

A *felon* is a closed space infection of the palmar digital bulb which can easily follow a skin lesion or a bagatelle injury (Jebson 1998a). The terminal phalanx is swollen, red, and painful.

A *collar button abscess* is a purulent infection of the interdigital subfascial web space (Jebson 1998b). Symptoms include painful swelling, redness, fluctuance, and tenderness of the web space with neighbored fingers being in an abducted posture.

A pyogenic *dumbbell infection* is located at the dorsoradial aspect and involves the thenar space, the first web and interosseous spaces, and the abductor pollicis muscle (Jebson 1998b). Mostly, the infection begins at the thenar space before extending into the peripheral and deep spaces.

Suppurative flexor tenosynovitis is a pyogenic infection of one or several flexor tendon sheaths which mostly is not only located at the digits but also in the midcarpal palm (Langer 2009).

In *radiograms*, swelling and obliteration of the tissue planes are characteristic. Bubbly gas inclusions are derived either from skin disruption or from gas-forming pathogens. Radiograms should always be ordered in the presence of phalangeal soft-tissue infection to confirm or exclude accompanying osteitis, osteomyelitis or even infective arthritis. Other than in paronychia, bone involvement is frequent in felons (Fig. 1c, d). When the infection has spread into the depth down to the osseous and/or articular surfaces, radiologic signs of osteitis include subtle periosteal thickening, indistinctly demarcated erosions,

◀ **Fig. 2** Contrast-enhanced MRI of suppurative soft infections. **a** Massive phlegmon (cellulitis) at the dorsum of the metacarpus. In the T1-weighted SE image after gadolinium, the subcutaneous layer appears thickened and presents with increased contrast enhancement. Areas of low signal intensity are included and are suspicious of initial abscess. **b–d** Suppurative flexor tenosynovitis of the index finger following an open cut injury. The flexor tendon sheath is semi-circumferentially thickened. After application of gadolinium, marked contrast enhancement of the tendon sheath is evident on the T1-weighted SE images with fat-saturation (**b** and **d**) when compared with the non-enhanced image (**c**). Areas of low signal intensity are not included, and therefore, abscess formation must not be assumed. Inflammation of the adjacent soft tissues is accompanying

and focal subperiosteal osteopenia (Capitanio and Kirkpatrick 1970). After progressing to osteomyelitis, sharp osteolyses appear. When subtle osteopenia of the subchondral articular bone plate becomes visible, concomitant arthritis of the metacarpophalangeal and interphalangeal joints must be assumed. Radiograms are also needed for the search of radiodense foreign bodies. Both US and MRI are useful tools for differentiating cellulitis from abscess formation in the soft tissues (Fig. 2a).

2.2 Supportive Flexor Tenosynovitis

Suppurative tenosynovitis is caused by spread from a subcutaneous abscess or by a penetrating injury with inoculation of pathogens from which most common are *Staphylococcus aureus* and Streptococci (Langer 2009). The proximal interphalangeal joint and the middle phalanx are preferred sites of puncture wounds. Symptoms are summarized by the Kanavel's signs: Flexed posture and swelling of the affected digit, tenderness over the flexor sheath, and pain on passive extension of the digit. Lymphadenitis is usually present. Rarely, a V-shaped phlegmon involving two or more fingers can develop due to communicating tendon sheaths. More frequent is a phlegmon that migrates from the thumb proximally into the carpal tunnel thereby causing a hyperacute carpal tunnel syndrome.

Radiograms serve to exclude concomitant osteomyelitis and/or arthritis and to detect foreign bodies (Resnick 1976; Capitanio and Kirkpatrick 1970; Kothari et al. 2001). Osteopenia and cortical erosions at the neighbored bone may be evident. Infectious tenosynovitis can nicely be demonstrated with US

(Jeffrey et al. 1997). There is a thickened, moderately hyperechoic tendon sheath directly aside the hypo- to anechoic synovial fluid. An enclosed foreign body is detectable by means of its hyperechoic pattern and its distal acoustic shadow. Foreign bodies are usually found in the center of infections. The same diagnostic criteria apply for tenosynovitis in MRI (Fig. 2). The inflamed tendon sheath is thickened, hyperintense in T2-weighted sequences, and presents an intense, peripheral contrast enhancement in T1-weighted, fat-saturated sequences after gadolinium (Towers 1997; Beltran 1995). Intravenous gadolinium is helpful in differentiating encapsulated synovial fluid in tendon overuse from suppurative tenosynovitis, both presenting with a thickened synovium. The transaxial imaging plane is most important for detection, whereas both the coronal and sagittal planes enable precise assessment of the longitudinal extension of tenosynovitis. Often, secondary edema in the adjacent soft tissues and in the tendon itself (tendinitis) is accompanying.

2.3 Tuberculosis of the Tendon Sheaths

Musculoskeletal tuberculosis is currently beginning to rise again. *Mycobacterium marinum*, *avium* or *kansasii* are the pathogens (Hausman and Lissner 1992; Hoffman et al. 1996). Clinical symptoms are mild and inconclusive. Only a doughy, painless swelling along the flexor tendons can be present at clinical examination. Thus, the “great masquerader” of tuberculosis should always be taken into consideration when a palmar, indolent soft-tissue swelling of unknown origin fails to medical and surgical treatment.

Radiograms are usually normal in soft-tissue tuberculosis. Infrequently, foggy and indistinct spots of calcification can be found, but can be hidden by bony structures in standard views. CT is usually not indicated to search for these calcifications, but when performed for other reasons, peritendinous location of foggy calcifications is highly suggestive of tuberculosis. In the differential diagnosis, an acute inflammatory onset is suspicious for hydroxyapatite deposition disease, whereas a chronic, insidious course is characteristic of soft-tissue tuberculosis or sarcoidosis. In US, tuberculous tenosynovitis can be assessed by means of a synovial fluid and the thickened tendon sheaths, which is hyperechoic in comparison with non-tuberculous tenosynovitis. In MRI,

the tuberculous tendon sheaths appear distended and swollen and show a marked synovial contrast enhancement (Hoffman et al. 1996; Jaovisidha et al. 1996). These findings often contradict the minor patient’s symptoms and are therefore guiding for the final diagnosis (Fig. 3a). The differential diagnosis includes chronic tenosynovitis of other origin, e.g. tenosynovial sarcoidosis.

Aside the tendon sheaths, other soft-tissue compartment of the hands can be infected by atypical mycobacterial bacilli in individuals with impaired resistance (Hoyen et al. 1998). *Mycobacterium marinum* is seen in soft-tissue infections of fishermen and aquarium workers and *Mycobacterium terrae* in infections of gardeners (Fig. 3b).

2.4 Infections of the Deep Palmar Spaces

Superficial infections can continuously spread into the deep compartments of the palm, often with the primary infection already healed when the deep abscess becomes symptomatic. Pain and function impairment are almost always present. However, redness and swelling can be missed because superficial tissue is covering the affected spaces. In the depth, there are anatomically defined compartments (Fig. 4a) (Jebson 1998b): (1) the thenar space (built by the short muscles of the thumb), (2) the hypothenar space (built by the short muscles of the little finger), (3) the carpal tunnel (bordered by the palmar flexor retinaculum), (4) the Guyon’s canal (superficial and ulnar-sided to the carpal tunnel), (5) the Parona’s space (deep to the flexor tendons at the distal forearm), and (6) the metacarpal space (deep to the flexor tendons at the metacarpus).

Radiograms are only performed to exclude concomitant osteomyelitis. This is also possible with the use of skeletal scintigraphy (*NUC*). An abscess is classically visualized in US by means of an anechoic or hypoechoic center associated with distal acoustic shadowing, and a hyperechoic wall of granulation tissue (Jeffrey et al. 1997). Membranous septa are often seen within the abscess. However, there are some diagnostic limitations: While huge and focal abscesses are reliably detectable with US, small abscesses deep in the carpal tunnel remain difficult to visualize due to acoustic absorption phenomena of the superficially traversing flexor tendons. Furthermore, it is difficult to depict the entire extent of a

Fig. 3 Synopsis of the different sites of tuberculosis at the soft tissues and bones of the hand. **a** Tuberculous tenosynovitis in a female presenting with a doughy, painless swelling of her palm. In the contrast-enhanced T1-weighted SE scan with fat = saturation, there is a communicating tenosynovitis of the flexor pollicis longus and the flexor digitorum tendons at the levels of the Parona's space, the carpal tunnel, and the metacarpal space. **b** Tuberculous abscess in the subcutaneous layer of the thenar space (fat-saturated PD-weighted FSE image). Surprisingly, micro-bacterial evaluation revealed *Mycobacterium marinum* in this patient who was retrospectively identified as a hobby

angler. **c** Tuberculous dactylitis of the thumb in a 1-year-old infant. There is the characteristic spina ventosa of the first metacarpal bone with increased volume, central osteolysis, and thickened compact bone. **d** Tuberculous arthritis of the wrist in an advanced stage with destruction, collapse, and ankylosis of the carpus. The ongoing inflammatory process is indicated by cystic radiolucencies, indistinct joint contours, and soft-tissue swelling. Calcifications in the soft tissues are also seen. Figures **a**, **c**, and **d** with permission from Schmitt R, Lanz U. Diagnostic imaging of the hand and wrist. Thieme International. Stuttgart, New York 2008

multi-compartmental abscess formation and to differentiate it from a sympathetic effusion. Abscesses can also be detected and determined in size by using CT imaging, although its capability is inferior to that of MRI. In CT, the signs of an abscess are the semi-liquid center of about 30–50 HU and the peripheral, contrast-enhancing wall (Jaovisidha et al. 1996). Preferentially, MRI should be applied if an abscess of the deep palmar spaces is suspected (Fig. 4b, c). MRI

provides the most precise information for these purposes (Hopkins et al. 1995; Towers 1997; Beltran 1995). The semi-liquid center of an abscess is hyperintense in T2-weighted sequences and hypointense in T1-weighted sequences, in the latter with a strong peripheral enhancement seen after intravenous application of gadolinium. This pattern of contrast enhancement differentiates an abscess from a phlegmon as well as from a serous fluid collection.

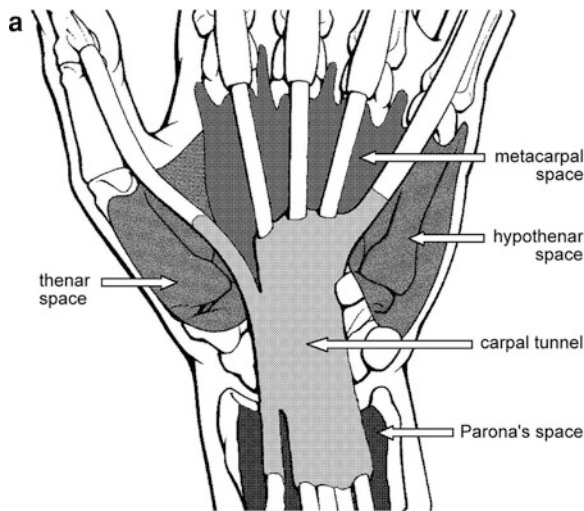

Fig. 4 Infections of the deep palmar spaces. **a** Schematic illustration of the deep palmar spaces (view into the palm). Indicated are the thenar and hypothenar spaces, the Parona's space (deep to the flexor tendons), the carpal tunnel, and the metacarpal space (deep to the flexor tendons). The Guyon's tunnel that is located ulnar-sided to the carpal tunnel is not depicted. **b–c** Deep palmar abscess extending over several deep

spaces. Sagittal T1-weighted SE images before (**b**) and after (**c**) application of gadolinium. The contrast-enhanced images comprehensively depict suppurative tenosynovitis of the flexor tendons in the Parona's space, the carpal tunnel, and the metacarpal space. Central areas of low signal intensity in the Parona's and metacarpal spaces are typical of an abscess formation

2.5 Gangrenous Infection

Gangrene is a rare anaerobic infection of the soft tissues caused by gas- and toxin-producing anaerobic pathogens (Hausman and Lisser 1992; Hoyer et al. 1998). The most common pathogen is *Clostridium perfringens*. The infection spreads in the subcutaneous space and within the compartments along the fasciae. Muscle ischemia and devitalized tissues may proceed and are considered as predisposing factors. The initial symptom can solely be local tenderness, followed by rapidly spreading inflammation. Cutaneous crepitation can be present, but does not confirm gangrenous infection. Life-threatening impairment of the general condition soon develops.

Survey radiographs characteristically show patchy gas inclusions in the soft tissues, especially in the subcutaneous and subfascial layers. Low-kilovoltage radiographs and CT imaging can be advantageous in equivocal cases.

2.6 Pyomyositis and Necrotizing Fasciitis

These infection types are extremely rare at the distal forearm and hand and are mentioned here for completeness only.

Pyomyositis is a muscle infection mostly caused by *Staphylococcus aureus* in immunodeficient patients (Gonzales 1998). The intra-muscular mass is characterized by an abscess formation in contrast-enhanced MRI (or CT imaging).

Necrotizing fasciitis is a serious, life-threatening infection of the superficial and deep fasciae in the absence of muscular and cutaneous infections (Gonzales 1998). Pathogens are *Streptococcus pyogenes* alone or in combination with *Staphylococcus aureus*. In imaging, the fasciae appear thickened and inflamed. Gas bubbles and fluid collections can be included.

3 Osteomyelitis

Osteomyelitis of the hand is usually the result of a soft-tissue infection caused by penetrating injuries with implantation of pathogens into the soft tissues and contiguous spread to the bone via the tendon sheaths, fasciae, and lymphatic vessels (Hausman and Lisser 1992; Tsai and Failla 1999; Resnick 1976; Barbieri and Freeland 1998). In open fractures, pathogens can be directly inoculated into the bone. These "secondary" types of osteomyelitis are

Fig. 5 Osteomyelitis and initial bacterial arthritis of the metacarpophalangeal joint of the little finger following a fist blow. **a** Obliteration of the soft-tissue planes and focal, subchondral demineralization at the dorso-ulnar segment of the fifth metacarpal head, depicted on a semi-pronated, oblique X-ray view. **b** Diffuse edema is present in the periarticular soft tissues as well as in the metacarpal head and the base of the

proximal phalanx (coronal, fat-saturated PD-weighted image). **c** and **d** Sagittal T1-weighted SE images before and after application of gadolinium without and with fat saturation show hyperenhancement of the dorsal soft tissues with the joint capsule and synovia included and in the inflamed bone marrow of the metacarpal head

frequent because the hands are predisposed to injuries in workaday life. On the contrary, the hematogenous spread of (“primary”) osteomyelitis is rare at the hand skeleton. The spectrum of pathogens includes *Staphylococcus aureus*, *Streptococcus pyogenes* and group B streptococci, and *Escherichia coli* (Tsai and Failla 1999; Barbieri and Freeland 1998; Reilly et al. 1997). *Haemophilus influenzae* is a frequent pathogen in childhood, while fungal and tuberculous pathogens are more often seen in adulthood (Hoyen et al. 1998).

Osteomyelitis is defined as an infection of the bone marrow and the ossified bone substance itself (Pineda et al. 2009; Barbieri and Freeland 1998). Subcategories imply the osteitis (infection of the bone cortex) and the infectious periostitis (infection of the periosteal cloak). Further classification is based on the time course with differentiation of acute, subacute, and chronic osteomyelitis, all of them with fluent and non-definitive transitions (Pineda et al. 2009).

3.1 Time Course of Osteomyelitis

3.1.1 Acute Osteomyelitis

Acute osteomyelitis presents with acute redness, swelling, pain, and functional impairment of the hand area affected aside fever and general complaints (Tsai and

Failla 1999; Barbieri and Freeland 1998). Acute osteomyelitis leads to progressive bone destruction.

Radiograms provide the imaging basis of acute osteomyelitis (Pineda et al. 2009; Resnick 1976; Gold et al. 1991; Schauwecker 1989). However, one should keep in mind that radiologic findings lag behind the onset of the infection by about 8–10 days. The earliest signs include obliteration of the parossal soft tissue fat planes and a focal area of decreased bone density (Capitanio and Kirkpatrick 1970). In the next days, aggressive bone destruction follows in a permeative pattern. Radiolucent, poorly defined osteolyses appear at the infectious focus (Fig. 5a). Finally, the infection leads to endosteal scalloping and cortical disintegration, and subtle or marked periosteal lesions at the metaphyseal level. In the acute phase of osteomyelitis, MRI is the imaging method of choice for two reasons (Pineda et al. 2009; Santiago-Restrepo et al. 2003; Gold et al. 1991; Hopkins et al. 1995; Towers 1997; Morrison et al. 1993): First, inflammatory bone marrow edema is the earliest finding which can be appreciated with MRI as early as 3 days after the onset of infection. The edema and exudates within the medullary space produce ill-defined high signals on fat-suppressed T2-weighted or STIR images and a low signal on T1-weighted images (Figs. 5b, 6a). Second, contrast-enhanced T1-weighted images

Fig. 6 Acute osteomyelitis of the distal end of the radius following 3 months after palmar plate osteosynthesis. After plate removal, X-ray views were completely unremarkable with regard to osteomyelitis. In MRI, a territorial zone of bone marrow edema (**a** and **b**) and peripheral contrast enhancement (**c**) is visible at the meta-epiphyseal section of the radius, and a

parossal abscess located in the soft tissues between the radius and ulna is also recognizable. PD-weighted FSE sequence with fat-saturation (**a**), non-enhanced T1-weighted SE sequence (**b**), and contrast-enhanced T1-weighted SE sequence with fat-suppression (**c**), all acquired in the coronal plane

acquired in 3 planes allow a comprehensive assessment of the osteomyelitic extent by better differentiation of hypervascularized areas from non-viable and edematous areas in the affected bone and the soft tissues (Figs. 5d, 6c).

Complete clinical information is required for the differential diagnosis of permeative (“moth-eaten”) bone lesions (Santiago-Restrepo et al. 2003; Resnick 1976; Capitanio and Kirkpatrick 1970). With this respect, healing of osteomyelitis can be correctly assessed only when judging both the clinical and imaging findings, because in the healing phase bone resorption is still continuing and simulating progressive osteomyelitis in radiograms, although the clinical symptoms are already improving (Erdman et al. 1991). The differential diagnosis includes malignant bone tumors, such as osteosarcoma, Ewing’s sarcoma, and bone lymphoma. In most cases, bone destruction in acute osteomyelitis is more rapid and extensive in comparison with the malignant tumors mentioned.

3.1.2 Subacute Osteomyelitis

Brodie’s Abscess

In staphylococcal osteomyelitis, an intra-osseous abscess can develop in individuals with immunologic deficiency, mainly in young boys. At the hand and forearm, there is a predilection for the distal ends of the radius and ulna. In *radiograms*, a round or elongated radiolucency with surrounding osteosclerosis, tortuous shape, and a connection to the growth plate is characteristic of a Brodie’s abscess (Pineda et al. 2009; Miller et al. 1979). In MRI, the so-called

“penumbra sign” is indicative. This sign describes a well-defined lesion which is composed of a central colliquation zone and a small peripheral zone of increased contrast enhancement surrounded by bone marrow edema in T1-weighted images (Grey et al. 1998). Mostly, Brodie’s abscesses are located in the metaphysis, less frequently in the epiphysis (Fig. 6). However, locations in the diaphysis and cortex have been described making differentiation to osteoid osteoma difficult even with the use of CT and MRI.

Plasma-Cell Osteomyelitis and Garré’s Sclerosing Osteomyelitis

These special forms of osteomyelitis are infrequently found at the hands (Reilly et al. 1997). They are characterized by the appearance of osteosclerosis and the tendency of a chronic course. A pathogen usually cannot be isolated, both entities are non-purulent. A pathogenetic association to chronic recurrent multifocal osteomyelitis has been assumed. The diagnosis of Garré’s osteomyelitis should be restricted to those cases of sclerosing osteomyelitis in which no sequestrum and granulation tissue can be found.

3.1.3 Chronic Osteomyelitis

The chronic stage is characterized by the development of sequestra, the formation of involucrum, and the deformation of the bone affected (Barbieri and Free-land 1998; Kaim et al. 2002). A *sequestrum* is a necrotic bone fragment which has developed from destruction of the cortical or cancellous bone (Pineda et al. 2009). Often, pathogens are harbored inside the sequestrum maintaining chronic osteomyelitis and

flare-up acute episodes. Surrounding *granulation tissue* separates the sequestrum from the viable bone. New bone formation is induced by the periostitis and is therefore located peripherally around the altered cortex and the necrotic tissue, the so-called *involucrum*. In many cases, infection-induced channels (so-called *sinus tracts*) are connecting the area of dead bone with the cutaneous surface composed of an osseous break (so-called *cloaca*) (Pineda et al. 2009).

In *radiograms*, a sequestrum has an increased radiodensity, sharp margins, and is located within the medullary bone (Pineda et al. 2009; Santiago-Restrepo et al. 2003; Gold et al. 1991; Kaim et al. 2002). The size varies from sub-millimeter to several millimeters. New bone formation, the involucrum, leads to contour irregularities, bone deformation, and increased radiodensity (Fig. 8). Differential diagnosis includes the osteoid osteoma which is frequently found at the hand, and the rare fibrous dysplasia. MRI is helping to assess the devitalized tissue in chronic osteomyelitis. A sequestrum is of low signal intensity in all sequences, whereas the surrounding granulation tissue is of high signal intensity in STIR or T2-weighted sequences, and of intermediate to low signal intensity on T1-weighted images. After application of gadolinium, the granulation tissue is enhancing, whereas the sequestrum remains low signal (Hopkins et al. 1995; Towers 1997; Morrison et al. 1993). The involucrum has low signal intensity on all pulse sequences and is separated from the cortical bone by a periosteal reaction zone which is of intermediate signal intensity on T2-weighted or STIR images (Pineda et al. 2009; Gold et al. 1991). The periosteal reaction zone is highly suspicious of containing infectious material, when presenting as a mass of high signal intensity on T2-weighted images. In this area of infection, a break traversing both the cortical bone and the involucrum is characteristic of a cloaca. Often, a sinus tract extends from the cloaca and appears with a tram track-like enhancement in the adjacent soft tissues before reaching the cutaneous surface with an orifice (Santiago-Restrepo et al. 2003). In chronic osteomyelitis, CT is particularly useful to identify a sequestrum and to differentiate between granulation tissue and an involucrum (Fig. 8c, d). Therefore, CT is essential for planning surgical therapy, and—most importantly—for detecting sequestra which must be excised (Pineda et al. 2009; Santiago-Restrepo et al. 2003; Gold et al. 1991).

Differentiation of active from inactive osteomyelitis is of high clinical importance, but challenging in diagnostic imaging (Erdman et al. 1991). Ongoing activity of infection must be assumed when the radiologic appearance has changed in follow-up studies, and when a sequestrum or a subperiosteal cloaca is still provable. A disadvantage of MRI is the inability to distinguish infectious from reactive inflammation (Pineda et al. 2009).

3.2 Etiology of Osteomyelitis

3.2.1 “Primary” (Hematogenous) Osteomyelitis

In septicemia, the respiratory, genitourinary, gastrointestinal systems, and the skin serve as infectious sources which however remains unknown in up to 50% of the cases (Hausman and Lisser 1992; Pineda et al. 2009; Barbieri and Freeland 1998). Infrequently, hematogenous spread of pathogens leads either to acute osteomyelitis of the distal sections of the radius and ulna (Gold et al. 1991; Reilly et al. 1997) or to acute pyogenic arthritis of the wrist (Murray 1998). Hematogenous osteomyelitis usually originates in the metaphysis, where bacterial implantation is facilitated by the slow blood flow in the venous sinusoids. Both bone marrow edema and accumulation of pus increases the bone pressure and promote further osteomyelitic extension which follows an age-dependent pattern (Resnick 1976): (a) In infants up to 1 year, only a few metaphyseal vessels penetrate the bone plate to reach the epiphysis and therefore being responsible for simultane osteomyelitis and purulent arthritis in infancy. However, the combined infection is difficult to detect due to the unossified epiphyses at this age. (b) In children and adolescents, the metaphyseal vessels turn sharply at the open growth plate without penetrating them. This unique pattern of vascularity explains the predilection of juvenile osteomyelitis to affect the dia-metaphysis only. (c) In adulthood, many metaphyseal vessels are connected to the epiphyseal vessels via the closed bone plate. This free vascular communication allows metaphyseal osteomyelitis to migrate to the epiphysis.

Radiograms show “moth-eaten” osteolyses and less often sequestra (Resnick 1976; Capitanio and Kirkpatrick 1970). Later in the course, periostitis and periosteal bone formation is more extended when compared

Fig. 7 Brodie's abscess in the distal end of the radius in a young man with no history of trauma or bone surgery. At the meta-epiphyseal junction, a sequestrum surrounded by an abscess and the so-called “double-line sign” are seen in a

coronal PD-weighted sequence with fat-saturation (a). Reformatted CT images in the coronal (b) and sagittal (c) planes confirm the sequestrum and prove the presence of a cloaca on the palmar site of the radius

to secondary osteomyelitis spread from soft-tissue infection. Chronic osteomyelitis is characterized in radiograms by bone remodeling with more or less intense osteosclerotic areas. Even the primary development of chronic sclerosing osteomyelitis is possible. MRI is the modality of choice for early diagnosis, therapy planning, and the follow-up (Hopkins et al. 1995; Towers 1997; Morrison et al. 1993). It provides all the information about the extension of osteomyelitis, particularly about soft-tissue complications. Osteomyelitic abscesses and osteonecrosis can be detected with fat-saturated T1-weighted sequences after intravenous administration of gadolinium. *Skeletal scintigraphy* is suitable to exclude or confirm the presence of osteomyelitis before lesions can be detected in plain radiograms, especially if MRI is not available (Pineda et al. 2009; Schauwecker 1989).

3.2.2 “Secondary” (Spread From Soft Tissues) Osteomyelitis

Secondary forms of osteomyelitis develop from the adjacent soft tissues. At the hand, secondary osteomyelitis is much more frequent in comparison with primary osteomyelitis (Hausman and Lisser 1992; Tsai and Failla 1999; Resnick 1976).

Osteomyelitis of the Fingers

Phalangeal manifestation is by far the most common form of osteomyelitis at the hands with the distal phalanx being most often affected. The inoculation of pathogens is caused by two different ways: First, the organisms reach directly the periosteum or bone via

the disrupted skin and the deep tissue layers. With this respect, even surgery can result in osteomyelitis, e.g. the pin tract infection (Tsai and Failla 1999). Second, there is initially a soft-tissue infection like a felon or suppurative flexor tenosynovitis after a puncture wound (Hausman and Lisser 1992; Beltran 1995; Jeffrey et al. 1997). These soft-tissue infections do not only extend longitudinally via the tendon sheaths and the fascial planes but also invade into the depth. The soft-tissue focus causes initial periostitis, then infectious invasion of the cortex, and finally osteomyelitis after invading the medullary bone via the cortical haversian and Volkmann's canals (Resnick 1976). Frequently, the formation of sequestra can result and maintain chronic fistulae.

In *radiograms*, positive findings cannot be expected in the first 10 days after an injury (Resnick 1976; Capitanio and Kirkpatrick 1970; Gold et al. 1991). As the result of the inward migrating infection from the soft tissues, discrete focal osteopenia and mild periostitis are the initial signs in osteomyelitis of the digits (Fig. 5a). Bone destruction with “moth-eaten” and permeative osteolyses subsequently follows. Finally, osteosclerotic transformation is typical of chronic osteomyelitis (Fig. 8). The radiologic examination should always include the search for foreign bodies which can cause and maintain infections of the fingers (Peterson et al. 2002). MRI is useful for depicting the infected soft tissues—particularly to prove or rule out an abscess (Fig. 6)—and for assessing the extension of osteomyelitis (Hopkins et al. 1995; Towers 1997; Morrison et al. 1993). However, the vast majority of paronychias and felons

Fig. 8 Two patients suffering from chronic osteomyelitis of the finger skeleton. **a** and **b** In the first patient, X-rays show increased bone density of the proximal phalanx due to marked periosteal reaction with initial development of an involucrum and a cloaca. The periosteum is elevated at the dorsum. **c** and **d** In the second patient, all signs of chronic osteomyelitis are

present in the index finger. In the metacarpal bone, several sequestra surrounded by granulation tissue, cloacae at the palmar and dorsal sites and an involucrum can be depicted in the transaxial (**c**) and sagittal (**d**) CT images. A *pin* has been introduced in the metacarpal base

do not involve the bone of the distal phalanx, and therefore, the role of MRI is mainly to exclude osteomyelitis. The use of CT is limited mainly for detecting sequestra (Figs. 7, 8) and intra-osseous abscesses (Kothari et al. 2001).

Bites

Bites at the hands are mostly caused by domestic animals, less frequent by humans, e.g. a fist blow to the mouth of the opponent (Gonzalez et al. 1993). Staphylococcal or streptococcal species are inoculated through the wound, particularly *Eikenella corrodens* in human bites, and *Pasteurella multocida* in cat bites (Resnick 1976). The rate of infectious complications such as soft-tissue infection, bacterial arthritis, and osteomyelitis is up to 50%. Symptoms are dominated by diffuse soft-tissue swelling, redness, impairment or loss of function and the local bite defect.

In *radiograms*, foreign bodies in the soft tissues must be excluded. In oblique views, subtle cortical lesions can sometimes be detected at the injury site after a deep bite down to the bone surface (Resnick 1976; Capitanio and Kirkpatrick 1970). Mostly, however, radiologic signs of osteomyelitis and/or bacterial arthritis appear first in about 8–10 days after the injury.

3.2.3 Special Forms of Osteomyelitis

Tuberculous Osteomyelitis

Skeletal tuberculosis that is a hematogenous infection caused by the *Mycobacterium tuberculosis* complex develops in the post-primary stage of tuberculosis. Pulmonary tuberculosis is evident in about half of the cases, but mostly inactive at the time of skeletal manifestation. Overall, the hands are involved only in

about 5% of musculoskeletal tuberculosis with two age groups (Hoyen et al. 1998; Benkeddache and Gottesman 1982; Hsu et al. 2004): Tuberculous osteomyelitis is more common in children under 5 years, while tuberculous arthritis is mostly manifested in adults. However, transition of tuberculous osteomyelitis to tuberculous arthritis has been observed, and also the reversed infection route. Other than in pyogenic infections, meta-epiphyseal spread of tuberculous osteomyelitis is possible in childhood. Clinical presentation at the hand skeleton is characterized by a chronic course and by a wide range of symptoms (Benkeddache and Gottesman 1982). It is not unusual that painless swelling, focal tenderness, and a draining sinus are noticed over months to years before the final diagnosis is found. One should consider that incidence of tuberculosis is currently increasing.

Radiologic signs of tuberculous osteomyelitis are heterogeneous. They include soft-tissue swelling, diffuse osteopenia, “moth-eaten” osteolyses, and marked bone expansion when periosteal bone formation has been induced (Benkeddache and Gottesman 1982). One metacarpal or phalangeal bone is affected in about 70% of tuberculous infections, two or several bones in the remaining cases. The affected bones appear thickened and with increased radiodensity. Both tuberculous bone thickening and soft-tissue swelling leads to a sausage-like deformity of the ray affected. The clinical condition is termed “tuberculous dactylitis”, and the radiographic appearance is the “spina ventosa” presenting with characteristic cyst-like bone expansion (Fig. 3c). Differential diagnosis of dactylitis also includes osteomyelitis of pyogenic, syphilitic, fungal, and leprosy origin as well as fibrous dysplasia, sarcoidosis, hyperparathyroidism, and sickle cell anemia. Sequestra are uncommon in skeletal tuberculosis. Osteosclerotic bone is seen at the thickened periosteum and at the borders of marginal erosions in case of concomitant tuberculous arthritis. In contrast-enhanced MRI, an intense, ring-shaped enhancement is observed at the small tubular bone(s) affected in tuberculous osteomyelitis (Hsu et al. 2004).

Chronic Recurrent Multifocal Osteomyelitis

Chronic recurrent multifocal osteomyelitis (CMRO) is a rare, aseptic condition of osteomyelitis seen in

children and adolescents and is characterized by a prolonged or fluctuating course. Aside psoriatic skin lesions, osteomyelitic lesions of unknown origin appear synchronously (Kothari et al. 2001). Causative organisms are usually not identified, and therefore, both immunologic phenomena and a genetic predisposition have been discussed in the pathogenesis. Probably, there is an association to the entities of plasma-cell osteomyelitis and Garre’s sclerosing osteomyelitis.

In *radiograms*, involved bones have findings typical of osteomyelitis and/or Brodie abscess with osteosclerotic lesions side by side with osteolytic destruction. The clavicles and the bones of the lower extremity are preferred locations. *Scintigraphy* is useful in identifying the multifocal involvement of CRMO (Kothari et al. 2001). Contrast-enhanced MRI is well suited for the follow-up.

3.3 Differential Diagnosis

Osteosarcoma and Ewing’s sarcoma are very rare at the hand skeleton. These malignant bone tumors must be taken into differential diagnostic consideration, when moth-eaten or permeative lesions are found in the metaphysis or diaphysis of the short tubular bones of the hand and when typical inflammatory signs are initially absent in osteomyelitis. Furthermore, advanced soft-tissue sarcomas can also lead to bone destruction and can simulate the radiographic pattern of osteomyelitis. However, soft-tissue sarcomas as well as their osseous spread are rare at the hands.

4 Infectious Arthritis

Infectious arthritis is an acute joint disease which is either caused by the articular implantation of a pathogen (“primary infectious arthritis”) or is triggered as an immunologic answer (“reactive post-infectious arthritis”) following a nasopharyngeal, respiratory, urogenital or intestinal infection, e.g. acute rheumatic fever following streptococcal tonsillitis (Resnick 1976; Murray 1998). The discussion of whether infectious arthritis manifests in parallel with or complementary to an immunologically induced bacterial arthritis is ongoing.

Staphylococci are the most common pathogens in about 70% of all bacterial joint infections (Hausman and Lisser 1992; Murray 1998; Graif et al. 1999). Some group preferences are evident: Streptococci and *Haemophilus influenzae* are frequently seen in children, *Neisseria gonorrhoeae* in young women, and gram-negative rods in patients with immune deficiency. Tuberculous, viral or parasitic pathogens can be isolated less commonly (Hoyen et al. 1998). Chlamydia, *Borrelia burgdorferi* (Lyme disease), *Mycobacterium leprae*, *Schistosoma haematobium* as well as hepatitis B and rubella viruses have been identified aside others in the synovial fluid recently. Risk factors of acquiring septic arthritis include diabetes mellitus, liver cirrhosis, alcohol or drug abuse, malignancy, and the advanced age.

4.1 Bacterial Arthritis

Three different pathways (Tsai and Failla 1999; Resnick 1976) are possible in pyogenic joint inflammation (Figs. 1a, b): First, bacterial arthritis is caused by spread of soft-tissue infection or by osteomyelitic transmission from a neighbored bone. This pathway is mostly seen at the finger joints. Second, pathogens can be directly inoculated via a penetrating injury as occurring in cuts, stabs and bites, and artificially during a diagnostic or surgical procedure at the joint. All joints of the hand can be involved in this pathway, but the metacarpophalangeal and proximal interphalangeal regions are clearly preferred (Resnick 1976). Third, bacterial arthritis arises from hematogenous seeding of pathogens in patients suffering from severe sepsis or severe immunologic deficiency. The carpal joints are mostly affected by hematogenous arthritis (Murray 1998).

The distribution pattern of pyogenic arthritis is usually monoarticular (Resnick 1976). The symptoms comprise low-grade fever, chills, and the focal signs of infection (swelling, redness, heat, arthralgia, tenderness). The classical disease course begins at the synovial membrane which becomes thickened and edematous, thereby producing synovial fluid and pus. The inflamed, pannus-like synovium initially induces cartilage destruction, and then leads to deep erosions at the subchondral bone plate. Depending on the violence of the pathogen, the infected joint is progressively destroyed.

In *radiograms*, signs of pyogenic arthritis follow a time-dependent pattern (Resnick 1976; Murray 1998; Gonzalez et al. 1993). Initially, obliteration of the periarticular soft-tissue planes (so-called “soft-tissue sign”) and a widened joint space caused by an infectious joint effusion are seen. Intra-articular gas formation is occasionally recognizable in gram-negative bacterial arthritis. Hyperemia-induced osteopenia is evident in about 8–10 days later (Fig. 9a), at first in the subchondral bone plate, then covering the entire epiphyseal area (so-called “collateral sign”). Synovial inflammation (Figs. 9b, e) leads subsequently to focal bone erosions at the bare areas and soon involves the entire articular space with poorly defined margins and progressive destruction of the joint (so-called “direct sign of arthritis”). The joint space narrows progressively with advanced destruction of the articular cartilage. Coarse erosions and destructive joint collapse are characteristic radiographic findings in bacterial arthritis (Fig. 9d–f). Finally, fibrous or bony ankylosis can develop at the end of the healing process. Another complication is the development of secondary osteoarthritis.

Most cases of infectious arthritis at the hand can be assessed clinically. At the wrist, the differential diagnosis includes rheumatoid arthritis, which however presents with a typical articular distribution pattern at the hands, and tuberculous arthritis, which progresses more slowly compared to bacterial arthritis (Graif et al. 1999). However, differential diagnosis can be challenging when other joint diseases like the calcium pyrophosphate dehydrate (CPPD) deposition disease, gout arthropathy or rheumatoid arthritis precede the joint infection (Murray 1998). In this situation, indium- or technetium-labeled leukocyte bone scans may be useful for differentiation (Pineda et al. 2009; Schauwecker 1989).

4.2 Tuberculous Arthritis

Tuberculosis osteomyelitis is commonly seen in children, while tuberculous arthritis is mostly affecting adults suffering from other underlying disorders (Hoyen et al. 1998; Benkeddache and Gottesman 1982; Hsu et al. 2004). The pathways of tuberculous arthritis comprise either primary joint infection or initial osteomyelitis followed by secondary spread to the joint(s). Typically, the latter is characterized by a

Fig. 9 Hematogenous arthritis of the wrist in a 52-year-old woman. Probably, the staphylococcal dissemination originated from an acute maxillary sinusitis. The image collection includes the initial imaging findings **a–c** 15 days after onset of the symptoms, and a follow-up examination **d–f** 4 weeks later for monitoring the antibiotic therapy response. **a–c** Initial imaging findings: diffuse osteopenia of the wrist, no erosions detectable (**a**). In the PD-weighted FSE sequence with

fat-saturation (**b**) and in the non-enhanced T1-weighted SE image (**c**), diffuse bone marrow edema, carpal joint effusions, and synovitis are evident. **d–f** Follow-up imaging findings: multi-locular erosions have developed at the wrist bones and the distal forearm. While deep erosions can already be seen in the dorso-palmar X-ray view (**d**), the finest erosions are only detectable in the contrast-enhanced T1-weighted SE sequence with fat-saturation (**e**) and in high-resolution CT (**f**)

less destructive course. The stages from articular swelling to final joint destruction are passed through slowly over a period of months to years.

In *radiograms*, signs of tuberculous arthritis are first seen in about 2–4 months after the onset of symptoms (Hoyen et al. 1998; Benkeddache and Gottesman 1982). The radial side of the wrist and midcarpus are mainly affected. The radiographic features are best summarized by the Phemister’s triad consisting of periarticular osteopenia, peripheral erosions, and mild joint space narrowing (Fig. 3d): The initial signs are soft-tissue swelling and periarticular osteopenia. The joint space is preserved over a long time, but is finally narrowing as the tuberculous synovitis progresses. Fine erosions at the subchondral bone plate lead to delineation of the articular contours. In contrast, marginal punched-out defects and central defects caused by granulomatous proliferation are characteristic of the cystic form of carpal tuberculosis which presents with a “nibbling of cheese” pattern. Extensive bone destruction and fibrous or

bony ankylosis can develop if antituberculous medication is delayed or insufficient. Calcifications are observed in concomitant soft-tissue abscesses and during healing. In early stage of tuberculous arthritis, the differential diagnoses include non-infectious arthropathy such as rheumatoid arthritis, skeletal sarcoidosis in case of cystic tuberculosis, and more unlikely the pyogenic arthritis.

5 Rare Infections of the Hand Skeleton

5.1 Syphilis

The spirochete *Treponema pallidum* is the pathogen of congenital syphilis as well as in acquired syphilis (Hoyen et al. 1998; Sachdev and Bery 1982). Symptoms of the survived congenital infection include saber shins, a saddle nose, palate perforation, and the

Fig. 10 Venereal infections of the hand. **a** Characteristic syphilitic dactylitis. In this child, dactylitis was limited to the metacarpal bone of the left thumb. The affected bone is increased in volume and radiodensity due to massive periosteal hyperostosis. Courtesy of Dr. A.M. Davies, Birmingham, UK. **b** Very rare case of an acquired gonococcal arthritis of the wrist in a 63-year-old woman. Marked osteopenia of the carpal, distal forearm, and the proximal metacarpal bones is evident. The heights of the radiocarpal and midcarpal cartilage are decreased, although there is a joint effusion with displaced soft-tissue planes. Pre-existing osteoarthritis of the trapezio-metacarpal joint

Hutchinson's triad (barrel-like teeth, keratitis, and nerve deafness). Three stages are discernable in the acquired disease: Focal skin ulceration develops at the site of infection (primary syphilis), followed by generalized skin eruption several weeks later (secondary syphilis). After healing, there is a prolonged syphilitic dissemination in almost all organ systems with the patients mostly being symptom-free. Many years later, about half of the patients develop cutaneous, cardiovascular, neurologic, and/or musculoskeletal symptoms due to granulomatous ("gummatous") lesions (tertiary syphilis). The hand skeleton is rarely involved.

Initially, the *radiographs* of newborns suffering from congenital syphilis reveal erosive irregularities at the epi-metaphyseal junctions induced by osteochondritis (Sachdev and Bery 1982). After these findings have disappeared, inflammatory enchondral and periosteal hyperostosis is causative of dense and thickened

tubular bones. Bilateral and symmetric involvement of the metacarpals or phalanges is characteristic of syphilitic dactylitis in childhood. The radiographic appearance resembles that of osteoidosteoma and tuberculous dactylitis (Fig. 10a). In tertiary syphilis, both the pathogenesis (osteochondritis, periostitis, and osteomyelitis) as well as the radiologic appearance is similar to that of tuberculosis, however, with the joints being less severely involved. The main finding is periosteal proliferation leading to significant enlargement of the tubular bones.

5.2 Gonococcal Arthritis

Gonococcal arthritis develops about 2 weeks after the venereal infection with *Neisseria gonorrhoeae*. Polyarticular symptoms are observed in gonococcal sepsis only. Thus, gonococcal infection should be considered in sexually active patients presenting with migratory polyarthralgias. Mostly, however, there is a monoarticular infection with the carpal joints being predominantly affected among other joints (Hoyen et al. 1998) (Fig. 10b). If no gonococci can be proved in the joint fluid, differential diagnosis should include reactive arthritis and the postgonococcal Reiter's syndrome.

5.3 Leprosy (Hansen's Disease)

In Africa, South America and Asia, leprosy is a chronic infection caused by *Mycobacterium leprae*. The clinical presentation is determined by an incubation period over months and combinations of neural, osseous, and dermal leprosy (Hoyen et al. 1998). Lymphadenopathy is seen in most cases. Involvement of peripheral nerves is characteristic, particularly with implantation of pathogens in Schwann's cells of the ulnar and peroneal nerves. Subsequently, progressive denervation with sensory and motor impairment leads to repetitive traumatic lesions and extensive superinfections. Leprous arthritis is either of hematogenous origin or spread from the leprosy bone marrow and the soft tissues. The joint infection is located at the carpal, metacarpophalangeal, and proximal interphalangeal joints. Finally, reactive arthritis can follow

Fig. 11 Rare bacterial, fungal, and parasitic infections at the hand. **a** Leprosy. There are acro-osteolyses at the terminal phalanges leading to the “candystick” deformity of the middle and ring fingers. Additionally, sclerosing osteomyelitis of the middle phalanx of the middle finger is visible. Courtesy of Dr. A.M. Davies, Birmingham, UK. **b** Mutilation stage of meningococcal infection in an infant with osteomyelitic destruction of the distal radial section and of the entire wrist. All fingers have been amputated before because of severe septic embolism.

Courtesy of Dr. A.M. Davies, Birmingham, UK. **c** Mycetoma of the hand in a child presenting with multi-locular soft-tissue masses and advanced osteopenia. Manifestation of mycetoma at the hand is very rare. Courtesy of Dr. A.M. Davies, Birmingham, UK. **d** Filariasis with detection of a calcified worm remnant in the soft tissue of metacarpus. This was an incidental finding in a woman suffering from known filariasis of her breasts. Courtesy of Dr. M. Langen, Würzburg/Germany

leprosy in a typically symmetric pattern and is associated with erythema nodosum.

Two different groups of leprosy abnormalities are visible in *radiograms* (Enna et al. 1971): First, specific granulomatous lesions directly induced by the pathogens are found at the metacarpal and phalangeal bones in less than 10% of musculoskeletal leprosy (osteitis leprosa multiplex cystica). Initially, soft-tissue swelling is evident followed by periostitis as the infection extends to the bones. Signs of leprosy osteomyelitis are focal osteopenia, enlarged nutrient channels, and finally advanced bone destruction. Second, unspecific neuropathic lesions account for the great majority of leprosy. Progressive bone destruction is the result of neuropathic articular malfunction, repetitive injuries, and additional superinfections. Neuropathic leprosy is associated with significant bone resorption and acro-osteolyses leading to the characteristic “candystick appearance” of the metacarpals and phalanges with the index finger predominantly affected (Fig. 11a). However, this radiographic appearance is also seen in Charcot’s osteoarthropathy as found in syringomyelia, syphilis, and diabetes mellitus. Due to limited access to advanced imaging techniques in the non-developed

countries, US and MRI are applied only in rare cases of neural leprosy for depicting the enlarged or compressed nerves (Martinoli et al. 2000). Finally, neural calcifications have been reported.

5.4 Rare and Atypical Infections of Bacterial Origin

These infections comprise a heterogeneous group with the hand skeleton being rarely involved (Hausman and Lissner 1992; Hoyer et al. 1998). The radiographic appearance is unspecific in most diseases. Occasionally, clinical or imaging findings can guide for final diagnosis, like the “doigt en lorgnette” aspect (shortened phalanges due to infectious bone resorption) in yaws (Jones 1972), or the late, but fulminant ball-and-socket destruction of the digits secondary to septic emboli in meningococemia (Patriquin et al. 1981) (Fig. 11b). Some infections do not affect the hand skeleton although the site of inoculation has been there, as seen in rickettsial-induced cat-scratch disease which is characterized by chronic lymphadenopathy proximally to the elbows. Essential information is summarized in Table 1.

Table 1 Rare and atypical infections of bacterial origin at the musculoskeletal system

Type of infection	Pathogen	Occurrence	Imaging findings
Yaws	<i>Treponema pertenue</i>	Africa South America South Pacific Islands West Indies	Similar to those of syphilis in secondary and tertiary yaws Phalanges thickened (“dactylitis”) or shortened (“doigt en lorgnette”) Distal phalanges spared
Meningococemia	<i>Neisseria meningitidis</i>	Ubiquitous	Fulminant in childhood late after meningococcal sepsis Ball-and-socket deformities of the fingers as the result of septic emboli
Lyme disease	<i>Borrelia burgdorferi</i> transmitted by the <i>Ixodes ricinus</i> tick	Ubiquitous Northeastern United States preferred	Joint effusions only No radiographic findings in the presence of intermittent and migrating arthralgia Chronic oligoarthritis very rarely
Brucellosis	<i>Brucella abortus</i> , <i>melitensis</i> or <i>suis</i>	Midwestern United States Saudi Arabia South America Southern Europe	Septic arthritis and osteomyelitis No specific manifestations on imaging Like “atypical” tuberculosis
Actinomycosis	<i>Actinomycis israelii</i>	Ubiquitous	Most frequent at mandible, spine and lung Hand very rarely affected Combination of osteolysis, sclerosis, and abscess

5.5 Viral Infections

Synovial infections have been observed in hepatitis B, rubella (measles), mumps, variola (smallpox), parvo-B19-infection, in vaccinia and others. The carpal, metacarpophalangeal, and proximal interphalangeal joints can be involved. Episodic, symmetric polyarthritis is observed which usually heals out. However, in adolescents growth disturbance can be associated. Carpal involvement can result in carpal tunnel syndrome.

Infections with *rubella* viruses can occur before birth (intrauterine rubella), or after birth (postnatal rubella), the latter induced either by contagious infection or by active immunization. The carpal and phalangeal joints are affected mostly by migratory symptoms, and only in rare cases erosive arthropathy resembling on juvenile chronic arthritis develops.

Variola (smallpox) is frequently manifested at the elbow joints, whereas the hands are typically spared. In the acute infection phase, radiographic signs are similar to those of purulent osteomyelitis or arthritis. The articular spread of variola tends to become chronic.

Patients suffering from the *human immunodeficiency virus (HIV)* infection do not provide a specific

infection pattern at the hands (Eustace et al. 1996). However, these individuals are often affected by opportunistic bacterial infections (septic osteomyelitis and/or arthritis, and pyomyositis), by seronegative spondylarthropathic diseases, and by the development of Kaposi’s sarcoma.

5.6 Fungal Infections

Fungal infections of the deep body layers and the musculoskeletal system are rare in comparison with their cutaneous manifestation (Amadio 1998). Almost always, individuals suffering from immunosuppression, malignant or chronic renal diseases are affected. Notably, candidiasis of the joints and bones is extremely rare, although *Candida* organisms reside on the human mucosal membranes. Fungal infections can be transmitted by traumatic inoculation of pathogens from the cutis into the depth or by hematogenous dissemination. Histoplasmosis, mycetoma (Fig. 11c), sporotrichosis, and coccidioidomycosis are tropical diseases which can induce polyostotic bone infections. None of the fungal diseases present with a

Table 2 Fungal infections at the musculoskeletal system

Type of infection	Pathogen	Occurrence	Imaging findings
Candidiasis (Moniliasis)	<i>Candida albicans</i>	Immunosuppression, antibiotic therapy, or diabetes mellitus common	Oral candidiasis, and disseminated abscesses In systemic candidiasis, osteomyelitis and arthritis extremely rare at the hand skeleton
Aspergillosis	<i>Aspergillus fumigatus</i>	Immunosuppression common	Mostly lung and chest wall affected Musculoskeletal system and hands rarely involved Localized bone destruction and soft-tissue mass
Coccidioidomycosis	<i>Coccidioides immitis</i>	United States Mexico South America	Lung and visceral dissemination Protuberances preferred in skeletal manifestation Well-defined osteolyses
Sporotrichosis	<i>Sporothrix schenckii</i>	Ubiquitous Immunosuppressed individuals preferred	Primary infection of the skin and lymph nodes Carpal and phalangeal joints often involved Marginal erosions and osteomyelitis
Histoplasmosis	<i>Histoplasma capsulatum</i> <i>Histoplasma dubosii</i>	United States Africa	Visceral and bone involvement common Cystic bone lesions at the wrist and hand skeleton
Mycetoma (Maduromycosis)	Mixed infection with <i>Actinomyces</i> , <i>Nocardia</i> , and <i>Streptomyces</i> pathogens	India Tropical climates Africa	Madura foot most common Chronic granulomatous infection of the subcutis and underlying bones Hand very rarely affected
Blastomycosis	<i>Blastomyces dermatitidis</i>	North America Central America South America	Lung, lymph nodes, and skin affected Skeleton involved in 50% of cases, the carpus included Unspecific bone destruction (erosions, osteomyelitis, osteoclerotic margins)
Cryptococcosis (Torulosis)	<i>Cryptococcus neoformans</i>	Ubiquitous	Predilection for the CNS Osteolytic foci at the axial skeleton and long bones, hand very rarely affected

specific radiographic appearance at the hand skeleton. The various symptoms range from self-limiting arthralgia over acute polyarthritis to mutilating joint destruction (Amadio 1998). The radiologic appearance is cystic or honey-combed or even erosive (Comstock and Wolson 1975). As a rule, fungal arthritis has a slow course when compared to acute pyogenic arthritis. As in other bone and joint infections, MRI provides detailed information about the extent of bone and soft-tissue involvement. Table 2 summarizes possible fungal infectious disease of the musculoskeletal system.

5.7 Parasitic Infections

Parasitic infections are extremely rare at the hands. Late in the natural disease course, dead parasites can cause bizarre calcifications in the soft tissues (Samuel 1950) (Fig. 11d). The form of these calcified remnants is either cystic (echinococcosis), spotty (cysticercosis) or linear and curled (filariasis, *Loa loa*, Guinea worm disease). When such atypical calcifications are detected and equivocal in origin, one should consider the presence of one of these rare parasitic infections.

6 Key Points

- Approximately 95% of all hand infections are located within the soft tissues, with only 5% involving bone or joint.
- The majority of superficial soft-tissue infections can be managed clinically without the need of imaging. However, radiographs, CT or MRI is required in two clinical settings: First, if spread of infection from the soft tissues to the adjacent bones or joints is suspected. Second, if a deep palmar abscess is suspected.
- In acute osteomyelitis, radiographic signs typically lag behind the onset of the infection by 8–10 days. In the majority of cases, initial findings are very subtle, before marked and poorly defined bone destruction appears.
- MRI is the most powerful imaging tool in detecting and comprehensively staging soft tissue and bone infections. Intravenous gadolinium is recommended for better differentiating abscesses from diffuse infections and the surrounding edema.
- CT imaging is best suited in chronic osteomyelitis for depicting the osseous structures, particularly for detecting sequestra that should be surgically removed to reduce the risk of reactivation of the osteomyelitis.
- Tuberculosis of the flexor tendon sheaths, the bones or the joints of the hands should be considered with slowly progressive infections associated with painless swelling and/or a draining sinus.
- Full clinical information is required for correct interpretation of the destructive bone and joint changes. Identification of the causative pathogen is mandatory to indicate the appropriate antibiotic therapy. Imaging-guided aspiration can be useful for this purpose.

Abstract

Bone tumours affecting the hand and wrist are rare. Only 2% of a series of 4,277 bone tumours were located in the hand or wrist. Furthermore, primary bone tumours are uncommon when compared with tumours arising in the soft tissues of the hand. Haber described 2,321 tumours of the hand with only 38 cases involving bone.

1 Introduction

Bone tumours affecting the hand and wrist are rare. Only 2% of a series of 4,277 bone tumours were located in the hand or wrist (Dahlin 1995). Furthermore, primary bone tumours are uncommon when compared with tumours arising in the soft tissues of the hand. Haber described 2,321 tumours of the hand with only 38 cases involving bone (cited by Garcia and Bianchi 2001).

The majority of bone tumours that affect the hand are benign. Of a series of 469 cases reported by Campanacci and Laus (cited by Garcia and Bianchi 2001), only ten were malignant tumours, six of which were metastases. The most frequent benign lesion is enchondroma and the most common malignant lesion is chondrosarcoma (Wilner 1982; Campbell et al. 1995). In Campbell et al. series of 80 bone tumours of the hand and wrist, gender distribution was equal and there was no left- or right-sided predominance (Campbell et al. 1995). The proximal phalanges and metacarpals are the most commonly affected locations (Wilner 1982; Campbell et al. 1995). Radiographs are sufficient to allow accurate diagnosis in the majority

of bone tumours of the hand and wrist. Computed tomography (CT) allows characterization of tumour matrix and presence of bone destruction. Magnetic resonance imaging (MRI) provides information regarding the extent of marrow involvement and soft tissue invasion.

This chapter reviews the most common benign and malignant bone neoplasms of the hand and wrist. The incidence, demographics, clinical presentation, distribution and imaging characteristics of these tumours specific to this location are discussed.

2 Benign Bone Tumours of the Hand and Wrist

2.1 Benign Cartilaginous Tumours

2.1.1 Enchondroma

Enchondromas are located more frequently in the hand and wrist than any other part of the body, accounting for up to 54% of all cases (Unni 1996). It is believed that the tumour develops from fragments of cartilage that originate from the central physis (O'Connor and Bancroft 2004). They most frequently occur in the proximal phalanx, followed by the metacarpal and middle phalanx (Takigawa 1971). Carpal enchondromas are rare and account for approximately 2% of hand enchondromas (Takigawa 1971).

Typically, patients present with a pathological fracture following minor trauma. Alternatively, the tumour presents as a slowly enlarging mass or is discovered incidentally on radiographs obtained for other reasons (Fig. 1). Multiple hand enchondromas may be encountered in association with either Ollier disease or Maffucci syndrome. Ollier disease is characterized by multiple enchondromas (Fig. 2), whereas the presence of multiple enchondromas in association with soft tissue haemangiomas is termed Maffucci syndrome (Fig. 3). The distribution of lesions tends to be in either a monomelic or hemimelic fashion. Both conditions are usually associated with bone deformity. Several authors have reported an association between enchondromatosis and chondrosarcoma of the hand (Fig. 4). Jaffe found malignant change in 50% of his cases of Ollier disease (cited by Liu et al. 1987). Liu et al. found the incidence of chondrosarcoma developing in Ollier disease to be

Fig. 1 Enchondroma. There is a lytic, mildly expansile tumour in the proximal phalanx containing punctate cartilage calcification

30% (Liu et al. 1987). Schwartz et al. estimated that development of chondrosarcoma in Maffucci syndrome was an 'almost certainty' (cited by O'Connor and Bancroft 2004). To the best of our knowledge, there are only 7 reports in the literature of chondrosarcoma of the hand arising from a pre-existent

Fig. 2 Ollier disease. Multiple enchondromas arising in the metacarpals and phalanges

benign solitary enchondroma, confirmed on histology and radiology (Culver et al. 1975, Justis and Dart. 1983, Nelson et al. 1990, Sbarbaro and Straub. 1960, Trias et al. 1978, Wu et al. 1983). This may relate more to the difficulty of establishing the presence of a pre-existing unequivocally benign lesion when a relatively small calibre bone is involved.

Radiographs show the enchondroma to be typically located in the meta-diaphyseal region of the tubular bones of the hand. It is classically a well-defined radiolucent intramedullary lesion containing thin internal trabeculations (Fig. 1). Endosteal scalloping, cortical thinning and expansion of the bone are commonly identified (O'Connor and Bancroft 2004). Associated chondroid calcifications are noted less often in enchondromas of the hand than at other skeletal locations. Cross-sectional imaging is rarely

Fig. 3 Maffucci syndrome. Multiple enchondromas in association with soft tissue angiomas. Multiple calcified phleboliths are present

required to make the diagnosis but CT helps clarify the presence of chondroid matrix and is superior to MRI at delineating endosteal scalloping. Enchondroma has a distinctive appearance on MR imaging, with multiple lobules of high signal intensity on T2W, fat suppressed and STIR sequences. The high signal characteristic is due to the hyaline cartilage content in these lesions. Low signal septae are often seen separating the lobules. Low signal foci corresponding to chondroid matrix may also be apparent. Radiographic features concerning for malignant transformation include cortical destruction and an associated soft tissue mass. A zone of lucency developing in a previously mineralized cartilage lesion is also suspicious for malignancy (Sun et al. 1985). MR imaging is useful in evaluating the extent of soft tissue extension in cases where malignant transformation is suspected.

2.1.2 Periosteal Chondroma

Periosteal chondroma (also termed juxtacortical chondroma) is a solitary, benign cartilaginous lesion

Fig. 4 Malignant transformation in Ollier disease. Multiple enchondromas with a large chondrosarcoma arising in the second metacarpal

that arises in the periosteum or adjacent soft tissues (O'Connor and Bancroft 2004). It is a rare tumour that was first described by Liechtenstein and Hall in (1952). It represents less than 2% of bone neoplasms (Robbin and Murphey 2000). The lesion is most common in males usually presenting in the second decade of life but the age range is broad (de Santos and Spjut 1981). While the lesion most commonly affects the metaphyses or metadiaphyses of the long bones, between 25 and 29% involve the hands and feet (deSantos and Spjut 1981; Boriani et al. 1983).

Scalloping of the cortex is a typical radiographic feature and can range from minimal change to displacement of cortex into the medullary cavity (Fig. 5). Sclerosis is typically present at the base of the lesion. Overhanging edges are seen at the margin which may completely or partially encircle the lesion. A visible soft tissue mass with associated chondroid matrix is seen in about 50% of cases and is more commonly associated with small lesions of the hands and feet (deSantos and Spjut 1981; Robbin and

Fig. 5 Periosteal chondroma. **a** There is an eccentric lytic lesion arising in the base of the middle phalanx in a child. **b** 11 years later, the lesion extends down to the subarticular margin

Murphey 2000). CT and MRI are useful in demonstrating the presence of an outer periosteal shell, soft tissue mass and calcified matrix. MRI demonstrates a juxtacortical mass of low to intermediate T1 and high T2 signal reflecting the hyaline cartilage content of the lesion. Robinson et al. found that size was the most reliable criteria for differentiating periosteal chondrosarcoma from periosteal chondroma (Robinson et al. 2001). In their series, periosteal chondrosarcomas were larger and never less than 3 cm in size. Other features such as intramedullary extension on

radiographs and intramedullary oedema on MRI were less specific.

2.1.3 Osteochondroma

Osteochondromas are benign bony projections that are capped by cartilaginous tissue. They typically arise in long tubular bones that develop by enchondral ossification. The lesion is believed to originate from an aberrant focus of cartilage. Although osteochondromas are the most common benign bone tumour, occurrence in the bones of the hands and feet is uncommon. In Ostrowski and Spjut's series of 240 lesions of the hand and feet, only 3% were osteochondromas (Ostrowski and Spjut 1997). Only 4% of osteochondromas involve the hands (Unni 1996).

The proximal phalanx is the most common location of solitary hand osteochondroma (O'Connor and Bancroft 2004i, Kamath et al. 2007). The metacarpals are a less common location (Fig. 6). In Unni's series of 1,024 solitary osteochondromas, only 4 (0.39%) were present in the metacarpals (Unni 1996). Solitary osteochondroma of the carpus is even rarer. It most frequently affects the scaphoid but has been reported in the capitate, hamate, lunate and trapezium (Heiple 1961; Malhotra et al. 1992; Van Alphen et al. 1996; Takagi et al. 2005; Koti et al. 2009). Since solitary osteochondroma of the hand is rare, patients should be assessed for hereditary multiple exostoses (HME).

Osteochondromas are usually asymptomatic in the hand unless they lie in a position that interferes with function. Trigger finger due to impingement of the flexor tendons by an osteochondroma has been reported (Al-Harthy and Rayan 2003). Growth around a joint may lead to blocking of motion at the joint or a pseudomallet deformity (Karr et al. 1984; Murase et al. 2002). In children, osteochondroma may be extremely small and difficult to identify as a cause of finger deformity (Moore et al. 1983). Fracture at the base of the lesion may occur (O'Connor and Bancroft 2004).

HME is an autosomal dominant skeletal disorder affecting the enchondral skeleton during growth, characterized by thickening and deformity of the growing bone with formation of numerous cartilage-capped exostoses. The overall incidence of hand lesions in HME is 79% (Solomon 1967). In this condition, the ulnar metacarpals and proximal phalanges are most commonly affected, with the thumb,

Fig. 6 Osteochondroma. It is arising from the surface of the distal 4th metacarpal. Note that there is continuity of trabeculae within the lesion and the underlying medullary bone

distal phalanges and carpal bones less commonly involved. Shortening of the 4th and 5th metacarpals is also a characteristic feature of the condition. Multiple lesions are typical in these patients with an average of 11.6 exostoses per hand (Fig. 7) (Cates and Burgess 1991). They affect the forearm (40–60%) more commonly than the upper arm. It has been concluded that an increasing distal radius involvement in HME is associated with a greater severity of the disease process overall (Taniguchi 1995). Disruption of the normal epiphyseal growth plate in HME leads to limb length discrepancies and angular deformity at the ends of long bones. This can present around the hip, knee, elbow and wrist. At the wrist, ulnar shortening leads to secondary bowing deformity of the distal radius giving rise to a pseudo-Madelung deformity (Fig. 7) (Vanhoenacker et al. 2001).

The risk of developing chondrosarcoma in a solitary osteochondroma is between 2 and 3% rising to 5–25% in patients with HME (Crandall et al. 1984, Garrison et al. 1982). However, these risks may be overstated as most series originate from tertiary orthopaedic oncology referral centres. The mean age of malignant transformation is 30 years and the most common site is the ilium (Garrison et al. 1982). To our knowledge, only one chondrosarcoma of the hand developing from a solitary osteochondroma has been reported in the literature (Cash and Habermann 1988). As with solitary osteochondromas, more peripherally located tumours are less likely to undergo malignant transformation in patients with HME. A chondrosarcoma of the hand arising in a

Fig. 7 Hereditary multiple exostoses (diaphyseal aclasis). Multiple small osteochondromas and a pseudo-Madelung deformity of the wrist

patient with HME has only twice been reported in the literature (Fig. 8) (Ostlere et al. 1991; Saunders et al. 1997).

Osteochondromas of the hand are typically sessile lesions which show continuity with the underlying medullary cavity of the bone of origin (Fig. 6). Most osteochondromas related to HME are juxta-epiphyseal in location (Fig. 7); the non-epiphyseal end of bone being the next most common and the diaphysis the least common location. Radiographs aid in demonstrating complications of osteochondromas such as fracture, growth disturbance, osseous deformity or malignant change. Any increase in size of a lesion after skeletal maturity is concerning for sarcomatous change and necessitates further evaluation. Loss of a previously well-defined margin, lucency within a previously mineralized area in the cartilage cap and a cap thickness of 2 cm or above are also concerning

features (Fig. 8b) (Ostlere et al. 1991). MR imaging provides precise information about thickness of the cartilage cap that has high signal intensity on T2 spin echo sequences and is important when assessing potential malignant transformation. It also provides information regarding complications such as reactive bursa formation, neural impingement and vascular compromise.

Two cases of dysplasia epiphysealis hemimelica (Trevor's disease) have been reported in the hand both arising at a proximal interphalangeal joint (De Smet 2004). This condition is characterized by asymmetric overgrowth of epiphyseal cartilage or an accessory epiphyseal ossification centre. This leads to excessive growth of the epiphysis with resultant bony protrusion. Though a distinct condition from osteochondroma, radiographs demonstrate an osteochondroma-like protruberans arising from an epiphysis (Fig. 9).

2.2 Giant Cell Tumour of Bone and Giant Cell Reparative Granuloma

Giant cell tumour of bone (GCTOB) is a benign, locally aggressive primary tumour of bone. Histologically, the tumour is characterized by the diffuse presence of osteoclastic, multinucleated giant cells in a background of mononuclear cells (Murphey et al. 2001). It accounts for 4.5% of primary bone tumours (Murphey et al. 2001) and 21% of benign skeletal tumours (Moser et al. 1990). The tumour most commonly occurs in the distal femur, proximal tibia and distal radius of skeletally mature individuals (Fig. 10). Only 2–3% of tumours arise in the bones of the hand (Minguella 1982; Athanasian 2004). A review of 1,228 cases of GCTOB found almost 1% occurred in the metacarpals (Fig. 11) and 1% in the phalanges (Averill et al. 1980). In a series of 452 cases of GCTOB, 57 occurred in the hand and wrist (James and Davies 2005). In this series, 11 (2%) cases were located in a metacarpal and 3 (1%) in a phalanx, the rest comprising lesions of the distal radius and ulna. Involvement of the carpal bones is very rare. In a literature review of GCTOB published in 2006, Shigematsu et al. found only 29 of 193 (15%) reported cases of GCTOB of the hand occurred in the carpus (Shigematsu et al. 2006). With the exception of the pisiform, all the carpal bones were represented with the hamate being the most common location.

Fig. 8 Malignant transformation in hereditary multiple exostoses. **a** PA oblique radiograph and **b** coronal T1-weighted MR image showing a large peripheral low-grade chondrosarcoma arising from the second metacarpal. Note the thick cartilaginous cap in the MR image (>2 cm)

Fig. 9 Dysplasia epiphysealis hemimelica (Trevor disease). There is a modelling deformity with an osteochondroma-like mass arising from the distal ulnar epiphysis

There is a slight female preponderance in cases of GCTOB arising in the small bones of the hand (Athanasian et al. 1997; Biscaglia et al. 2000). The age range is similar to that of GCTOB at other locations, occurring most commonly in the third decade

though the age range is wide (Athanasian et al. 1997; James and Davies 2005). Lesions in skeletally immature individuals account for between 2 and 6% of all GCTOB (Picci et al. 1983; Kransdorf et al. 1992). When arising in the small bones of the hand and wrist, patients usually present with pain and swelling but may also present with a pathological fracture (Biscaglia et al. 2000). The average duration of symptoms is between 6 and 8 months (Sanjay et al. 1996; Biscaglia et al. 2000).

GCTOB is usually monostotic, but multicentric cases have been described. The rate of multicentric GCTOB in the hand and wrist is between 7 and 18% (James and Davies 2005; Wold and Swee 1984; Sanjay et al. 1996) compared to less than 1% at other locations. GCTOB is generally considered a benign lesion but does have metastatic potential with risk of spread to the lungs. The overall risk of metastasis in GCTOB is between 1 and 9% (Harness and Mankin 2004; Jaffe 1935; Jaffe et al. 1940; Rock et al. 1984). Of a series of 21 cases occurring in the hand, 5% developed pulmonary metastases (Averill et al. 1980). Tumours of the distal radius have been implicated in the literature as the most common primary site in

Fig. 10 Giant cell tumour. **a** PA radiograph showing a subarticular, expansile, lytic lesion in the distal radius with a trabeculated contour. **b** Coronal T1-weighted and **c** Axial T2-weighted MR images showing the extent of the lesion and low signal areas due to the presence of haemosiderin

patients with pulmonary metastases (Athanasian et al. 1997). Earlier and higher rates of recurrence in GCTOB of the hand, compared to the tumour at other sites, have been reported (Patel et al. 1987). The risk of recurrence in the hand is reported as 83% (Averill et al. 1980) compared to 25% at other locations (O'Donnell et al. 1994; McDonald et al. 1986). Malignant GCTOB is known to occur and may be primary but usually occurs as a secondary tumour, usually due to sarcomatous transformation following radiotherapy. Malignant GCTOB of the distal radius has been reported (Pho 1981), but to the best of our knowledge, it has not been reported in the small bones of the hand and wrist.

Lesions in the distal radius demonstrate an eccentric, expansile, lytic lesion located in a subarticular position involving the epiphysis and metaphysis as is typically seen elsewhere in the skeleton (Fig. 10a). In

skeletally immature patients, the tumour is typically metaphyseal though extension across the growth plate into the epiphysis is rarely observed (Kransdorf et al. 1992; Picci et al. 1983). The metacarpals and phalanges effectively represent the equivalent of a long bone in the hand (Fig. 11). The tumour occurs in a more central location in the bones of the hand probably due to the limited volume of bone (James and Davies 2005). A narrow zone of transition is seen at the metaphyseal margin of the lesion, and there is typically no matrix mineralization. Internal trabeculation is common but the pattern may vary from fine striations to coarse trabeculation (Fig. 10a). Periosteal reaction is unusual unless there is a complicating fracture (James and Davies 2005). Thinning of the cortex and extension into the soft tissues is well recognized in GCTOB. Campanacci et al. described a grading system based on radiographic findings: Stage I

Fig. 11 Giant cell tumour. **a** PA radiograph at presentation showing a small area of permeative bone destruction in the proximal 1st metacarpal. **b** 4 months later without treatment the tumour has enlarged dramatically and is destroying much of the metacarpal

where lesions do not distort or perforate the cortex; Stage II where lesions expand or distort the cortex but do not extend into soft tissues; and Stage III where there is cortical destruction and soft tissue extension (Campanacci et al. 1979). Stage III tumours are associated with a higher rate of recurrence (O'Donnell et al. 1994). Technetium 99-m bone scintigraphy may demonstrate a classic “doughnut” configuration with avid uptake at the periphery of the tumour and a relatively photopenic centre. The routine use of bone scintigraphy has been advocated by some authors where hand lesions are identified given the higher frequency of multicentric lesions at this location (Averill et al. 1980; Wold and Swee 1984; Peimer et al. 1980).

Lesions in the hand and wrist show similar MR imaging characteristics to GCTOB elsewhere in the body (Fig. 10b). MRI defines the intra- and extra-osseous extent of the tumour. Low signal intensity on all sequences can be seen which is indicative of chronic haemosiderin deposition in GCTOB (Fig. 10c) (Aoki et al. 1996). Fluid–fluid levels may be demonstrated within the tumour mass, indicating the presence of secondary aneurysmal bone cyst (ABC) formation.

Giant-cell reparative granuloma (GCRG) is a reactive process that most commonly involves the

mandible, maxilla and small bones of the hands and feet. It has been suggested that this lesion may be morphologically related or may constitute the same clinical entity as GCTOB (Gouin et al. 2003). Others have however expressed a differing opinion (Murphey et al. 2001). Histologically, GCRG is characterized by fibroblasts and clusters of multinucleated giant cells surrounded by foci of haemorrhage which may also contain areas of osteoid matrix and aneurysmal bone cyst formation (Yamaguchi and Dorfman 2001; Murphey et al. 2001; Macdonald et al. 2003). In general, GCRG affects a younger age group than GCTOB, with presentation often seen in skeletally immature patients. Sex distribution is equal in GCRG of the hands and feet (Ratner and Dorfman 1990). As with GCTOB, clinical presentation may be non-specific. GCRG most commonly affects the phalanges, followed by the metacarpals and carpal bones (Fig. 12) (Yamaguchi and Dorfman 2001). The tumours are metaphyseal in location, and unlike in GCTOB, involvement of the epiphysis is rare (Murphey et al. 2001). To our knowledge, extension of GCRG across an unfused physis has not been reported. The tumours may have an expansile, lytic radiographic appearance and may demonstrate cortical destruction (Fig. 11). Pathological fracture and periosteal reaction are rarely seen (Wold et al. 1986).

2.3 Bone Cysts

Aneurysmal bone cyst (ABC) is rare accounting for between 5 and 6% of benign bone tumours (Huvos 1991). ABCs are composed histologically of blood-filled cavities lined by giant cell osteoclasts, fibrous tissue and woven bone. The most common locations of ABC are the proximal tibia, humerus and pelvis. ABC of the hand is rare. In a series of 516 ABCs, only 17 lesions occurred in the hand (Fuhr and Hendron 1979). Of 95 cases reviewed by Tillman et al., only 3 were in the hand (Tillman et al. 1968).

ABC most commonly presents in the second decade of life and has an equal distribution among males and females. In a review of the literature, Platt and Klugman concluded that ABC of the hand most commonly involves the metacarpals (52%) followed by the phalanges (36%) and carpal bones 4% (Platt and Klugman 1995). An unusual case of ABC arising in a sesamoid bone of the hand has been reported

Fig. 12 Giant cell reparative granuloma. **a** PA radiograph **b** Coronal T1-weighted and **c** Coronal STIR MR images showing a lytic, expansile lesion destroying the proximal third of the first metacarpal

(Havulinna et al. 2005). Trauma is implicated in association with almost half of the published cases of hand ABC; however, many authors suggest this is coincidental and has simply drawn attention to a pre-existing lesion. Typically, the patient presents with a slowly enlarging mass that may or may not be painful (Athanasian 2004). On examination, there may be extensive swelling and warmth. Patients may present with a pathological fracture.

Radiographs of the hand demonstrate a central, expansile, lytic lesion that causes cortical thinning. ABCs are normally epiphyseal or metaphyseal in location (Fig. 13). Subperiosteal ABCs are eccentrically located and tend to involve the metaphysis or metadiaphysis. These lesions grow outside the confine of normal bone but are limited externally by periosteum and internally by endosteum (James and Davies 2006). Only two cases of subperiosteal ABC have been reported in the hand, one in a metacarpal and the other in a phalanx (Fig. 14a) (Alnot et al. 1983; Maiya et al. 2002). ABCs may be surrounded by a sclerotic margin. Matrix trabeculations are sometimes observed and may be mixed or lytic. Pathological cortical fractures are associated with a periosteal reaction. When the lesion presents in the distal phalanx, significant bone destruction may occur. The natural history of ABC is that of progressive enlargement and bone destruction though some authors have noted spontaneous healing or healing following minor disturbance such as fracture or biopsy (Chalmers 1981; Leeson et al. 1988). MR and CT imaging, as in other skeletal locations, may

Fig. 13 Aneurysmal bone cyst. Two different cases both in children. There a lytic, expansile, juxta-epiphyseal lesions arising in the proximal phalanx and distal radius

demonstrate fluid–fluid levels which are suggestive but not diagnostic of ABC (Fig. 14b, c). The possibility of secondary ABC formation in a pre-existing lesion should always be considered. Both radiologically and histologically the lesion may be confused with telangiectatic osteosarcoma; however, the latter entity is rarer than ABC in the hand. Although ABC can be locally aggressive, it is not known to have

Fig. 14 Subperiosteal aneurysmal bone cyst. **a** Oblique radiograph showing a thin shell of periosteal new bone arising from the second metacarpal. **b** Axial T1- and **c** Axial T2-weighted fat suppressed MR images showing an eccentric lesion with fluid–fluid levels

metastatic potential. Local recurrence after curettage has been widely reported.

Simple bone cyst, also termed unicameral bone cyst, is a tumour-like lesion of unknown cause. It consists of a bony cavity, lined by a thin membrane and filled with fluid. It most commonly arises in the proximal humerus and proximal femur with 85% occurring pre-skeletal fusion. Involvement of the hand and wrist is rare. Radiographic features, irrespective of site, are those of a benign looking, lytic lesion arising in the metaphysis of a long bone. Frequently, cases present with a pathological fracture following only minor trauma (Fig. 15a). In time the cyst will grow away from physis with the laying down of normal intervening trabecular bone (Fig. 15b).

Intraosseous ganglia are benign non-neoplastic bone lesions that are histologically similar to their soft tissue counterpart. The terms intraosseous ganglion, subchondral cyst or geode are often applied interchangeably, although the latter are more frequently used to describe juxta-articular lesions associated with degenerative or inflammatory joint disease (Williams et al. 2004). They appear as well-defined subarticular lytic lesions. When not associated with degenerative joint disease, they can mimic other juxta-articular lesions such as giant cell tumour (Fig. 16). Cases arising in the carpal bones are not uncommon, can be multiple and bilateral (Logan et al. 1992; Lorente et al. 1992).

Fig. 15 Simple bone cyst. **a** PA radiograph showing a pathological fracture through a lytic lesion in the distal radial metaphysis. **b** 2 years later the fracture has healed. The lesion is mildly expansile and has started to grow away from the distal radial growth plate

2.4 Osteoid Osteoma

Osteoid osteoma is a benign osteoblastic tumour that was first described in 1935 (Jaffe 1935). The tumour consists of an area of variably calcified osteoid tissue within a stroma of relatively loose vascular connective tissue. A rim of sclerotic reactive bone, less than 2 cm in diameter, surrounds the lesion and there may be a

Fig. 16 Intraosseous ganglion. Two different cases showing subarticular lytic lesions involving **a** the distal ulna and **b** the distal radius. This second case also shows scapho-lunate disassociation

periosteal reaction. Approximately 10% of cases of osteoid osteoma involve the hand and wrist: 6% the phalanges, 2% the metacarpals and 2% the carpal bones (Jackson et al. 1977). The middle phalanges are the least commonly affected bones in the hand (Bednar et al. 1993; Ambrosia et al. 1987; Marcuzzi et al. 2002; Rex et al. 1997).

In general, osteoid osteoma most commonly presents in the second decade of life and has a 2:1 male to female ratio (Jackson et al. 1977). In Marcuzzi et al. series of 18 cases of osteoid osteomas of the hand and wrist, the male: female ratio was equal and the average age at presentation was 27 years (Marcuzzi et al. 2002). Typical clinical symptoms are of gradually increasing pain and swelling. Juxta-articular location can lead to restriction of movement. Physical signs often vary depending on the site of clinical symptoms. Proximal and middle phalanx involvement may be associated with a grossly enlarged phalanx with hypertrophy of the soft tissues, while distal phalanx involvement may lead to finger clubbing and hypertrophy of the nail (Marcuzzi et al. 2002; Rosborough 1966). The average duration of symptoms for osteoid osteoma of the hand and wrist before diagnosis is between 13 and 15 months (Bednar et al. 1993; Doyle et al. 1985; Marcuzzi et al. 2002). However based on reports in the literature, painless osteoid osteoma appears to occur in the digits more frequently than in any other skeletal location (Basu et al. 1999; Lawrie et al. 1970; Rex et al. 1997; Wiss and Reid 1983).

Osteoid osteomas may arise centrally in the medulla, in the cortex or in a subperiosteal location. As with

other skeletal sites, the cortex is the most common location for osteoid osteomas of the hand and wrist.

Subperiosteal lesions are extremely rare in the hand, with only limited reported cases (Crosby and Murphy 1988; Kayser et al. 1998; Shankman et al. 1997). The typical radiographic appearance is that of a small, radiolucent lesion or nidus surrounded by an area of bone sclerosis (Fig. 17). Lesions noted in the subperiosteum have atypical radiographic findings (Fig. 18). Of 18 hand and wrist osteoid osteomas reported by Marcuzzi et al., only two had characteristic appearances on radiographs (Marcuzzi et al. 2002). Initially, these were normal in almost all patients, with bony abnormality becoming visible from 6 to up to 25 months. As with other skeletal locations, bone scintigraphy of osteoid osteoma of the hand and wrist shows a well-defined focal area of increased activity during all three phases of a technetium-99 MDP scan. Findings can be non-specific with diffuse uptake of radionuclide in the area of the lesion. CT is the most specific investigation (Fig. 18b) (Assoun et al. 1994). This characteristically shows a lytic lesion with a central granular opacity surrounded by a sclerotic margin. While MRI is the most sensitive imaging modality, it lacks specificity and can be misleading in the absence of radiographs and radionuclide scans (Assoun et al. 1994). The typical MRI pattern is that of a lesion composed of a hypointense, sclerotic centre with a high T2 signal rim surrounded by marrow oedema (Kreitner et al. 1999). Soft tissue oedema is also commonly present. MRI however is often non-specific particularly when there is diffuse oedema. It is also non-specific in differentiating osseous neoplasms

Fig. 17 Osteoid osteoma. There is sclerosis and thickening of the middle phalanx with a faint lucent cavity containing a focus of calcification representing the nidus of the lesion

like osteoid osteoma from low-grade infection and florid reactive periostitis (Ehara et al. 1994).

2.5 Focal Proliferative Periosteal Processes

Florid reactive periostitis (FRP) was first reported in 1933 by Mallory (cited by Jambhekar et al. 2004). Subsequently, bizarre parosteal osteochondromatous proliferation (BPOP) of the phalanges was described as a new radiopathological entity by Nora et al. (1983). Initially, these two conditions were considered to represent two distinct processes. Yuen et al. proposed a hypothesis that the two entities, along with turret exostosis, are part of a continuous spectrum of the same process (Yuen et al. 1992). They suggested that initial subperiosteal haemorrhage causes a localized fusiform periostitis consistent with FRP. Later the periostitis becomes incorporated into cortex and remodelling leads to a broad-based cancellous protruberance that is characteristic for BPOP. Sundaram

et al. reported a series of three cases where a presumptive radiographic diagnosis of FRP was made, biopsy withheld and the patients closely followed-up with serial radiographs (Sundaram et al. 2001). They observed maturing of the periosteal reaction as expected in BPOP, leading them to also conclude that FRP can progress to BPOP.

2.5.1 Florid Reactive Periostitis

The term Florid reactive periostitis was first used by Spjut and Dorfman in their series of 12 cases (Spjut and Dorfman 1981). Because of its histological resemblance to nodular fasciitis, other names used to describe the entity have included Fasciitis ossificans and Parosteal fasciitis (Hutter et al. 1962; Kwittken and Branche 1969). Dupree and Enzinger, in a series of 21 cases, used the term Fibro-Osseous pseudotumour of the digits. They dispute its periosteal origin suggesting it arises from soft tissues and surrounding fibrous structures (Dupree and Enzinger 1986).

FRP is more frequent in the second and third decades of life (Callahan et al. 1985; Rogers et al. 1999). According to Flechner and Mills, there is a slight female preponderance (quoted by Solana et al. 2003). An antecedent history of trauma is present in between 10 and 50% of cases of FRP (Spjut and Dorfman 1981; Michelsen et al. 2004). The majority of cases involve the proximal phalanx, followed by the middle phalanx, metacarpal and distal phalanx in decreasing order of frequency (Rogers et al. 1999). Radiographs typically demonstrate soft tissue swelling with intralesional calcification (Howard et al. 1996). Periosteal reaction is present in approximately 50% of cases and can either be lamellated or mature (Fig. 35.20a) (Howard et al. 1996; Spjut and Dorfman 1981). Cortical erosions associated with FRP have been described in several series (Spjut and Dorfman 1981; Dupree and Enzinger 1986; Landsman et al. 1990; Jongewood et al. 1985; Howard et al. 1996). All were successfully managed with marginal resection which led Howard et al. to conclude that lesions with cortical erosion should not be considered an aggressive form of the disease. The main radiological differential diagnoses include osteomyelitis and parosteal osteosarcoma. Concern regarding a delay in treatment for potential malignancy often leads to hastily performed surgical procedures (Jambhekar et al. 2004). Sundaram et al. advocate more prospective radiological diagnosis of FRP with close

a Radiograph showing periosteal new bone formation along the 1st metacarpal with a faint eccentric nidus located distally. **b** Axial CT reveals the nidus formed by the subperiosteal cavity and containing a small focus of calcification

clinical and radiographic follow-up to allow more appropriate and timely intervention (Sundaram et al. 2001).

2.5.2 Bizarre Parosteal Osteochondromatous Proliferation

Since its initial description by Nora, several case series and case reports of BPOP have been published. Of 65 cases in Meneses series, 36 (55%) were located in the hand (Meneses et al. 1993). Though the age at which presentation occurs is wide, peak incidence tends to be in the third and fourth decades (Meneses et al. 1993). There is no sex predilection. An antecedent history of trauma is uncommon but is reported by some authors (Meneses et al. 1993; Michelsen et al. 2004). Typically, presentation is insidious and characterized by a slow-growing, usually painless mass. Radiographs demonstrate a well-margined mineralized mass arising from the cortical surface of the affected bone (Fig. 19b) (Nora et al. 1983). Though the cortex is classically unaffected, one case report describes cortical erosion in association with BPOP, but this was in the distal radius (Helliwell et al. 2001). The lesion can measure from 0.4 to 4 cm (Nora et al. 1983; Dhondt et al. 2006). Occurrence is 4 times more common in the hand than the foot. Fifty

percent of cases affect the proximal phalanges with the remainder evenly distributed between the middle phalanges and metacarpals (Bednar et al. 1995 quoted by Torreggiani et al. 2001). The distal phalanx tends not to be involved. The characteristic radiological findings that differentiate BPOP from osteochondroma are the lack of cortical flaring at the margin of the protruberance and the absence of continuity of the lesion with medulla of underlying bone. Rybak et al. however have reported a series of histologically proven BPOP cases where medullary communication was demonstrated leading them to hypothesize that a continuum also exists between BPOP and osteochondroma (Rybak et al. 2007). None of the cases in this series were in the hand.

CT is of value in demonstrating the relationship between the lesion and underlying cortex and establishing that there is not continuity with the medullary cavity. There are a number of reports of the characteristic MRI appearances of BPOP (Tannenbaum and Biermann 1997; Torreggiani et al. 2001; Orui et al. 2001). The lesion is of low signal intensity on T1-weighted images and high signal intensity on T2 and STIR-weighted images (Torreggiani et al. 2001). The medulla and surrounding soft tissues are usually normal in appearance though Orui reported a case with oedema in both medulla and surrounding soft tissues (Orui et al. 2001).

Fig. 19 Focal proliferative periosteal processes. **a** Florid reactive periostitis, **b** bizarre parosteal osteochondromatous proliferation and **c** turret exostosis

Definitive treatment is surgical excision. The recurrence rate is however high. There was recurrence in 18 of the 35 cases in Nora's series and 22 of 40 cases where follow-up was available in Meneses series. A case of fibrosarcoma in association with BPOP has been reported in the distal fibula (Choi et al. 2001) To the authors knowledge, this is the only reported case of malignancy associated with BPOP. There have been no reported cases of metastatic disease.

2.5.3 Turret Exostosis

Turret exostosis is a rare complication of trauma to the fingers. It is thought to result from breach of the periosteum with formation and subsequent ossification of subperiosteal haemorrhage. The index and little finger digits are most frequently involved (Wissinger et al. 1966; Lee and Kaplan 1974; Bourguignon 1981). The phalanges are the typical location for the lesion, but a case involving a metacarpal has

been reported (Rubin and Steinberg 1996). The lesion usually occurs on the dorsal surface of the affected phalanx with only one case reported to date arising on the volar aspect (Mohanna et al. 2000).

A firm mass is usually palpable on clinical presentation, and there may be loss of function of the digit distal to the exostosis due to excursion of the extensor tendons (Mohanna et al. 2000). There is almost always an antecedent history of trauma usually in the form of a laceration. Radiographically, the earliest finding is soft tissue swelling. A poorly defined, fragmented collection of subperiosteal new bone may be seen up to about 4 months from the initial injury (James and Davies 2005). The mature lesion demonstrates a narrow body with a smooth dome and usually lies deep to the extensor apparatus (Fig. 19c). Most authors recommend a 6-month period between the episode of trauma and local excision of the lesion (Rubin and Steinberg 1996; Mohanna et al. 2000). Excision of the lesion before it has fully

matured may result in recurrence. Serial radiographs and bone scan can be used to assess maturity of the lesion which is indicated by well-defined cortical margins on radiographs and decreasing activity on bone scintigraphy [Rubin].

2.5.4 Subungual Exostosis

Subungual exostosis is an uncommon benign condition arising in a distal phalanx beneath or adjacent to the nail bed. Though it most commonly occurs in the great toe, between 10 and 20% of cases are identified in the fingers (Landon et al. 1979; Carroll et al. 1992; Hoehn and Coletta 1992; Ippolito et al. 1987; Izuka et al. 1995). There is no preponderance for a particular digit in the hand. The incidence of subungual exostosis is 1.5 times higher in females than males (Izuka et al. 1995). Patients usually present in the second and third decades of life. Clinical presentation typically involves pain, swelling or surrounding ulceration of the nail bed. Secondary soft tissue infection may result. The aetiology remains unclear though trauma is felt by some authors to be the most likely precipitating factor (Landon et al. 1979; Resnick and Niwayama 1988).

The tumour is histologically characterized by mature trabecular bone and an overlying fibrocartilaginous cap. This feature distinguishes the tumour from osteochondroma which has a hyaline cartilage cap (Carroll et al. 1992). Radiographs demonstrate a mature trabecular bony excrescence arising from the dorsal aspect of the distal phalanx (Fig. 20). The fibrocartilage cap is radiolucent. The lesion may have a narrow or broad attachment, but there is no continuity with the underlying medulla, a distinguishing feature from osteochondroma. There should be no bony destruction (Landon et al. 1979). Occasionally, the lesion may be strictly more paraungual than subungual in location (Fig. 20). No cases of malignant change have been reported in the literature.

2.5.5 Periostitis Ossificans

Myositis ossificans occurring in the hand is an extremely rare entity. When it occurs in a juxtacortical location, it is termed periostitis ossificans and may mimic BPOP or FRP (Fig. 21) (James and Davies 2005). It is usually seen in young adults. Patients may present with a rapid onset of pain, a palpable mass, oedema, joint contractures and decreased range of

Fig. 20 Subungual and paraungual exostoses

motion (Cushner and Morwessel 1992; De Smet and Vercauteren 1984; Ray and Basset 1984).

Initial radiographs may be normal or demonstrate a non-calcified soft tissue mass. The mass undergoes peripheral mineralization at 7–14 days, and adjacent periosteal reaction may also be observed (Fig. 21). By 6–8 weeks, a densely calcified periphery develops and a lucent centre is observed on radiographs. As the lesion matures, it undergoes ossification from the margins inwards. This ‘zoning’ phenomenon is the hallmark of myositis ossificans and helps differentiate it from parosteal osteosarcoma both radiologically and histologically (Fig. 21c).

2.6 Miscellaneous Benign Tumours

Chondroblastoma (CB) occurring in the hand and wrist is extremely rare and accounts for between 3 and 4% of all CB (Neviaser and Wilson 1972; Schajowicz and Gallardo 1970; Bloem and Mulder 1985). It typically occurs in an older age group to CB at other locations, most commonly presenting in the

Fig. 21 Periostitis ossificans. **a** PA radiograph showing peripheral mineralization (zoning phenomenon) and reactive periosteal new bone. **b** Coronal STIR MR image showing the thin low signal intensity rim corresponding to the

mineralization and a florid surrounding inflammatory response. **c** Sagittal CT reconstruction confirming the peripheral mineralization and periosteal reaction along the adjacent metacarpal

third decade of life (Davila et al. 2004; Bloem and Mulder 1985). Cases of CB occurring in the phalanges, metacarpals and carpal bones have been documented. The clinical presentation, as at other locations, almost always involves pain (Bloem and Mulder 1985). The typical radiographic appearance is of a lytic lesion with sclerotic margins, bony expansion, matrix mineralization and occasional septation (Dahlin and Unni 1986; Davila et al. 2004). At MRI, a secondary aneurysmal bone cyst component is frequently present and marrow oedema surrounding the lesion may be identified (Davila et al. 2004).

Osteoblastoma of the hand and wrist is also very rare and accounts for between 5 and 6% of all osteoblastomas (Adler 2000). On radiographs, osteoblastoma is typically eccentrically located and demonstrates a large focus of central osteolysis, between 4 and 10 cm in diameter, and a small area or peripheral sclerosis. In the short tubular bones, the lesions are much smaller, centrally located and expansile. They are well circumscribed and predominantly radiolucent (Adler 2000). Osteoblastoma has been reported in carpal, metacarpal and phalangeal bones (Wilner 1982). It is usually a solitary tumour however 3 cases of multifocal osteoblastoma involving the small bones of the hand and wrist have been reported (Adler 2000; Allieu et al. 1989; Muren et al. 1991).

Fibrous dysplasia of the hand and wrist is very uncommon. In a series of 225 cases of monostotic fibrous dysplasia, only 3 hand cases were reported (Schajowicz 1981). Of the cases described in the English speaking literature, the majority have been located in the metacarpal bone and have been of the polystotic form (Amillo et al. 1996; Gropper et al. 1985; Hayter and Becton 1984). An expansile, lytic lesion involving the shaft with a sclerotic border, trabeculations and a partially calcified matrix is described on radiographs in one of these cases (Fig. 22) (Gropper et al. 1985). Periosteal reaction and soft tissue extension as delineated on MRI has been reported (Amillo et al. 1996). Pathological fracture through an involved metacarpal was the presenting feature in another case (Hayter and Becton 1984).

Intraosseous epidermal cysts, or epidermal inclusion cysts, are squamous epithelial-lined benign cysts within bone. Peak incidence is within the 25–50 age group with a male to female ratio of 3:1 (Fisher et al. 1958). The most common site is the terminal phalanx of the left middle finger (Fisher et al. 1958). On radiographs, they usually appear as a well-defined, unilocular, osteolytic lesion with a sclerotic margin (Fig. 23) and may exhibit spotty calcifications (Musharrafieh et al. 2002; Patel et al. 2006). Enchondroma is the major differential diagnosis, but unlike intraosseous epidermal cysts, it is rarely symptomatic in the absence of a fracture.

Fig. 22 Fibrous dysplasia. Polystotic involvement of the thumb, index and middle fingers. There is mild bony expansion with a ground glass matrix

Glomus tumours are benign hamartomas. They arise from the normal glomus apparatus within subcutaneous tissue. The tumours mainly occur in women and are most commonly located in the distal phalanx, usually in a subungual location (Fig. 24) (Dahlin et al. 2005). Intraosseous glomus tumours of the hand are extremely rare. Only ten had been reported in the literature by 1981 (Chan 1981). To our knowledge, only one further case has subsequently

Fig. 23 Intraosseous epidermal cyst. Well-defined, rounded, lytic lesion in the tip of the terminal phalanx

Fig. 24 Glomus tumour. Pathological fracture through well-defined lytic lesion in the terminal phalanx

been described (Johnson et al. 1993). MRI has proved to be a valuable method of imaging glomus tumours (Theumann et al. 2002; Opdenakker et al. 1999). Most glomus tumours demonstrate high signal on spin echo T2-weighted sequences and avid enhancement post-gadolinium injection (Theumann et al. 2002). Cases have been reported where a tumour was present despite a negative MRI. On this basis, it has been

Fig. 25 Bone island.
a Solitary sclerotic focus in the lunate, **b** Multiple small bone islands clustered around the bone ends (osteopoikilosis)

suggested that in the correct clinical context, surgical exploration should be considered even if MRI findings do not support the diagnosis (Dahlin et al. 2005).

Bone islands (enostosis) are relatively frequently encountered on routine imaging of the hand and wrist for other indications. They represent a focus of mature compact bone and are best considered a benign tumour-like lesion (Greenspan 1995). Radiographs demonstrate a sclerotic focus that often has a round or oval appearance which blends with the adjacent cancellous bone (Fig. 25a). CT shows a localized spiculate margin to the lesion and MRI will demonstrate the lesion to be low signal on all sequences. In the multiple form, osteopoikilosis, the bone islands are clustered around the bone ends (Fig. 25b).

There is a spectrum of vascular tumours that may arise in bone from benign haemangioma to malignant angiosarcoma. All are uncommon in the hand and wrist. Of particular note is that these lesions, including low-grade haemangioendothelioma, can be multicentric and so should be considered in the differential diagnosis when imaging reveals multiple lytic bony lesions (Fig. 26).

3 Malignant Bone Tumours of the Hand and Wrist

3.1 Chondrosarcoma

Chondrosarcoma of the hand accounts for 1.5% of all chondrosarcomas (Unni 1996). From a Mayo Clinic series of 29 primary malignant tumours of the hand and

wrist, 12 were chondrosarcomas (Unni 1996). A literature review by Damron et al. however identified only one case of chondrosarcoma from a total of 2,588 tumours of the hand (Damron et al. 1995). This may be explained by the fact that chondrosarcoma of the hand and wrist more commonly occurs from malignant degeneration of a pre-existing lesion than as primary chondrosarcoma (O'Connor and Bancroft 2004).

Chondrosarcoma of the hand and wrist occurs in an older age group than chondrosarcoma at other locations with presentation most commonly in the 6th and 7th decades of life (Saunders et al. 1997; Ogose et al. 1997). Females are slightly more commonly affected than males with a ratio of 1.3:1 (Saunders et al. 1997). Typical clinical features are of pain and swelling though not always in combination (Ogose et al. 1997; O'Connor and Bancroft 2004). Cawte et al. reported duration of symptoms between 1 month and 3 years before presentation (Cawte et al. 1998). Roberts and Price however noted a very long history in their older patients, averaging 19 years (Roberts and Price 1977).

As already discussed in this chapter, chondrosarcoma arising from pre-existing solitary enchondromas or osteochondromas or in conditions of enchondromatosis or multiple hereditary exostoses are well documented in the literature (Figs. 4 and 8). These “secondary” chondrosarcomas account for 27% of chondrosarcomas reported in the hand (Saunders et al. 1997). In all locations, 15–28% are secondary (Huvos and Marcove 1987; Salib 1967).

Chondrosarcoma of the hand is located at similar locations to enchondroma, originating near the site of

Fig. 26 Multifocal haemangioendothelioma. **a** PA radiograph, **b** Coronal T1-weighted and **c** STIR MR images showing extensive infiltration of the 5th metacarpal with a further focus of tumour in the hamate

the epiphyseal growth plate of the bone: proximally in the phalanx and distally in the metacarpal (Fig. 27) (Palmieri 1984; Roberts and Price 1977). The tumour most commonly occurs at the proximal phalanx (Saunders et al. 1997; Ogose et al. 1997; O'Connor and Bancroft 2004). Of a series of 88 chondrosarcomas of the hand reported by Ogose et al., the 5th digit was most commonly affected and the 4th was least commonly involved (Ogose et al. 1997). In the same series, the majority of chondrosarcomas located in the distal phalanx affected the thumb. Chondrosarcomas have been rarely described arising in the carpal bones (Dahlin and Salvador 1974; Granberry and Bryan 1978; Young et al. 1990; Ogose et al. 1997).

Chondrosarcoma of the hand can be difficult to differentiate radiographically from benign cartilaginous tumours particularly in the absence of clear extension through the cortex and an associated soft tissue mass (Cawte et al. 1998; Murphey et al. 2003). In a study of 160 cases of chondrosarcomas of the small bones of the hands and feet, endosteal erosion, cortical destruction and expansion were observed in 90% of the 111 cases where imaging was available (Ogose et al. 1997). Other features included an associated soft tissue mass (80%), poor margination (79%), mineralization (74%), a permeative lytic

pattern (50%) and a periosteal reaction (14%) (Fig. 27). Extension of tumour across the joint in the hand has been described (Patil et al. 2003). In a study comparing the radiographic appearances of enchondroma and chondrosarcoma of the hands and feet, calcification of the chondroid matrix was observed in equal numbers (Cawte et al. 1998). Pathological fractures are observed in both enchondroma and chondrosarcoma. MRI better defines the extent of soft tissue involvement. Tumours classically demonstrate high signal on T2-weighted images and low signal on T1-weighted images, reflecting the hyaline cartilage content of the tumour (Fig. 27b, c).

The periosteal or juxtacortical type makes up an extremely rare subset of chondrosarcoma of the hand. Of 23 patients with chondrosarcoma of the small bones of the hand, Patil et al. identified one periosteal tumour (Patil et al. 2003). A further paper by Roberts and Price identified two patients out of 19 cases of chondrosarcoma of the hand that had a periosteal location. Review of the literature reveals a further two case reports (Wu et al. 1983; Jokl et al. 1971). A faintly radio-opaque mass with saucer-shaped erosion of the underlying phalanx was described in one case (Wu et al. 1983). Another description was of a radiolucent mass with stippling and calcification

Fig. 27 Malignant transformation of enchondroma to chondrosarcoma. **a, b** PA radiographs obtained 18 months apart showing a significant increase in size of the lesion with cortical breaching. **c** Sagittal T1-weighted and **d** Axial T2-weighted fat saturated images showing the full extent of both intraosseous and extraosseous spread

around the middle phalanx (Jokl et al. 1971). Roberts and Price observed that the degree of cortical destruction and soft tissue tumour was less marked than in conventional chondrosarcoma (Roberts and Price 1977). It is probably for this reason that the distinction between periosteal chondroma and low-grade juxtacortical chondrosarcoma is sometimes difficult to make.

Most published series report no metastatic disease associated with chondrosarcoma of the hand (Patil et al. 2003; Palmieri 1984; Roberts and Price 1977) but in one study of patients with chondrosarcoma of the small bones of the hands and feet, Ogose et al. reported 12 distant metastatic lesions from the 70 patients where follow-up was available (Ogose et al. 1997). The risk of local recurrence after surgery

necessitates long-term follow-up of these patients (O'Connor and Bancroft 2004).

3.2 Osteosarcoma

Osteosarcoma of the small bones of the hand is rare. Of 2,589 cases of skeletal osteosarcoma, Okada et al. found only 10 arising in the hand (Okada et al. 1993). A review of the English literature by Fowble et al. in 2005 found a total of 41 cases of osteosarcoma of the hand in 39 patients (Fowble et al. 2005). Since then a further 4 cases have been reported (Jones et al. 2006; Muir et al. 2008; Abe et al. 2007; Mathov et al. 2008).

Despite an age range of presentation between 13 months to 85 years (Sanchis-alfonso et al. 1994; D'antona 1934 quoted by Carroll 1957), osteosarcoma of the hand appears to affect an older age group than conventional osteosarcoma, the mean age being 42 years. Risk factors include Paget's disease, previous radiation treatment, trauma and metastasis from primary osteosarcoma located elsewhere in the skeleton (Fowble et al. 2005). Clinical presentation is typically pain and swelling (Okada et al. 1993). The long duration of symptoms, long interval before local recurrence and excellent response to treatment suggest that lesions in this location are less aggressive than conventional osteosarcomas (Okada et al. 1993).

Osteosarcoma of the hand shows a preferential distribution around the MCP joints, often sited within the metacarpal heads and bases of the proximal phalanges, with a slight predilection for the second and third digits (Fowble et al. 2005). These sites represent the fastest growing growth plates and the longest bones of the hand. Lesions of the carpus have only been reported twice, one in the scaphoid and the other in the trapezium (Marcuzzi et al. 1996; Bickerstaff et al. 1988). Two cases of bilateral osteosarcoma of the hand, both in patients with Paget's disease, have previously been reported (Drompp 1961; Friedman et al. 1982).

The radiographic findings are similar to the appearance of osteosarcoma at other sites with matrix mineralization, bone destruction and florid periosteal reaction (Fig. 28). The tumour is generally intramedullary in location with extension into the soft tissues (Fig. 28b). The presence of intramedullary involvement is helpful in distinguishing the lesion from benign entities such as BPOP and FRP that can otherwise

Fig. 28 Osteosarcoma. **a** Radiograph showing a mixed lytic and sclerotic lesion arising in the proximal half of the 5th metacarpal. **b** Coronal T1-weighted MR images showing the

tumour infiltration and low signal intensity areas due to the malignant mineralization

appear similar on radiographs (Jones et al. 2006). The absence of zonal organization in osteosarcomas as characterized by peripheral density and central lucency can also help differentiate it from benign entities (Jones et al. 2006). MRI better assesses the soft tissue involvement and degree of intramedullary extension (Fig. 28b). The lesion may be isointense on T1-weighted imaging and of high-signal intensity on T2-weighted imaging (Honoki et al. 2001).

There appears to be a greater propensity for lesions to arise from the surface of the bone when compared to osteosarcoma at other sites. The majority of these surface tumours are parosteal with only two reported periosteal osteosarcomas of the hand (Okada et al. 1993; James and Davies 2005; Jones et al. 2006; Muir et al. 2008). Surface osteosarcomas often appear as a densely calcified mass adjacent to a metacarpal or phalanx on radiographs (Fig. 29) (Revell et al. 2000). They can be connected to bone by a stalk that may only be demonstrated on CT. These lesions may be difficult and sometimes impossible to differentiate from benign disorders on imaging (Okada et al. 1993). A rare variant of parosteal osteosarcoma is the osteochondroma-like parosteal osteosarcoma that has been reported in the hand (Fig. 30). On imaging, these lesions appear as a 'pasted on' ossified mass with an intact underlying cortex and no medullary involvement (Lin et al. 1998). Of the 6 cases of osteochondroma-like parosteal osteosarcoma reported by Lin

Fig. 29 Parosteal osteosarcoma. **a** The radiograph shows a densely calcified mass adjacent to a metacarpal. **b** Sagittal T1-weighted MR image showing the lesion invading the underlying medulla

et al., none of which occurred in the hand, all were misdiagnosed as benign entities on radiological and histological assessment.

Fig. 30 Osteochondroma-like parosteal osteosarcoma. **a** The radiograph shows an ossifying mass overlying the metacarpals. **b** The CT shows it to be arising from the surface of the 3rd metacarpal but there is no trabecular continuity that would exclude the diagnosis of an osteochondroma

3.3 Ewing sarcoma

Ewing sarcoma (ES) of the hand has an incidence of between 0.3 and 1% of all ES of bone (Dahlin and Unni 1986; Kissane et al. 1983). Of 377 cases reported by the intergroup Ewing's sarcoma study, only two had lesions in the hand (Reinus et al. 1985). In Baraga's series of 43 cases of ES of the hand and feet, 11 involved the hands (Baraga et al. 2001). The demographics are similar to ES of bone at other sites with peak incidence in the second decade and males twice as commonly affected as females (Baraga et al. 2001). Typical clinical features are of pain and swelling and presentation may be acute or insidious. An antecedent history of trauma is uncommon (Dick et al. 1971; Dreyfuss et al. 1980).

ES of the hand is most likely to occur in the metacarpal bones (Lacey et al. 1987). In a literature review of ES of the phalanges, Yamaguchi et al. found that the proximal phalanx was most commonly involved (Yamaguchi et al. 1997). To the best of our knowledge, ES has never been reported in a carpal bone though it is known to occur in the tarsal bones of the feet. The tumour typically occurs in the meta-diaphyseal region of the short tubular bones of the hands and feet but may occupy the whole length of the bone (Baraga et al. 2001).

The classic radiographic findings of a permeative lytic lesion, with associated areas of sclerosis and a soft tissue mass, are almost as commonly seen in ES of the small bones of the hands and feet as at other locations (Fig. 31) (Reinus et al. 1985, Baraga et al. 2001). In the hand, it is less commonly a purely lytic lesion and more often demonstrates blastic or mixed change than at other sites (Baraga et al. 2001). Bone expansion is more commonly seen than elsewhere in the skeleton likely due to a smaller volume of bone (Reinus et al. 1985; Baraga et al. 2001). Reinus et al. originally reported a lower incidence of periosteal reaction in ES of the bones of the hands and feet than at other locations, but in Baraga et al. subsequent larger study, the rate was equal to ES at other sites (Reinus et al. 1985, Baraga et al. 2001). MRI can be used to accurately quantify the extent of the soft tissue mass both prior to and after chemotherapy (Ozaki et al. 1995). The main differential diagnosis for ES in the small bones of the hands is osteomyelitis, and misdiagnosis can lead to significant delay in treatment (Durbin et al. 1988).

A better prognosis than for ES arising at other sites has been reported (Daecke et al. 2005). This is thought to be due to less soft tissue in the extremities allowing for comparatively early presentation, diagnosis and excision with a wide margin (Yamaguchi et al. 1997). Smaller tumour volume and a lower incidence of metastasis at presentation are also thought to be important factors (Daecke et al. 2005). Akanwenze et al., in their series of 5 cases, have however reported a similar survival rate to ES at other sites (Anakwenze et al. 2009).

3.4 Metastasis

Metastasis to the hand is rare and accounts for approximately 0.1% of all metastatic bone lesions

Fig. 31 Ewing sarcoma. **a** Radiograph showing typical features of an onion skin and spiculated periosteal reaction along the 4th metacarpal. **b** Two contiguous coronal STIR MR

images showing extensive tumour infiltration of the metacarpal with soft tissue extension and multiple small skip metastases in the carpal bones and adjacent metacarpal

(Kerin 1983). In a series of approximately 75,000 patients diagnosed with a primary malignancy, 5 patients with metastasis to the bones of the hand and wrist were identified (Amadio and Lombadri 1987). Metastasis to the hand may rarely be the initial presentation of occult malignancy (Abrahams 1995). It is in this context in particular that acrometastasis can be misdiagnosed as other skeletal pathologies such as infection or inflammatory arthritis both clinically and radiologically.

Any bone in the hand and wrist can be involved, though the most commonly reported site is the terminal phalanx (Healey et al. 1986; Libson et al. 1987; Kerin 1983). This is probably because arterial flow is greatest in this area of the hand (Mulvey 1964). No one digit is preferentially involved (Wu and Guise 1978). The carpus is less commonly affected, being involved in only 10% of cases in two large studies of bone metastases to the hand and wrist (Healey et al. 1986; Kerin 1983; Libson et al. 1987). The majority of patients are in their fifth decade or older.

Of skeletal wrist and hand metastases, 40–50% are from primary bronchial carcinoma (Fig. 32) (Kerin 1983). This is thought to be due to the fact that primary tumours in the lung can shed cells directly into the systemic arterial circulation, whereas potential secondaries from other sites pass through the capillary bed of the lung or liver first. Wolff et al. (1966) reported

Fig. 32 Lytic metastases. Radiographs showing examples of bronchial metastases to the fingers in three different patients

metastases from the breast accounting for 25% of bone secondaries in the hand (cited by Amadio and Lombadri 1987). Renal cell carcinoma accounts for 10% of bone metastases to the hand and wrist (Ghert et al. 2001). Subdiaphragmatic tumours are generally more likely to metastasize to the feet, however in Kerin's review of the literature, metastatic hand lesions from the prostate, cervix and uterus were all noted (Kerin 1983). Sarcomatous metastases to the hand are much less frequent than metastases from carcinoma.

Clinically the patient may present with pain, swelling and loss of function. In the presence of widespread metastases at other locations, the

Fig. 33 Sclerotic metastasis. Radiograph showing a rare case in the 4th metacarpal from a primary mucinous adenocarcinoma of the colon

diagnosis may be straightforward. However in cases of occult malignancy, the lesion may clinically resemble osteomyelitis, septic arthritis or an acute monoarticular rheumatoid arthritis.

Metastases of the hand appear most frequently as nonspecific lytic, aggressive lesions (Fig. 32). The pattern of bone destruction varies but usually a thin rim of cortication is present around the lesion. The neoplasm may expand the cortical shell as it enlarges. Sclerotic forms have been described and are typical of metastatic osteosarcoma, but have also been seen with prostate and breast metastases (Fig. 33) (Abrahams 1995). Periosteal reaction is uncommon (Healey et al. 1986; Libson et al. 1987; Wu and Guise 1978; Chung 1983; Kerin 1958; Mulvey 1964). A soft tissue component is frequent (Libson et al. 1987). In juxta-articular lesions subchondral bone is usually spared and joint involvement is rare (Healey et al. 1986; Libson et al. 1987; Kerin 1958; Mulvey 1964).

The prognosis for patients with metastases to the hand and wrist is extremely poor with, in one series,

50% of patients dead within 6 months (Amadio and Lombardi 1987).

3.5 Lymphoma

Lymphoma involving bone usually occurs in the setting of widespread systemic disease. Non-hodgkins lymphoma however can arise primarily in bone. This is uncommon accounting for 3% of all extranodal lymphomas (Pinheiro et al. 2009). In a review of 82 cases of primary lymphoma of bone, Beal et al. found the femur to be the most common site of presentation, followed by the pelvis and tibia (Beal et al. 2006). In a Mayo clinic series of 422 cases of malignant lymphoma of bone, only 2 involved the small bones of the hand (Ostrowski et al. 1986). The authors do not state whether these were cases of primary lymphoma of bone or part of a multifocal disease. Only a few isolated case reports of primary lymphoma of bone occurring in the small bones of the hand have been published probably reflecting its rarity (Davies et al. 1994; Archer et al. 2009; Baskar et al. 2009; Chua et al. 2009; Pinheiro et al. 2009). Of these in only one case, a solitary lesion involving the first metacarpal, was disease confined to the hands (Davies et al. 1994).

Primary lymphoma most commonly presents in adults with a median age in the 5th or 6th decades with males more frequently affected than females (Shoji and Miller 1971; Boston et al. 1974; Davies et al. 1994). Clinical presentation in the hand typically involves pain and swelling, often at an affected joint, and may mimic a rheumatological disorder (Archer et al. 2009; Baskar et al. 2009). Constitutional 'B' symptoms are rare in primary bone lymphoma (Boston et al. 1974; Beal et al. 2006). Radiographs demonstrate a destructive lytic deposit with an associated soft tissue mass (Fig. 34). Despite the extensive destruction, pathological fractures are uncommon (6%) (Boston et al. 1974). MRI and CT may both demonstrate more extensive local disease than suggested on radiographs. A bone scan is required in all patients presenting with primary lymphoma of bone to assess for the presence of multifocal disease. Patients usually present with early stage disease and with modern curative modalities, the prognosis is excellent (Beal et al. 2006).

Fig. 34 Lymphoma. **a** Radiographs at presentation and **b** 4 months later. There is rapid progression of the permeative lytic lesion in the 5th metacarpal and on the latter film there is evidence of a further deposit in the 1st metacarpal

Fig. 35 Myeloma. There is a lytic lesion arising in the base of the 3rd metacarpal. The appearances are similar to both a metastasis and giant cell tumour

Fig. 36 Multiple myeloma. Multiple small cortical lucencies involving all the metacarpals

3.6 Multiple Myeloma

Multiple myeloma is the malignant proliferation of plasma cells involving more than 10% of bone marrow. Involvement of the extremities is rare and seen in less than 1% of all solitary bone plasmacytomas (Celik et al. 1996). Osteolytic lesions involving the small bones of the hand, either isolated or associated with multiple lytic lesions at other

sites, have rarely been reported in multiple myeloma and plasma cell leukaemia (Fig. 35) (Farman and Degnan 1976; Ozguroglu et al. 1999; Dastgir et al. 1994, Antonijevic et al. 1994 Celik et al. 1996; Wandroo et al. 2005; Capalbo and Mascolo 2007). Lesions arising in the phalanges are most commonly described, but Capalbo and Moscolo have reported a

case of multiple lesions involving the metacarpals and phalanges of both hands (Fig. 36). Antonijevic et al. have described multifocal lesions of both hands and feet presenting simultaneously (Antonijevic et al. 1994).

Typical radiographic features are that of an expansile lytic lesion with cortical erosion. Patients may present with a pathological fracture through a lytic lesion which could be initially mistaken for an enchondroma (Dastgir et al. 1994). Diagnosis is usually made by means of biopsy and routine haematological tests. A skeletal survey is mandatory once the diagnosis has been made to assess for synchronous lesions. Solitary bone plasmacytomas account for 5–7% of all bone plasmacytomas and generally have a good prognosis with a long duration of relapse free survival after local treatment. Celik et al. however have reported a case of solitary plasmacytoma of the 5th phalanx that had a short duration of remission and aggressive type of clinical relapse (Celik et al. 1996).

4 Conclusion

Bone tumours of the hand and wrist are infrequently encountered in general clinical practice. The clinical history, physical findings and radiographic features are sufficient to make the diagnosis in the majority of cases. A wide variety of tumour and tumour-like lesions however can present in the hand and wrist. Due to their rare occurrence at this site, they present diagnostic challenges for both the radiologist and the clinician. Knowledge of the imaging characteristics specific to each lesion can facilitate more appropriate and timely management. The imaging findings should always be considered in conjunction with the demographics, clinical presentation and distribution for each individual case.

The superficial location leads to earlier presentation, allowing expeditious diagnosis and treatment of malignant neoplasms. This often results in a better clinical outcome when compared to the same tumours at other skeletal sites. Though rare, it is important to remember the possibility of a malignant neoplasm when encountering an aggressive bone lesion in the hand or wrist. It is also important to consider benign lesions that radiographically appear aggressive and may be misdiagnosed as malignant tumours. Thorough evaluation of the clinical history, imaging

findings and any available histopathology should be made before arriving at a diagnosis in these cases.

5 Keypoints

- Though uncommon, a variety of tumour and tumour-like lesions may present in the bones of the hand and wrist
- The majority are benign
- Enchondroma is the commonest benign tumour
- Chondrosarcoma is the commonest malignant primary tumour
- A spectrum of benign proliferative disorders of the phalanges exists which may require close clinical and radiographic follow-up to avoid confusion with a malignant process
- Malignant tumours of the hand frequently have a better prognosis than at other skeletal sites due to earlier presentation
- The distribution of a lesion and demographic features of the patient should be considered in conjunction with the imaging findings when assessing bone lesions of the hand and wrist

Abstract

Masses of the hand and wrist are a common clinical problem. Soft-tissue tumors of the hand and wrist are far more frequent than bone tumors. If clinical examination is equivocal, imaging is often requested. This chapter aims to present an overview of the imaging characteristics of the most frequent tumor and tumor-like soft-tissue lesions of the hand and wrist.

1 Introduction

Masses of the hand and wrist are a common clinical problem. Soft-tissue tumors of the hand and wrist are far more frequent than bone tumors (de La Kethulle de Ryhove et al. 2000; Capelastegui et al. 1999). If clinical examination is equivocal, imaging is often requested. This chapter aims to present an overview of the imaging characteristics of the most frequent tumor and tumor-like soft-tissue lesions of the hand and wrist.

2 Benign Soft-Tissue Tumors

2.1 Synovial Cyst, Ganglion Cyst and Tendon Sheath Cyst

2.1.1 Definition and Nosological Classification

Cystic lesions are the most common mass lesions arising in the hand and wrist, accounting for 50–70% of all soft-tissue tumors of the hand and wrist (De Beuckeleer et al. 2001; Angeledes 1999). The terminology of cystic lesions is very confusing and depends on a combination of parameters such as topography, the presence or absence of joint communication, and the histologic composition.

The term *synovial cyst* describes a continuation or herniation of the synovial membrane through the joint capsule. In the French literature, the term “arthro-synovial” cyst is preferred, which refers to its intimate relationship with the adjacent joint. Indeed, there is always a communication with the adjacent joint, and the histologic composition is identical to those of the joint cavity. It consists of a collection of intraarticular fluid, lined by a continuous layer of “true” synovial cells. Usually associated joint diseases are present, like osteoarthritis, inflammatory, and posttraumatic joint diseases. Thirty percent of the lesions are associated with underlying interosseous ligament injury (Lowden et al. 2005). The elevated intraarticular pressure, due to an accumulation of joint fluid in these diseases causes herniation of joint fluid and synovium through a “locus minoris resistentiae” within the joint capsule.

Ganglia contain also mucinous fluid, but their wall consists of a (discontinuous) layer of flattened pseudosynovial cells, surrounded by connective tissue (pseudocapsule).

A communication with the adjacent joint is not always present.

There remains much controversy in the literature, concerning the pathogenesis of ganglion cysts. Several theories have been proposed, including displacement of synovial tissue during embryogenesis, proliferation of pluripotential mesenchymal cells, degeneration of connective tissues after trauma, and migration of synovial fluid into the cyst (synovial herniation theory).

Based upon the similar appearance on imaging, surgery and similar wall composition of synovial

cysts and ganglion cysts, we believe that the synovial herniation hypothesis is the most satisfactory. According to this theory, synovial cysts or ganglion cysts are formed by a herniation of synovium through a breach in the adjacent articulation.

Whereas a synovial cyst has a continuous synovial lining of true synovial cells, the wall composition of a ganglion cyst consists of a discontinuous layer of pseudosynovial cells.

A ganglion cyst may represent an advanced stage of a degenerated synovial cyst, in which the continuous synovial lining and the communication with the joint may be lost during the process of degeneration (Vanhoenacker et al. 2006b).

A *tendon sheath cyst* consists of a special subtype of a ganglion cyst located on the course of a tendon sheath.

2.1.2 Clinical Findings

Cystic lesions of the hand and wrist occur most frequently between 20 and 40 years of age, but may arise in the pediatric population and the elderly (Nahra and Bucchieri 2004; Wang and Hutchinson 2001). There is a female predominance (Nahra and Bucchieri 2004). Half of the patients are asymptomatic (Lowden et al. 2005), whereas the others may suffer from chronic wrist pain, tenderness or functional impairment (Peh et al. 1995).

The lesion may fluctuate in size, particularly during flexion of the wrist.

The majority of ganglion cysts are located at the dorsal aspect of the wrist adjacent to the scapholunate ligament (60–70%), whereas volar wrist cysts account for approximately 18–20%. Approximately two-thirds of anterior wrist ganglions arise from the radiocarpal joint and one third arise from the scaphotrapezium joint (Greenhyke et al. 1992). Volar cysts may cause median and ulnar nerve palsies (Kobayashi et al. 2001; Christiaanse et al. 2010). Some cysts may adhere directly to the tendon sheath (Nahra and Bucchieri 2004). Rarely, cysts arise from the dorsal aspect of the interphalangeal joints, often secondary to Heberden osteoarthritis in elderly patients (Nahra and Bucchieri 2004).

2.1.3 Imaging Findings

The role of imaging is to define the cystic nature of those lesions and to demonstrate a possible

communication with the joint. This is important for the surgeon, because the resection of the communicating stalk with the joint is essential to avoid post-surgical recurrence of the cyst.

2.1.4 Conventional Radiography

Standard radiography is non-specific and may reveal an ill-defined or rounded, non-calcified soft-tissue mass. Rarely gas, or calcified loose bodies may be seen within in a communicating cyst.

2.1.5 Ultrasound

On US, synovial cysts and ganglion cysts appear as anechoic masses (Fig. 1), and may have a visible communication with a joint (Fig. 1) or tendon sheath (Fig. 2a). The lesion may be multiseptated and may contain some fine internal septations. US is an accurate technique to define the cystic nature in superficial cysts around the wrist and the hand, but it has limited ability to visualize deeper lying structures and their relationship with the adjacent joint. Furthermore, cysts containing debris or hyperplastic synovium may simulate solid mass lesions on ultrasound examinations (Vanhoenacker et al. 2006b).

2.1.6 CT-Scan

Due to its low soft-tissue contrast, CT is of limited value in assessing soft-tissue lesions. Para-articular cysts are of lower attenuation than muscle and of higher attenuation than fat. Rim enhancement is seen after intravenous contrast administration (Steiner et al. 1996). A possible communication with the joint is sometimes difficult to define on axial images.

2.1.7 MRI

MR imaging demonstrates the exact location and extent of the cystic lesions, and its relationship to the joint and surrounding structures (Fig. 2b, c). The diagnosis of a cystic mass is usually straightforward by analysis of the signal intensities of the lesion. They are typically hypo- or iso-intense to muscle on T1-weighted images, and homogeneously hyperintense on T2-weighted images. However, there are some pitfalls. Atypical cyst content due to debris or hemorrhage may alter the imaging appearance of the cysts. Chronic inflammation may cause marked thickening of the synovial membrane and, therefore,

mimic a solid soft-tissue mass. Cystic lesions are well circumscribed, but may be lobulated, or multicystic with internal septa. Ruptured cysts, due to an elevated pressure, are irregularly delineated and must be differentiated from other soft-tissue tumors and hemorrhagic or inflammatory lesions.

After gadolinium contrast administration, subtle rim enhancement of the peripheral fibrovascular tissue in the cyst wall is seen, but there is never central enhancement like in other well-delineated soft-tissue lesions with high signal intensity on T2-weighted images, such as myxoma, myxoid liposarcoma, hemangioma, synovial sarcoma, and mucinosis.

2.2 Epidermoid Cyst

2.2.1 Definition and Histopathology

Epidermoid cyst, also known as epidermal inclusion cyst or infundibular cyst, results from the proliferation of surface epidermal cells within the dermis. The lesion is typically located within the subcutaneous tissue and is often secondary to trauma. It is more frequently seen in men than in women (Nahra and Bucchieri 2004).

Macroscopically, the lesion is filled with keratin (Ergun et al. 2010). The walls of the cyst resemble follicular epithelium (Murphy and Elder 1991). The cyst wall may rupture with secondary foreign body-type reaction, granulomatous reaction, granulation tissue or abscess formation (Murphy and Elder 1991; Jin et al. 2008).

2.2.2 Imaging

On plain radiographs, epidermal cyst may be located in the subcutaneous tissue or within the bone (most frequently at the terminal phalanges of the fingers). Lesions located within the dermis may cause well-defined osteolysis on the adjacent bone (Fig. 3a)

Ultrasound is more sensitive than clinical examination for the diagnosis of a epidermoid cyst (after palpation, 93.5%; after ultrasonography, 99.3%) (Kuwano et al. 2009). The lesion is usually well defined. Echogenicity varies with the content of the cyst. The lesions are usually hypoechoic, with posterior acoustic enhancement. Large lesions may show intralesional hyperechoic debris or keratin clusters (Fig. 4) (Gielen et al. 2006). Rupture of the cysts may

Fig. 1 Ganglion cyst. **a** Longitudinal ultrasound showing a well-defined anechoic structure at the palmar aspect of the carpus. **b** Longitudinal ultrasound shows a stalk-like connection with the adjacent radiocarpal joint

result in changes in shapes (either lobulations, protrusions or abscess pocket formations), pericystic changes, and increased vascularity on power Doppler ultrasound (Jin et al. 2008).

In the case of epidermoid inclusion cysts occurring in the fingertips, there may be bony involvement in which the cyst erodes into the bone causing a lytic lesion within the distal phalanx. Cortical destruction and osteolysis may mimic a malignant or infectious process (Nahra and Bucchieri 2004).

On CT and MRI, the lesion is well defined. MR features depend on the chemical composition of cholesterol and keratin content. Lesions with a high lipid content are hyperintense on both pulse sequences, whereas acrySTALLINE form of cholesterol and the presence of keratin and microcalcifications may result in a low signal on T2-weighted images. After administration of intravenous gadolinium contrast, there is lack of contrast enhancement in non-complicated epidermoid cysts (Fig. 3b–d) (Ergun et al. 2010).

2.3 Lipoma

2.3.1 Definition

Lipomas are well-encapsulated masses composed of mature adipose cells. They are the most frequently encountered benign lipomatous lesions of the hand (Peh et al. 1995; Ergun et al. 2010).

2.3.2 Clinical Findings

Lipomas are most frequently located under the skin (superficial lipoma) but can also be seen in muscles (often within thenar or hypothenar muscles), bones, and tendons (deep seated lipoma) (Peh et al. 1995; Ergun et al. 2010). The lesions are usually asymptomatic, but may occasionally compress adjacent nerves, vessels, or tendons (Peh et al. 1995). Most frequently, lipoma affects patients in the fifth to sixth decade (De Beuckeleer et al. 2001)

2.3.3 Imaging

Radiographs are usually normal, but a low to intermediate density may be seen in larger lesions (Murphey et al. 2004).

On ultrasound, superficial lipomas have an elongated shape and are usually parallel to the skin. Intramuscular lesions are often more difficult to distinguish from the surrounding muscle fibers. The reflectivity is highly variable ranging from hypo- to hyper-reflective compared to subcutaneous fat.

CT shows a homogeneous mass with low density (–60 to –130 HU). Intramuscular lesions may contain thin fibromuscular septa. There is no significant contrast enhancement.

On MRI, the lesion has similar signal characteristics as subcutaneous fat on all pulse sequences. Fat-suppression techniques show homogeneous suppression. Minor (<2 mm) internal septa and a low signal intensity capsule may be seen. After administration of intravenous gadolinium contrast, there is no contrast enhancement, except for the peripheral fibrous capsule or the subtle internal septa (Fig. 5) (Ergun et al. 2010).

2.4 Lipomatosis of Nerve

2.4.1 Definition

Lipomatosis of nerve has also been designated in the past as fibrolipomatous hamartoma, fibrofatty overgrowth, lipomatous hamartoma, lipofibroma, neurolipoma,

Fig. 2 Cyst of the tendon sheath. **a** Longitudinal ultrasound showing a well-delineated sonoluculent structure along the course of the flexor tendon of right fourth finger. **b** Sagittal SE T1-weighted image. **c** Axial TSE T2-weighted image in another

patient with a tendon sheath cyst of the flexor tendon. The lesion is isointense to muscle on T1-weighted images (**b**) and hyperintense on T2-weighted images (**c**)

Fig. 3 Subcutaneous epidermoid cyst with involvement of the adjacent bone of the terminal phalanx of the right fifth finger. **a** Plain radiograph showing a well-defined osteolytic defect at the radial side of the distal phalanx. Note cortical destruction of the radial cortex. **b** Coronal SE T1-weighted image. The lesion is of intermediate signal intensity with some internal areas of

relatively high signal. **c** Coronal TSE T2-weighted image. High signal intensity of the lesion. **d** Coronal SE T1-weighted image after intravenous injection of gadolinium contrast. There is only subtle peripheral enhancement of the lesion (Case courtesy of C. Kenis, Antwerp)

intraneural lipoma and fatty infiltration of the nerve and neural fibrolipoma. In 2002, the WHO adopted the designation of lipomatosis of nerve (Christopher et al. 2002). It is a very rare tumor, characterized by a proliferation of fatty and fibrous components that surrounds the thickened nerve bundles and infiltrates both the epineurium and the perineurium. Its cause is unknown, but some consider this condition as a congenital lesion, since it is occasionally present at birth whereas others believe to exist a relationship with a history of a prior trauma.

2.4.2 Clinical Findings

This tumor affects predominantly children or young adults. Males are affected more frequently than females

Lipomatosis of nerve occurs chiefly in the volar aspects of the hands, wrist, and forearm and usually

involves the median nerve. A soft-tissue mass is frequently present several years before onset of symptoms. Lipomatosis of nerve usually gives rise to pain, paresthesia, or decreased sensation or muscle strength, in the area innervated by the affected nerves. It may be associated with bone overgrowth and macrodactyly of the fingers, a condition described as macrodystrophia lipomatosa (Fig. 6) (Vanhoenacker et al. 2005; Vanhoenacker et al. 2006a).

2.4.3 Imaging

On plain radiographs, lipomatosis of nerve may manifest by a soft-tissue mass or only be suspected by indirect signs such as the presence of macrodactyly, usually affecting the second and third digits of the hand. There is a soft-tissue and osseous

Fig. 4 Subcutaneous epidermoid cyst. **a** Clinical picture showing a small soft-tissue lesion with bluish skin discoloration at the third finger. **b** Longitudinal ultrasound showing a well-defined subcutaneous lesion with variable echogenicity (anechoic components and some internal hyperechoic debris)

hypertrophy including long, broad and splayed phalanges (Fig. 6).

CT and MRI can identify the nervous origin of the tumor due to the presence of tortuous tubular structures, corresponding to enlarged nerve bundles within a predominantly fatty mass (Fig. 7). These structures, clearly depicted on MRI, show low signal intensity on both T1- and T2-weighted images according to their fibrous content. The tumor has the tendency to spread along the branches of the nerve, with a significant variation in the distribution of fat along the nerves and their innervated muscle. The contrast between the low-signal nerve fascicles and surrounding high-signal fat results in a “cable-like” appearance of the tumor, when visualized on axial planes on T1-weighted MR images (Fig. 7) and a “spaghetti-like” appearance on coronal planes. The MR imaging findings of lipomatosis of nerve are very

characteristic, obviating the need for biopsy (Marom and Helms 1999). Lipomatosis of nerve must be differentiated from a nerve sheath lipoma associated with altered sensibility along the course of some nerves. MRI allows differentiation between these two entities, since lipoma manifests as a focal mass separated from the nerve bundles.

2.5 Giant Cell Tumor of Tendon Sheath (GCTTS)

2.5.1 Definition

GCTTS are benign proliferative lesions of synovial origin and represent a localized extra-articular form of pigmented villonodular synovitis (Nguyon et al. 2004; Peh et al. 1995). In the hand and the wrist, this is the second most common soft-tissue lesion after a ganglion cyst. The pathogenesis remains unclear but is probably due to a reactive inflammatory process. GCTTS may arise from the tendon sheath, joint capsule, bursae, fascia or ligaments (Nguyon et al. 2004; Peh et al. 1995). Histologically, they are composed of histiocytes, macrophages, multinucleated giant cells and hemosiderin due to repeated hemorrhage (Nguyon et al. 2004; Peh et al. 1995; Wan et al. 2010).

2.5.2 Clinical Findings

The lesions are more common in the fingers than in the wrist and palm. The most affected site is the volar aspect of the first three digits (Ushijima et al. 1986). They are usually well-circumscribed firm masses that grow slowly and are typically painless. If located near a joint, they may cause decreased joint motion (Capelastegui et al. 1999).

2.5.3 Imaging

Standard radiography may be normal or display a well-circumscribed soft-tissue mass in about half of the patients. Pressure erosions at the underlying bone is present in about 20% of patients, while periosteal reaction, calcifications, or cystic changes are extremely unusual (De Beuckeleer and Vanhoenacker 2006; Wan et al. 2010; De Schepper et al. 2007).

Ultrasound shows a hypoechoic, solid mass with well-defined margins usually located near tendons

Fig. 5 Deep-seated lipoma of the hand in a 43-year-old woman. **a** Axial SE T1-weighted image. Note the presence of a dumbbell shaped mass at the flexor compartment of the hand. The lesion is well defined and isointense to subcutaneous fat.

b Sagittal fatsuppressed TSE T2-weighted image. There is homogeneous fat suppression of the lesion. **c** Axial fatsuppressed SE T1-weighted image after intravenous injection of gadolinium contrast. There is absence of enhancement of the lesion

Fig. 6 Macrodystrophia lipomatosa. Posteroanterior radiograph of the right hand. Note osseous and soft-tissue enlargement, affecting the second finger. (From Vanhoenacker et al. 2006a, with permission)

(Fig. 8). Bone erosions due to pressure of the tumor on the cortex may be demonstrated as well. The tendon usually exhibits normal shape and echogenicity. Contrary to ganglia, the giant cell tumor lacks posterior

acoustic enhancement, presents always with internal echoes, and shows hypervascularity on color or power Doppler imaging (Wan et al. 2010).

MR images typically show a well-defined mass adjacent to or enveloping a tendon, with a signal intensity similar to or less than that of skeletal muscle on T1-weighted images. On T2-weighted images, the signal intensity is predominantly low, with a variable degree of heterogeneity. Blooming artifact is seen on gradient-echo sequences due to the presence of hemosiderin (Wan et al. 2010). GCTTS usually enhance after gadolinium contrast administration (Fig. 9).

Fibroma of the tendon sheath may have a similar presentation as GCTTS on MR imaging (Sect. 2.10), but it lacks giant cells (Nguyen et al. 2004)

2.6 Pigmented Villonodular Synovitis

2.6.1 Definition

The articular counterpart of giant cell tumors of the tendon sheath is also known as pigmented villonodular synovitis (PVNS).

PVNS is a rare monoarticular arthropathy that usually occurs between the ages of 20 and 50, with a peak incidence between the third and the fourth decades of life. There is no sex predilection.

It usually involves the knee (80%) or the hip, while the ankle, elbow, shoulder, and wrist are less frequent locations.

Fig. 7 Lipomatosis of nerve of the median nerve at the level of the carpal tunnel in a 40-year-old man. **a** Axial SE T1-weighted MR image. **b** Axial gradient echo T2*-weighted MR image. **c** Sagittal SE T1-weighted MR image and corresponding preoperative view (**d**) of the median nerve. A heterogeneous mass is seen within the carpal tunnel. There is

a mixed SI of fatty components, fibrous components and neural fascicles (**a, b, c**, cable-like appearance). The signal intensity and localization are highly characteristic of lipomatosis of the median nerve. Note fusiform thickening of the median nerve (**d**). (From Vanhoenacker et al. 2006a, with permission)

Fig. 8 Giant cell tumor of the tendon sheath. Longitudinal ultrasound showing a well-defined hypoechoic mass adjacent to the flexor tendon. There is increased Doppler signal at the periphery of the lesion

2.6.2 Clinical Findings

The clinical picture is characterized by the insidious onset of monoarticular swelling in young adults, stiffness, and progressive pain. Symptoms tend to be continuous, but exacerbations occur from time to time. Aspirated synovial fluid is typically xanthochromic or serosanguineous.

Microscopically, the lesions are composed of solid or finger-like masses of hyperplastic synovium with multinucleated giant cells, xanthoma cells, and intra- and extracellular hemosiderin, lying in a fibrous stroma. Long-standing lesions show fibrosis and hyalinization.

When the villi become matted together, clefts lined by synovial cells are seen and may give an appearance alarmingly similar to synovial sarcoma.

2.6.3 Imaging Findings

Conventional radiographs may be normal, or show a non-specific periarticular soft-tissue mass and associated joint effusion. Visible calcifications are extremely unusual. The presence of calcifications should suggest an alternative diagnosis such as synovial osteochondromatosis. Despite the absence of calcification in PVNS, high iron content may be present within the synovium, producing a higher radiodensity than adjacent joint effusion or soft tissue. Associated bone erosions (Fig. 10a) with sclerotic margins may be present on both sides of the affected joints, particularly in joints with a tight capsule, such as the wrist. These erosive changes are probably due to a pressure phenomenon resulting from entrapment of soft-tissue masses between articulating surfaces. These lesions are usually present in non-marginal locations and may be multiple. If solitary, they may mimic primary osteolytic bone neoplasms. The preservation of the articular space until late in the disease and the absence of peri-articular osteopenia are helpful in the differential diagnosis from an inflammatory synovitis.

Ultrasonography shows a heterogeneous mass lesion. Sometimes related enlarged or disconnected synovial cysts or bursae with internal septa are noted.

CT is able to sharply define lytic bone lesions associated with pigmented villonodular synovitis. Also associated intraosseous soft-tissue masses extending with a narrow pedicle to the synovium are easily visualized. Joint effusion is atypical, and the tumoral mass itself is also not as characteristic as on MR imaging. Sometimes a high attenuation tissue is

Fig. 9 Giant cell tumor of the tendon sheath. **a** Axial SE T1-weighted image. A hypointense structure is surrounding the flexor tendons of the thumb. **b** Axial TSE T2-weighted image. The lesion is of low signal intensity. **c** Axial SE T1-weighted image after intravenous injection of gadolinium contrast

(subtraction image). There is marked inhomogeneous enhancement of the lesion. **d** Sagittal SE T1-weighted image in another patient with a giant cell tumor of tendon sheath. A hypointense structure is surrounding the flexor tendon, which is a typical location for a GCTTS

identified within the joint, due to the presence of hemosiderin. The differential diagnosis consists of iron deposition in the joint due to hemophilia or chronic bleeding and calcification. Enhancement after intravenous contrast administration appears to be the rule.

The MR appearance of pigmented villonodular synovitis as a rule is quite characteristic, due to the presence of hemosiderin within the synovial masses. A heterogeneous, hyperplastic synovial process with significant areas of low signal intensity on all

Fig. 10 Pigmented villonodular synovitis. **a** Plain radiograph of the left wrist. There are multiple erosions at the distal aspect of the scaphoid bone and at the proximal aspect of the triquetral bone. **b** Coronal SE T1-weighted image. The lesion is located

intra-articularly within the wrist joint and is of low signal intensity (isointense to muscle). Note also erosions at the carpal bones. **c** Coronal gradient T2* image showing blooming artifact of the lesion

sequences, particularly T2-weighted images, is typical. The presence of hemosiderin causes local changes in susceptibility and therefore loss of MR signal. This is especially true for gradient-echo sequences and at high field strengths. This decreased signal intensity is most prominent in the periphery of the lesions (the so-called “blooming” artifact) (Fig. 10b, c). Occasionally, intralesional areas of high signal intensity on both pulse sequences may be present, due to fat, edema, or inflammation. Joint effusion appears as hyperintense areas entrapped between the low signal intensity areas on T2-weighted images.

After gadolinium contrast administration, homogeneous or septal enhancement may be observed. The differential diagnosis on MR imaging includes other causes of chronic hemarthrosis such as chronic trauma, hemophilia, synovial hemangioma and “burnt out” rheumatoid pannus and amyloid arthropathy. These disorders can be separated on the basis of clinical history, laboratory findings, and enhancement pattern. In hemophilia, there are usually diffuse changes in cartilage and bone, including cartilaginous and subchondral erosions, as well as joint space narrowing. Synovial chondromatosis could potentially simulate pigmented villonodular synovitis on MR, and in general this is true for all low signal intensity masses with calcified or

ossified components. This should be no problem, since these areas are well recognized on plain films and CT. Tophaceous gout may also mimic PVNS, if there is a high concentration of calcium within the tophus. Finally, desmoid tumors, benign fibrous histiocytoma and sclerosing hemangioma could be mistaken for pigmented villonodular synovitis due to their low signal on MR imaging, which is due to their dense fibrous content. The lack of intraarticular changes should alert one to consider another diagnosis besides pigmented villonodular synovitis.

MR imaging is the imaging technique of choice to evaluate the possible extra-articular extension and areas of the joint, which are difficult to see arthroscopically.

2.7 Vascular Tumors and Lymphatic Tumors

2.7.1 Definition

Benign vascular tumors are common benign soft-tissue masses, which can be classified into localized hemangioma and diffuse angiomas. Klippel-Trénaunay syndrome is a separate entity in which hemangiomas are accompanied by unilateral hypertrophy of the

Fig. 11 Maffucci's syndrome. Plain radiograph of the left hand. Note multiple enchondromas and soft-tissue haemangiomas with intralesional phleboliths

extremity. Maffucci's syndrome consists of the combination of hemangiomas and enchondromatosis (Fig. 11). Semimalignant vascular tumors include hemangioendotheliomas (Nguyon et al. 2004; Peh et al. 1995; Ergun et al. 2010). Hemangiomas represent a broad spectrum of vascular tumors which may be classified by vessel size into capillary, cavernous, venous or arteriovenous malformations (Ergun et al. 2010). Apart from vessels, the lesions contain variable amounts of non-vascular elements including thrombus, fat, fibrous tissue, bone and muscular tissue (Nguyon et al. 2004; Schmitt 2008; Ergun et al. 2010).

Lymphangiomas of the hand are rare.

2.7.2 Clinical Findings

Most hemangiomas are asymptomatic, but they may present at an early age secondary to cosmetic deformity or pain. Women are more affected than men, and the incidence peaks in early adulthood. A familial disposition may occur (Schmitt 2008). The hand is

frequently affected. The cutaneous and subcutaneous compartments are often involved, and there is frequently an overlying skin discoloration (Fig. 12a). Less often, the lesion is found in tendon sheaths (Fig. 12), muscles or the median nerve (Nguyon et al. 2004; Schmitt 2008).

Capillary hemangiomas are most frequent and are usually located in the skin and subcutaneous tissue. Clinically, they are characterized as port-wine spot lesions. Because of the superficial location, the diagnosis is often made clinically and imaging is rarely required.

Venous hemangiomas typically involve the deep structures (Ergun et al. 2010).

2.7.3 Imaging

Radiographs often provide little information (Fig. 12b). Phleboliths are sometimes seen (Fig. 11). Linear or arciform calcifications are less common (Nguyon et al. 2004; Schmitt 2008). Adjacent osseous remodeling can occur (Fig. 13a), including erosion, overgrowth, periosteal reaction, and osteoporosis (Nguyon et al. 2004).

On ultrasound, hemangiomas have a variable appearance, presenting as circumscribed or diffuse, homogeneous or inhomogeneous lesions. Doppler reveals blood flow within the lesion (Fig. 12c) (Nguyon et al. 2004).

On MRI, arteriovenous malformation often appears as an enlarged vascular channel without a discrete soft-tissue mass (Ergun et al. 2010).

Cavernous hemangiomas are well-circumscribed lobulated masses which are usually isointense to muscle on T1-weighted images, with variable areas of interspersed fat (Fig. 13b). On T2-weighted sequences, the lesion is heterogeneously hyperintense (Fig. 13c), as a result of the mixed amounts of fat and pooled blood in larger vessels. Thrombotic vessel segments have different signal intensities depending on the age of thrombosis (Fig. 12). Fast blood flow generally causes a flow void with a dark lumen, whereas a slow or stagnant flow in dilated or tortuous vessels can cause increased signal ("paradoxical enhancement"). Linear or serpiginous flow voids with round filling defects may be demonstrated on both pulse sequences, indicating the presence of high-flow vessels and phleboliths (Fig. 14). Smaller cavernous hemangiomas are more likely to have an atypical appearance (Nguyon et al. 2004).

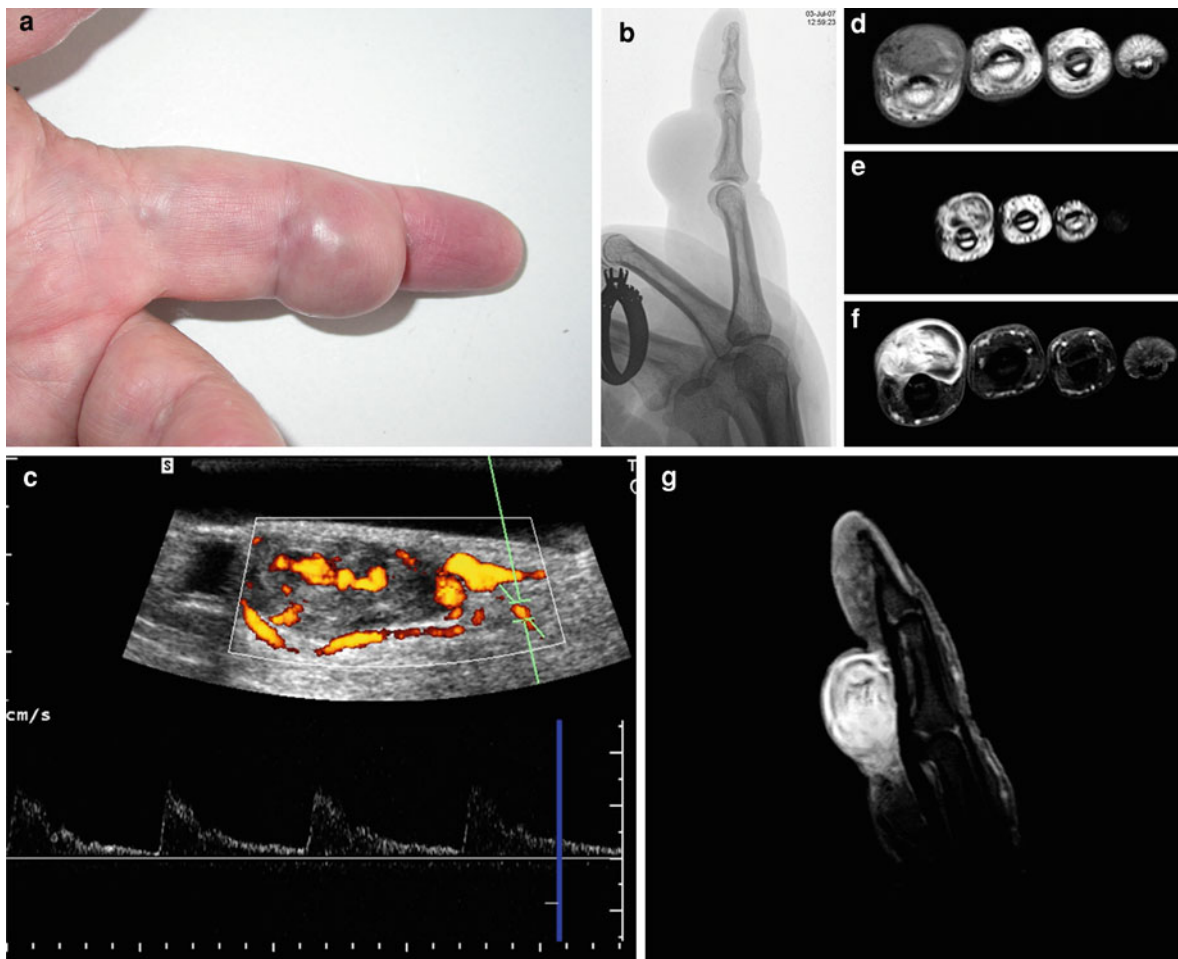

Fig. 12 Partially thrombosed arteriovenous malformation adjacent to the flexor tendon. **a** Clinical image showing a soft-tissue mass at the palmar aspect of the index. There is bluish discoloration of the overlying skin. **b** Plain radiograph (lateral view) demonstrates a non-specific soft-tissue mass at the palmar aspect of the index. **c** Longitudinal ultrasound showing an oval shaped hypo-echoic structure with increased intralésional power Doppler signal and an arterial feeder at the proximal side of the lesion. **d** Axial

T1-weighted images shows that the lesion is of heterogeneous signal intensity. Areas of high signal intensity may correspond to thrombosis. **e** Axial TSE T2-weighted image. The lesion is heterogeneous with areas of high and low signal intensity. **f**, **g** Axial and sagittal fatsuppressed T1-weighted images after intravenous injection of gadolinium contrast. There is heterogeneous enhancement of the lesion. Areas of non-enhancement may correspond to thrombosis of vascular structures

After intravenous injection of gadolinium contrast, occasionally the arterial feeders and draining veins may be seen both on CT- (Fig. 15) and MR Angiography. Delayed imaging after a few minutes allows evaluation of the precise extent of the tumor (Schmitt 2008) (Fig. 13d, e).

On CT, lymphangiomas usually have a negative density due to high lipid content of the lymphatic fluid.

On T1-weighted MR images, the lesion is of intermediate signal intensity, whereas it is typically hyperintense on T2-weighted images.

2.8 Benign Neurogenic Tumors

2.8.1 Definition

The most frequent subtypes of neurogenic tumors in the hand and wrist are neurinomas (schwannomas) and neurofibromas.

Schwannomas originate from the Schwann cells surrounding the peripheral nerves. The lesions are eccentric to the nerve of origin and are surrounded by a capsule of connective tissue. A schwannoma originates usually from the deeper and broader

Fig. 13 Haemangioma of the thenar muscle. **a** Plain radiograph of the left hand. There is a non-specific soft-tissue mass (*asterisks*), containing some streaks of fat and causing pressure erosion of the ulnar side of the first metacarpal and proximal phalanx of the thumb (*arrows*). **b** Coronal SE T1-weighted image shows a well-defined lobulated mass in the thenar muscle (*arrows*) with areas of interspersed fat. **c** Coronal fatsuppressed T2-weighted image. The lesion is located within the thenar muscle and has a heterogeneous

high signal intensity. There is also osseous remodeling of the ulnar side of the cortex of metacarpal 1. Note some streaks of high signal within the medullary bone of metacarpal 1, due to intra-osseous extension in the metacarpal bone. **d, e** Coronal SE fatsuppressed T1-weighted images after intravenous injection of gadolinium contrast. There is marked serpiginous enhancement of the intramuscular and intraosseous component of the lesion (metacarpal 1 and proximal phalanx of the thumb)

nerves of the hand and wrist and is primarily located at the palmar side (Schmitt 2008; Ergun et al. 2010).

Neurofibromas cause diffuse thickening of the nerve sheath. The nerve fascicles run through the concentric tumor. The lesion involves the smaller cutaneous nerves and has no capsule. Neurofibromas occur as solitary lesions or in conjunction with von Recklinghausen disease (Neurofibromatosis type I). Multiple schwannomas as part of schwannomatosis is much more rare.

2.8.2 Clinical Findings

Patients present with a palpable mass (Fig. 16a) and rarely complain of pain. Pain may be elicited by percussion of the mass (Hoffmann-Tinel sign).

2.8.3 Imaging Findings

Plain radiographs are usually normal, but parosseous neurogenic tumors can cause scalloping of the adjacent bone.

On ultrasound, neurinomas are located eccentric to the surrounding nerve, whereas neurofibromas are

Fig. 14 Haemangioma of the finger. **a** Axial SE T1-weighted image and **b** coronal SE T1-weighted image shows a well-defined lobulated at the flexor side of the third finger. **c** Coronal fatsuppressed T2-weighted image. The lesion is predominantly of high signal intensity. Note also some intralesional round areas of low signal intensity (phleboliths)

concentric in relation to the affected nerve. The Hoffman-Tinel sign can be provoked by sonographic palpation of the affected nerve.

On MRI, benign nerve sheath tumors are well-demarcated masses. The lesions are isointense or slightly hyperintense to muscle on T1-weighted images and heterogeneously hyperintense on T2-weighted images. A target sign consisting of a central low signal and a hyperintense periphery is highly suggestive for a neurogenic tumor (Fig. 16). Other morphological signs of neurogenic tumors are the split fat sign (displaced fat around the mass on the neurovascular bundle), the fascicular sign (nerve fascicles on the course of the tumor), and the presence of a fusiform mass on the course of the involved nerve (Schmitt 2008; Ergun et al. 2010).

2.9 Glomus Tumor

2.9.1 Definition

The glomus tumor is a neoplasm consisting of cells which closely resemble smooth muscle cells of the normal glomus body. The glomus body is an arteriovenous anastomosis that has an important role in thermoregulation. It is located in the subungual region, digits, and palms. The lesion shows both muscle fibers and epithelial-appearing glomus cells (Enzinger and Weiss 1995).

2.9.2 Clinical Findings

Glomus tumors are uncommon, with an equal frequency of occurrence in both sexes. The most common location is the subungual tissue at the tip of the finger. For this location however, there is a striking female predominance. Glomus tumors are also seen at the palm, wrist, forearm, and foot. Multiple lesions may be present, especially during childhood. Glomus tumors cause a radiating pain which is elicited by a change in temperature. Clinical examination usually reveals a characteristic blue-red nodule. Therapy aims at complete excision, still leaving a recurrence rate of 10% (Enzinger and Weiss 1995).

2.9.3 Imaging

Plain films may show a small mass at the dorsal aspect of the finger, associated with a small erosion of the adjacent bone. However, this sign is non-specific and is only found in 12–60% of glomus tumors (Drape et al. 2009) Ultrasound may detect

Fig. 15 Arteriovenous malformation of the thumb. **a** Clinical image showing a soft-tissue mass at the palmar aspect of the thumb. **b** Axial contrast-enhanced CT showing an intramus-

cular mass within the thenar with heterogeneous contrast enhancement. **c–d** CT-angiography (MIP and VRT image) showing the feeding arteries and draining veins

lesions as small as 2 mm (Drape et al. 2009; Matsunga et al. 2007). Ultrasound is more sensitive than plain films to detect cortical erosions at the dorsal aspect of the distal phalanx in up to 78% of cases (Drape et al. 2009). Ultrasound is able to detect 92% of glomus tumors (Drape et al. 2009; Marchadier et al. 2006). The lesion is usually rounded and the

echogenicity may be variable (usually hypoechoic to the subungual region). Most glomus tumors are hypervascular on power Doppler (Fig. 17a, b), but 21% of the lesions may be hypovascular (Drape et al. 2009).

On MRI, glomus tumors are of low to intermediate signal intensity on T1-weighted images and of

Fig. 16 Schwannoma of the median nerve. **a** Clinical image showing a soft-tissue mass at the palmar aspect of the wrist. **b** Plain radiograph. Non-specific soft-tissue mass at the palmar aspect of the wrist (*arrows*). **c** Axial SE T1-weighted image.

Well-defined hypointense mass on the course of the median nerve (*arrow*). **d** Axial fatsuppressed TSE T2-weighted image. Target-like appearance consisting of a hyperintense periphery and central areas of relatively hypointense signal

high signal intensity on T2-weighted images. After intravenous administration of gadolinium contrast, moderate to strong enhancement is seen (Fig. 17c–f). MR angiography is a very useful technique to demonstrate the hypervascular nature of the lesion and an entangled arteriovenous anastomosis. Delayed imaging is sometimes required to demonstrate the hypervascular nature of some lesions (late interstitial diffusion of a minority of lesions) (Drape et al. 2009).

2.10 Fibroma of the Tendon Sheath

2.10.1 Definition

A fibroma of the tendon sheath is a circumscribed tumor, rarely larger than 2 cm in diameter, attached to the tendon sheath of the digits. The thumb is the most commonly involved digit (Nguyen et al. 2004; Plate et al. 2003). Histologically, the lesion is composed of scatters benign fibroblasts with dense collagen, but lack giants cells and xanthoma cells, in

Fig. 17 Subungual glomus tumor. **a** Transverse ultrasound. Note a small hypoechoic subungual lesion causing cortical erosion of the dorsal aspect of the distal phalanx (*arrow*). **b** Longitudinal ultrasound showing increased intralesional power Doppler signal. **c** Sagittal SE T1-weighted image. There is a well-defined subungual hypointense lesion (*arrow*),

causing cortical erosion of the distal phalanx. **d** Sagittal fatsuppressed TSE T2-weighted image. Hyperintense signal of the lesion (*arrow*). **e, f** Sagittal and axial SE fatsuppressed T1-weighted images after intravenous injection of gadolinium contrast. Marked enhancement of the tumor (*arrow*)

contradistinction to GCTTS (Nguyen et al. 2004; Peh et al. 1995; Wan et al. 2010).

2.10.2 Clinical Findings

They are less common than GCTTS and they often present as slow-growing, firm, and non-tender masses. The mean age of presentation is 42 years (Nguyen et al. 2004). Lesions are typically located on the flexor surfaces, occurring most often in men (75%) (Fox et al. 2003).

2.10.3 Imaging Findings

Pressure erosion of the underlying bone on plain films is very rare. Ultrasound shows a non-specific

hypoechoic mass adjacent to the tendon sheath (Fig. 18a). The lesion is usually hypointense on MR sequences, and no or minimal enhancement is seen.

Increased capillary vascularity near the lesion surface may cause minor peripheral enhancement (Figs. 18, 19). The MR imaging findings vary when areas of increased cellularity or myxoid change occur within the lesion. Myxoid changes within the lesion may cause an intermediate to high signal intensity on T2-weighted images, whereas areas of increased cellularity may enhance (Ergun et al. 2010; Fox et al. 2003). In these instances, differentiation of fibroma of the tendon sheath from other tumors, such as giant cell tumor of the tendon sheath, is problematic (Fig. 18d).

Fig. 18 Fibroma of the tendon sheath of the left fifth finger. **a** Longitudinal ultrasound. Polylobular hypoechoic lesion adjacent to the flexor tendons. Note some increased power Doppler signal at the proximal part of the lesion. **b** Axial SE T1-weighted image. The lesion is isointense to muscle (*arrow*). **c** Axial TSE T2-weighted image. The lesion remains of low

signal intensity. **d** Axial SE fatsuppressed T1-weighted images after intravenous injection of gadolinium contrast. There is moderate enhancement of the lesion (*arrow*). In case of contrast enhancement, differentiation of a tendon sheath fibroma from a GCTTS may be difficult

2.11 Palmar Fibromatosis (Dupuytren Disease)

2.11.1 Definition

Palmar fibromatosis was originally described in 1831 by the French physician Dupuytren and is often referred to as Dupuytren disease or contracture. It is the most common of the superficial fibromatoses, affecting 1–2% of the general population. The disease is seen almost exclusively in Caucasians and is rare in populations of African or Asian descent.

The etiology of palmar fibromatosis is not completely understood, but it is thought to be multifactorial, including associations with trauma, microvascular injury, immunologic processes, and genetic factors (Murphey et al. 2009).

2.11.2 Clinical Features

The disease most commonly occurs in patients over 65 years of age, with a frequency of 20% in this

age group. Men are three to four times more likely to be affected by the disease than women, and lesions are bilateral in 40–60% of patients. Patients present clinically with painless, subcutaneous nodules (Murphey et al. 2009). These nodules may progress slowly to fibrous cords or bands that attach to and cause traction on the underlying flexor tendons, resulting in flexion contractures of the digits. The fourth and fifth digits are most commonly involved. Patients commonly have related diseases such as plantar fibromatosis (5–20%), Peyronie disease, and knuckle pad fibromatosis. Other associated diseases include diabetes mellitus (20% of patients), epilepsy (50% of male patients and 25% of female patients), alcoholism (particularly liver disease related to alcoholism), and keloid (Murphey et al. 2009).

2.11.3 Imaging Findings

Plain radiographs are typically normal, other than the flexion contractures.

Fig. 19 Typical MR characteristics of a fibroma of the index. **a** Axial SE T1-weighted image. The lesion hypointense to muscle (arrows). **b** Coronal fatsuppressed TSE T2-weighted

image. The lesion remains of low signal intensity (arrow). **c** Coronal gradient echo T2*-weighted image. There is absence of blooming artifact (arrow)

Fig. 20 Palmar fibromatosis. **a** Transverse ultrasound. **b** Longitudinal ultrasound. Hypoechoic nodule adjacent to the flexor tendon of the palm of the hand (third ray)

Ultrasound reveals hypervascular, hypoechoic nodules (Fig. 20) in the palmar subcutaneous tissues, superficial to the flexor tendons.

CT shows non-specific, nodular soft-tissue thickening.

At MR imaging, there are multiple nodular or cordlike, superficial soft-tissue masses that arise from

the proximal palmar aponeurosis and extend superficially in parallel with the flexor tendons. Lesion length varies from 10 to 55 mm (2–10 mm in diameter), and lesions terminate in either a branching or nodular configuration at the level of the distal metacarpal.

The signal intensity of palmar fibromatosis is variable along with the cellularity and the collagen content of the lesion. Lesions of low signal intensity on all pulse sequences are relatively hypocellular and contain abundant dense collagen. In contradistinction, the lesions of intermediate signal intensity on both T1- and T2-weighted images are more cellular or mixed, with less abundant collagen (Murphey et al. 2009; Yacoe et al. 1993). Lesions with a higher cellular component have been shown to have a higher local recurrence rate following local excision. This information is important because preoperative MR imaging may assist the surgeon in determining the appropriate timing for excision (Yacoe et al. 1993; Robbin et al. 2001). After intravenous administration of gadolinium contrast, hypercellular lesions are enhancing more vividly than hypocellular lesions (Murphey et al. 2009).

2.12 Desmoid Tumors (Desmoid Type Fibromatosis)

2.12.1 Definition

Extra-abdominal desmoids are rare benign soft-tissue tumors arising from connective tissue of muscle, overlying fascia, or aponeurosis. They have been

designated previously as desmoids tumor, aggressive fibromatosis, or musculoaponeurotic fibromatosis. The term “desmoid” means band-like or tendon-like lesion (De Schepper and Vandevenne 2006). Currently, the term desmoid type fibromatosis is used. The lesions can be regarded as deep seated fibromatosis in contradistinction to palmar fibromatosis which is a superficially located. Desmoid fibromas are infiltrative tumors, known for their frequent recurrences. Complete surgical excision is often difficult.

2.12.2 Clinical Features

The most commonly encountered locations are the upper arm (28%), chest wall and paraspinal area (17%), thigh (12%), neck (8%), knee (7%), pelvis or buttock (6%), lower leg (5%). The hand and forearm is rarely affected in up to 5% (Murphey et al. 2009; Berthe et al. 2003). Desmoids occur most frequently in patients in the second to fourth decades of life, with a peak incidence between the ages of 25 and 35 years (Murphey et al. 2009). The lesion is typically deeply seated and poorly circumscribed. Slow insidious growth is the rule, and most lesions are painless (Murphey et al. 2009).

2.12.3 Imaging Findings

Plain radiographs are often normal. A non-specific soft-tissue mass may be apparent in patients with larger lesions. Calcification is uncommon, although underlying pressure erosion or cortical scalloping may be seen.

The US appearance of desmoid-type fibromatosis has not been extensively described. Ultrasound may demonstrate a non-specific poorly defined, hypo-echoic soft-tissue mass. Large lesions may demonstrate posterior acoustic shadowing. Increased vascularity is seen on Doppler-ultrasound (Murphey et al. 2009).

On CT, the lesion has a variable attenuation and enhancement (up to 110 HU). The attenuation is usually similar to that of skeletal muscle, but lesions with more prominent collagen content may reveal mildly higher attenuation. Low attenuation is rare and

is associated with myxoid components. The margins are often indistinct (Murphey et al. 2009).

On MRI, the lesion may be well demarcated or ill defined. The signal intensity of desmoid-type fibromatosis is variable, dependent on the extent of collagen and degree of cellularity of the lesion. Low signal intensity areas on T2-weighted images correspond histologically to hypocellular and collagen-rich portions of the tumor, whereas more cellular areas with a large extracellular space are of high signal on T2-weighted images. In addition, high T2 signal may be seen in myxoid portions.

Postcontrast MR images typically reveal heterogeneous and often moderate to marked enhancement of these lesions. Hypocellular, collagenized bands do not enhance and therefore are often accentuated at postcontrast MR imaging (Fig. 21) (Murphey et al. 2009).

2.13 Synovial Chondromatosis

2.13.1 Definition

Primary synovial chondromatosis represents an uncommon benign neoplastic process with hyaline cartilage nodules in the subsynovial tissue of a joint, tendon sheath (Fig. 21), or bursa. The nodules may enlarge and detach from the synovium (Murphey et al. 2007). Synovial chondromatosis may be divided into primary and secondary forms. Secondary chondromatosis represents a non-tumoral condition associated with underlying degenerative, destructive or posttraumatic joint disease that causes intraarticular chondral bodies. On the contrary, primary synovial chondromatosis can be regarded as a true benign neoplastic disorder (Murphey et al. 2007; Buddingh et al. 2003).

2.13.2 Clinical Findings

Male adults are the most commonly involved patient population.

Primary chondromatosis involves usually large joints such as the knee and hip. The metacarpophalangeal, interphalangeal, and distal radioulnar joints

Fig. 21 Desmoid tumor. **a** Axial SE T1-weighted image. Ill-defined intramuscular lesion in the thenar muscle. The mass is of heterogeneous signal with isointense and hypointense areas compared to muscle. **b** Axial fatsuppressed TSE T2-weighted image. Heterogeneous signal intensity with areas of low and intermediate signal. The areas of low signal intensity on both pulse sequences correspond to areas of hypocellularity and collagenized areas. **c** Axial SE fatsuppressed T1-weighted images after intravenous injection of gadolinium contrast. Hypocellular, collagenized areas do not enhance

of the hand and wrist are less commonly involved (Murphey et al. 2007). Primary synovial chondromatosis can also involve extraarticular sites (Sect. 17.2.14). This subtype arises probably in synovium about the tendons or bursa and is frequently referred to as tenosynovial (Fig. 22) or bursal chondromatosis, respectively (Murphey et al. 2007).

2.13.3 Imaging

Radiologic findings are frequently pathognomonic. Radiographs reveal multiple intra-articular calcifications (70–95% of cases) of similar size and shape, distributed throughout the joint, with typical chondroid “ring-and-arc” pattern of mineralization. Extrinsic erosion of bone is seen in 20–50% of cases. The joint space is typically maintained, unless the disease is complicated by secondary osteoarthritis.

Ultrasound shows a heterogeneous mass containing foci of hyperechogenicity, representing either chondral fragments or fronds of synovium with underlying cartilage nodule formation. The nodules are usually multiple and have a lobular contour. If the lesion contains sufficient mineralization or enchondral ossification, posterior acoustic shadowing may be present (Murphey et al. 2007). Synovial chondromatosis is avascular on power Doppler (Roberts et al. 2004).

Computed tomography (CT) may depict calcified intra-articular fragments and more subtle extrinsic bone erosion.

Magnetic resonance (MR) imaging findings are more variable, depending on the degree of mineralization, although the most common pattern (77% of cases) reveals low to intermediate signal intensity with T1-weighting and very high signal intensity with T2-weighting with hypointense calcifications. These signal intensity characteristics on MR images and low attenuation of the non-mineralized regions on CT scans reflect the high water content of the cartilaginous lesions. CT and MR imaging depict the extent of the synovial disease (particularly surrounding soft-tissue involvement) and lobular growth. Following intravenous administration of contrast, peripheral or arc-like enhancement may be observed (Wittkop et al. 2002). With delayed imaging after intravenous

Fig. 22 Tenosynovial chondromatosis of the finger. **a** Plain radiograph. Chondroid-like calcifications adjacent to the flexor side of the proximal and middle phalanx (*white arrows*). There is scalloping of the adjacent cortical bone (*black arrows*).

b Sagittal TSE T2-weighted image. The lesions are of variable signal intensity corresponding to calcified and non-calcified chondroid areas. Note the intimate relationship with the flexor tendons and the presence of cortical erosions (*arrows*)

contrast administration, an indirect MR arthrographic effect may be obtained, showing multiple intraarticular nodules within the joint cavity (Brassens and Cotten 2010).

Secondary synovial chondromatosis can be distinguished from primary disease both radiologically (underlying articular disease and fewer chondral bodies of variable size and shape) and pathologically (concentric rings of growth) (Murphey et al. 2007).

2.14 Soft-Tissue Chondroma (Tenosynovial Chondromatosis)

2.14.1 Definition

Soft-tissue chondroma, also known as extraskeletal chondroma or chondroma of soft-tissue parts is a rare

soft-tissue tumor accounting for only 1.5% of benign soft-tissue tumors (Hondar Wu et al. 2006). The origin is not known but is assumed to be synovial, since the lesion is typically attached to the synovial capsule or tendon sheath (Ergun et al. 2010).

2.14.2 Clinical Features

Soft-tissue chondroma occurs at almost any age, but most commonly in 30–60-year-old patients. The tumor occurs most commonly in the hands and feet (Hondar Wu et al. 2006). Men are affected more often than women in the third decades of life. When the disease is diagnosed in older patients (after the fifth decade), there is a female predominance (Murphey et al. 2007). The patient presents most frequently with a painless mass or only mild tenderness upon palpation of the lesion. Duration of the symptoms ranges

Fig. 23 Typical example of a malignant soft-tissue tumor of the wrist (highly malignant sarcoma NOS). **a** Sagittal SE T1-weighted image. **b** Sagittal fatsuppressed TSE T2-weighted image. **c** Sagittal fatsuppressed SE T1-weighted images after intravenous injection of gadolinium contrast. The lesion is large, inhomogeneous on T2-weighted images and shows marked and inhomogeneous enhancement

between 5 and 18 years with a median of 2 years (Fetsch et al. 2003).

2.14.3 Imaging Features

Plain films demonstrate calcifications in 33–80% of soft-tissue chondromas. The pattern of calcifications is variable, including curvilinear, punctate, mixed and dystrophic or focal dense pattern (Fig. 22) (Hondar Wu et al. 2006).

On MRI, the signal intensity varies along with the degree of calcified matrix within the lesion (Fig. 22). Highly calcified lesions are of low signal intensity on both pulse sequences, whereas non-calcified lesions are of intermediate signal intensity on T1-weighted images and of high signal on T2-weighted images. The high signal is due to a high water content of the mucopolysaccharide component or myxoid changes (Hondar Wu et al. 2006). Following intravenous

Table 1 MR Imaging features that may suggest malignancy (modified from De Schepper and Bloem 2007)

Large volume (any lesion exceeding 3 cm in H/W)
Ill defined margins
Inhomogeneity on all pulse sequences
Intralesional hemorrhage
Intralesional necrosis
Extensive and peripheral enhancement pattern (with papillary projections) on static contrast examination
Rapid enhancement with steep slope on dynamic contrast examination
Extracompartmental extension
Invasion of adjacent bones and neurovascular bundles.

administration of contrast, septal or peripheral enhancement may be observed, corresponding to fibrovascular tissue surrounding the avascular nodules (Ergun et al. 2010).

Fig. 24 Myositis of the thenar in a 7-year-old boy, presenting with pain and swelling at the thumb.
a Plain radiograph. Note calcifications in the thenar (arrow). **b** Coronal SE T1-weighted image 9 month later shows an intramuscular ossified mass with central high signal intensity (fatty bone marrow) with peripheral and central areas of low signal (Courtesy of J. Vandevenne, Genk)

3 Malignant Soft-Tissue Tumors

Malignant soft-tissue tumors are much more rare than benign tumor and tumor-like conditions in the hand and wrist (de La Kethulle de Ryhove et al. 2000; Capelastegui et al. 1999).

Soft-tissue sarcomas of the hand may be found in young adults and clinical symptoms are usually non-specific, as most patients present with a painless mass without functional deficit.

Plain radiographs and CT are usually non-diagnostic. Amorphous (synovial sarcoma, extraskeletal osteosarcoma) or arc-like (extraskeletal chondrosarcoma) calcifications may be seen in certain malignant tumors. Destruction of the adjacent bone is very rare.

Most malignant soft-tissue tumors are hypoechoic on ultrasound and may show intralesional necrosis. The tumor extent cannot be reliably determined on ultrasound.

MRI is the imaging modality of choice for grading (differentiation between benign and malignant tumors and assessment of malignancy grade) and local staging of malignant soft-tissue tumors of the hand and wrist (H/W).

Important grading parameters which may suggest malignancy based on MR imaging (Fig. 23) are summarized in Table 1. There are some exceptions to these rules of thumb as some malignant tumors may have relatively well-defined margins and may demonstrate homogeneous enhancement (e.g. clear cell sarcoma). The value of each individual parameter being rather low, correct differentiation can be achieved by a combination of multiple parameters (Gielen et al. 2004; Van Rijswijk et al. 2004). Although a correct histologic diagnosis (tissue specific diagnosis) of malignant soft-tissue tumors cannot be reached based on imaging studies alone, the main task of the radiologist is to select any soft tissue that may be potentially malignant. These lesions should be further evaluated by incisional biopsy without jeopardizing definitive treatment options (Terek and Brien 1995).

The most common malignant soft-tissue tumors involving the hand are synovial sarcoma, liposarcomas, rhabdomyosarcoma, clear cell sarcoma, myxofibrosarcoma, malignant vascular tumors (angiosarcoma and Kaposi sarcoma), and malignant peripheral nerve sheath tumors. As the imaging features of these histologic subtypes are often non-

Fig. 25 Foreign body (wood). **a** Ultrasound shows a central hyperechoic wood fragment surrounded by a hypoechoic inflammatory reaction. **b** On power Doppler examination, there is increased signal at the periphery of the lesion

specific, further discussion is beyond the scope of this chapter.

4 Pseudotumoral Lesions

4.1 Myositis Ossificans

Myositis ossificans (MO) is a benign condition of heterotopic bone formation, which can mimic soft-tissue malignancies. It is rarely seen in the hand region (Chadha and Agarwal 2007; Van Zwieten et al. 2007). The ossification on plain films is centripetal (in contrast to the ossification in extraskeletal osteosarcoma).

Zonal pattern is the typical imaging characteristic (Fig. 24) (Ergun et al. 2010). Detailed discussion of the imaging features of MO is beyond the scope of this chapter.

4.2 Foreign-Body Granuloma

4.2.1 Definition

Foreign body granuloma is usually observed due to previous penetrating trauma, in which the foreign body is not properly retrieved.

4.2.2 Clinical Findings

Most patients will present with a palpable mass, pain, and discomfort.

4.2.3 Imaging Findings

Plain radiographs are only capable of demonstrating radio-opaque foreign bodies, where ultrasound is the imaging technique of choice to demonstrate non-radio-opaque foreign bodies and the surrounding inflammatory reaction (Fig. 25).

In the early course of the lesion, high T2-signal and contrast enhancement is seen surrounding the foreign body, while the granulation tissue may be of low T2-signal without contrast uptake in the chronic stage of the disease (Ergun et al. 2010).

4.3 Rheumatoid Nodule

4.3.1 Definition

Rheumatoid nodules may be rarely observed in cases of long-standing RA, or other rheumatic disease such as lupus, spondylarthropathy, agammaglobulinemia and rheumatic fever. Rarely, it may precede the articular manifestations of rheumatic disease. Histologically, the lesion consists of chronic inflammation, with or without central necrosis.

4.3.2 Clinical Findings

The lesions are usually located at the dorsal aspect of the hand within the subcutaneous tissue (particularly at sites of pressure or repetitive trauma), but bursae, joints, tendons and ligaments may be involved as well (Ergun et al. 2010).

4.3.3 Imaging Findings

Ultrasound is non-specific. MRI may demonstrate iso- to hypointense lesions compared to muscle on

Fig. 26 Examples of pseudomasses due to metabolic diseases. **a** Clinical picture of tophaceous gout. Peri-articular soft-tissue swelling best seen at the proximal interphalangeal joint of the third finger. **b** Corresponding plain radiograph showing the soft-tissue swelling and adjacent periosteal new bone formation. **c** On ultrasound, there is a hypoechoic mass with

intralesional reflections with retro-acoustic shadowing due to urate deposition. **d** Pseudogout (hydroxyapatite deposition disease) in another patient. Plain radiograph showing linear and amorphous calcifications at the joint capsule of the distal interphalangeal joint of the index

T1-weighted images. Solid lesions are hypointense on T2-weighted images, whereas cystic lesions are hyperintense. The enhancement pattern is variable ranging from marked in solid lesions to peripheral ring like in cystic lesions (Ergun et al. 2010).

4.4 Gout, Tophaceous Pseudogout, and Other Metabolic Disease

Crystal disease such as gout and pseudogout (hydroxyapatite and calcium pyrophosphate dehydrate

Fig. 27 Tenosynovitis. **a** Transverse ultrasound of the extensor tendons of the wrist showing fluid surrounding the extensor tendons of compartment 4. **b** Longitudinal power Doppler examination shows increased signal within the tendon sheath and tendons. **c** Axial fatsuppressed TSE T2-weighted image showing increased fluid around the flexor tendons of the third and fourth finger (*arrows*) in another patient with known rheumatoid arthritis

deposition disease) and amyloid deposition may occasionally present as peri-articular soft-tissue masses (Fig. 26). Imaging findings are discussed in another chapter of this book.

4.5 Tenosynovitis and Soft-Tissue Abscess

Tenosynovitis consists of inflammation of the tendon sheath. The etiology may include acute and chronic trauma, infection or inflammatory or metabolic disease (Fig. 27).

Infection of the hand and wrist can rapidly spread along the numerous tendon sheath, fascial planes, and lymphatics of the hand. Imaging findings are discussed elsewhere in this book.

4.6 Anomalous and Accessory Muscles

4.6.1 Definition

Accessory muscles are congenital anatomic variants that may clinically simulate mass lesions. The most encountered accessory muscles of the hand and wrist are the accessory palmaris longus muscle, the extensor digitorum brevis muscle, the accessory abductor pollicis minimi muscle, and the anomalies of the flexor digitorum muscles.

4.6.2 Clinical Findings

The lesion may present as a wrist mass. Palmaris longus and accessory flexor digitorum superficialis muscle may be associated with median or ulnar nerve entrapment.

4.6.3 Imaging Findings

Ultrasound shows a hypoechoic structure with a typical striated appearance of muscle. Dynamic ultrasound will show changes in the shape of the mass with active muscle contraction. Accessory muscles are isointense to muscles on all MR pulse sequences.

4.7 Anomalous Osseous Structures

Accessory osseous structures such as a carpal boss may sometimes simulate soft-tissue masses clinically. A carpal boss consists of a firm osseous prominence on the dorsum of the hand at the base of the second or third metacarpal and adjacent to the capitate and trapezoid bone (Fig. 28). On MRI, there may be reactive bone

Fig. 28 Carpal boss. **a** Plain radiograph (*lateral view*) showing a bony prominence at the dorsal aspect of the carpometacarpal joint (*arrow*). **b** Sagittal fatsuppressed TSE T2-weighted image. Note bone marrow edema and subchondral cyst formation at the carpo-metacarpal joint (*arrows*)

Fig. 29 Hypothenar hammer syndrome. **a** Axial SE T1-weighted image shows a well defined oval mass superficial to the flexor tendons and immediately distal to the hamulus of the hamate. The lesion is of high signal with

central area of lower signal intensity. **b** Axial TSE T2-weighted image shows comparable signal intensities, consistent with thrombosis. **c** CT-angiography shows occlusion of the ulnar artery (*arrow*)

marrow edema and associated joint effusion at the carpo-metacarpal joint (Nguyen et al. 2004).

4.8 Bizarre Parosteal Osteochondromatous Proliferation (BPOP)

This reactive lesion and other surface lesions of bone are discussed in [Tumours and Tumour-like Lesions of Bone](#).

4.9 Knuckle Pads

Knuckle pads are caused by focal fibrous thickening dorsally at the proximal interphalangeal (PIP) or metacarpophalangeal (MCP) joint may precede the development of palmar fibromatosis. They are

usually asymptomatic. Imaging features are non-specific. On MRI, a nodular thickening is seen at the dorsal aspect of the PIP or MCP joint, with intermediate signal intensity compared to muscle on both pulse sequences and moderate enhancement (Murphey et al. 2009).

4.10 Subcutaneous Granuloma Annulare

Subcutaneous granuloma annulare is a rare inflammatory dermatosis that may be encountered in children, usually located in the pretibial area or the scalp. The lesion presents as an ill-demarcated fast-growing painless subcutaneous lesion, with variable signal intensity and contrast enhancement.

4.11 Hypothenar Hammer Syndrome

A posttraumatic partially thrombosed palmar aneurysm resulting from repeated trauma to the wrist (hypothenar hammer syndrome) may mimic a soft-tissue tumor (Van Zwieten et al. 2007).

The typical location of the lesion on the distal part of the ulnar artery distal to the hamulus of the hamate, the history of repeated trauma, the signal intensity of the lesion (indicative of thrombosis), and direct demonstration of occlusion of the ulnar artery on different imaging modalities (Doppler-ultrasound, MR and CT-angiography) may allow a correct diagnosis (Fig. 29).

5 Conclusion

Most benign soft-tissue tumors or tumor-like conditions of the hand have a predilection for certain location in the hand or wrist or may present with characteristic imaging features. This applies particularly for ganglion cysts, epidermoid inclusion cysts, lipoma, haemangiomas, glomus tumors, and nerve sheath tumors. These lesions can be confidently characterized by imaging. On the contrary, malignant tumors and certain locally aggressive tumors such as desmoid tumor present with non-specific imaging features. Further histologic confirmation is mandatory in order to allow proper management of these lesions.

6 Key Points

- Soft-tissue tumors of the hand and wrist (H&W) are more frequent than bone tumors.
- Benign tumors largely outnumber their malignant counterparts.
- There are some tumors having the H&W as a preferential location, i.e. ganglion cysts, GCTTS, lipomatosis of nerve...
- Benign tumors mostly have distinctive features on MRI, i.e. cysts, GCTTS, hemangiomas, lipomas, neurogenic tumors...
- Ultrasound is the initial technique for evaluation of superficial cystic lesions and may have role in the evaluation of small glomus tumors
- MRI is the preferred technique that contributes substantially in detection, staging, grading, and

characterization of soft-tissue tumors. There is only a limited role for plain radiography or CT scan.

- The goal of MRI is to characterize as much as benign tumors and to advocate a biopsy in MRI-non-specific lesions.

Abstract

In any textbook dealing with conditions affecting a particular anatomical site, there will be some which do not fit conveniently under the standard chapter headings. The purpose of this chapter is to review these miscellaneous localised and systemic disorders that may affect the hand and wrist.

1 Introduction

In any textbook dealing with conditions affecting a particular anatomical site, there will be some which do not fit conveniently under the standard chapter headings. The purpose of this chapter is to review these miscellaneous localised and systemic disorders that may affect the hand and wrist.

2 Paget's Disease

Paget's disease of bone is a benign disorder affecting 3–4% of the population over 40 years of age predominantly in Caucasian races (Smith et al. 2002). There is recent evidence of decreasing prevalence (Cundy 2006). The abnormality in Paget's disease is excessive and abnormal remodelling of bone. Three pathologic phases have been described: the lytic phase, the mixed phase and the blastic phase. Initially there is osteolysis, followed by trabecular and cortical thickening and enlargement in the mixed phase of the disease, followed by sclerosis in the blastic phase. Paget's disease is usually polyostotic and asymmetric.

Fig. 1 Paget's disease. There is bony sclerosis and expansion of the proximal phalanx of the middle finger

Polyostotic disease (65–90%) is more frequent than monostotic disease.

Involvement in the hand and wrist has been reported infrequently, although bone scintigraphy studies reveal hand localisation varying from 6.4 to 11.6% (Friedman et al. 1982). Clinically, Paget's disease in the hands is usually asymptomatic; however, several cases with pain in the hands have been reported (Friedman et al. 1982). When Paget's disease occurs in the hand, there is usually a polyostotic involvement (Haverbush et al. 1972). Monostotic localisation in the hand is less frequent (De Smet et al. 1994; Rodriguez-Peralto et al. 1994; Calif et al. 2007). It typically affects the phalanges and metacarpals, with carpal involvement rare and distal phalangeal involvement almost unknown. The most common radiographic pattern of disease in the hand is sclerosis (Fig. 1; Haverbush et al. 1972) and is seen in 45% of cases (Friedman et al. 1982). However, all patterns as found elsewhere in the body (cortical destruction, bone expansion, coarsened trabeculae and bone sclerosis) may be seen in the hand (Friedman et al. 1982). Sarcomatous transformation is the most sinister complication of Paget's disease and is rarely seen in the hand. A review by Lopez et al. (2003) looked at 340 cases of Paget's sarcoma in the literature and identified no cases in

the hand and wrist. Isolated cases of malignant transformation have, however, been recorded (Friedman et al. 1982). The MR imaging appearances of Pagetic marrow can be variable (Smith et al. 2002) but a useful diagnostic sign is the preservation of the hyperintense marrow signal on T1-weighted images (Fig. 2; Boutin et al. 1998; Kaufmann et al. 1991; Sundaram et al. 2001; Vande Berg et al. 2001).

3 Sarcoid

Sarcoidosis is a granulomatous disorder of unknown cause that affects multiple organ systems. It is characterised by the presence of multiple non-caseating granulomas, most commonly seen in the lungs, lymph nodes, skin and eyes. The diagnosis is made by a combination of clinical, radiological and histological features.

Skeletal involvement has been reported in 1–13% of patients with the disease. Radiographic evaluation is often limited to the hands or feet, which demonstrate predominantly osteolytic lesions. The hand is the commonest site of skeletal sarcoidosis. The lesions may be unilateral or bilateral, but symmetrical involvement is unusual. Lesions in the hand are most commonly seen in the middle and distal phalanges, and less often in the proximal phalanges and metacarpals (Van Linthoudt and Ott 1986). There are several types of lesion that are seen. The characteristic lesion is the alteration of the trabecular lattice resulting in a honeycomb lytic appearance (Fig. 3). Cystic lesions may also occur leading to a punched-out appearance that may be located centrally or eccentrically (Fig. 3). Osseous destruction may appear rapidly if these lesions are associated with cortical erosion, which can lead to pathological fracture (Neville et al. 1976, 1977). Periosteal new bone formation is uncommon.

Acro-osteolysis (terminal phalangeal resorption) has been reported in sarcoid involvement of the hands (Fig. 4). The finding is non-specific. In both the hand and the wrist, tenosynovitis is a recognised complication of sarcoidosis (Katzman et al. 1997; Moore 2003). Other soft tissue changes can be seen on MR imaging. These include focal and diffuse muscle lesions, soft tissue infiltration and masses (Moore 2003). MR imaging may also be useful in the

Fig. 2 **a** Radiograph and **b** coronal T1-weighted MR imaging of Paget's disease of the distal radius. The radiograph was initially misinterpreted as showing a giant cell tumour but the preservation of the hyperintense marrow signal in **b** is highly suggestive of Paget's disease

Fig. 3 Sarcoidosis. There is involvement of the proximal and middle phalanges of both hands. The appearances are more punched-out on the *left* with honeycomb osteolysis on the *right*

Fig. 4 Sarcoidosis. At presentation, **a** showing eccentric soft tissue swelling and lacy osteolysis of the middle phalanx of the middle finger; 14 years later, **b** showing soft tissue swelling of both index and middle fingers and progression of disease with terminal phalangeal resorption and further destruction of the middle phalanx of the middle finger. There is now also involvement of the proximal phalanges of both fingers

differential diagnosis, for example in the evaluation of soft tissue nodules distinguishing gout from sarcoidosis. Intermediate-weighted MR images typically show tophi as hypointense, whereas sarcoid nodules will usually be hyperintense.

Lofgren syndrome is a well-recognised manifestation of sarcoidosis, with patients exhibiting arthralgias, erythema nodosum and bilateral hilar lymphadenopathy. Polyarthritis involving the interphalangeal joints, wrists, elbows, knees or ankles is common. Monoarthritis and effusion are uncommon. Ten to thirty-five percentage of sarcoidosis patients will also experience joint symptoms due to granulomatous arthritis with a chronic transient or relapsing arthropathy. Sausage-like dactylitis of the fingers can also occur (Fig. 4). Pain is usually not severe. The uptake of FDG in PET scanning from sarcoid tissue is non-specific. However, Brudin et al. (1994) have described how the degree of FDG uptake correlates with disease activity, and although FDG PET is not useful for initial diagnosis, it could be used for evaluating the extent of active disease and monitoring response to therapy (Love et al. 2005).

Fig. 5 Reflex sympathetic dystrophy. There is intense juxta-articular osteopenia mimicking an acute inflammatory arthropathy

4 Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy (RSD) is a distinct condition that occurs in a variety of clinical situations. There are several terms that are used to describe the same condition including: causalgia, algodystrophy, Sudeck's atrophy, post-traumatic osteoporosis and complex regional pain syndrome. Although the cause is often idiopathic, many visceral, musculoskeletal, neurological and vascular conditions can cause RSD with trauma the most common. The most frequent site for RSD is in the hand. Clinical symptoms include stiffness, pain, tenderness and weakness. Radiographic changes range from soft tissue swelling with juxta-articular osteopenia (Fig. 5) to a more generalised osteopenia (Fig. 6). The former can mimic the

Fig. 6 Reflex sympathetic dystrophy. In this chronic case affecting the right hand, there is intense generalised osteopenia with multiple intracortical lucencies. Note the normal bone density of the unaffected left hand

presentation of an acute inflammatory arthropathy but in RSD there is no joint space narrowing or erosions. Both three-phase bone scintigraphy and MR imaging can be used to assess the “activity” of this disorder over time (Park et al. 2009).

5 Haematological and Marrow Disorders

This section covers the imaging manifestations in the hand and wrist of haematological and marrow disorders including haemophilia, sickle cell anaemia and thalassaemia.

5.1 Haemophilia

Haemophilia and related bleeding disorders are a group of conditions that are characterised by abnormality in blood coagulation caused by deficiency in

certain plasma clotting factors. The two most common types associated with intraosseous and intraarticular bleeding are haemophilia A (deficiency in clotting factor VIII) and haemophilia B (deficiency in clotting factor IX). Haemarthrosis occurs in 75–90% of people with haemophilia and in time leads to a haemophilic arthropathy. This begins between the ages of 2–3 years and increases in frequency till the ages of 8–13 years. The joints most commonly affected include the knee, elbow, ankle, hip and shoulder. Usually, a single joint is involved in each episode, though eventually multiple joints become affected in this disease. Intraarticular bleeding is rare in the hand and wrist. A well-recognised but rare complication occurring in approximately 2% of patients with severe haemophilia is the so-called haemophilic pseudotumour. These result from chronic recurrent haemorrhage that may be intraosseous, subperiosteal or arise in the soft tissues. The bones most frequently involved, in order of decreasing frequency, are the femur, pelvis, tibia and the small bones of the hand

Fig. 7 Haemophilic pseudotumour proximal phalanx of the thumb. The age of the patient and the radiographic appearances mimic an aneurysmal bone cyst

Fig. 8 Sickle cell disease. A young child with severe hand-foot syndrome showing medullary lucencies and periosteal new bone formation involving all the long bones of the hand and the distal ulna. The visible mineralised carpal bones are not involved

Fig. 9 Thalassaemia. The marrow hyperplasia is causing severe generalised osteopenia, trabeculation and minor expansion of the long bones

(Park and Ryu 2004). Cases have also been reported affecting the distal forearm bones (Ahlberg 1975; Shaheen and Alasha 2005). Cases involving the hand and wrist are usually of intraosseous origin, whereas pseudotumours arising in the lower limbs and pelvis tend to be extraosseous with secondary pressure erosion of adjacent bones. In the long bones of the hand, intraosseous haemophilic pseudotumour shows an expansile benign-appearing lytic lesion mimicking amongst other pathologies an aneurysmal bone cyst (Fig. 7; Shaw and Wilson 1993).

5.2 Sickle Cell Disease

Sickle cell disease is one of the hereditary haemoglobinopathies characterised by an abnormal haemoglobin chain (HbS). Clinical manifestations of the disease include painful crises affecting the bones and joints of the extremities. In children with sickle cell anaemia, 30% will present with hand-foot syndrome

Fig. 10 Two different cases of neurofibromatosis. **a** Multiple soft tissue lumps due to subcutaneous neurofibromas and bone erosions in the index and middle fingers. **b** There is focal gigantism and sclerosis of the index and middle metacarpals and fingers

between the ages of 6–24 months with pain and swelling of the hands due to marrow infarction (Watson et al. 1963). The radiographic changes are those of a dactylitis with osteolysis and periosteal new bone formation (Fig. 8; Bohrer 1970). Hand–foot syndrome is rare after 6 years of age because the red marrow recedes from the distal tubular bones of the hand and is replaced by yellow marrow with reduced oxygen requirements. Severe dactylitis may cause premature growth plate fusion thereby causing relative shortening of one or more long bones of the hand (Cockshott 1963). Ischaemic changes in the carpal bones are uncommon (Lanzer et al. 1984).

5.3 Thalassaemia

Thalassaemia is a hereditary haemoglobinopathy with an abnormality in the globin chain production of the red blood cell. This can involve a deficiency in alpha-globin chain synthesis or beta-globin chain synthesis. In severe untreated cases, there is generalised osteopenia and the tubular bones of the hand are expanded secondary to marrow hyperplasia (Fig. 9; Caffey

1957; Middlemiss and Raper 1966). There is also cortical thinning with a coarse, trabeculated appearance. When MR imaging is used in the assessment of the tubular bones of the hand, the findings may include an indistinct physal–metaphyseal junction, altered signal intensity in the metaphysis, physal widening and metadiaphyseal and epiphyseal lesions. Severe radiographic changes are not often seen in the developed world these days as most cases are treated from early infancy with repeated blood transfusions thereby reducing the marrow hyperplasia.

5.4 Other Marrow Disorders

The radiographic appearances in the hands of other marrow and deposition disorders such as Gaucher’s disease and Niemann–Pick disease are relatively minor when compared with changes elsewhere in the skeleton. The authors have reported a single case of Erdheim–Chester disease presenting with a lytic lesion in a metacarpal mimicking a giant cell tumour or metastasis (Davies et al. 2010). Marrow malignancies are covered in chapter “Tumours and Tumour-like Lesions of Bone”.

Fig. 11 Tuberous sclerosis. Multiple cyst-like radiolucencies involving the first and fifth metacarpals and all the fingers

6 Amyloidosis

Amyloidosis is the deposition of abnormal insoluble proteins in soft tissues and bone. It is not a single disease entity with to-date over 20 variants identified. The World Health Organization has proposed a classification based on the precursor fibril protein (Westermarck et al. 2002). This includes primary systemic, secondary systemic, familial, dialysis-related, etc. Soft tissue amyloid deposition produces nodules that are often prominent over the joints of the hand and wrist. Similar deposits in the carpal canal may lead to carpal tunnel syndrome. Ten to thirty percentage of patients with primary amyloidosis have carpal tunnel syndrome. Typically, a bilateral

Fig. 12 Macrodystrophia lipomatosa in a child. Focal gigantism of the index and middle fingers with bony overgrowth and soft tissue syndactyly

distribution is seen, and signs and symptoms related to carpal tunnel syndrome often precede other manifestations of the disease. Amyloid deposition has also been documented in the wrists of patients on dialysis for chronic renal failure with carpal tunnel syndrome. The radiographic findings of amyloidosis in the hand and wrist include asymmetric soft tissue masses, periarticular osteoporosis, widening of the articular spaces and subchondral cysts and erosions. The appearance differs from rheumatoid disease of the hands and wrist as there is preservation of the joint space with soft tissue nodular masses. Extensive joint destruction is occasionally encountered in amyloidosis resulting from neuropathic arthropathy or osteonecrosis of the epiphyseal surfaces. On MR imaging, the amyloid deposits tend to be iso- or slightly hypointense with respect to muscle (Cobby et al. 1991; Kiss et al. 2005).

Fig. 13 Macrodystrophia lipomatosa in an adult: focal gigantism of the index and middle fingers with periarticular exostoses

7 Haemochromatosis

Haemochromatosis results from excessive iron storage in the soft tissues. It may be primary, inherited as an autosomal recessive disorder, or secondary to chronic anaemias with multiple transfusions and dietary iron overload. In the hand and wrist, calcium pyrophosphate dihydrate (CPPD) crystal deposition causes chondrocalcinosis of the triangular fibrocartilage in up to 60% cases. In chronic cases, particularly the primary form, a structural arthropathy develops with a predilection for the second and third metacarpophalangeal joints with joint space narrowing and hook-like exostoses on the radial aspect of the metacarpal heads (Schumacher 1964).

8 Phakomatoses

The phakomatoses are a group of neurocutaneous syndromes typified by the development of benign tumours and malformations, especially in organs of

ectodermal origin. The two such conditions that may manifest in the hands are neurofibromatosis and tuberous sclerosis. In neurofibromatosis, this includes soft tissue masses, bone erosion from adjacent neurofibromas and localised gigantism (macroductyly; Fig. 10). In tuberous sclerosis, there may be multiple cyst-like radiolucencies, periosteal thickening and localised gigantism (Fig. 11; Bernauer 2001).

9 Macrodystrophia Lipomatosa

This is a rare congenital form of localised gigantism due to overgrowth of the mesenchymal tissues particularly hypertrophy of adipose tissue. This results in enlargement of one or more adjacent digits (Fig. 12; Hildebrandt et al. 1993). Most of the reported lesions are present at birth and are associated with a high incidence of local anomalies including syndactyly, polydactyly and clinodactyly. In the adult, the bony hypertrophy can be associated with periarticular exostoses (Fig. 13). The condition may also be associated with carpal tunnel syndrome (Ranawat et al. 1968).

Fig. 14 Hypertrophic osteoarthropathy. Child with long-standing, untreated cyanotic heart disease. There is a single-layer lamellar periosteal reaction along the distal radius and ulna, the metacarpals and to a lesser extent the phalanges. There is also evidence of digital clubbing

Fig. 15 Hypertrophic osteoarthropathy. Adult with known bronchogenic carcinoma. There is symmetrical coarse periosteal new bone formation along all the metacarpals and to a lesser extent the phalanges

10 Hypertrophic Osteoarthropathy

Originally called hypertrophic pulmonary osteoarthropathy, this condition was first described in the French literature at the end of the nineteenth century (Marie 1890). Clinical presentation is with pain and tenderness of the extremities with digital clubbing. Although most commonly associated with lung diseases, classically bronchogenic carcinoma, the term pulmonary has been dropped in recognition of the non-pulmonary associations (Table 1). The typical radiographic appearance is symmetrical periosteal new bone formation along the tubular bones. This occurs in the diaphyses of the radius and ulna, and less frequently in the metacarpals and phalanges. The severity can vary

from simple elevation of the periosteum (Fig. 14), to a lamellated “onion-skin” appearance, to irregular periosteal “cloaking” with an undulating contour (Fig. 15; Ali et al. 1980; Pineda et al. 1987). The differential diagnosis for hypertrophic pulmonary osteoarthropathy includes pachydermoperiostitis sometimes referred to as primary hypertrophic osteoarthropathy. This is a rare, often familial, lesion predominantly of males with a predisposition for Afro-Caribbean populations. Clinically, there is clubbing of the fingers, thickening of the skin and hyperhidrosis. Compared with hypertrophic pulmonary osteoarthropathy, it is relatively pain free. The bones most commonly affected are the radius and ulna, followed by the tubular bones of the hands. The periosteal reaction is similar to hypertrophic pulmonary osteoarthropathy but is more solid and spiculated and also involves the epiphyses to produce outgrowths around joints (Fig. 16).

Fig. 16 Pachydermoperiostosis in an adult of Afro-Caribbean ethnic origin. Digital clubbing with coarse periosteal new bone formation along the distal radius and proximal phalanges

11 Congenital Insensitivity to Pain

Congenital insensitivity to pain, first described in 1932 (Dearbon 1932), is a rare hereditary sensory and autonomic neuropathy characterised by the congenital inability to register pain or temperature changes (Rahalkar et al. 2008; Reilly 2009). The principal orthopaedic manifestations are recurrent fractures, neuropathic joints and osteomyelitis (Silverman and Gilden 1959; Siegelman et al. 1966; Karmani et al. 2001). The changes in the hand include acro-osteolysis, amputations and secondary osteomyelitis (Fig. 17; Gwathmey and House 1984). In children, epiphyseal separation and growth plate fragmentation may occur at the wrist.

Fig. 17 Congenital insensitivity to pain. There is extensive terminal phalangeal resorption (acro-osteolysis) secondary to the underlying neuropathy. The appearances are non-specific and may be seen in other causes of neuropathy such as leprosy or following “trauma” such as frostbite

12 Toxic Agents and Pharmacological Agents

Toxic effects manifested in the hand may be localised or systemic. An example of a localised toxic effect is soft tissue necrosis and contractures secondary to snake bite venom (Huang et al. 1978). Snake and scorpion venom have also both been reported as causing acro-osteolysis (Qteishat et al. 1985). Osteolysis resulting from secondary infections due to animal bites is well recognised. The animals include domestic pets, rodents, exotic animals such as camels (Al-Boukai et al. 1989) and of course humans (Resnick et al. 1985).

Systemic toxic effects include lead poisoning seen in the past in children who had ingested lead-based paints. Radiographs show a radiodense line paralleling the growth plates in the metaphyses of

Fig. 18 Lead poisoning. An infant with a radiodense “lead line” in the distal radial and ulnar metaphyses

the distal radius and small tubular bones of the hand (Fig. 18; Leone 1968; Sachs 1981). Multiple lead lines may be seen if the exposure to the lead has been repeated. The differential diagnosis of radiodense lines in the distal radial metaphysis include other forms of heavy metal poisoning (e.g. bismuth and phosphorus) and the healing phase of rickets and scurvy and treated leukaemia. A toxic cause of more generalised bony sclerosis is fluorosis that is endemic in certain areas of India. In children, this may be associated with rickets-like changes (Christie 1980). An unusual form of occupational acro-osteolysis has been described in polyvinylchloride (PVC) poisoning (Gama and Meira 1978). The typical radiographic feature is a band of osteolysis through the terminal phalanges (Fig. 19a). With removal of exposure to the PVC manufacturing process, there is healing of the defects with shortening and widening of the terminal phalanges (Fig. 19b). A similar appearance may be seen with familial acro-osteolysis (Hajdu–Cheney syndrome) and has also been reported in a guitarist (Destouet and Murphy 1981).

Fig. 19 Polyvinylchloride (PVC) poisoning. **a** Typical band-like acro-osteolysis across the terminal phalanges. **b** On removal from exposure to the PVC manufacturing process, there has been healing of the defects with shortening and widening of the terminal phalanges

Fig. 20 Teratogenic effects of thalidomide therapy during pregnancy. The child has been born with proximal phocomelia and severe skeletal abnormalities of the hand

Fig. 21 Dialysis-related aluminium bone disease. Osteomalacic pattern with Looser's zone in the 2nd and 3rd metacarpals

Fig. 22 Radionecrosis. Historical case of a seamstress who underwent protracted fluoroscopy for the removal of a sewing needle embedded in the soft tissues. This caused skin ulceration and contractures and radionecrosis of the metacarpals (from the collection of Dr Philip Jacobs—deceased)

Prolonged and excessive exposure to numerous pharmacological agents may cause skeletal abnormalities identifiable on radiographs of the hand. These range from the devastating teratogenic effects of thalidomide (Fig. 20) to the rickets-like or osteomalacia pattern associated with phenytoin, phenobarbital, deferoxamine, diphosphonates and dialysis-related aluminium toxicity (Fig. 21). Hypervitaminosis A can cause generalised periosteal reactions (Caffey 1951) and hypervitaminosis D sclerotic metaphyseal bands (De Wind 1961).

13 Radiation Changes

It was not long after the discovery of X-rays in 1895 by Wilhelm Roentgen that the deleterious effects were being reported. An eminent British Radiologist,

Fig. 23 Idiopathic Multicentric Osteolysis (Carpal-Tarsal Osteolysis). **a** Child showing marked resorption of the carpal bones with involvement of the bases of the 2nd and 3rd metacarpals. **b** Same case as an adult showing disease progression with further involvement of the metacarpals

John Hall-Edwards, working at the General Hospital in Birmingham was one of the first to give a comprehensive description of the adverse effects of X-rays on the bones of the hand—using his own hands for case material (Hall-Edwards 1908). Complications include radiation-induced dermatitis with an increased risk of malignant transformation, growth plate damage in children and radionecrosis of the bones (Fig. 22; Hartwell et al. 1964; De Smet et al. 1976). Radiation-induced damage to the hands from diagnostic X-rays is mercifully rare in this day and age but modern radiologists do need to be aware of the potential increase in radiation dose to the hands when undertaking interventional procedures under either fluoroscopic or CT control. Radiation-induced tumours of the hand following radiotherapy are rare (Libshitz and Cohen 1982). It is possible that the incidence of radiation-induced osteochondromas in the hands may rise due to the increasing use of

whole-body irradiation in children as part of the preparative regimen for haematopoietic stem cell (bone marrow) transplantation.

14 Massive Osteolysis

Bone destruction is a non-specific feature of numerous different bone conditions. There is a rare group of idiopathic disorders causing significant bone destruction that can be categorised under the title of primary osteolysis syndromes (Resnick 2002). The commonest is known as Gorham's disease or Massive Osteolysis characterised by uncontrolled, destructive proliferation of vascular or lymphatic vessels within bone and the surrounding soft tissues (Gorham and Stout 1955). Radiographs show dramatic, progressive resorption of bone that can cross joints and involve adjacent bones. The shoulder and the pelvis are the most common sites

of involvement but cases have been reported in the hand (Patel 2005). Another rarer form of primary osteolysis is Idiopathic Multicentric Osteolysis also known as Carpal-Tarsal Osteolysis. Radiographs show progressive carpal bone resorption with in time involvement of the metacarpals (Fig. 23). Cases may be associated with a nephropathy (Warady et al. 1991).

15 Key Points

- the hand is the commonest site of bone involvement with sarcoid.
- the hand is the commonest site for reflex sympathetic dystrophy (complex regional pain syndrome).
- dactylitis may be seen in numerous diseases including sarcoidosis and sickle cell anaemia.
- hypertrophic osteoarthropathy may be associated with both pulmonary and non-pulmonary disorders.

Abstract

Orthopaedic procedures of the hand and wrist are performed for a wide variety of pathologic conditions. Acute fracture fixation and treatment of fracture complications account for the majority of surgical interventions. Other indications for surgery include management of chronic arthropathy, ligament or tendon injury, soft tissue and bone tumours and infection.

1 Introduction

Orthopaedic procedures of the hand and wrist are performed for a wide variety of pathologic conditions. Acute fracture fixation and treatment of fracture complications account for the majority of surgical interventions. Other indications for surgery include management of chronic arthropathy, ligament or tendon injury, soft tissue and bone tumours and infection.

It is important for the radiologist to understand the primary aims of surgical treatment in order to accurately assess the post-operative imaging to identify potential complications. The aims of surgery include:

- Restoration of normal anatomy
- Pain management

- Restoration of function
- Treatment of cosmetic disfigurement
- Prevention of secondary osteoarthritis (OA)

There are a large number of fixation devices and prostheses available to the orthopaedic surgeon, and radiologists should be familiar with the most commonly used devices. It is important to distinguish between acceptable and unacceptable alignment of the bony structures and metalware, and to recognise when poorly positioned devices may lead to complications. In soft tissue reconstruction, it is necessary to know when normal structures have been utilised to achieve the repair (e.g. tendon harvesting), in order to be able to recognise the anatomy on cross-sectional imaging.

Common complications include non-union and mal-union of fractures, poor operative correction of bone and joint deformity and mal-positioned orthopaedic hardware. Non-union of joint arthrodesis, implant failure and infection may also be encountered.

Radiographs are the primary imaging modality used to supplement clinical examination in the post-operative period. Cross-sectional imaging may be required when complications arise. The choice of image modality is guided by clinical findings, and may depend on the presence of orthopaedic metalware which limits the use of MRI in particular.

CT is excellent for documenting bony detail and is useful for assessment of fracture healing and some hardware complications. US is a useful alternative to MRI for assessment of the soft tissues. Nuclear medicine studies are rarely required, but white cell scans may occasionally be useful for evaluation of infected implants.

2 Fracture Fixation

2.1 Indications

Fixation of hand or wrist fractures is indicated when the fracture fragments lie in an unacceptable position, or the fracture pattern is unstable and redisplacement likely.

Fixation of a hand or wrist fracture would also be considered in certain circumstances where the patient's personal circumstances or characteristics would make such treatment more appropriate. These relative indications include:

- Co-existent skeletal injuries where mobility will be assisted by crutches or load bearing through the wrist
- Bilateral hand or wrist fractures
- Co-existent soft tissue injuries which require early treatment, physiotherapy or rehabilitation out of plaster cast
- Patient request (e.g. professional sportsman/woman)

2.2 Implant Choice

A variety of implants are used to stabilise fractures in the hand and wrist. These are either applied to directly stabilise the fracture fragments (Kirschner wires, or internal fixation materials), or applied indirectly to stabilise the fracture fragments from a distance (external fixators).

2.2.1 Kirschner Wires

These are small, thin pins made of stainless steel or titanium. They come in a variety of diameters, typically 1.0–1.6 mm in diameter. They have a sharp tip at one end or both ends (“double-ended”). K-wires with a threaded tip are designed for use as guide wires for cannulated devices and should never be left in situ, since removal is extremely difficult without adequate anaesthesia.

When inserted, the K-wires should engage both cortices to be mechanically effective. They cannot compress fracture fragments, and will only maintain a reduction achieved by other means. Most often, they are inserted percutaneously after a closed reduction, but may occasionally be used following open reduction. K-wires may need to cross joints to be mechanically effective in some circumstances, and this provides a potential route for spread of infection (Fig. 1).

2.2.2 Internal Fixation Materials

Internal fixation may be achieved by the use of compression screws, plate and screw devices or bone anchors.

The best known screw, the Herbert screw, was designed for use in the scaphoid. The pitch varies along the length of the screw, so that differential longitudinal movement occurs in the fracture fragments at each end of the screw as it is tightened, bringing the fragments closer together resulting in fracture compression. The ‘Headless Compression Screw’ (HCS), which provides significantly greater

Fig. 1 AP and lateral radiographs acquired a few weeks following K-wire fixation of an open fracture of the distal phalanx due to a dog bite. There is osteomyelitis of the distal phalanx with marked lytic bony destruction. In addition, the presence of the K-wire has allowed spread of infection across the DIP joint into the middle phalanx, with diffuse osteopenia and periosteal reaction

fracture compression and stability, has now largely replaced the Herbert screw. It is sometimes possible to fix fractures percutaneously by utilising cannulated screws, which have a central channel through which a thin guide wire can be inserted under image guidance across the fracture allowing the screw to be introduced over the temporary guide wire (Fig. 2).

Traditional ‘plate and screw’ implants for the hand and wrist have undergone a revolution in design in recent years. These changes have involved three separate developments:

- Angular stability
- Anatomic implants
- Indirect reduction technique (in distal radius fractures)

Anatomic implants such as the volar plate are commonly used in distal radial fractures. Modified contoured implants traditionally used by craniomaxillofacial (CMF) surgeons in the maxilla, mandible

and facial bones have been adapted for use in the small bones of the fingers.

Bone anchors are small metallic or absorbable implants which are inserted into a small drill hole made in bone. Pre-threaded with suture material, they allow soft tissues to be reattached to the bone when this interface has been disrupted by injury. The most common use of these implants in the hand and wrist, is in the treatment of ulnar collateral ligament (UCL) injuries in the metacarpophalangeal (MCP) joint of the thumb (skiers thumb).

2.2.3 External Fixation

This technique involves the application of two or more threaded pins into the bone on each side of the fracture. These pins are then connected by means of an externally applied rigid bar, which may be radiolucent to help in assessment of radiographs. The pins must engage the cortex on both surfaces to withstand the forces attempting to redisplace the fracture.

When the distal fragment is large and not comminuted, two pins can be placed in the distal fragment, so that the fixator does not cross the adjacent joint (non-bridging fixator), and does not prevent joint movement. However, if one fracture fragment is small, and unable to securely hold two threaded pins, the pins must be placed in a bone beyond the adjacent joint.

2.3 Distal Radial Fractures

Traditionally, K-wires were used to treat extra-articular and simple-articular fractures in the elderly, although evidence has suggested that they may be significantly less effective in maintaining reduction in osteoporotic bone (Greatting and Bishop 1993). For this reason, internal fixation is increasingly employed in the elderly wrist fracture, although K-wires are still utilised for unstable epiphyseal fractures in children (Fig. 3). Radiographs are utilised to ensure K-wire and fracture alignment is maintained until fracture healing is achieved and the wires can be removed.

Implants placed on the dorsal surface of the distal radius were commonly complicated by attrition rupture of the extensor tendons, and are now less frequently utilised.

Current implants are ‘anatomic’ and designed to fit flush to the volar surface of the distal radius. The plate

Fig. 2 Oblique PA radiograph (a) demonstrating an un-united waist of scaphoid fracture at 6 weeks. The fracture has been stabilised by a cannulated screw (b), and has now fully united. Note that the pitch of the screw is wider distally than proximally. NB: the screw is inserted distal to proximal, so the tip of the screw is in the proximal scaphoid

Fig. 3 PA and lateral radiographs (a) of a teenager with an unstable Salter–Harris type II fracture. The PA and lateral radiographs (b) acquired following K-wire fixation demonstrate

good fracture reduction. Each K-wire traverses two bony cortices, ensuring mechanical stability

forces the distal fragments to re-align in a perfect position with multiple sub-chondral angularly stable screws (Fig. 4). This technique is known as ‘indirect reduction’ and is widely used in all types of distal radius fractures. It has the added advantage of

automatically correcting any malrotation of the distal fragment. There are over 40 different designs of volar locking plates for the distal radius currently available.

A variety of neurovascular, soft tissue and osseous complications may arise as a result of volar plate

Fig. 4 Lateral radiograph (a) of a displaced volar shearing, comminuted and intra-articular fracture of the distal radius. PA and lateral radiographs (b) acquired following volar plate fixation demonstrate good restoration of anatomical alignment, with the articular fragments maintained by the sub-chondral screws. The screws in the proximal plate do not engage the

dorsal cortex of the distal radial metaphysis, consequently they do not protrude into the soft tissues, but the resulting lack of bicortical fixation may be prone to early redisplacement. Note also the minimally displaced fracture at the base of the ulnar styloid

fixation (Berglund 2009). Flexor pollicis longus tendinopathy and rupture may be associated with a distally mal-positioned volar plate and plate ‘lift-off’. Fracture mal-reduction may also contribute to tendon rupture. Extensor tendon ruptures may be seen with overlong or mal-positioned screws (Fig. 5). Intra-articular screw placement within the radio-carpal joint may also be encountered, and pre-dispose to accelerated secondary OA change. Other complications include carpal tunnel syndrome, complex regional pain syndrome and delayed union (Arora et al. 2007).

Patients’ with pain or crepitus over the flexor or extensor tendons may be assessed by US to identify tendon impingement with the volar plate and exclude tendinopathy, and tendon rupture. The relationship of mal-placed screws to tendons can also be assessed. Significant tendon disease may necessitate removal of the volar plate once bony union is achieved.

External fixation is usually reserved for open or excessively comminuted fractures, although this mode of fixation is the preferential choice for some surgeons. Pins are placed in the radial shaft and the shaft of the index (second) metacarpal. The pins must engage the cortex on both surfaces to withstand the forces attempting to redisplace the fracture, and it is important to obtain consistent positioning of serial post-operative radiographs to ensure there is no metalware failure, and the pins remain fixed in the bone cortices.

2.4 Scaphoid Fractures

Internal fixation is indicated in the treatment of displaced waist of scaphoid fractures and undisplaced proximal pole scaphoid fractures. It is most frequently employed in the treatment of non-union of scaphoid

Fig. 5 PA and lateral radiographs (a) of a distal radial fracture fixed with a volar plate. The plate is positioned too far distally, and is not aligned with the centre of the shaft of the distal radius. One of the radial styloid screws is extra-osseous (white arrows). An oblique transverse US image (b) shows the screw (white arrow) extending into the extensor group I tendons (broken white arrows)

fractures in order to improve the chances of bony union. Cannulated screws are most commonly used and stabilise both the fracture fragments and interposed bone graft.

Grafting and fixation of scaphoid non-union is not indicated if there is established OA, and other salvage procedures such as denervation, proximal row carpectomy or wrist arthrodesis may be required. Radiographs are notoriously inaccurate in demonstrating avascular necrosis of the proximal pole (Downing et al. 2002). Pre-operative MR imaging is more accurate in assessing the vascularity of the proximal fragment.

Fracture non-union and hardware failure occurs in up to 8% of patients undergoing dorsal percutaneous cannulated screw fixation of undisplaced scaphoid fractures (Bushnell et al. 2007). Fracture healing on serial radiographs is normally expected by 12 weeks

Fig. 6 PA radiograph (a) of a fractured scaphoid stabilised by a cannulated compression screw. It is difficult to assess fracture union on this examination, although there is clear evidence of lysis around the screw, suggesting loosening due to non-union. Sagittal oblique CT (b) confirms the presence of fracture non-union. In addition the proximal end of the screw impinges within the scapho-trapezial joint

post-fixation, and a persistent fracture line indicates delayed or non-union. Persistent non-union is more frequent in patients undergoing fixation of chronic non-union, even with bone grafting, and occurs in up to one-third of cases (Megerle et al. 2008). If radiographs are equivocal, CT is a reliable method of evaluating the status of fracture healing (Fig. 6). Progressive lucency around the screw is indicative of screw loosening. Avascular necrosis of the proximal pole segment is manifest by sclerosis, sub-chondral flattening and fragmentation. Screw fracture is rarely encountered.

2.5 Hamate Fractures

The treatment for non-displaced hamate fractures is usually conservative. However, the majority of displaced fractures are treated by either fixation with pins or screws (Fig. 7), or by excision of the fragment (Walsh and Bishop 2000) if a symptomatic non-union of the hook of the hamate is present. Non-union is common in displaced fractures managed non-operatively, although long-term outcome may be no worse than those treated operatively (Scheufler et al. 2005). Compression screw fixation generally achieves better fracture stability than fixation with Kirschner wires, although this does not necessarily correlate with outcome scores (Wharton et al. 2010).

Fig. 7 Oblique PA and lateral radiographs (a) of a displaced dorsal hamate fracture associated with dislocation of the fourth and fifth metacarpal bases. The post-operative PA and lateral radiographs (b) demonstrate good anatomical alignment of the

fracture fragment maintained by three cortical screws. The metacarpal dislocation has been reduced, and the K-wire transfixing from third to fifth metacarpals helps maintain stability during ligamentous healing

CT imaging of hamate fractures is utilised to detect occult fractures (Welling et al. 2008), to aid surgical planning of complex fractures, or to diagnose fracture non-union. Serial radiographs are required post-operatively to assess progression of bony union and exclude hardware failure. The PA and oblique views may be supplemented with a lateral view in cases with associated carpo-metacarpal dislocation, to assess adequacy of reduction. CT is rarely required in the post-operative period but may be helpful where bony union is equivocal.

2.6 Other Carpal Bones

Carpal fractures at other sites occur much less frequently. The peculiar anatomy of each carpal bone (irregular shape and significant surface area coverage by articular cartilage) does not lend itself to an easy solution when designing an internal fixation implant. However, the usually dense cancellous bone in this region, allows intrasosseous devices to be designed, which will stabilise each carpal bone fracture appropriately.

When carpal bones dislocate, they are usually held in a reduced position by multiple K-wires inserted percutaneously. These are an excellent implant choice because compression is not required between bones as the ligaments heal. K-wires used for these indications will normally remain in place for approximately 8 weeks.

2.7 Metacarpal and Phalangeal Fractures

K-wires remain popular in the management of metacarpal fractures because of the high cortex:cancellous ratio of these bones. A combination of PA, oblique and true lateral post-operative radiographs, dependant on fracture location, may be required to assess fracture alignment. Good fracture reduction is especially important for intra-articular fractures to maintain function and prevent long-term secondary OA.

Internal fixation using plates and screws is indicated in unstable, irreducible and open fractures. They are employed in cases where early skeletal stabilisation will facilitate earlier movement and rehabilitation.

Fig. 8 Oblique radiograph (a) of an angulated, transverse fracture of the proximal phalanx of the middle finger. The PA and lateral radiographs (b) demonstrates anatomical fracture reduction and fixation with a CMF type implant. Note that the screws transfix the opposite cortex. The limited thickness and small size of the implant, combined with the lateral placement of the plate, suggest that this fixation is at significant risk of early redisplacement and failure. Larger implants situated on the dorsal surface of the bone (to resist the force of the flexor tendon) have a greater chance of success

Scaled down versions of standard long bone implants are too bulky for the confined areas adjacent to the bones of the hand, and often cause adhesion of the soft tissues in contact with the implant, requiring plate removal and division of peritendinous adhesions (tenolysis), as a second surgical procedure in up to 75% of cases (Buchler and Fischer 1987). Hand fracture implants now closely match the original CMF implants rather than orthopaedic implants. A whole new generation of anatomic implants for use in certain pre-defined areas of the hand has evolved (Fig. 8), such that external fixators are now rarely used in the hand (Fig. 9).

Radiographs are evaluated for fracture or displacement of either the plate or screws.

3 Prosthetic Joint Replacement

3.1 Indications

Joint prostheses are rarely indicated in the management of hand and wrist conditions. Finger joints require flexibility and mobility to be useful. Implants can rarely provide this since the surgical approach

itself will result in stiffness. The function of the wrist joint demands both stability and flexibility, both of which are difficult to create and match in a prosthetic joint.

The commonest indication for arthroplasty in the hand and wrist is rheumatoid arthritis. Prosthetic joint replacement is indicated when an individual's personal needs or lifestyle are such that arthrodesis would be unsuitable. In some instances, this may be unilateral, with an arthrodesis preferred in the opposite wrist to provide maximum stability and strength.

Osteoarthritis is more common than rheumatoid arthritis, but OA patients have very different demands of hand and wrist function, and prosthetic replacement is usually unsuitable because of their greater functional needs. Prosthetic replacement may be considered for secondary OA of a single interphalangeal joint, when the remaining interphalangeal joints are unlikely to develop similar changes, but their function can be significantly downgraded by the arthritic changes present in the affected joint.

3.2 Implant Choice

3.2.1 Wrist

There are a number of different implants available, although none have proved overwhelmingly successful. Most have two parts, one for each side of the wrist 'joint'. They are made of metal, although a high density plastic insert is situated between the components in most implants.

Prostheses can either be described as 'constrained' or 'unconstrained', depending on the design characteristics and the relative freedom of movement between the components, or as 'cemented' or 'uncemented'. Newer designs try to mimic the natural movements of the wrist and carpal bones/ligaments.

Serial radiographs should be assessed for prosthesis alignment and migration, and bony osteolysis (Fig. 10). Early designs were subject to distal component loosening, although this is less frequently encountered with newer implants. Proximal subsidence may be identified but is often non-progressive and asymptomatic (Adams 2004). However, outcome measures for wrist arthroplasty are comparable or slightly worse than wrist fusion (Cavaliere and Chung 2008), and surgical options need to be carefully assessed.

Prosthetic surgery in the distal radioulnar joint (DRUJ) is more frequently indicated than in the

Fig. 9 Lateral radiograph (a) of a longitudinal, coronal plane fracture of the base of the middle phalanx, with separation and depression of the intra-articular fragments. The fracture has been stabilised with an external fixator (b), although fracture reduction is difficult to assess on the lateral view due to the

presence of the fixator. The PA view demonstrates persistent displacement of an articular fragment on the ulnar side of the base of the phalanx. Following removal of the fixator, the lateral radiograph (c) demonstrates incomplete fracture reduction and incomplete bony union

radiocarpal joint (Kopylov and Tagil 2007). This type of surgery is most frequently performed to stabilise the unstable distal ulnar stump after excision (Darrach's procedure). Prosthetic surgery is also indicated in degenerative disease of the DRUJ and after unreconstructible fracture of the ulnar head. Prostheses either replace the distal ulna alone (distal ulnar prosthesis) (Fig. 11), or both the distal ulna and sigmoid notch of the distal radius (DRUJ prosthesis). They are usually uncemented.

3.2.2 Hand

Interphalangeal or metacarpophalangeal replacements are either made of:

- Silicon
- Metal and plastic
- Pyrocarbon

Silicon implants are commonly used for multiple MCP joint replacements in rheumatoid arthritis. Long-term outcomes for silicone implants are good with 63% survivorship at 17-year follow up (Trail et al. 2004), and have better outcomes than non-surgical groups (Chung et al. 2009). Metal and plastic

implants mimic other large joint prostheses in other areas of the body but are almost always inserted without the use of cement. Pyrocarbon implants are radiopaque and are always inserted cementless.

Post-operative radiographs are assessed for the position of each implant, and joint alignment. At long-term follow up, loosening, bony osteolysis and prosthetic deformity and fracture may occur (Fig. 12). Fracture of silicone prostheses eventually occurs in up to two-thirds of cases, although clinical outcomes may not be adversely affected (Trail et al. 2004). Amyloid- and silicone-induced synovitis is a well documented complication of silicone implants and is also referred to as giant cell arthritis. Patients present with pain and swelling localised to the affected joint. Onset of symptoms can vary from 6 months to 9 years. Radiographs may show nodular soft tissue swelling, well defined sub-chondral lytic defects and erosions. The bony changes evolve over time and must be distinguished from pre-existing arthropathy which necessitates review of previous radiographs. MRI demonstrates effusions with peri-articular low signal intensity silicone particles and fibrosis in

Fig. 10 PA radiograph (a) of a 'Re-Motion' wrist prosthesis, in a patient with severe rheumatoid arthritis. The prosthesis is angulated and there is reasonable bone density around the wrist. Although there is no subsidence or change in position of the prosthesis, a follow up radiograph (b) acquired 3 years

later, demonstrates progressive bony lysis around both proximal and distal components, due to either infection or sterile loosening caused by repetitive loading on the radial border of the prosthesis secondary to malposition

addition to prosthetic deformity and fracture. The sub-chondral lucencies are lower signal intensity on T2W images than typical sub-chondral cysts (Chan et al. 1998). However, most diagnoses can be made on conventional radiographs.

4 Arthrodesis

4.1 Indications

Arthrodesis (surgical fusion) is performed to stabilise a joint by permanently removing its movement in order to remove pain or improve the position of a stiff

joint. Surgical removal of the remaining cortical bone is performed on each side of the joint, so that a healthy, vascular bed of cancellous bone is exposed. Opposing cancellous surfaces are brought together and an implant is used to stabilise them whilst osseous healing occurs. Following successful fusion, the implant may be removed in a second surgical procedure if there are soft tissue complications.

Arthrodesis of the wrist may be total or partial. A total wrist arthrodesis involves the radiolunate, radioscaphoid, scapholunate, scaphocapitate and capitulate joints. The third CMC joint is not always surgically prepared for fusion, but is often left untouched with the intention of removing the stabilising

Fig. 11 PA radiograph of an uncemented distal ulnar prosthesis inserted to treat instability of the distal ulnar stump after excision of the ulnar head (Darrach's procedure)

implant at a later date once fusion is sound. This preserves an important movement in the hand, allowing 'cupping' of the fingers and improved dexterity.

A 'partial' wrist arthrodesis is otherwise known as 'intercarpal arthrodesis'. Adjacent carpal bones are arthrodesed to produce a specific anatomical fusion depending on the primary condition (rheumatoid arthritis, OA or carpal instability). Radiolunate arthrodesis is indicated in rheumatoid arthritis to prevent ulnar drift of the hand from the radius. Scaphotrapezotrapezoid joint arthrodesis is indicated for OA, and when preservation of carpal height is required.

OA of the first CMC joint is very common and a wide range of surgical options are available including arthrodesis. In the hand, the most commonly fused joint is the MCP joint of the thumb. Instability and pain may produce loss of power and precision grip. The terminal joints of the thumb and the fingers are usually fused for patients with OA to restore the

effective length of the digit, and improve stability, pain, dexterity and fine movements.

4.2 Implant Choice

4.2.1 Wrist

4.2.1.1 Total Wrist Arthrodesis

Total wrist arthrodesis can be difficult to achieve in patients with OA, and requires specifically designed implants which are strong, but which do not cause irritation of the overlying gliding tendons. These implants come with two different pre-set angles, so that the wrist is arthrodesed in either 20° of extension (commonly utilised) (Fig. 13) or in neutral flexion/extension. One of each type may be used in bilateral arthrodesis to give different abilities with each wrist. The newer versions of these implants include locking screw options to provide angular stability when used in osteoporotic bone.

Rheumatoid patients often have a thin dermis and a potential for poor wound healing. Successful bony fusion can be achieved by the use of an intramedullary stainless steel pin (usually of 3 or 4 mm diameter), without the risks of a substantial metal implant. This is introduced through the head of the middle metacarpal (or occasionally in the second intermetacarpal space) and passed across the carpus and into the medullary canal of the radius (Fig. 14). No rotational stability is provided by this implant, but healing is usually so rapid that this is not a functional problem.

4.2.1.2 Partial Wrist Arthrodesis

Four corner fusion of the lunate, triquetrum, hamate and capitate using a circular plate device was introduced in 1999. It is usually performed in combination with total excision of the scaphoid, as a salvage procedure for scapholunate advanced collapse (SLAC), and scaphoid non-union advanced collapse (SNAC), and has largely replaced traditional fusion procedures using wires, staples and compression screws (Fig. 15). Scaphoidectomy alone would result in inevitable carpal collapse, and a 'four corner arthrodesis' prevents this complication.

Early studies demonstrated higher complications rates than with conventional methods of fusion. Radiographic non-union (26%) and dorsal hardware

Fig. 12 PA radiograph (a) of a patient with severe interphalangeal (IP) joint erosive OA with joint deformity and subluxation. The post-operative radiograph (b) illustrates the silastic implants from the second to fourth PIP joints, with restoration of normal joint alignment. There has also been an arthrodesis of the DIP joint of the index finger. A follow up film

(c) 2 years later (after removal of the arthrodesis screw) shows early deformation of the implants, with early bony resorption of the cut ends of the proximal phalanges. There is recurrent ulnar drift particularly affecting the middle finger. There is no fracture of the implants, and no soft tissue swelling

impingement (22%) are most frequently encountered (Vance et al. 2005). Other complications include implant breakage or back-out, and carpal tunnel syndrome (Bedford and Yang 2010). However, a recent study has shown a much higher rate of radiographic union, achieved over a mean follow up period of 22 months, with very few other complications observed (Bedford and Yang 2010).

Serial radiographs are used to assess the progress of bony union and identify hardware failure. Cross-sectional imaging is rarely required, but US may have a role when dorsal impingement or protruding screw tips through the carpal tunnel floor are suspected clinically.

4.2.2 Hand

Arthrodesis of the first CMC joint with screw and plate fixation may be complicated by plate failure and non-union (Fig. 16). However, there is no evidence that other surgical options such as trapeziectomy and ligament reconstruction offer any significant advantage (Wajon et al. 2009). Complications include tendon adhesion or rupture and complex regional pain syndrome (type I). These occur in up to 10–22% of patients.

Crossed K-wires or small intraosseous screws (such as mini-Herbert screws or HCSs) are used to arthrodesis finger joints (Fig. 17). If the finger joint is larger in cross-sectional area, a dorsal tension band wiring system may be used which gives the advantage of allowing early movement. The tension band wiring system consists of two parallel K-wires crossing the fusion site obliquely, with a dorsal ‘figure-of-8’ wire loop (Fig. 18).

Screw fixation results in bony fusion in 85–100% over 7–10 weeks (Leibovic 2007). Complications include screw migration, breakage and infection (Fig. 19). K-wire fixation allows fusion in 5–10% of flexion which improves dexterity, but is associated with higher rates of non-union and other complications.

5 Osteotomy

5.1 Indications

Osteotomy is indicated when the shape of a bone requires modification. In the wrist, this is most commonly required for fracture malunion of the distal

Fig. 13 Lateral radiograph of total wrist arthrodesis using a wrist fusion plate. The arthrodesis has been performed with the wrist in slight extension to allow improved power grip

radius, usually for an extra-articular deformity, but occasionally for more complex intra-articular deformity. The relative shortening of the radius caused by fracture is usually a 3D deformity which requires radial osteotomy and bone grafting to correct it. However, in unusual circumstances, if the radial deformity is simply one of shortening, an ulnar shortening osteotomy alone will realign the DRUJ surfaces (Fig. 20).

Osteotomy is also sometimes indicated for malunion of the scaphoid, when the classical ‘hump back’ deformity of a flexed scaphoid has resulted in secondary carpal instability, or in finger fractures which

Fig. 14 Wrist arthrodesis in a rheumatoid patient achieved using a single longitudinal Steinman pin

have healed with rotation. This produces a significant functional problem as the fingers ‘cross over’ each other as they bend into a fist.

Other indications for osteotomy relate to altering the pattern of load transfer across the joint. This used to be frequently performed for early OA, but is now reserved for conditions such as Kienbocks disease (where the radius is usually shortened at the metaphyseal level), and ulnar abutment (where the distal ulnar shaft is shortened to reduce the force across the degenerate or damaged TFCC).

5.2 Implants

Standard internal fixation implants are used for stabilisation of osteotomies around the wrist. For the distal radius, these are usually angularly stable implants, because indirect reduction techniques are used to correct the misshaped bone (Fig. 21).

Increasingly, surgeons are using ‘anatomic’ implants (shaped like the bone they are trying to correct) in radial osteotomy. These are usually applied on the volar surface of the distal radius. This did present problems in placing a large piece of cortico-cancellous bone graft into the defect when the ‘natural’ access for the graft was from the larger gap

Fig. 15 Coronal and sagittal CT images (a) of a patient with a SNAC wrist. There is scaphoid non-union, scapholunate diastasis, DISI deformity and carpal collapse with secondary OA in the mid-carpal joint. There is also an un-united fracture of the radial styloid. A PA radiograph of the hand (b) shows the

post-operative appearances following scaphoidectomy and a four corner fusion. The screws are well-sited in the capitate, hamate, lunate and triquetrum. However, there is residual dorsal angulation of the lunate with minor volar subluxation due to insufficient seating of the plate

Fig. 16 Lateral radiograph of the thumb following arthrodesis of the first CMC joint with a mini fragment screw and plate fixation. The plate has fractured due to non-union of the arthrodesis with recurrent subluxation of the CMC joint

on the dorsal bone surface. However, the significant mechanical strength and stability provided by modern locking plates allows morselised cancellous bone or

bone substitute to be packed into the defect through a small aperture.

Radial and ulnar osteotomies are generally very successful procedures. Complications are usually technique-related such as incomplete correction of deformity, implant-related issues (incorrect screw length, malposition of the implant) or delayed/non-union of the osteotomy. Similar complications exist in osteotomy of the scaphoid and fingers, but non-union is a more significant risk in scaphoid osteotomy than wrist or finger osteotomy.

6 Curettage and Bone Graft

6.1 Indications

Bone cysts are not uncommon in the phalanges, but are rare in the wrist. Occasionally, benign bone cysts and tumours, such as enchondromata, will require curettage and bone grafting.

Bone grafting is used more frequently to promote healing in conditions such as scaphoid non-union or after radial osteotomy.

Fig. 17 Lateral radiograph showing satisfactory alignment of an IP joint arthrodesis with a compression screw. The joint is fixed in approximately 45° of flexion to help preserve function

6.2 Implant Choice

A structural bone graft is important in certain circumstances, and this will usually be harvested from the iliac crest (non-vascularised) or the distal radius on a vascular pedicle (vascularised). If the area to be grafted is stabilised by an appropriate strong implant (such as in corrective osteotomy for distal radius malunion), cancellous autograft or, increasingly, bone substitute will be indicated. Cancellous autograft can be harvested from the ipsilateral distal radius or the olecranon. Bone substitutes are either osteogenic (such as those containing bone morphogenic proteins (BMP) or hydroxyapatite) or inert stimulators of new bone growth (such as calcium sulfate). The former are more likely to be radiologically visible for months or even years after implantation, whilst the latter are usually only visible radiologically for a few weeks.

Radiographs are usually sufficient for follow up evaluation. MRI is indicated in cases where tumour recurrence is suspected (Fig. 22). The increasing use of bone substitutes has developed in response to the complications associated with harvesting of bone graft—particularly from the iliac crest. Haematoma, meralgia paraesthetica (injury to the lateral cutaneous nerve of the thigh) and scar tenderness may be encountered.

Fig. 18 PA and lateral radiographs of a first MCP arthrodesis performed for an unstable joint with secondary OA. The joint has been stabilised with K-wire and dorsal tension band wiring. Sound bony union has been achieved with the joint in flexion, although ideally the wires should penetrate the palmar cortex

7 Tendon Repair

7.1 Indications

Tendon repair is indicated after traumatic division, attrition rupture or avulsion of the tendon insertion.

7.2 Implant Choice

No implants are used in primary tendon repair, which is achieved by intratendinous suturing of the tendon ends using non-absorbable suture material. Secondary reconstruction is performed when primary repair is not possible due to delayed presentation, infection, poor skin cover or other associated injuries. This usually involves two separate surgical procedures. The first stage is a re-creation of the tunnel for the tendon graft, which is necessary because of scarring and adhesions within the tendon sheath. It is achieved by the anatomical placement of a silastic rod (usually 2 mm

Fig. 19 Two examples of screw complications. In a PIP joint arthrodesis (a), the screw is placed too close to the dorsum of the cortex in the proximal phalanx, leading to loosening and bony lysis around the screw with non-union of the arthrodesis and recurrent joint malalignment. In the DIP joint arthrodesis

(b), the screw is not sufficiently engaged within the middle phalanx. This arthrodesis will almost certainly fail, so a repeat arthrodesis was performed (c) which showed good screw alignment, but with some lysis around the screw indicating early loosening

Fig. 20 PA radiograph (a) demonstrating uniplanar radial malunion with resultant length discrepancy between the radius and ulna, and abutment of the distal ulna onto the lunate and triquetrum. The post-operative radiograph (b) following shortening osteotomy of the ulna using a compression plate shows restoration of radioulnar alignment

Fig. 21 PA and lateral radiographs (a) of a young adult with malunion of a distal radial fracture with residual dorsal angulation. There is also non-union of the ulnar styloid, and the DRUJ was clinically unstable. The post-operative

radiographs (b) demonstrate bony union across the radial osteotomy which has been maintained in anatomic alignment with a volar plate. The ulnar styloid fracture has been stabilised with a compression screw to attempt to stabilise the DRUJ

diameter) along the whole length of the tendon sheath, around which a smooth lining forms over a number of months. It is replaced (in a second operation) with a tendon graft, which can now glide smoothly. This technique is most frequently performed on the flexor surface, but can also be used in extensor tendon defects.

Adhesion formation within the tendon sheath is common following tendon repair. Other complications include tendon re-rupture, pulley failure (or failure to recognise pulley injury at the time of repair), joint contracture and triggering (Lilly and Messer 2006). Breakdown of the repair requires further surgical repair, but clinical differentiation from adhesion formation may be difficult.

US can reliably assess the tendon repair, although access may be limited by finger flexion. Small headed 'hockeystick' probes allow improved visualisation. The repaired tendon is thickened and hypoechoic, and is surrounded by low reflective granulation tissue. Suture material is echogenic. Dynamic US evaluation of the tendon during gentle passive and active flexion/extension demonstrates paradoxical movement of the tendon ends when there is breakdown at the repair site.

8 Ligament Repair

8.1 Indications

Intrinsic ligament repair of the wrist is usually restricted to the ligaments of the proximal carpal row (the scapholunate and lunotriquetral ligaments). Surgical repair can be performed in the acute situation (usually within 3–4 weeks of injury) when the procedure is a true 'repair'. A high index of suspicion is essential to make an early diagnosis. Late presentation is more common and requires reconstruction rather than repair because of the irreversible shrinkage that occurs in the torn ligament surfaces over time.

Ligament injury secondary to joint dislocation is common in the thumb and fingers, although surgical repair is rarely necessary. Radiological monitoring of joint congruity will be necessary for 3–4 weeks after injury. Tears of the UCL of the thumb are caused by forced hyperextension and abduction. The ligament may either be partially or totally ruptured. Displaced UCL tears with the ligament remnant overlying the adductor aponeurosis (Stener lesion) will not heal and

Fig. 22 PA radiograph (a) of a benign enchondroma within the proximal phalanx. The lesion has been treated by curettage and non-vascularised bone graft (b). However, several years later the patient presented with recurrent swelling and pain, and repeat radiograph (c) shows resorption of the bone graft

material with internal lucency, cortical breakthrough and periosteal reaction. The coronal and sagittal T2FS MRI images (d) show high SI cartilage matrix. The appearances are strongly suggestive of chondrosarcoma transformation, which was confirmed following ray amputation

requires surgical repair or reattachment using a bone anchor.

8.2 Implant Choice

8.2.1 Wrist

Acute intrinsic ligament repairs must be stabilised until healing has occurred. This is either performed with multiple K-wires between the adjacent carpal bones, or with a small intraosseous screw, placed so as to hold the two adjacent bones tightly together. In both situations, the implants are always removed.

Reconstruction of an intrinsic ligament requires the same post-operative internal stabilisation as acute repair. Reconstruction of the scapholunate ligament is achieved by the use of a tendon graft, most usually from the flexor carpi radialis (FCR), passed through a substantial hole made in the scaphoid (up to 3 mm in diameter), and anchored to the lunate with a small bone anchor. This is termed as a Brunelli procedure, although other modifications are described (Brunelli and Brunelli 1995; Van Den Abbeele et al. 1998) (Fig. 23). The majority of patients experience improvement in pain and grip strength, although there is no long-term evidence to

confirm that this will reduce the risk of development of OA.

A similar ligament reconstruction using tendon grafts is occasionally undertaken for instability of the first CMC joint of the thumb (Fig. 24). The procedure was described by Eaton and Littler using the FCR tendon, although other tendon grafts can be used (Brunelli et al. 1989; Eaton and Littler 1973). Long-term follow up has demonstrated good outcomes in the majority of patients, with prevention of secondary OA in those patients without pre-existing arthropathy (Eaton et al. 1984).

Post-operative radiographs demonstrate the location of drill holes and bone anchors, and the alteration in radiological measurements of instability. The radiographic appearances of scapholunate diastasis may persist post-operatively. Failure of reconstruction may be indicated by anchor migration. MRI can visualise the ligament reconstruction, but integrity throughout the whole of the tendon graft may be difficult due to magic angle effects. Interpretation of MRI will depend on knowledge of the exact procedure.

8.2.2 Hand

Stabilisation of an unstable finger dislocation is performed with a trans-articular K-wire, usually left in situ for 3 weeks.

Fig. 23 PA radiograph (a) acquired following a Brunelli procedure for reconstruction of the scapholunate ligament. The tunnel within the scaphoid is clearly evident, and there is persistent scapholunate diastasis. The coronal (b), sagittal (c) and axial (d) T1W MR images also clearly show the scaphoid tunnel and ligament graft as low-signal intensity

(black arrows). There is susceptibility artefact from the resorbable bone anchor in the dorsal aspect of the lunate (broken arrow). The graft appears intact. However, there is early articular cartilage loss on the proximal scaphoid (white arrow), which was not present on the pre-operative imaging, and there is residual dorsal tilt of the lunate

Fig. 24 PA radiograph (a) of a patient following trapeziectomy and arthrodesis of the scaphotrapezoid joint, and ligament reconstruction of the first CMC joint performed to treat pain and instability secondary to OA. The osseous tunnel, created for ligament reconstruction, is seen in the base of the first MC which remains subluxed. The screw has an area of lysis around it, suggesting loosening and persistent non-union. A coronal oblique CT image (b) confirms non-union of the arthrodesis and demonstrates the osseous tunnel within the first MC

Reattachment of an avulsion of the UCL of the thumb is usually performed with a small bone anchor. US may be utilised to identify failed ligament reconstruction. The ligament will be thickened and hypoechoic, and dynamic evaluation with radial stress helps identify abnormal joint widening. Adhesions between the repaired UCL and the adductor aponeurosis may cause pain and limitation of movement of the aponeurosis, which may be seen on US during flexion and extension of the MCP joint. Treatment is with physiotherapy.

Avulsion of the palmar (volar) plate is a common injury caused by hyperextension of, usually, the proximal interphalangeal joint. A small fleck of avulsed bone can often be seen adjacent to the palmar surface of the middle phalangeal base, or more subtle changes of erosion or blunting of the edge of the middle phalanx may also be noted. Avulsion of a fragment of bone which comprises more than one-third of the total articular surface will lead to inevitable instability of the joint and must be very carefully monitored. Subtle radiological evidence of dorsal subluxation of the affected joint must be sought in the first few weeks after injury, or in cases where functional recovery is delayed. If persistent subluxation or frank instability of the joint is identified, surgical reattachment of the volar plate to the base of the middle phalanx is indicated.

9 TFCC Repair

9.1 Indications

The triangular fibrocartilage complex (TFCC) stabilises the ulnar side of the wrist and the DRUJ. It is often injured during a fall onto the outstretched hand, and is associated with distal radius fractures. Injury to the ulnar styloid can be associated with a TFCC tear—especially if the ulnar styloid is fractured at its base. Repair of the TFCC is indicated if there is instability of the ulnocarpal joint or the DRUJ.

It is important to stress that not all abnormalities of the TFCC are true tears secondary to physical injury. Defects are commonly seen in the TFCC as either a congenital finding or a degenerative feature and the term ‘TFCC tear’ should be used with discretion, as this implies a traumatic aetiology. It may be prudent to describe these findings as ‘TFCC defects’—where their aetiology is uncertain or yet to be determined.

9.2 Implant Choice

Repair is either performed through an open approach or arthroscopically. Whichever method is chosen, a

Fig. 25 PA and lateral radiographs (a) of the wrist following a ligamentous reconstruction of the DRUJ. Osseous tunnels can be seen in the distal radius (white arrows) and ulna (broken white arrows). The patient had persistent symptoms of pain and instability, and there is separation of the radius and ulna at the DRUJ. An axial T2WFS MR image (b) demonstrates a part of the tendon graft (curved white arrow) deep to the ECU tendon. However, the graft did not appear continuous and no graft is seen entering either the radial (white arrow) or ulnar (broken white arrow) tunnels. There is also marked recurrence of volar DRUJ instability indicating failure of the graft reconstruction

series of strong nylon sutures are passed through the cartilage disc to secure it to the external joint capsule. If the TFCC is irreparable, then a DRUJ ligament reconstruction may be indicated. The Adams procedure utilises a palmaris longus tendon graft to stabilise the DRUJ with drill holes placed through the distal radius and ulna (Adams and Berger 2002) (Fig. 25). Instability of the DRUJ in the presence of

skeletal deformity, should first be addressed by correction of the skeletal deformity, which may be sufficient to restore complete stability (Lawler and Adams 2007). Recovery of strength and motion after repair, is seen in 85% of patients with chronic DRUJ instability (Adams and Lawler 2007).

If symptoms persist following TFCC repair, imaging may be required to exclude other causes of ulnar sided wrist pain, including ECU tendonitis or tendon subluxation, ulnar impaction, pisotriquetral chondromalacia or OA, and secondary OA of the DRUJ. In recurrent injury repeat MR arthrography may be required. Complications of DRUJ stabilisation include recurrent pain and instability. Radiographs document the location of the drill holes and the alignment of the DRUJ.

10 Conclusions

Radiological interpretation of the post-operative hand and wrist requires a thorough knowledge of the objectives of treatment in order to distinguish between acceptable findings and genuine complications on post-operative radiographs. Radiologists should be aware when cross-sectional imaging is indicated to provide diagnostic information that can help determine management protocols.

The range of orthopaedic implants and techniques of soft tissue reconstruction continue to evolve, and it is important to engage with the hand surgeon to be conversant with new techniques and procedures that are introduced in order to be able to correctly interpret radiological investigations.
