As with other purchasing decisions, people confronted with a change in transportation price generally act differently in the ultrashort run, the "market period," the short run, and the long run – Table 36.1 offered some examples. Immediate reactions, in the ultrashort term, to a public transportation fare rise may, for example, be dramatic, with people, almost on principle, making far less use of services, even boycotting it, but knee-jerk reaction is extremely short lived and seldom considered by economists, although it is often of interest to politicians. This behavior is usually short lived. In the slightly longer "market period," people revert to their initial behavior relatively unresponsive to a price change either because they do not consider it a permanent change or because technical constraints limit their immediate actions; the elasticity is virtually zero. Over time, people can adjust their behavior and, in the short run can change their travel patterns by switching modes, combining trips, and cutting out some travel, and businesses can reschedule the use of their vehicle fleets and modify their collection and delivery patterns. The demand for cars travel, therefore, becomes more elastic in

relation to the new price. In the long term, people can change the type of car they use and their employment and residential locations, and industry can modify their entire supply chain. Taking a specific context, when considering the effect of general rises on commuter travel costs, the necessity of having to make journeys to work is likely to result in minimal changes in travel patterns in the short term, but over a longer period, relocations of either residence or employment may produce a more dramatic effect. This implies that one must take care when assessing elasticity coefficients and it is useful to remember that cross-sectional studies tend to offer estimates of long-run elasticity while time-series studies reflect short-term responses.

Elasticities are also generally found to increase the longer the journey under consideration. This is not simply a function of distance but rather a reflection of the absolute magnitude of, say, a 10 % rise on a \$5 fare compared with that on a \$500 fare. It is also true that longer journeys are made less frequently, and thus, people gather information about prices in a different way. Additionally, they often tend to involve leisure rather than business travel; this suggests that distance may be picking up variations in trip purpose. In the air transportation market, for example, DeVany (1974) found in a classic study that price elasticity rose from -0.97 for a 440-mile trip in the United States to -1.13 for an 830-mile trip.

Turning to the effects of income on travel behavior, while there is ample evidence that travel is a normal good in the sense that more is demanded at higher levels of income, this generalization does not apply to all modes of travel or to all situations. At the national level, income exerts a positive influence over car use, but this is not so clear-cut with public transportation use, and in some cases the latter becomes an “inferior good” with its use falling after some level of income has been attained. Gwilliam and Mackie (1975), for example, suggest that the long-run elasticity of demand with respect to income was of the order -0.4 to -1.0 for urban public transportation trip making in the United Kingdom. They argue that although car ownership rises with income, and hence some trips are diverted from public transportation, there is still a limited offsetting effect inasmuch as wealthier households make more trips in total. This effect would seem to be less relevant today with much higher levels of automobile ownership in developed countries, a fact borne out in the findings of Crôte et al. (2009) in the context of Mexico.

The income elasticity of demand for many other modes of transportation is seen to be relatively high, and especially so for modes such as air transport. Taplin (1980), for example, suggests a figure of the order of 2.1 for vacation air trips overseas from Australia. By its nature, air travel is a high-cost activity with the absolute costs involved being high even where mileage rates are low so that income elasticities of this level are to be expected. There is also some evidence that wealth influences the demand for air travel, with Alperovich and Machnes’s (1994) study of the Israeli market founding a wealth elasticity of 2.06.

As with price, income changes exert somewhat different pressures on travel behavior in the long run compared with the short. In general, a fall in income produces a relatively dramatic fall in the level of demand, but as people readjust their expenditure patterns in the long term, the elasticity is likely to be much lower.

Reza and Spiro (1979), for example, produce an estimate of 0.6 for the short-run income elasticity of demand for petrol rising to 1.44 in the long run. If one assumes that gasoline consumption is a proxy for trip making, then one could attempt to justify this in terms of a slow reaction to changing financial circumstances a reluctance, for example, to accept immediately the consequences of a fall in income. In fact, the situation is likely to be more complex because the long run may embrace changes in technology, and possibly locations, that alter the fuel consumption-trip-making relationship. Thus, these figures may still be consistent with the initial hypothesis regarding the relative size of short- and long-run income elasticities of demand for travel.

The demand for any particular travel service is likely to be influenced by the actions of competitive and complementary suppliers – the cross-elasticity effect. Strictly speaking, it is also influenced by prices in all other markets in the economy that touch upon the importance of motoring costs vis-à-vis the demand for public transportation services. There are wide variations in results that generally reflect the adoption of alternative estimation procedures and time-lag allowances, as well as the peculiarities of the local travel situation. One of the more interesting points is the almost total insensitivity of the demand for urban car use to the fare levels of both bus and rail public transportation modes. This fact, which has been observed in virtually all studies of urban public transportation, is the main reason that attempts by city transportation authorities to reduce or contain car travel by subsidizing public transportation fares have, in the main, proved unsuccessful.

Transportation demand is also sensitive to the quality of service offered, although measurement of relevant elasticities is challenging because many service attributes are essentially intangible and because of this are treated more as service qualitative. It is noticeable, for example, from empirical studies that public transportation demand is sensitive to changes in service quality attributes such as reductions in speed or frequency of services; other attributes that are often intuitively seen as important are not easily isolated. Lago et al. (1981) examined a wide range of international studies concerned with urban public transportation service elasticities and concluded that increased service levels do not generate proportional increases in passengers and revenues, but their analysis looked at service quality attributes in isolation rather than at a package of service features and missed many qualitative attributes. The survey also highlights that service quality is far more important when the initial level of service is poor; the general elasticities found for peak period ridership, for instance, are much lower than those for the off peak. Further, it found that the service headway is one of the more important service variables; the studies examined indicate an elasticity of -0.42 compared with -0.29 for in-vehicle bus travel time.

36.5 Using Travel Behavior and Travel Demand Information

Now we deviate a little from what is often contained in previous handbooks that are concerned with the “science” of analyzing travel behavior, and spend some time on

more practical matters of how research on travel behavior and demand is often applied. This is very much in the realm of regional political science, but germane to the context in which more positive aspects of the science of travel behavior and demand are treated. The implicit view of Milton Friedman (1953) on model performance can be recalled here, "The ultimate goal of a positive science is the development of a 'theory' or 'hypothesis' that yields valid and meaningful (i.e., not truistic) predictions about phenomena not yet observed." Simply producing a model of travel behavior that tells stories about the past is unlikely to be either useful or good science.

While there are numerous studies and texts on academic modeling of travel behavior in reality, the importance of this for regional science is just how useful the analysis is for forecasting. While there may be a historic interest in knowing why particular land-use patterns have emerged or why particular local industries have thrived, the main rationale for studying travel behavior and travel demand is to be able to use the information gleaned for policy development. This means understanding not only why the current demand patterns exist but also how they may change in the future. Most existing models can explain ongoing trends fairly well, and the importance of trend breaks to some extent but are poor at explaining new trends. The advent of real-time information systems and mobile communication platforms has, for example, added to the way people view trip making and the speed at which they change their travel plans. The switch to large-scale service sector employment is changing the perceptions of working hours. These were developments not foreseen 20 or so years ago when much of the thinking surrounding the then current travel behavior and demand models was emerging.

One of the main purposes of trying to get a handle on travel behavior and demand is to assist in policy-making, both in the public and the private sector. While there is a plethora of academic interest in trying to improve our understanding of why people travel and the nature of their trips when they do go into motion, there is somewhat less study of travel behavior by the private sector that provides hardware such as rail track and automobiles and software such as insurance or those that cater for some of the side effects of travel, such as medical services. Just reflecting on the last of these, changes in modes of road travel between public and private means affect the types of injuries associated with accidents and the incidents of ailments such as severe asthma. In terms of the automobile industry, the differing driving patterns of various age and income groups affect the demands for their models, as do social attitudes toward various modes of transport.

Aside from those directly involved in transportation, there are others with an interest in travel behavior, not least of which are the fiscal authorities. Transportation is both a large generator of taxation revenue and a major sump hole for subsidies. There are also matters of the demands of transportation users such as the military that are seldom considered within conventional academic modeling or at least the material that appears in the public domain.

Each group has an interest in a particular aspect of travel behavior. Transportation and land-use planners often want a longer view to assess the implications of fixed, often multimodal, infrastructure investments and their interactions with

economic and social development. The car industry is focused just on forecasts that lead to the commercial success of its products, and this involves a somewhat shorter time horizon. Most tax authorities do not often go beyond the myopia of trying to balance this year's books.

Following the greater academic herd, we focus on the types of demand analysis used in land-use transportation planning and policy-making. Here hard numbers are generally concerning the future use of links and nodes in the relevant transportation system. These are needed in particular for engineering design purposes and in the estimation of costing to ensure appropriate funding is available.

The situation is not a very satisfactory one, and despite the efforts of analysts, the poor quality of transportation forecasts used in the field has been known for some time. The 1970s saw considerable debate in the United Kingdom, for example, over inaccuracies in the forecasting of car ownership, a major input into traffic modeling, and of the traffic forecasts themselves in the 1980s. The forecasts for the M25 London orbital road, for instance, were that, on 21 of the 26 three-lane sections, the traffic flow would be between 50,000 and 79,000 vehicles a day in the 15th year of operation, whereas the flow within a very short time was between 81,400 and 129,000.

In the 1990s, a series of studies in the United States, including those by the likes of Kain (1990) and Pickrell (1992) brought into question the forecasts of transit ridership and financial costs of investments. Pickrell's study of programs funded by the United States Urban Mass Transportation Administration, for example, found that the ten projects examined produced major underestimates of costs per passenger (e.g., the costs for the Miami heavy rail transit were 872 % of those forecast, and for Detroit's downtown people mover, they were 795 %); only the Washington heavy rail transit project experienced actual patronage more than half of that forecast. Updating of this work and looking at cost and ridership forecast for 47 United States transit systems indicates only limited improvements over time (Button et al., 2010) when allowance is made for the composition of projects (e.g., light and heavy rail) and for whether an investment was in a strictly new system or an extension of an existing one.

More recently, a series of studies by Flyvbjerg et al. (2005) looking across a range of surface transportation forecasts have shown considerable inaccuracies extending to most western economies and provide confirmation of the poor performance of forecasts. There emerges, in particular, a tendency for overprediction of capacity utilization and underprediction of the outcome costs of investments – for example, for ten rail projects from a variety of countries, the passenger forecasts overestimated traffic by 106 %, whereas for road projects, there is a tendency for the forecasts to be wrong by about 20 % but with the errors spread equally around the ultimate flows. In terms of costs, an examination of 58 rail projects indicates overruns averaging nearly 45 % and for 167 road investments, overruns of 20.4 %.

It is not just the public sector decision-making per se that is often based on poor traffic forecasts. An American study by JP Morgan (1997) of 14 privately financed and operated toll roads found that only one exceeded the projected return, with four projects over estimating forecasting returns by at least 30 %. The overall conclusion being “reducing the uncertainty associated with these forecasts represent one of the

major challenges for transportation agencies, traffic consultants, investment bankers and investors.” In a study of over 100 international, privately financed road project appraisals conducted between 2002 and 2005, Bain (2009) concludes that “. . . in terms of error, the predictive accuracy of traffic models – used for toll road or toll free road forecasts – is poor.” Again there emerges a proclivity to overestimate traffic flows, with the ratio of actual to forecast traffic falling below unity for the majority of studies, although in some cases the predictions underestimated by up to 51 %. The accuracy of forecasts does not appear to have improved over time, although, of course, that is not to say that some have not proved to be very reliable.

Travel behavior and demand forecasts are a major factor in both the decisions to undertake investments and in their design; serious errors in foreseeing changing patterns of travel can thus result in misuses of resources across modes and probably between travel and other activities in the economies concerned. The problem may well, in fact, be considerably worse than the quantifications by Pickrell, Flyvbjerg, and others cited earlier, in that there is no way of knowing if forecasts of investments that were rejected were biased and instrumental in the rejections. If so, then resources that would have earned a social return in those projects would have been transferred to some other use where the net benefits are less. We only have data on the investments that actually materialized and relating to policies that have actually been adopted.

The difficulties that emerge, however, are only partly a function of strict forecasting errors; there are three broad and entwined reasons why travel behavior and demand forecasts are generally poor: technical problems of the type we have discussed, carrying out the forecast, and using the forecast. The last of these is very much in line with the public choice theory of economic science that focuses on rent seeking and coalitions of interest. Thus while we have tended to couch the discussion as normative issue, it could be reexpressed in positive scientific terms along the lines of Friedman.

Each facet of the problem however is not constant, is often entwined with another, and can vary with circumstances. Regarding the first, there is a widespread proclivity to look at the technical merits of the models being used, rather than their practical use as a forecasting instrument; elegance, sophistication, and the ability to backcast are often seen as criteria for a good forecasting model, whereas in many cases, forecasting exogenous variables is more difficult than predicting traffic flows however well the model fits historical data. There are, however, clearly challenges in the collection of the data needed to calibrate the parameters of the models needed to produce forecasts and in predicting even the short-term future path of many explanatory variables. Most forecasts rely on extrapolations of previous behavior, but divergences from historical relationships do occur and are often seen in wider institutional changes reflecting social priorities and attitudes to things like the environmental impacts of transportation, its safety, and its security. The use of such techniques as sensitivity analysis and simulations can provide some insights, but the range of possibilities, and thus the potential for error, increases as the length of the forecast period gets longer.

Availability of data is always a problem for forecasting travel behavior, and the situation may be getting worse. There are certainly better survey design techniques

and more ways to gather travel-related data ranging from online surveys to the use of global positioning systems for tracking movement. There is also evidence of improvements, although some may disagree, in our ability to produce reasonable medium- and long-term forecasting of such things as income, demographics, and fuel prices that feed into travel behavior projections. Against this, the move toward lighter regulation and privatization of travel facilities has changed and often reduced the public sources of data, and especially economic data, available to forecasters to carry out their work.

Despite these largely technical and operational challenges, the problems in forecasting accuracy would often seem to lie more in the way forecasting is actually done and the way results are used. A problem initially highlighted by Kain (1990) is that forecasts and travel behavior analysis are not politically neutral, and many decisions regarding transportation investments and policy are not made in the public interest, but to some degree serve the ends of those who are making or using them. Basically, the forecasting process and output can be seen as captured by those who commission the forecasts and then make use of them. These may be politicians who wish to win reelection and thus positively assess the short-term gains of supporting high-use/low-cost investments provided by some forecasts against other less “optimistic” projections, or they may be bureaucrats concerned with increasing public sector activities. Under some forms of government, and particularly federal systems, “pork-barrel politics” can incentivize the use of biased forecasts by local agents to gain central funding: a principal-agent issue. The system is, in strict terms, corrupt and even if forecasters are neutral in their work, this has little influence on the way their output is interpreted and used. Thus, to try and close the gap between forecast and actual outcomes is often seen as a matter of institutional reform, rather than better science (Wachs, 1990).

The forecasting problem should not be seen as being unique to the public sector; there are similar institutional issues when considering some forms of private sector forecasts, especially when they involve concessions. The incentive for those tendering for such things as build-operate-transfer projects, according to Bain, is to be optimistic with forecasts so as to win the contract and gain financial support. While the evidence for this practice is largely anecdotal in the case of tolled roads, there is more support in the context of airport concessions where *ex post* renegotiations are relatively common when traffic flows fall short of forecasts.

36.6 Conclusions

From an economic perspective, transportation is not at all special; when deciding whether to use it, people compare its relative generalized cost against the perceived potential benefits. As with most things, people are often disappointed because the benefits of the trip do not live up to expectation or the costs include elements they had not foreseen. From the point of view of assessing the impact of policies that change travel behavior on regional economic performance or local social conditions, it is the perceptions rather than the actuality, however, that are important.

Modeling of this, despite the veneer of simple mathematics that is often used as the language of debate, is far from easy, especially in terms of providing good forecasts of travel behavior to feed into regional analysis. The situation becomes even more complicated in practice because of the ways forecasts are used is not neutral but reflects a larger “political” process that itself needs to be modeled.

The progress that has been made in terms of the pure technique of travel behavior and demand modeling has, however, been significant in terms of moving away from what was essentially seen as a mechanical, engineering process to one that embodies an acceptance that human behavior is more complex and less systematic than the early analyses assumed. It has also become more integrated into larger regional and urban modeling, with interactive relationships largely replacing the idea of a recursive structure with land-use characteristics having a one-way influence on travel behavior, activity analysis being the most important element in this.

Abstract

Activity-based analysis (ABA) is an approach to understanding transportation, communication, urban, and related social and physical systems using individual actions in space and time as the basis. Although the conceptual foundations, theory, and methodology have a long tradition, until recently an aggregate trip-based approach dominated transportation science and planning. Changes in the business and policy environment for transportation and the increasingly availability of disaggregate mobility data have led to ABA emerging as the dominant approach. This chapter reviews the ABA conceptual foundations and methodologies. ABA techniques include data-driven methods that analyze mobility data directly as well as develop inputs for ABA modeling. ABA models include econometric models, rule-based models and microsimulation/agent-based models. This chapter concludes by identifying major research frontiers in ABA.

37.1 Introduction

Activity-based analysis (ABA) refers to treating individual actions in space and time as a basis for understanding human mobility and communication behavior and related systems such as cities, economies, and the physical environment. ABA is replacing aggregate trip-based approaches as the basis for forecasting and knowledge construction in transportation science and urban planning. ABA has long recognized advantages over trip-based approaches, not the least being theoretical validity. In addition, ABA can capture complex constraints and linkages that determine mobility better than aggregate, trip-based approaches. ABA also admits a wider range of policy variables, including non-transportation solutions to mobility problems.

Until recently, the data and computers did not exist to apply ABA to realistic scenarios. These limits have been shattered by increasingly powerful computers but especially by individual-level data available through wireless location-aware technologies embedded in infrastructure, attached to vehicles, and carried by people. These data are enhancing activity data analysis and modeling techniques. They are also leading to a new, data-driven approach to ABA based on exploratory analysis and visualization methods.

The next section of this chapter discusses the conceptual and practical foundations of ABA. It first reviews the traditional, trip-based approach and identifies key weaknesses. The activity-based approach resolves some of these weaknesses by treating mobility and communication not as disembodied flow but as humans conducting the activities that comprise their lives. The [Section 37.3](#) reviews policy and technological changes that are leading to advances and wider application of the ABA approach. [Section 37.4](#) reviews data collection and data analysis methods for ABA. The [Section 37.5](#) discusses activity-based models of travel patterns and urban dynamics using econometric, rule-based, and simulation methods. [Section 37.6](#) identifies ABA research frontiers.

37.2 Conceptual Foundations of Activity-Based Analysis

The past century of transportation science was dominated by a trip-based approach to understanding and predicting human mobility. This approach focuses on isolated acts of mobility as the primary object of study. A *trip* is a movement of a person, goods, and/or vehicle from an origin to a destination (possibly the same location) motivated by positive factors at the locations (push factors at the origin, pull factors at the destination) and attenuated by negative factors related to the cost of mobility between the directed pair. Each trip occurs independently of other activities and trips that occur during individuals' lives. People, events, and activities are atemporal; time is simply a component of mobility cost. Finally, the trip-based approach treats mobile entities not as unique objects but as undifferentiated flows between areas such as traffic analysis zones, postal units, or census geography (although it

can consist of subflows representing different cohorts) (Pinjari and Bhat 2011). Weaknesses of the trip-based approach include (McNally and Rindt 2007):

- No recognition that mobility derives from activity participation
- The treatment of mobility events as resulting from independent and generally unencumbered choice processes, simplifying the complex spatial and temporal constraints that delimit (and sometimes determine) choice
- A focus on utility maximization, neglecting alternate heuristics related to factors such as decision complexity and habits
- A neglect of the roles played by interpersonal relationships and information in influencing activity, mobility, and communication behavior, including *information and communications technologies* (ICTs)

The activity-based approach focuses on the individual and her or his need to participate in activities that have limited availability in time and space. Mobility is not fundamental but an epiphenomenon: it derives from the need to be physically present for many activities and the “inevitability of distance” between activity locations (Ellegård and Svedin 2012). Telepresence via ICTs can substitute for physical presence but can also complement physical mobility by providing more information about events and opportunities as well as capabilities for interpersonal interaction and coordination. Individual and joint allocation of scarce time is the meaningful starting point to understand activity, travel, and communication at all scales: from the tasks required to fulfill daily projects to the annual and decadal dynamics that affect cities, regions, and the planet (Pred 1977). Strengths of the activity-based approach are (McNally and Rindt 2007):

- Recognition that mobility derives from activity participation
- Explicit treatment of the complex temporal and spatial constraints on activity participation and mobility
- Flexibility to accommodate a wide range of decision processes and heuristics
- Explicit treatment of social organization, social networks, and ICTs that influence activity and mobility behavior

Table 37.1 summarizes major components of activity theory. As Table 37.1 illustrates, mobility – trips or tours – is only a component of a more expansive view of human behavior that includes activity patterns and scheduling as well as the social context that influence these activities.

The view that human activities in space and time are the meaningful starting point to understand and manage transportation, cities, and regions dates back to the time-use studies of Chapin (1974) and an influential paper by Jones (1979) that articulated the ABA framework in its contemporary form. But much of the conceptual foundation for ABA was developed by Torsten Hägerstrand in his time geographic framework (Pinjari and Bhat 2011; McNally and Rindt 2007).

Time geography underlies many of the core ideas in ABA, including an ecological perspective on human and physical phenomena, the need to build macro-level explanations from the micro-level and situating travel within a larger context, facilitating the recognition of non-transportation solutions to transportation problems. Basic time geographic concepts such as the individual trading time for

Table 37.1 Elements of activity theory

Element	Description
Activity	The main purpose underlying behavior conducted at a specific location and time interval; often classified as <i>fixed</i> versus <i>flexible</i> activities based on the relative ease of rescheduling and relocation
Activity frequency	The number of times an activity occurs during a given time period
Activity location	Geographic or semantic location where an activity occurs
Activity pattern	Set of activities to be conducted during a specific time interval
Activity schedule	Planned sequence and timing of activities to be conducted during a specific time interval
Time budget	Available time for mobility, communication, and activity participation during a given time interval; often expressed relative to flexible activities and constrained by fixed activities
Trip	Physical movement between activity locations
Interaction	Communication between individuals or locations
Tour	A multi-stop and often multipurpose trip involving several activity locations
Mode	Technique or service used to generate mobility and/or communication behavior
Activity space	Geographic region within which a set of activities occur; can be the composite of discrete activity locations or the smallest spatial region or subnetwork that encompasses the activity locations
Activity environment	Spatiotemporal configuration of activity locations within a given geographic environment
Household	Basic unit of domestic maintenance; influences activity participation through task organization, coordination, and sharing
Social network	Interpersonal relationships, both formal and informal, that influence activity participation
Lifestyle	Socioeconomic and demographic factors that influence activity, mobility, and communication behavior

space in movement among activity locations distributed in time and space may seem trivial since they are so close to everyday life experiences. But this is precisely the point Hägerstrand is making: we neglect seemingly inconsequential but critical factors in our scientific explanations of human behavior; the trip-based approach is an exemplar. Time geography provides a conceptual framework that obligates recognition of basic constraints underlying human existence, as well as an effective notation system for keeping track of these existential facts (Ellegård and Svedin 2012).

37.3 Policy and Technology Context for Activity-Based Analysis

Transportation scientists, engineers, and planners have long recognized the weaknesses of a trip-based approach with respect to validity and accuracy, and the potential of an individual-level, activity-based approach for better understanding and more accurate predictions of transportation and related

human–physical systems. However, until recently there has been little incentive for ABA in policy and planning. There was also little capability with respect to data and computing power.

The last century has witnessed an unprecedented explosion in human mobility due to the development of technologies and services such as steamships, railroads, private automobiles, and commercial aviation. In today’s world, people travel to a degree that would have seemed magical to our ancestors. While there are obvious benefits from mobility, there is also increasing recognition of its market failures such as congestion, poor air quality, accidents, sprawled cities, obesity, social exclusion, and global warming. High mobility levels are also increasingly under threat from aging infrastructure that is not being sufficiently renewed, increasing urbanization (especially in the Global South), and increasing motorization as newly emergent economies generate rising levels of wealth.

It is also increasingly difficult to separate mobility and communication behaviors. The telegraph, telephone, and the Internet have revolutionized communication, but these technologies were tightly coupled with location. The rise of mobile telephony and pervasive computing has liberated telecommunication from specific places, allowing it to be more integrated with people and their activities. This is creating tighter, more complex linkages between mobility and communication. Evidence indicates that the “Death of Distance” argument that geographic location would become irrelevant is naïve: communication complements as well as substitutes for mobility, leading to higher mobility demands at all geographic and temporal scales as well as greater complexity of mobility and activity patterns.

Increasing recognition of transportation market failures, threats to mobility, and the tighter integration of mobility and communication behavior have lead to new scientific, policy, and planning initiatives in Europe, North America, and increasingly elsewhere. The business and policy environment for transportation policy and planning is evolving beyond simple measures and prescriptions that focus primarily on measuring throughput relative to cost. There is wider consensus that mobility should be managed, not simply maximized. There is also recognition that evaluating transportation performance requires a fuller range of measures including indicators of effectiveness, equity, community livability, and sustainability. Planners have also realized that solving transportation problems requires thinking outside the system to the broader activity and communication patterns that drive complex mobility behavior. This may include non-transportation remedies for transportation problems (e.g., work flextime, different trading and service hours).

Approaching policy questions from the ABA perspective starts with underlying activity patterns, their interdependencies, and the potential rebound effects that occur from policy changes. [Figures 37.1a, b](#) provide a simple example (after Ben-Akiva and Bowman 1998). [Figure 37.1a](#) illustrates a daily activity pattern that includes being at home, working, stopping at a day-care center to and from work, and shopping for groceries. Implementing this activity pattern is a single tour from home to the day-care center and work in the morning, shopping in the late afternoon, stopping again at the day-care center and back home in the evening, mostly alone in a private vehicle.

Fig. 37.1 (a) Activity-based approach to policy analysis: before policy intervention. (b) Activity-based approach to policy analysis: after policy intervention

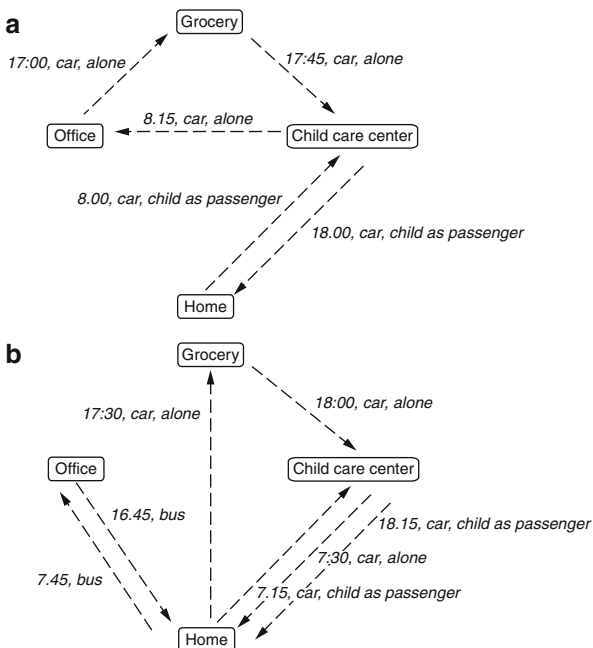

Figure 37.1b illustrates the outcome of a policy intervention: an employer-sponsored public transit incentive combined with higher parking costs. Implementation of the activity pattern now requires three home-based tours: trips to/from childcare center by car in the morning, commuting by bus to and from work during peak times, and shopping by private vehicle in the late afternoon with a stop at the childcare center on the way home. Is this new policy a success? A trip-based approach would likely reach this conclusion since it would focus on the commuting behavior and find a reduction in travel demand by private vehicle. However, an activity-based approach would be more likely to conclude that the new policy was a mixed success due to the shifting of travel and activity patterns and the increase in home-based trips by car. An activity-based approach would capture the linkages between these events and suggest that the transportation policy change should be accompanied by supportive, non-transportation policies such as incentives for day-care centers at work places and/or residential areas.

ABA is more challenging than a trip-based approach: the number of sequencing, timing, location, mode, and route choice possibilities for only a daily activity pattern is combinatorial. There are also a large number of household, social network, and informational linkages that determine daily, weekly, monthly, annual, decadal, and lifetime activity patterns. Activity-based comprehensive urban models also consider the reactions and dynamics of broader infrastructure, economic, sociodemographic, and political systems. Determining a meaningful boundary around the system being analyzed and the level of resolution for representing different components is critical. This requires judgment that considers the scientific

and policy questions being asked, as well as theoretical correctness and consistency (Ben-Akiva and Bowman 1998).

With respect to capabilities for ABA, digital data collection, storage, and processing costs have collapsed to an astonishing degree. *Location-aware technologies* (LATs), digital devices that can report their geographic location densely with respect to time, have become inexpensive and effective. They are increasingly embedded in vehicles and infrastructure and carried by people in consumer products such as smartphones. LATs are generating massive amounts of fine-grained data about mobility and communication dynamics as well as the dynamics of the broader social and environmental systems within which they are embedded. Computers are also much better at handling these data. In addition to dramatic increases in computing power, *geographic information systems* (GIS) and *spatial database management systems* (SDBMS) have evolved well beyond their origins in computer-based paper maps to include a wide range of tools managing, querying, analyzing, and visualizing dynamic and moving objects data. *Social media* available through mobile communication devices allow users to obtain better information transportation systems, share user-generated content, and even participate in management and governance.

New interdisciplinary fields such as *computational transportation science* (see <http://ctscience.org/>) are emerging to exploit data collection, processing, and communication capabilities to solve vexing and increasingly critical transportation challenges. Private sector companies such as IBM envision smarter transportation, smarter cities, and a smarter and more sustainable planet by collecting fine-grained sensor data, processing these data into meaningful metrics, and sharing this information widely to support more collaborative decision-making (see www.ibm.com/smarterplanet). There are critical privacy questions that must be resolved (discussed below), but these data and tools have the potential to revolutionize transportation science and planning from the “bottom up”: a new science and practice built from individual activities in space and time as the core concept.

37.4 Activity Data Collection and Analysis

ABA includes a rich suite of tools for empirical measurement and analysis of mobility and communication behavior. The conceptual origins for this approach are based in time geography, but this approach has been revolutionized by the rise of LATs and the availability individual-level mobility and communication data. These data can be analyzed directly for empirical patterns. They can also be used as inputs to ABA models, as well as in model calibration and validation. Data-driven methods are also used in *mobility mining*: open-ended exploration of moving objects data to search for novel hypotheses.

Space–Time Paths. The basic conceptual entity in ABA is the fundamental time geographic entity, the space–time path, and its extension, the space–time prism. The *space–time path* represents actual mobility (recorded or simulated) of an entity moving in geospace with respect to time. (A *geospace* is a low-dimensionality

Fig. 37.2 A space–time path among activity locations

space – usually three dimensions or fewer – where distances between location pairs represent shortest path relations in some real-world geography). [Figure 37.2](#) illustrates a space–time path between four activity locations in geographic space (the latter conceptualized as tubes with locations in space and extents in time reflecting their availability).

Semantically, the path is a continuous mapping from time to geospace. In practice, data are typically a sequence of sampled locations strictly ordered by time. Traditionally, these data were collected using recall methods such as travel–activity diaries, prospective methods such as experiments where study participants solve contrived activity and travel scheduling problems. These traditional data collection methods are fraught with problems, including nonparticipation biases, recall biases, and accidental or willful inaccuracies (in the case of travel diaries) as well as difficulties in creating meaningful scenarios (in the case of prospective methods). LATs such as assisted GPS technologies in smartphones allow more accurate and higher volume data collection to support space–time path reconstruction. However, this often comes at the expense of path semantics such as the context for the mobility episode including the planned and executed activities. Semantics can be recovered by overlaying paths with high-resolution georeferenced land-use and infrastructure data. This method can produce errors related to data inaccuracies and activity ambiguities (e.g., what is a person doing while in a coffee house – dining, working, socializing, or some combination of the above?).

The sequence of sample locations can be generated in several ways depending on the data collection method (Andrienko et al. 2008; Ratti et al. 2006):

- *Event-based recording*: Time and location are recorded when a specified event occurs; this is typical of traditional diary methods but also characterizes data

from cell phones, for example, a person calling from a mobile phone generating a location sample.

- *Time-based recording*: Mobile object positions are recorded at regular time intervals; this is typical of GPS and related technologies.
- *Change-based recording*: A record is made when the position of the object is sufficiently different from the previous location; this includes dead-reckoning methods as well as mobile objects database technologies that avoid recording some locations to manage data volume.
- *Location-based recording*: Records are made when the object comes close to specific locations where sensors are located; examples include radiofrequency identification and Bluetooth sensors.

The path must be reconstructed from the temporally ordered sequence of sample locations. The standard method is linear interpolation between temporally adjacent sample points. This requires the least amount of additional assumptions but admits physically unrealistic motions such as infinite acceleration and deceleration at sharp corners. Interpolation via Bezier curves generates a smoother, more physically realistic space–time path (Macedo et al. 2008; Miller 2005a).

Three types of error occur in space–time paths. *Measurement error* refers to error in the recorded location or timestamps. This is equivalent to the well-studied problem of measurement error in polylines in geographic information science. *Sampling error* refers to capturing a continuously moving object using discrete sampling. One way to deal with this is to treat the unobserved segments between sampled locations as an uncertainty region delimiting possible locations for the object between observations (Macedo et al. 2008). This is equivalent to another fundamental time geographic concept, the space–time prism, to be discussed below. *Combined measurement and sampling error* comprises the third type of space–time path error; this is equivalent to measurement error in a space–time prism since under these conditions the space–time prism is a sequence of linked, imperfectly measured space–time prisms.

Space–time paths contain many properties that are useful for understanding human mobility behavior. Analytical methods for paths include (Andrienko et al. 2008; Long and Nelson 2012):

- *Path descriptors* include both *moment-based descriptors* (such as the time, location, direction, and speed at any moment) and *interval-based descriptors* (such as the minimum, maximum, and mean speed; the distribution and sequence of speeds and directions; and the geometric shape of the path over some time interval).
- *Path comparison methods* allow quantitative comparisons among space–time paths, particularly with respect to geometric similarity in space–time and with respect to semantics (such as the sequence of locations visited). Methods include path distance measures such as the Fréchet distance and sequence measures such as least common subsequences.
- *Pattern and cluster methods* for identifying synoptic spatial–temporal patterns from large collections of mobile objects.
- *Individual-group dynamic methods* for characterizing collective movement behavior such as flocking, for example, methods that examine the relative motions among mobile objects.

Fig. 37.3 A planar space–time prism

- *Spatial field methods* for translating movement patterns of objects into fields or surfaces that summarize mobility and activity frequency by geographic location.
- *Spatial range methods* for identifying and characterizing the geographic area that contains the observed mobility of one or more mobile objects.

Long and Nelson (2012) provide a succinct but comprehensive review of these methods.

Space–Time Prisms. The *space–time prism* represents potential mobility: it delimits possible locations for a space–time path during some unobserved time interval. Figure 37.3 illustrates a planar space–time prism.

A prism can have two interpretations. As noted above, the prism can be an uncertainty region for an under-sampled space–time path. In contrast, Hägerstrand (1970) conceptualized the prism as a measure of space–time accessibility. The prism encompasses all locations that can be reached during the unobserved time interval given constraints on the object’s speed. Activities, conceptualized as tubes at specific locations with limited extent in time (see Fig. 37.2), must intersect the prism to a sufficient degree (at least as long as the minimal activity time) for the activity to be feasible for that person at that time and location.

The prism is difficult to state analytically over the entire interval of its existence. However, it is tractable to define the prism’s spatial extent at a moment in time as the intersection of only two of three simple spatial regions (Miller 2005a). It is also possible to define space–time prisms within transportation networks (Kuijpers and Othman 2009). Figure 37.4 illustrates a network time prism: the figure illustrates the accessibility locations within the planar network and the corresponding

Fig. 37.4 A network time prism

spatiotemporal region comprising the complete network time prism. In addition to being the envelope for possible space–time paths, these paths also give the prism an internal structure, including unequal visit probabilities within the interior (Winter and Yin 2011).

Prisms contain error propagated from the measured space–time anchors and object speed limits. Error distributions can be numerically generated through Monte Carlo simulation: generate many realizations of the prism and analyze the resulting data. This is a tractable approach for theoretical investigation but is not scalable to practical applications. Alternatively, it is possible to derive analytical characterizations of prisms and prism–prism intersection error in planar space using spatial error propagation theory and implicit function techniques applied to the intersection of circles and ellipses. However, some intersection cases are still open, and it is not scalable beyond pairs of prisms. Required is further investigation into tractable error approximations based on spatial error propagation methods (Kobayashi et al. 2011). More tractable are uncertain network time prisms based on spatiotemporal probability regions (not necessarily connected) for anchor locations and times within the network (Kuijpers et al. 2010).

Prisms can be used as inputs to activity models, in particular choice set or feasible activity set delimitation. Prism-based measures provide vividly different portrayals of accessibility across social, gender, and cultural dimensions relative to traditional place-based measures that tend to mask these differences (Kwan 1998). Prisms can capture activity time constraints within accessibility measures that are consistent with spatial choice, spatial interaction, and consumer surplus theory (Miller 1999).

Path–prism and prism–prism intersections represent potential interaction between two mobile objects. Both can be solved in planar space for a moment in time (Miller 2005a). Scalable techniques also exist for network prism intersections (Kuijpers and Othman 2009). Prism–prism intersections are also useful for capturing the possibility of joint activity behavior in activity-based measures and models (Neutens et al. 2007).

The space–time prism focuses on physical accessibility in geographic space or transportation networks. Path and prism concepts have been extended to encompass interactions within cyberspace (the virtual space implied by networked ICTs). Interaction and accessibility in cyberspace can be treated as direct relationships among space–time paths and prisms (Yu and Shaw 2008) or as indirect relationships mitigated by access to communication technologies (Miller 2005b). It is also possible to treat the STP as existing in a hybrid geo/information space (Couclelis 2009).

Mobility Mining. Increasing capabilities for collecting and processing mobile objects data is leading to the emergence of *mobility mining* as a new area of research. Mobility mining leverages mobile objects databases with advances in data mining techniques to create a knowledge discovery process centered on the analysis of mobility with explicit reference to geographic context. Mobility mining involves three major phases (Giannotti and Pedreschi 2008):

- *Trajectory reconstruction* from raw mobile objects data. The basic problem was discussed above; the specific problem in this context is to reconstruct trajectories from massive mobile objects data, especially when the data are collected using different methods and sampling methods/rates. This may involve preprocessing steps such as data selection, cleaning, and integrating with other geographic and sociodemographic data.
- *Pattern extraction* involves using spatiotemporal data mining methods to discover interesting (novel, valid, understandable, and useful) patterns in the reconstructed trajectories. Types of patterns include clusters, frequencies, classifications, summary rules, and predictive models.
- *Knowledge delivery* involves verifying and interpreting the discovered patterns, integrating these patterns with background knowledge and communicating this information to support scientific and applied decision-making.

Mobility mining and knowledge discovery from mobile objects databases are hypothesis-generation processes that should lead to more focused and conclusive investigation. These techniques and processes play roles in the scientific process similar to instrumentation such as a telescope, microscope, or supercollider: it allows analysts to see empirical phenomena that would otherwise be obscured or difficult to detect. Empirical patterns discovered during the data mining process are tentative until they have been verified using confirmatory statistics and interpreted in light of background knowledge and theory.

37.5 Activity-Based Modeling

Although theoretically and evidentially suspect, the trip-based approach offers a significant strength, namely, it is relatively straightforward to build scalable comprehensive models of transportation and urban systems that are easily calibrated, verified, summarized, and mapped. It is more challenging to build, verify, and digest comprehensive models built from the micro-level. LAT-based data, geometric growth in computing power, and the hard work of some very smart

people are making activity-based models more realistic, powerful, and understandable. Consequently, ABA is being increasingly applied in policy and planning analysis in Europe, the United States, and other locations.

Depending on the system being modeled, activity-based models can encompass a large number of decision variables over a wide range of temporal and spatial granularities and time frames. In addition, activity-based models are often components in broader comprehensive urban models and linked human–physical process models. Possible components of activity-based models include (Ben-Akiva and Bowman 1998):

- *Activity implementation* involving the execution and possible rescheduling of activity, travel, and communication plans based on empirical conditions in real time. This includes decisions such as mode and route choice, but also fine-grained context-specific behaviors such as speed, acceleration, merging and car-following behavior in automobiles, bicycling behaviors such as obeying stop signs, and pedestrian behavior within crowded environments.
- *Activity scheduling* includes activity selection, activity assignment within household and other social networks, activity scheduling, selection of activity locations, and methods and times for mobility. These events occur frequently and regularly at time scales ranging from real time to hourly, daily, weekly, monthly, seasonally, and annually.
- *Sociodemographic systems* include work, residence, ownership, and other life-altering personal, social, and economic decisions and events such as having children or buying a bicycle. These occur infrequently at the scales from annual to decadal.
- *Urban, social, and economic systems* include the infrastructure, services, institutions, and social and built environments that influence implementation, activity, and lifestyle decisions. These systems operate from real time (e.g., traffic conditions) through annual (e.g., housing dynamics) to decadal and beyond (e.g., compact versus sprawled cities).
- *Physical systems* include material, energy, hydrologic, biological, atmospheric, and other environmental systems that affect and are affected by the other activity domains. These operate in real time (e.g., air quality) to geologic (e.g., climate change).

Activity-based models slice, dice, and combine these components in different ways depending on the modeling domain and scope, as well as the strengths and weaknesses of the particular technique. Major types of activity-based modeling techniques are (i) *econometric models*, (ii) *optimization methods*, (iii) *computational process models*, and (iv) *microsimulation and agent-based models*. Some of these approaches can also be used in combination, for example, econometric models as a component of a larger microsimulation model or a computational process model used to derive agent behavior in an agent-based model.

Econometric Models. Econometric models are among the oldest activity-based modeling strategy, resulting from extending trip-based econometric models to encompass activity choice and trip-chaining behavior. These models have their foundation in the microeconomic theory of consumer choice. They require

Fig. 37.5 Nested logit representation of activity-travel behavior

specifying relationships between individual attributes, environment factors, and activity-travel decisions in the form of a utility function whose parameters are estimated from empirical data, assuming utility-maximizing choices. Econometric models of activity-travel behavior are often in the form of discrete choice models such as multinomial and nested logit models. [Figure 37.5](#) provides an example of a nested logit representation of activity-travel behavior (after Ben-Akiva and Bowman [1998](#)). Other nesting structures are possible depending on what activity facets are being analyzed. More elaborate econometric structures are also used, such as structural equations, hazard-based duration models, and ordered response models (Ben-Akiva and Bowman [1998](#); Pinjari and Bhat [2011](#))

Advantages of econometric models are a rigorous theoretical foundation and mature methodologies for model specification, calibration, and validation. Weaknesses include the empirically suspect assumption that individuals are perfectly rational utility maximizers and the lack of an explicit process theory to describe the activity-travel decision-making (Timmermans et al. [2002](#)).

Optimization Methods. Finding an ideal activity pattern based on criteria such as time, cost, and utility is similar to the problem of finding optimal tours through a transportation network with scheduled pickups and deliveries (Recker [1995](#)). There is a large literature in operations research and management science on problems such as assignment, scheduling, and routing subject to time windows.

These are complex combinatorial problems, but computational search methods have become very sophisticated and powerful. This is a normative approach: the idea is not to replicate real-world behavior but rather generate ideal patterns that can be used as benchmarks for evaluating real-world behavior with respect to efficiency. These comparisons can help identify empirical factors and heuristics that cause people to deviate from ideal patterns.

Rule-Based Models. *Computational process models* (CPMs) are a system of action–condition pairs (semantically expressed as “if–then” rules) that describe the activity–travel decision process in some empirical domain. Decision rules are often organized according to different subcomponents of the activity system. However, most CPMs focus on activity scheduling and implementation (e.g., Recker et al. 1986). Rules can be derived informally from intuition and knowledge based on previous research. Rules can also be inferred from empirical data using data mining techniques such as decision tree induction and association rules (Arentze et al. 2000).

CPMs are highly flexible, allowing a wide range of heuristics that better represent decision-making in the real world. However, a weakness is the difficulty in enumerating the large number of rules required for even for a modest activity scheduling and implementation problem. CPMs also do not have a mature theory and techniques for testing variables and distinguishing between good and bad models (Buliung and Kanaroglou 2007; McNally and Rindt 2007).

Microsimulation and Agent-Based Models. Microsimulation and agent-based models are computer-based methods for predicting the evolution of a complex system. *Microsimulation* refers to the computer-based modeling phenomena at the disaggregate level to better understand complex dynamics at the aggregate level. Microsimulation has a long tradition in social science, dating back to attempts to modeling the US economy in the 1950s with household and firm behavior as the fundamental units. Microsimulation models tend to fall into two categories. *Static models* typically rely on cross-sectional data and result in no change to the structure of the cross section (e.g., internal composition, sample size) as the model executes over time. *Dynamic models* rely on cross-sectional or longitudinal data and produce changes to the total number of micro-units. Dynamic models are used to forecast and track modifications of entities over longer time periods than static models (Buliung and Kanaroglou 2007).

Agent-based modeling (ABM) is closely related to microsimulation but has a stronger conceptual foundation. ABM views systems as collections of autonomous, adaptive, and interacting agents. An agent is an independent unit that tries to fulfill a set of goals in a dynamic environment. An agent is autonomous if its actions are independent (i.e., makes decisions without an external controlling mechanism) and adaptive if its behavior can improve over time through a learning process. Agents interact by exchanging physical resources and information and/or by reacting to presence or proximity. ABM describes a system from the perspective of its constituent units’ activities; this is appropriate when individual behavior cannot be described adequately through aggregate rules and activities are a more natural way of describing the system than processes (Bonabeau 2002).

The distinction between microsimulation, ABM, and rule-based techniques discussed previously can be vague, particularly in practice. Rule-based methods can be used to drive agent behaviors and microsimulations, and agents can be a central component of broader microsimulation models (e.g., Arentze et al. 2000). It is also possible to link these models with dynamic microscale traffic models to simulate the interrelationships among transportation demand, transportation system performance, and activity scheduling/implementation (see Bekhor et al. 2011).

Advantages of microsimulation and ABM include the explicit representation of micro-level behaviors and processes, the ability to develop and test behavioral theory, better understanding of macro-level processes produced by individual-level behaviors, maintaining the heterogeneity of information (such as individual identity) during simulation, minimization of model bias, better policy sensitivity, integration of processes operating at different temporal scales, and improved model transferability (Buliung and Kanaroglou 2007). Disadvantages include a lack of mature methodologies for calibration and validation, although these models lend themselves to expert engagement and judgment better than traditional, analytical models (Bonabeau 2002). It can also be difficult to make sense of microsimulation models and ABMs: these methods essentially generate a large dataset that must be explored and analyzed. This can be challenging since good scientific practice requires a careful experimental design for parameters that are not empirically derived. The design should vary parameters systematically while holding others fixed to assess the simulation outcomes, often with multiple simulation runs for each parameter combination to eliminate artifacts from random number generators. This can generate a huge amount of simulated results, particularly if there is a large number of parameters and parameter levels to explore.

37.6 Frontiers in Activity-Based Analysis

Much progress has been accomplished in ABA; this progress is likely to continue as favorable policy, computational, and data environments help scientists and practitioners propel it forward intellectually. This section briefly discusses major research frontiers in ABA.

Social Networks. Social networks are at the heart of time geography and ABA: space–time paths bundle to conduct shared activities, prisms intersect to allow this possibility, households are a fundamental unit for activity organization and sharing, and activity coordination and adjustments cascade through broader activity and social systems. Time geography and ABA are an ecological approach to transportation, cities, and societies with a complex web of interconnections (Pred 1977; Ellegård and Svedin 2012). Capturing the social network influences on activity, mobility, and communication behavior is a very active frontier in ABA (Neutens et al. 2008).

A major challenge in capturing social networks in ABA concerns basic definition, measurement, and data collection. Social networks can range from a few intimate individuals to hundreds of Facebook friends. The problem is that all of

these networks are relevant to activity behavior depending on the context. Measuring social networks is also difficult, particularly more genuine and enduring networks. Social influence within these networks can also vary depending on formal and informal relations. Finally, social networks have complex topologies such as Small World configurations that can generate complex dynamics.

LATs and social media can inform social networks in ABA. As mentioned above, path–path, path–prism, and prism–prism relationships indicate the possibility of social interaction, and methods for collective mobile objects data analysis are improving. Problems include dealing with coincidental proximity (e.g., friends versus strangers in a coffeehouse) and activity ambiguity (e.g., a coffeehouse again). Location data error is also a challenge: this can be substantial for some LATs in some environments (e.g., GPS receivers in city centers, cellular network location in rural areas).

Social media are convincing millions of people to share details of their lives online. The implications of these data for understanding and predicting activity, travel, and communication behavior should be obvious, including that people use these media to plan and coordinate activities. Challenges include nonrepresentation biases and unstructured data. Social media participants are not scientifically sampled, nor do people share everything about their lives (with some notable exceptions). Nevertheless, the massive size of these databases makes them valuable. Social media data are also unstructured: nonquantitative data such as text and imagery. Intriguingly, these data are increasing georeferenced due to social media applications in smartphones. One way to treat these data is from a mobility mining perspective: use social media data to generate hypotheses that can be tested with more focused, confirmatory techniques and scientifically sampled or experimental data.

Unfortunately, access to LAT and social data can be circumscribed due to proprietary and competitive reasons. This has the danger of leading to a computational approach that will revolutionize the social sciences but only as practiced in private sector companies and secret government agencies (Lazer et al. 2009).

Big Data and Knowledge Delivery. Big Data refers to data that has *high volume* (massive databases with millions of records), *high variety* (structured and unstructured data), and *high velocity* (often in real time). The Big Data mantra is to keep all of these data since they may be useful; the astonishing collapse in data storage costs over the past two decades makes this possible. In many locations in the world, we are moving toward sensed transportation systems with sensors embedded in infrastructure and vehicles, as well as high-resolution but remotely positioned sensors such as LiDAR. These data combined with consumer LAT data and social media will generate orders of magnitude more data about transportation and cities than currently exist.

A previous section of this chapter discussed the role of mobility mining in ABA. Research frontiers include not only dealing with massive transportation, mobility, and communication data but delivering actionable knowledge to decision-makers sufficiently fast, so they can act before the knowledge is irrelevant. This is a challenging frontier that involves elements of exploratory and confirmatory analysis as well as decision support.

Big Data also has the potential to create more collaborative transportation and social systems. This is a major motivation behind IBM's Smarter Planet initiatives. Collaborative transportation systems can range from ride/vehicle sharing to long-term strategic decision-making about transportation and urban futures. The challenge is to create not only the knowledge delivery techniques discussed in the previous paragraph but also the tools and environments for sharing, collaboration, and collective governance.

Locational Privacy. The benefits of an ABA reinvigorated through more data and computational power may not be realized if there is a public backlash due to abuses of these data. *Locational privacy* is the concept that the space–time signature that comprises activity patterns can reveal much about a person and her/his activities. This is a fundamental change: as the United States Supreme Court commented during a recent decision, LATs provide not isolated facets but a person's entire life.

Locational privacy protection strategies include *regulation*, *privacy policies*, *anonymity*, and *obfuscation*. Regulation and privacy policies define unacceptable uses of location data. Anonymity detaches locational data from an individual's identity. Obfuscation techniques degrade locational data through deliberate undersampling, aggregation, introducing measurement error, or some combination of the above. Scientific challenges include new research ethical protocols for dealing with location data, especially user-generated content and remote but high-resolution sensors that can reveal things and activities that were previously considered private. Another scientific challenge is dealing with deliberately degraded locational data; spatial and spatiotemporal error methods for mobile objects data are still lacking to a large degree. More generally, societies need to have conversations about the acceptable and unacceptable uses of these data if their role in building better transportation systems and communities is to continue its remarkable progress.

37.7 Conclusion

Activity-based analysis (ABA) is emerging as the dominant approach in transportation science and planning (Timmermans et al. 2002). It is a theoretically sound approach to transportation, cities, societies, and human–physical systems that focuses on a person's activities in time and space as the foundation. Changes in policy are encouraging a wider view of transportation, and the increasing availability of individual mobility data and scientific advances inspired by this favorable environment are making ABA methods scalable to realistic scenarios and problems.

Data-driven methods allow high-resolution measurement of fundamental ABA entities such as the space–time path (representing actual mobility) and the space–time prism (representing potential mobility, interpreted as path sampling error or space–time accessibility). There is a wide range of methods for measuring, comparing, and summarizing collections of space–time paths, but fewer methods for the space–time prism. These data can be used for empirical investigation, mobility data mining, and as inputs to ABA modeling.

ABA models attempt to solve or simulate activity behavior. Most models focus on the activity scheduling and implementation problems. These ABA core models can be linked with transportation system performance models to capture the dynamics of mobility demand and system response. These core models can also be embedded in broader models of cities, sociodemographics, and physical systems such as airsheds. Major modeling approaches include econometric models, optimization methods, computational process models, and microsimulation/agent-based models.

There are several ABA research frontiers; these include social networks, delivering knowledge in the face of Big Data, and location privacy. Progress along these frontiers will support the continuing rise of ABA in understanding and planning transportation and related systems.

Acknowledgments Dr. Walied Othman (University of Zurich) provided the Mathematica code to generate the network time prism (Fig. 37.4); this is available at <http://othmanw.submanifold.be/>. Ying Song (University of Utah) generated some of the graphics. Ying Song and Calvin Tribby (University of Utah) provided valuable comments on this chapter.

Abstract

This chapter begins with a discussion of how communications technologies have reduced the influence of distance on the location of economic activity. The origins of network analysis in regional science are described. The importance of social networks and social network science in sociology and related disciplines during the 1970s, 1980s, and 1990s is explained. This is followed by a discussion of new discoveries concerning the structure of the Internet that took place in the late 1990s. The rise of social media, the continued development of social network science, and the popularity of social network sites such as Facebook, Twitter, and LinkedIn in the new millennium are then depicted

“I almost wept when I awoke, and found that you had appeared to me in Time and not in Space, alas!” Thomas Hardy, *The Woodlanders*.

38.1 Introduction

Today, there can be little doubt that much economic activity is taking place on and because of social networks (SNs). However, the more interesting questions that we will consider in this chapter are the following: What aspects of SNs influence these activities, and do SNs affect previously established patterns of spatial activities and spatial interaction? Do they reflect and support existing geographical patterns, or do they create new geographies due to a weakening of the influence of distance?

From its earliest days, regional science (RS) was seen as an interdisciplinary activity that privileged a spatial and analytical approach to the social sciences, emphasizing location theory and spatial economics. The influence of physical, geographical distance and its impact on transportation costs and, more specifically, the location of economic activity were developed from the earlier work of many of the *German theorists* of the nineteenth and early twentieth centuries including von Thuenen, Alfred Weber, Walter Christaller, and August Losch (for a review of the work of each of these authors, see the classic economic geography text by Smith et al. 1969). Interest in networks was confined to physical transportation network canals, roads, railroads, and subsequently airline networks. Always distance and the physical separation of economic activities lay at the core of location theory.

Beginning in the 1990s, a trio of mutually supportive technologies, namely, the Internet, social media, and social networks, began to weaken the influence of distance leading to such phenomena as globalization and the increased integration of national economies through the expansion of multinational corporations. The influence of these and earlier technologies, including the telex and telephone, was discussed in popular texts such as *The Death of Distance* (Cairncross 2001). Cairncross clearly overstated the case by arguing that distance no longer mattered in terms of the location of economic activity and the strength of social interaction between locations but that it mattered less was beyond debate. Other researchers (Rietveld and Vickerman 2004), at least in the case of the influence of transport costs in regional science, have demurred from this view, suggesting that this supposed death of distance is “premature.” The question as to which view is most appropriate in the case of SNs remains ambiguous.

In this chapter on SNs and regional science, we will consider the development of a network science, the development of social media, the rise of social networks such as Facebook, the development of social media as a marketing tool, and the current state-of-the-art in determining just how important distance remains in a regional science that makes use of social network databases.

38.2 The Origins of Network Science in Regional Science

In the 1950s and 1960s, geographers and regional scientists were well aware of each other's research. Indeed the seminal works of von Thuenen, Weber, Christaller, and Loesch, mentioned above, were equally prominent in the research of both North American and British regional scientists and geographers. This work was subsequently codified and organized into a coherent argument in Haggett and Chorley's (1969) text: *Network Analysis in Geography*. Haggett and Chorley's summary and the research on which it was based emphasized the topological properties of networks and in particular both the structure of the network as a whole and the importance of nodes within the network as expressed by the number of their immediate connections in the network and their centrality within the network.

While this text was well received and indeed with its explicit discussion of *graph theory* laid the foundation for a network science, little further work on the topological structure of transportation networks occurred in the ensuing years, and for many regional scientists, this line of research appeared to have reached a natural conclusion with little promise of further insights (Waters 2006).

38.3 The Dark Ages of Network Science and the Resurgence of the 1990s

Regional scientists and geographers paid scant attention to network science in the decades that ensued, that is, throughout the remainder of the 1970s, the 1980s, and into the 1990s. This was not true of all the social science disciplines and sociology, especially, saw the importance of continued research in the analysis of the topological properties of social networks. During this time, there was a rapid, exponential rise in Sociological Abstracts that used the term "social network" in their abstract or title between 1970 and 2000. Important summaries of the state-of-the-art of social network analysis (SNA) in the social and behavioral sciences were provided by Scott (1992) and by Wasserman and Faust (1994). The latter authors included a review of the SN literature from the 1950s to the 1990s, a discussion of the methodologies and mathematics of SNA, and an appendix of software packages.

Scott (1992) provided a relatively complete synopsis of the subject of SNA within the discipline of sociology, noting that SNA had been used in various sociological studies including network studies of the financial powers among bank directors, social mobility, kinship and class structures, contacts in gangs

and other outlaw societies, and even science citations. Much of this work evolved from the research of *Harrison White* and his graduate students in the Department of Social Relations at Harvard University in the 1960s and early 1970s. These students included Stanley Milgram and Mark Granovetter, two of the most influential contributors to the SN literature. In 1969 Milgram and a colleague published a seminal article on *The Small World Problem* (Travers and Milgram 1969). It was here that he popularized the notion that everyone was connected by an average of “six degrees of separation,” an idea that was to have a major impact on subsequent SN research (see below). Granovetter’s original paper on *The Strength of Weak Ties* (Granovetter 1973) first identified the importance of “bridges” between tightly knit clusters within social networks, and this also became one of the most widely cited references in the SN research literature.

White’s students spread out across North America, accepting appointments in leading universities and establishing productive SN research centers. A journal, *Social Networks*, and an influential, peer-reviewed newsletter, *Connections*, published by the International Network for Social Network Analysis, were quickly established.

Scott’s original handbook (1992) provided a complete guide to SNA describing the history of the subdiscipline in sociology and then the representation of SNs as graphs or *sociograms* with links or ties to the nodes or points that represented the individuals that were connected with each other. Scott also gave detailed descriptions of methods for the storage of SN data and of measures of centrality of individuals within the network and the importance of nodes (individuals) that linked together network clusters (Granovetter’s bridges).

Scott (1992) reviewed existing software packages for conducting SNA including *UCINET* from the University of California, Irvine, and the *PAJEK* software that was specifically designed to handle large data sets such as those that were then beginning to emerge on the Internet. *UCINET* and *PAJEK* have remained two of the most popular software packages for SNA and SN visualization. Recent lists of SNA software may be found in the many new texts that are constantly appearing in this widely researched field (e.g., Scott’s new handbook (Scott, 2011) and references cited below). It should be noted that many of the analytical procedures discussed in the texts by Scott and by Wasserman and Faust were minor developments of earlier procedures. These included measures of nodal importance such as the degree of a node (namely, the number of ties attached to it) or measures of centrality (i.e., variations of measures designed to assess a node’s position within the network’s topological structure). Other analytical procedures were extensions of multivariate techniques such as cluster analysis, principal component analysis, and multidimensional scaling that had been applied to networks in the 1960s and 1970s (Waters 2006). What *was* new was the ability of these software packages to collect and store the enormously large, Internet-based data sets and to visualize the structure of these networks in an informative and intuitively pleasing manner.

38.4 Network Science at the End of the Millennium: New Findings

Toward the end of the 1990s, a series of papers (Watts and Strogatz 1998; Barabasi and Albert 1999) showed that many networks that exist in the natural world and also in socially constructed environments such as the World Wide Web exhibited the so-called *small world phenomenon* demonstrated in Milgram's experiment three decades earlier. Networks with large numbers of nodes were found to have surprisingly small average path lengths due to the fact that a small percentage of nodes had a large number of connections, that is, a high "*degree*" number. These nodes acted as hubs or bridges providing shortcuts across the topological structure of the network. The degree frequency distribution was shown to follow a *power law* or *Pareto distribution* with a so-called *heavy tail*. Barabasi and Albert (1999) referred to such SNs as being *scale-free* or *scale invariant*, and they argued that this arose due to *preferential attachment* where the probability of attaching to an existing node was proportional to its degree.

Pareto distributions and the *rank size rule* for city size distributions have long been observed to be of great significance in the physical world of regional science with new mechanisms for the emergence of power laws in urban systems and elsewhere being suggested by Reed (2001). However, it should be noted that more recently Willinger et al. (2009) have challenged what has been described as the "*scale-free Internet myth*." The scale-free myth has resulted in observations that such networks are robust to random failures because these are likely to occur at nodes with low-degree connectivity (because they are more common) and sensitive to targeted attack, such as terrorist activity, because such attacks would focus on the high-degree hubs. Willinger et al. (2009) argued that much of the work used to establish the scale-free myth was flawed in its collection and sampling design and then demonstrated that if the construction of an Internet router network is conceived as a constrained optimization problem in which traffic is distributed as a gravity model (well known to regional scientists), then preferential attachment models become irrelevant. High degree variance is simply a result of high variance in demand for bandwidth. Adding to the debate, Strogatz (2005) notes that there may be so many paths to the realization of a power law scaling that in the absence of other explanations these observations may simply be "all sound and fury" and signify "nothing" or alternatively, as in the case of city size distributions, it is often the deviations from the model, such as primate cities, that are truly interesting.

Markoff and Sengupta (2011) describe a recent study of 721 million Facebook users where the average degree of separation was 4.74, but when the results were restricted to the USA, the average separation dropped to 4.37. This research is important in regional economics because it emphasizes the global reach of SNs, the density of connections, and the linkage of clusters that allows for those engaged in Internet commerce to extend their reach with minimum marketing costs. Furthermore, the short paths linking everyone to everyone else in these very "small worlds" may well explain why ideas and products can go "viral" with such rapidity and why it is attractive for those engaged in both enforcement and insurrection alike to use the power of SNs for their own goals.

A mechanism for the ever-decreasing number of ties or links from one member of an SN to another has been suggested by the experiments of Watts et al. (2002). They suggest that SNs are becoming increasingly “searchable,” that is to say individual users are becoming more and more able to direct messages through networks to targeted individuals. If this is true, then it is also likely to be even more feasible for businesses also to take advantage of the inherent characteristics of SNs for economic gain. For this to be the case, the SNs used in the experiments designed by Watts et al. were endowed with the following characteristics that would appear to be plausible for real-world SNs. First, individual users had specific characteristics that allowed them to form groups; second, these groups were hierarchically organized; third, the groups themselves were the basis for social interaction; fourth, individuals were hierarchically clustered in more than one dimension, for example, by occupation and geography, and these dimensions were independent (perhaps not altogether a realistic assumption); fifth, individuals constructed a measure of *social distance* between themselves and others based on their perceived similarity over all dimensions (a global pseudo or structural distance); and sixth, individuals forwarded a message only to their direct connections within the network. For the experiment, parameter choices were made consistent with the inferred SNs in Milgram’s original experiment. The model, which is applicable to all peer-to-peer communication systems, was shown to yield results that are statistically indistinguishable from those of Milgram, though whether this guarantees that they are similar in other respects is open to question.

Connections, represented by SN ties, are important because they determine the structure of the network. Also the characteristics of ties are variable. They may be professional or social or they may be permanent or ephemeral. Equally important is *network contagion* or sharing because this relates to what passes across a network – information, ideas, money, product (digital or otherwise), disease, life-style, and happiness, among many others. According to Christakis and Fowler (2011), connection and contagion are governed by the following five rules.

Rule one relates to the fact that SN users shape and, indeed, constantly reshape their network. Usually we connect to others that are like us in terms of socioeconomic characteristics such as income, education, ethnicity, and language, among others. This is known as *homophily*. Socially, these others are likely to live nearby and thus be highly spatially autocorrelated reinforcing existing patterns of economic activity. Professionally, this is less likely to be so and this will have novel impacts on economic activity, enhancing, for example, tendencies toward globalization. SN users have considerable choice in terms of how they structure their connections including how many people they connect to and how dense are their connections and, to some degree, their centrality within their network. It is also important to note that some individuals will connect late or not at all. These are the “laggards” and nonparticipants, and it is just as important to be aware of their attributes and characteristics. Rule two states that our place in the network, our immediate connections and degree of centrality, affects our social and economic behavior. Rule three is closely associated for it states that our friends, our immediate connections, affect us. If they are happy, then we are likely to be happy too;

if they are obese, then we will have that tendency as well. Not only that but rule four states that this influence extends also to our friends' friends and even more surprisingly to our *friends' friends' friends* (three degrees of separation), after which the effect peters out. Christakis and Fowler (2011) have documented the impact of these rules in a series of pioneering studies explaining their effect on the spread of obesity, the spread of happiness, and the dynamics of smoking. Rule five relates to the emergent properties of the network itself. Thus, the network, which in these cases is referred to as an *excitable medium*, may develop properties that none of its members is aware of initially. This may occur with flash mobs, insurgent activities, or in disaster management.

38.5 The New Importance of Social Media

For our purposes, we define social media (SM) as the all-encompassing concept within which social networks are included. Kaplan and Haenlein (2010) provide a brief history of the development of social media and a definition that distinguishes social media from the related concepts of *Web 2.0*, *user-generated content*, and social networks. According to Kaplan and Haenlein, the history of social media has its earliest origins in 1979 with the development of Usenet by Tom Truscott and Jim Ellis. This system allowed for the posting of messages and thus a "society" of users, but although popular and still in use, it was not until almost 20 years later that the SM era really took off with the development of Open Diary by Bruce and Susan Abelson. This was followed by what was initially known as web logging which was almost immediately abbreviated to blogging. Eventually these activities were to spawn social networking sites such as MySpace and Facebook, founded in 2003 and 2004, respectively. These types of SM activities relied on both the development of Web 2.0 and the growing popularity of user-generated content (UGC).

Web 2.0, a term first used in 2004, provides the technical and ideological basis for SM activities. Web 2.0 was facilitated by the development of new technologies such as Adobe Flash, RSS (Real Simple Syndication), and AJAX. Respectively, these allowed for the addition of animation and video, for web feeds to update content rapidly, and for the continuous updating of websites without affecting the display. Through the use of these technologies, Web 1.0 evolved from a platform for individually created content into Web 2.0 where content was generated in a collaborative fashion, Wikipedia being perhaps the iconic example. UGC, a term that came into popular use in 2005, represents all the various ways in which people make use of SM. Kaplan and Haenlein (2010), p.61 use both Web 2.0 and UGC to define SM in the following way: "Social Media is a group of Internet-based applications that build on the ideological and technological foundations of Web 2.0, and that allow the creation and exchange of User Generated Content."

Kaplan and Haenlein (2010) employed ideas from media research to produce a two-factor classification of SM types. The first factor concerns social presence and media richness and is based on the concept of social presence theory which

Table 38.1 Social media classification (adapted from Kaplan and Haenlein 2010)

		Social presence/media richness		
		Low	Medium	High
Self- presentation/ self- disclosure	Low	Collaborative projects (e.g., Wikimapia, Wikipedia)	Content communities (e.g., YouTube, Flickr, Digg, TravBuddy)	Virtual game worlds (e.g., World of Warcraft, Runes of Magic)
	High	Blogs	Social networks (e.g., MySpace, Facebook, LinkedIn)	Virtual social worlds (e.g., Second Life; SmallWorlds)

measures the degree of physical, visual, and acoustic interaction that is achieved between the individuals communicating. Media richness is closely related to the concept of social presence. The second factor is based on social processes and concerns both self-disclosure and self-presentation. A selection of social media examples using this categorization is shown in Table 38.1. This chapter is primarily concerned with the high self-disclosure/self-presentation and medium social presence/media richness category that is appropriately labeled as “social networks.”

The history of social media may be traced back to 1997 (Boyd and Ellison 2007) when the Six Degrees SN site allowed users to create profiles, designate friends, and incorporate friends of friends to their lists. To navigate what they describe as the SM jungle, Kietzmann et al. (2011) offer an “ecology” based on seven building blocks of SM functionality, and for each they explore the implications of this functionality. The seven building blocks are, respectively, identity, conversations, sharing, presence, relationships, representation, and groups. Here, following the discussion in Kietzmann et al. (2011), we treat each attribute in turn, noting that these seven characteristics are by no means mutually exclusive.

Identity concerns the extent to which users reveal their personal characteristics. Usually these include their names and the standard socioeconomic parameters such as age, gender, profession, and location but not education and income (although owners of SN sites might infer the latter from correlations with the other characteristics). The entire package of socioeconomic indicators can then be used to create a geodemographic profile that can be used for subsequent “target marketing.”

SM sites usually provide various levels of data privacy controls for the protection of their members along with various filters and shields that also protect against information overload. Different sites may produce quite different identities for the same user. Thus, a LinkedIn “professional” profile may be quite different from a Facebook “social” profile. Secondary services such as DandyID allow SN users to record these different profiles in a single location. Dandy ID provides social analytics tools for allowing their users to determine how people are engaging their clients across the entire SM spectrum. For SM users that want to provide access to their profiles without revealing their identity, sites such as OAuth provide the necessary protection tools.

The conversations attribute reflects the extent to which SM site users communicate with each other. They may do this for personal reasons, for advocacy, or for

commercial purposes. These conversations may be brief as in the case of *microblogs* such as Twitter, Jaiku, Plurk, and Tumblr (Kaplan and Haenlein 2011) or more extensive as in traditional blogs. Microblogs can create what has become known as *ambient awareness* information that relates to the immediate surroundings as defined in time or space or both. Such information can be enormously useful for political action and location-based services or to assist in the marketing process. In a special issue of the journal *Business Horizons* dedicated to social media, Kaplan and Haenlein (2011) note that microblogs are useful in all three phases of marketing, namely, the prepurchase, purchase, and post-purchase phases. These include marketing research, marketing communications, and customer service, respectively. Examples cited by these authors include Dell Computer's Communities and Conversations team which has used customer tweets to redesign their Inspiron Mini 10 computer (marketing research), the airline JetBlue that uses its daily "cheep" tweets to fill empty seats (marketing communications), and Whole Foods Market to manage customer complaints (customer service).

Sharing on an SM site relates to the degree to which users receive or distribute and exchange content. Different SM websites are focused on sharing different objects of sociality. For example, LinkedIn users share data relating to professional careers, Flickr pictures, and YouTube videos. Important issues are how to grow the type of media that is shared and how to manage the shared content that might violate copyright laws or be offensive or inappropriate. Growing the media that are shared can be achieved by acquiring start-ups that offer new services. In 2012 Facebook bought both Lightbox, a photo-sharing site, and Karma, an app for the new activity of "social gifting." Sharing is commonly associated with social shopping services or deal-of-the-day sites such as Groupon, LivingSocial, and Google Offers, among others.

In this chapter, we are concerned with the impact of SNs on economic geography and regional science. A primary impact, as we note throughout this chapter, is the weakening of geography and distance, albeit that this impact varies with the type and purpose of the SN site. A second impact is that SNs allow for the creation of alternative, informal economies. Products can be bartered with no exchange of funds. This can be facilitated by the SN whereby contacts are made but products are exchanged in local markets or trade can take place entirely on the SN site through sharing. SN systems based on sharing are flourishing in countries such as Greece where the recession has caused a freezing of credit and record high unemployment making these systems a more palatable alternative. Systems can be operated using complementary or community currencies such as Cyclos, LETS (local exchange trading systems), and time banking, where, in the latter instance, time is used as a unit of currency. In Greece, the alternative local currency (ALC) that has replaced the Euro in some markets in towns such as Volos is referred to by its Greek acronym, TEM.

Presence relates to the ease with which users can determine if another user is available. As an example, Skype includes the following levels of accessibility: online, away, do not disturb, invisible, and offline. Kietzmann et al. (2011) note that "presence" can bridge the real and virtual worlds. Thus, SM sites such as

Foursquare provide locational information. Friends Around Me and similar SM sites are focused on geographical spaces and can be synced with Gowalla, Foursquare, Facebook, and Twitter, sites that allow for many of the operations mentioned above including profile development, conversations, and sharing of photos and virtual gifts. The Carbon Project software company has trademarked the term “geosocial networking.” User availability in time and space, as noted above, is vital for location-based services used for commercial and emergency notifications.

Relationships specify how users are linked to others. Those using LinkedIn to request a new connection are questioned as to whether they are a colleague, classmate, business contact, friend, or other. Clicking on “other” will require an email address of the intended contact to be provided before a request to connect is sent. Conversely, LinkedIn provides for the ability to see how others are connected and the degrees of separation between the user and his or her intended contacts. Relationships themselves may be characterized by the two attributes of structure and flow. These may be seen as two competing “camps.” Structure refers to the size, density, and centrality of an individual’s link within their social graph. This is the very heart of the social network science that has been developed over the decades and which was summarized in the work of Wasserman and Faust and Scott, discussed above. Flow has attracted more interest in the last decade and is concerned with how user relationships are defined by the use, exchange, and transformation of tangible and intangible resources between individuals in the SN.

Reputation – for relationships to be effective, processes that validate the authenticity and reputation of the users must be established. To assist in this process, various social metrics have been suggested. These metrics fall into two categories: empirical metrics that are based on, for example, simple measures such as the number of followers an individual has on Twitter or the number of “likes” a business has on Facebook and metrics based on mathematical formalizations (Nielsen and Krukow 2004). The most appropriate metric to measure reputation will vary depending on the individual, the business, or the SN website being used. Some social media sites, such as Social Mention, claim to track more than 100 SN sites so as to determine what is being said about a given individual, product, or business. Social Mention uses a number of metrics including strength, determined by the number of mentions; sentiment, measured by the ratio of positive to negative mentions; and reach, the numbers of different users that mention the target divided by the total number of mentions. Schubring (2012) assesses 12 different social media monitoring tools including Social Mention, some of which are free, while others such as Radian 6 may cost \$500/month or more depending on volume of traffic.

Groups – finally, Kietzmann et al. (2012) characterize SM by the extent to which users are ordered into categories or groups, and, as noted above, this is one reason that SM sites are “small worlds.” Groups may be user identified whereby individuals place their contacts into self-defined categories such as friends, business contacts, and interest groups in terms of hobbies or professional interests. Alternatively, groups may be similar to clubs in the offline world in the sense that they may be open to any member of the SN or might be by invitation

only or indeed might be secret. Many professional, regional science organizations including the North American Regional Science Council and the European Regional Science Association, for example, also have discussion groups in SN sites such as LinkedIn and can be “followed” on Facebook. In addition, sub-groups, such as NECTAR, within these organizations can also be joined. These groups usually have an open membership, but even so users must sign on to them. In this sense, they will be affected by the rules governing conversations mentioned above. Groups touch on almost all other aspects of SM sites, especially in the way they communicate, collaborate, and share and in the manner in which they develop trust and support among users.

38.6 The Development of Explicit Social Network Platforms

Since the founding of explicitly SN websites in the late 1990s (Boyd and Ellison 2007; Waters 2012), interest in social networking has developed with unsurpassed rapidity. Because of the speed with which the social networking world changes, the best sources of information are online resources such as Wikipedia. Indeed, since Wikipedia contributors are in some senses a social networked community, it would be ironic to ignore this resource. Wikipedia (2012) provides an alphabetized list of most of the existing SN sites including information on the emphasis of the site, the date when it was founded, how many registered users, whether registration is open or restricted and in what manner it is restricted, and how the sites are ranked by using a *page ranking* system.

Wikipedia also provides a list of *virtual communities* with over 100 million users. Although a virtual community is described as a “social network of individuals who interact through specific social media, potentially crossing geographical and political boundaries in order to pursue mutual interests or goals,” a number of these social networks are not included on Wikipedia’s previously mentioned list. These include Windows Live, Tencent Weibo, and Skype. Obviously, the definition of both a social network and a virtual community is somewhat fluid, and this is even more so when websites add to their services in an incremental fashion.

There are many ways of presenting and organizing information on social networking websites other than alphabetical lists. One of the more interesting approaches is simply to show the dominance of individual sites on a world map (Waters 2012) reflecting the influence of both language and national preferences. The map shows the dominating network in each country. The data was current as of February 2011. The map will continue to change rapidly. For instance by mid-2012, the number of Facebook users had risen from 640 million to more than 900 million. The map shows clearly that Facebook not only has the largest number of users but also the greatest global reach. While Qzone is the second most important SN site in numbers of users, it dominates only in China. Orkut, owned and operated by Google, is overwhelmingly dominant in Brazil. An aspatial group of SN websites by category is provided by the Social Media Influence website (Waters 2012).

38.7 Measuring Individual Influence Within Social Networks

Three companies, PeerIndex, Klout, and Kred that measure influence within a social network, use a combination of methods from social network analysis. Complete details of the algorithms are not revealed by the companies but are supposedly based on a combination of connections and activity. Perhaps the most detailed explanation of its methodology is provided by PeerIndex whose website states that on any given topic users' scores will reflect their authority (i.e., how much others rely on and trust their opinions and recommendations), their audience (size and responsiveness are important), and their activity (which is measured relative to the level of activity within their community and which should be consistent, i.e., neither frenetic nor spasmodic).

The PeerIndex website FAQ notes that "improving your scores is really pretty simple: share good and timely information, engage with authority figures in the topic, make sure your followers are largely real people, and we'll take care of the rest." Elsewhere, it is explained that topics only become viable for ranking when a group that is interested in a particular topic becomes both large and active.

The Kred website argues that they are the only site to measure influence within social networks that is fully transparent. Whether this is completely true or not is debatable. Kred measures both influence and outreach using both Twitter and Facebook activity, supposedly measuring trust and generosity. Influence is measured by a user's ability to inspire action assessed on how frequently they are "Retweeted, Replied, Mentioned and Followed on Twitter." Facebook interactions that count toward a user's Kred include Facebook "Posts, Mentions, Likes, Shares and Event Invitations." Outreach is assessed by a user's "generosity in engaging with others" plus how often a user retweets, replies, or mentions others. Interactions on Facebook that "count" include "Posts, Mentions, Comments and Likes." According to Klout, their scores reflect the true reach (how many people you influence), amplification (how much you influence them), and your network impact (the influence of your network).

Put simply, websites such as Alexa measure, in a general sense, the importance of a given social network, while sites such as PeerIndex, Klout, and Kred measure the influence of nodes, that is, individuals within those networks. This is akin to the work in the early days of network analysis where researchers measured the connectivity of both the entire network structure and the importance and connectivity of individual nodes within those networks.

38.8 Recent Developments in Network Science

A number of network science texts have been published in the last few years. For the regional scientist, two of the most important are Goyal (2007) and Hansen et al. (2011). The former contribution concentrates on economic applications of network science, the final chapters of the book providing a detailed treatment of labor markets, network formation, and research collaboration among firms; thus, spatial

influences are implied even if they are not discussed explicitly. The latter, edited text reviews the various subdisciplines and applications of network science, provides a series of case studies, and includes directions on how to use the NodeXL programming environment. SNs have many special characteristics such as grouping and clustering (noted above) that are not found to the same extent in technological and biological networks and as a consequence require specialized methods and techniques for revealing their structures. In addition to the SN handbooks discussed above, an Encyclopedia of Social Networks (Barnett 2011) has recently been published.

Specialized journals are being established on an ongoing basis, and important among these are Social Networks, Social Networks: An International Journal of Structural Analysis, International Journal of Virtual Computing and Social Networks, International Journal of Social Network Mining, Cyberpsychology, Behavior and Social Networking, Social Network Analysis and Mining, Network Science, Journal of Social Structure, The Journal of Mathematical Sociology, and Journal of Computer-Mediated Communication. Since 2008, SIGCOMM has organized an annual Workshop on Online Social Networks (WOSN) and since 2009 a Workshop on the Social Mobile Web (SMW).

38.9 The Decline of Distance and the Need for a Second Law of Geography

A primary attraction of joining a social network is that it supposedly weakens or even removes the constraints of distance. If this is true, then SNs must surely have a major impact on the spatial distribution of economic activity and will therefore be of great interest to regional scientists. To investigate these concerns, in December 2010 the Center for Spatial Studies at the University of California, Santa Barbara (UCSB), organized a workshop to determine a research agenda that would investigate the temporal and spatial constraints of SNs. Almost all the participants prepared position papers (and a final report was also issued for a review and web links, see Waters 2012). If there are no longer any spatial constraints, then Tobler's widely cited "*First Law of Geography*" (Tobler 2004) no longer applies and might be replaced by a *Second Law of Geography*: "Everything is connected to everything else, but things more closely connected are more related – and geography may well be irrelevant." Interestingly, when a debate was held on the First Law at an Association of American Geographers Conference and the discussion subsequently published in the annals of that organization, the "small world" literature was raised (Tobler 2004), but none of the commentators addressed the issue of the lack of spatial autocorrelation within an SN nor whether the pattern of SN memberships replicated real-world geography, distance decay, and spatial interaction. However, 6 years later this was a concern of the participants at the UCSB conference. It is to be expected that much of the ongoing research that will be conducted by regional scientists will be focused on this one issue.

Recent research into SNs suggests that for the most “social” of the SNs geography does matter. Barthelemy (2010) reviews a number of papers that document varying degrees of distance decay in real-world social networks. This might have been expected for mobile phone data where the probability that two individuals were connected was found to be proportional to the Euclidean distance between them raised to the minus 2 power (the classical version of the gravity model). Barthelemy’s discussion notes that in studies of the blogging SN, LiveJournal, on average users had eight friends of which 5.5 were geographically influenced and lived in close proximity with a distance decay function proportional to the inverse of the first power of distance, while the remaining 2.5 friends resulted from non-geographic processes. Another study reviewed by Barthelemy suggested that an exponent of approximately one is also appropriate for modeling the spatial separation of email correspondence of Live Blogger users and Facebook friends, respectively. In that study, the authors echoed Rietveld and Vickerman’s (2004) observation that “distance is not dead.” Further evidence in support of a strong geographical influence is provided by Scellato et al. (2010) for the BrightKite, Twitter, Foursquare, and LiveJournal SNs.

Thus, it may be concluded that both geography and other various and perhaps complex social processes will determine the links between friends in any given SN and that the purpose of a particular SN is likely to influence just how strong each component is. It might be expected that geography and distance would have a much weaker influence on connections in a business-oriented network such as LinkedIn. However, few comparisons of the geographies of Facebook and LinkedIn have appeared, and those that have been published have not explicitly addressed the spatial differences (Papacharissi 2009).

In a recent paper, Singleton and Longley (2009) have discussed the differences between online and offline geographic spaces, suggesting that much of the work on geodemographics that has been such a widespread and lucrative application of GIScience will now have to be recast so as to take into account the joint geographic and social aspects of SNs. The way forward would appear to be to adopt the new metrics developed by Scellato and his colleagues (Scellato et al. 2010) that include a “node locality” metric that measures the geographic closeness of the neighbors of a node and secondly a “geographic clustering coefficient” that measures how tightly connected the neighborhood of a node is based on the proportion of triangular links around a node where these are weighted by a distance decay function. It is measures such as these, which provide a link to earlier work on time-space geography that was originally developed by the Swedish geographer Torsten Hagerstrand that will allow regional scientists to determine the spatial, economic impact of SNs. The likelihood is that distance and geography will still have a strong role to play in any future regional science that makes use of social network analysis.

38.10 Conclusions

In the past, it became common wisdom that “The Internet Changes Everything.” Today, it can be argued with equal conviction that social networks will have

a similar impact on economic activity and that the three primary activities facilitated by the Internet, namely, access to and sharing of content (books, videos, and music), communication (email, instant messaging), and self-expression (blogs), can all be achieved through SNs. Indeed, it seems reasonable to suggest that Facebook itself does all of the above. That this will have a major impact on economic activity is now beyond dispute. The extent to which SNs will have a spatial impact and will attract the attention of regional scientists has yet to be determined and will be dependent on the degree to which they alter the spatial distribution of our activities. In the coming years, we can expect to see new books and extensive research on the spatial impacts of SNs.

Abstract

The relationship between urban development and transport is not simple and one way but complex and two way and is closely linked to other urban processes, such as macroeconomic development, interregional migration, demography, household formation, and technological innovation. In this chapter, one segment of this complex relationship is discussed: the two-way interaction between urban land use and transport within urban regions. The chapter looks at integrated models of urban land use and transport, i.e., models that explicitly model the two-way interaction between land use and transport to forecast the likely impacts of land use and transport policies for decision support in urban planning. The discussion starts with a review of the main theories of land-use transport interaction from transport planning, urban economics, and social geography.

M. Wegener

Spiekermann & Wegener, Urban and Regional Research, Dortmund, Germany

e-mail: mw@spiekermann-wegener.de

It then gives a brief overview of selected current operational urban models, thereby distinguishing between spatial-interaction location models and accessibility-based location models, and discusses their advantages and problems. Next, it reports on two important current debates about model design: are equilibrium models or dynamic models preferable, and what is the most appropriate level of spatial resolution and substantive disaggregation? This chapter closes with a reflection of new challenges for integrated urban models likely to come up in the future.

39.1 Introduction

The history of urban settlements is closely linked to transport. Cities appeared in human history when technological innovation required the spatial division of labor between specialized crafts and agricultural labor and gave rise to urban–rural travel and goods transport. Cities were established at trade routes, ports, or river crossings and became origins and destinations of trade flows. Cities were compact, as all movements were done on foot, until the railway and later the automobile opened the way to today’s sprawling agglomerations.

These brief notes already show that the relationship between urban development and transport is not simple and one way but complex and two way. On the one hand, spatial division of labor, i.e., the separation of locations of human activities in space, requires spatial interaction, i.e., travel and goods transport. On the other hand, the availability of transport infrastructure, such as roads, railways, and airlines, makes locations attractive as residences or business locations and so affects real estate markets and the choice of location of households and firms. Moreover, it becomes clear that the relationship between urban development and transport is closely linked to other urban processes, such as macroeconomic development, interregional migration, demography and household formation, and technological innovation.

In this chapter, one segment of the complex relationship between urban development and transport is discussed: the two-way interaction between urban land use and transport within urban regions. The macroeconomic dimension dealing with growth or decline of whole cities within urban systems is addressed in several other chapters, such as ► [Chaps. 45, “Interregional Input–Output Models,”](#) ► [46, “Interregional Trade Models”](#).

This chapter looks at *integrated* models of urban land use and transport, i.e., models which explicitly model the two-way interaction between land use and transport to forecast the likely impacts of land-use policies, such as zoning or building density or height constraints, and of transport policies, such as transport infrastructure investments, public transport improvements, or taxes or user charges, for decision support in urban planning. That excludes transport models per se which predict traffic patterns that result from different land-use configurations and land-use change models that predict likely land-use changes that result from a particular transport system, as well as models that deal only with one urban subsystem, such as housing or business location.

The discussion proceeds from a review of the main theoretical approaches of land-use transport models and a brief overview of operational models to current debates and new challenges that are likely to influence future development in this field.

There are in the literature several reviews of integrated land-use transport models, such as Wegener (2004) and Hunt et al. (2005).

39.2 Theory

Urban land-use transport models originated in the United States in the 1960s as part of the diffusion of operations research and systems theory into all fields of society. The first attempts to model the interaction between land use and transport were initiated by transport planners who felt that predicting future traffic flows without taking account of their impacts on location was inadequate. Hansen (1959) showed for Washington, DC, that locations with good accessibility had a higher chance of being developed, and at a higher density, than remote locations (“how accessibility shapes land use”). The recognition that mobility and location decisions co-determine each other and that therefore transport and land-use planning need to be coordinated led to the notion of the “land-use transport feedback cycle”. The set of relationships implied by this term can be summarized as follows (Wegener and Fürst 1999, see Fig. 39.1):

- The distribution of *land uses*, such as residential, industrial, or commercial, over the urban area determines the locations of households and firms and so the locations of human *activities* such as living, working, shopping, education, and leisure.
- The distribution of human *activities* in space requires spatial interactions or trips in the *transport system* to overcome the distance between the locations of activities.
- These spatial interactions are based on decisions of travelers about car availability, number of trips, destination, mode, and route. They result in *traffic flows* and, in case of congestion, in increased travel times, trip lengths, and travel costs.
- Travel times, trip lengths, and travel costs create opportunities for spatial interactions that can be measured as *accessibility*.
- The spatial distribution of accessibility influences, among other attractiveness indicators, location decisions of investors and results in changes of the *building stock* by demolition, upgrading, or new construction.
- These changes in building supply determine location and relocation decisions of households and firms and thus the distribution of *activities* in space.

This simple explanation pattern is used in many engineering-based and human-geography urban development theories. These start from origins and destinations, such as workers and workplaces, and from these infer trip volumes that best reproduce observed trip frequency distributions. It had already been observed by Ravenstein (1885) and Zipf (1949) that the frequency of human interactions, such as messages, trips, or migrations between two locations (cities or regions), is proportional to their size but inversely proportional to their distance. The analogy to the law of gravitation in physics is obvious.

Fig. 39.1 The land-use transport feedback cycle (Wegener and Fürst 1999, 6)

The gravity model was the first *spatial-interaction* model. Its physical analogy has later been replaced by better founded formulations derived from statistical mechanics (Wilson 1967) or information theory (Snickars and Weibull 1977). Only later did it become possible (Anas 1983) to link it via random utility theory (Domencich and McFadden 1975) to psychological models of human decision behavior.

From the spatial-interaction model, it is only a small step to its application as a location model. If it is possible to draw conclusions from the spatial distribution of human activities to the interactions between them, it must also be possible to identify the location of activities giving rise to a certain trip pattern. Wilson (1970) distinguishes four types of urban *spatial-interaction location* models: unconstrained models, production-constrained models, attraction-constrained models, and doubly constrained models. Unconstrained models deal with households without fixed residence or workplace, production-constrained models with households looking for a job, and attraction-constrained models with households looking for a residence. The doubly constrained model is actually not a location model but the familiar transport model (see ► Chap. 36, “Travel Behavior and Travel Demand”).

To give an example, the production-constrained spatial-interaction model is written as follows:

$$T_{ij} = A_i O_j D_j \exp(-\beta c_{ij}) \tag{39.1}$$

$$A_i = 1 / \sum_j D_j \exp(-\beta c_{ij}) \tag{39.2}$$

$$p_{ij} = \frac{D_j \exp(-\beta c_{ij})}{\sum_j D_j \exp(-\beta c_{ij})} \tag{39.3}$$

where T_{ij} are trips between zone i and zone j , O_i are trips generated by i and D_j trips attracted by j , and c_{ij} is the travel time or travel cost, or both, between i and j . The β is a parameter indicating the sensitivity to travel cost; because of its negative sign, more distant destinations are less likely to be selected. A_i is the so-called balancing factor ensuring that total trips equal O_i , and p_{ij} is the probability that a trip goes from i to j .

A second set of theories focuses on the *economic* foundations of land use. A fundamental assumption of all spatial economic theories is that locations with good accessibility are more attractive and have a higher market value than peripheral locations. This assumption goes back to von Thünen (1826) and has since been varied and refined in many ways (see ► [Chap. 27, “Classical Contributions: Von Thünen, Weber, Christaller, Lösch”](#)). Probably the most influential example of the latter kind is the model of the urban land market by Alonso (1964). The basic assumption of the Alonso model is that firms and households choose that location at which their bid rent, i.e., the land price they are willing to pay, equals the asking rent of the landlord, so that the land market is in equilibrium. The bid rent of firms results from the cost structure of their production function, i.e., sales price minus production and transport costs plus profit divided by size of land. A firm having a higher added value per unit of land is therefore able to pay a higher price than a firm with less intensive land utilization, everything else being equal. So it is not surprising that, say, jewelers are found in the center, whereas trucking companies have their yards on the periphery. Alonso’s model has been the point of departure for a multitude of urban-economics model approaches. In more advanced variations of the model, restrictive assumptions, such as the monocentric city or perfect competition and complete information, have been relaxed (e.g., Anas 1982).

A third group of theories used in land-use transport models are *social* theories. In social theories of urban development, the spatial development of cities is the result of individual or collective appropriation of space. Based on an adaptation of evolutionist thoughts from philosophy (Spencer) and biology (Darwin), the Chicago school of urban sociologists interpreted the city as a multispecies ecosystem, in which social and economic groups fight for ecological positions. Appropriation of space takes place in the form of immigration of different ethnic or income groups or tertiary activities into residential neighborhoods, and concepts of animal and plant ecology, such as “invasion,” “succession,” or “dominance,” are used to describe the phases of such displacement.

Social geography theories go beyond the macro perspective of social ecology by referring to age-, gender-, or social-group specific activity patterns which lead to characteristic spatiotemporal behavior and hence to permanent localizations. Action space analyses (e.g., Chapin and Weiss 1968) identify the frequency of performance of activities reconstructed from daily space-time protocols as a function of distance to other activities and draw conclusions from this for the most probable allocation of housing, workplaces, shopping, and recreation facilities or, in other words, for the most likely level of spatial division of labor in cities.

Hägerstrand (1970) made these ideas operational by the introduction of “time budgets,” in which individuals, according to their social role, income, and level of

technology (e.g., car ownership), command action spaces of different size and duration subject to three types of constraints: (i) *capacity constraints*, i.e., personal, nonspatial restrictions on mobility, such as monetary budgets, time budgets, availability of transport modes, and ability to use them; (ii) *coupling constraints*, i.e., restrictions on the coupling of activities by location and time schedules of facilities and other individuals; and (iii) *institutional constraints*, i.e., restrictions of access to facilities by public or private regulations such as property, opening hours, entrance fees, or prices. Only locations within the action spaces can be considered as destinations or permanent locations.

On the basis of Hägerstrand's action space theory, Zahavi (1974) proposed the hypothesis that individuals in their daily mobility decisions do not, as the conventional theory of travel behavior assumes, *minimize* travel time or travel cost needed to perform a given set of activities but instead *maximize* activities or opportunities that can be reached within their travel time and money budgets.

39.3 Operational Models

Lowry's (1964) *Model of Metropolis* was the first attempt to quantify the land-use transport feedback cycle in one integrated model. The model consists of two singly constrained spatial-interaction location models, a residential location model and a service and retail employment location model, nested into each other. In modern notation, the two models would be written as

$$T_{ij} = \frac{R_i \exp(-\beta c_{ij})}{\sum_i R_i \exp(-\beta c_{ij})} E_j \quad (39.4)$$

$$S_{ij} = \frac{W_j \exp(-\beta c_{ij})}{\sum_i W_j \exp(-\beta c_{ij})} P_i \quad (39.5)$$

where T_{ij} are work trips between residential zone i and work zone j and S_{ij} shopping trips between residential zone i to retail facilities in zone j . E_j are workers in j and P_i population in i to be distributed, and R_i are dwellings in i and W_j shopping facilities in j used as destinations in the two spatial-interaction models, and c_{ij} is the travel time between i and j . In the first iteration, only work trips to the workplaces of basic industries, i.e., industries exporting to other regions and not serving the local population, are modeled. The two spatial-interaction location models are linked by assumptions about how many people are supported by one worker and how many retail employees are supported by one resident. In each subsequent iteration, workers and residents are updated until they no longer change, i.e., until the system is in equilibrium.

The Lowry model stimulated a large number of increasingly complex land-use transport models in the USA and not much later also in Europe. Many of these early models were not successful because of unexpected difficulties of data collection

and calibration and the still imperfect computer technology of the time. More important, however, was that the models were mainly oriented toward urban growth and the efficiency of the transport system and had nothing to say about the ethnic and social conflicts arising in US cities at that time. Moreover, the models were committed to the paradigm of synoptic rationalism in planning theory, which was increasingly replaced by incremental, participatory forms of planning. In his “Requiem for Large Scale Models,” Lee (1973) accused the models of “seven sins”: hypercomprehensiveness, grossness, mechanicalness, expensiveness, hungri-ness, wrongheadedness, and complicatedness.

But many of the technical problems of the early models were solved by better data availability and faster computers. The spatial and substantial resolution of the models was increased, and they were based on better theories, such as bid-rent theory, discrete choice theory, and user equilibrium in transport networks (see ► Chap. 40, “Network Equilibrium Models for Urban Transport”). In addition, better visualization techniques made the results of the models better understood by citizens and policy makers. A new generation of models paid more attention to aspects of social equity.

The 1990s brought a revival in the development of urban land-use transport models. New environmental legislation in the USA required that cities applying for federal funds for transport investments demonstrate the likely impacts of their projects on land use. This had the effect that virtually all major metropolitan areas in the USA maintained an integrated land-use transport model. In Europe, the European Commission initiated a large research program *The City of Tomorrow*, in which integrated land-use transport models were applied in several research projects (Marshall and Banister 2007). Several integrated land-use transport models were applied in a growing number of metropolitan areas. New developments in data availability brought about by geographical information systems (GIS) and further advances in computer technology have removed former technical barriers.

It is impossible to present here all operational integrated land-use transport models existing in the world today. Instead a classification of models by the way they implement the feedback from transport to land use is proposed using a few examples, recognizing that in each group, there exists a great variety of approaches.

39.3.1 Spatial-Interaction Location Models

Spatial-interaction locations models retain the original Lowry concept by modeling the location of human activities as destinations of trips using the production-constrained spatial-interaction model. The most prominent urban model of this kind still operational today is the MEPLAN model developed by Echenique (1985) as well as its offsprings, TRANUS (de la Barra 1989) and PECAS (Hunt and Abraham 2005). All three models use a multi-industry, multiregional input–output framework (see ► Chap. 45, “Interregional Input–Output Models”) to predict the locations of production and consumption in the urban region, where households of different types are treated as industries producing labor and

consuming commodities. By iterating between the land-use parts and the transport parts of the models, general equilibrium between transport costs (including congestion) and land and commodity prices is achieved. The core equation of MEPLAN is

$$X_{irs} = X_{ir} A_{ir} f(c_{ir} + g_{irs}) Z_{is} \quad (39.6)$$

where X_{irs} are deliveries of industry i from region r to region s , X_{ir} is the supply of goods of industry i in r and Z_{is} the demand for such products in s , and c_{ir} are unit production costs of such products in r and g_{irs} their unit transport costs from r to s . A_{ir} is the balancing factor as in Eq. (39.1) ensuring that total trade flows from region r equal production in r .

The great advantage of spatial-interaction location models is their firm foundation in economic theory with respect to production and consumption. One possible criticism is that households are treated as industries producing labor and consuming commodities, with the consequence that residential location solely depends on workplace location, as if workers decided where to live on their way back from work.

In his most recent model RELU-TRAN, Anas reverses the causal direction of the input–output framework by modeling the location choice of consumers (households), producers (firms), landlords, and developers separately by utility-based production functions which include for households the costs of budget-constrained trips and for firms interindustry links as generated by the transport part of the model. As in the input–output models, by iterating between the land-use and transport parts of the model, general equilibrium between land use and transport is achieved (Anas and Liu 2007).

39.3.2 Accessibility-Based Location Models

The second group of land-use transport models predicts not actual spatial interactions but the opportunity for spatial interactions at potential locations. The indicator of opportunity for spatial interactions is called accessibility. Accessibility indicators can take a wide range of forms, from simple accessibility indicators, such as distance to the nearest bus station or motorway exit, to complex indicators measuring the ease of reaching all destinations of interest. The most frequently used complex accessibility indicator is potential accessibility or the total of all destinations of interest weighted by an inverse function of the effort to reach them measured in time or cost or a combination of both as “generalized cost”:

$$A_i = \sum_j D_j \exp(-\beta c_{ij}) \quad (39.7)$$

where A_i is the potential accessibility of zone i with respect to destinations of interest D_j and c_{ij} is the generalized costs of travel between i and j . The inverse similarity with the balancing factor of Eq. (39.2) is obvious.

Examples of operational accessibility-based location models in use today are IRPUD (Wegener 1982), RURBAN (Miyamoto and Udomsri 1996), MUSSA (Martinez 1996), DELTA (Simmonds 1999), and UrbanSim (Waddell 2002). These models predict location choices of households and firms with discrete choice models using multi-attribute utility functions in which accessibility indicators are combined with other attributes of potential locations to indicate their attractiveness from the point of view of households looking for a residential location or firms looking for a business location. In that respect, these models build on the bid-rent approach of Alonso (1964), although equilibrium between asking rents and bid rents on the land market is achieved only in MUSSA, whereas the other three models keep land prices fixed during a simulation period and defer the price response of landlords to the next simulation period.

As an example of accessibility-based location choice, the allocation of housing demand to vacant residential land by a multinomial logit model in the IRPUD model is shown (Wegener 2011a):

$$C_{kli}(t, t + 1) = \frac{L_{kli} \exp[\beta_k u_{kli}(t)]}{\sum_{il} L_{kli} \exp[\beta_k u_{kli}(t)]} C_k(t, t + 1) \quad (39.8)$$

where $C_k(t, t + 1)$ are new dwellings of type k developers plan to build in the whole region between time t and $t + 1$, $C_{kli}(t, t + 1)$ are dwellings of that type that will be built on land-use category l in zone i in that period, and L_{kli} is the capacity of vacant land for such dwellings given zoning and building density and height constraints. The parameters β_k indicate the selectivity of developers with respect to the attractiveness $u_{kli}(t)$ of land-use category l in zone i for dwellings of housing type k :

$$u_{kli}(t) = [u_{ki}(t)]^{v_k} [u_{kl}(t)]^{w_k} [u(c_{kli})(t)]^{1-v_k-w_k} \quad (39.9)$$

where $u_{ki}(t)$ is the attractiveness of zone i as a location for housing type k , $u_{kl}(t)$ is the attractiveness of land-use category l for housing type k , and $u(c_{kli})(t)$ is the attractiveness of the land price of land use category l in zone i in relation to the expected rent or price of the dwelling. The v_k , w_k , and $1 - v_k - w_k$ are multiplicative weights adding up to unity. The zonal attractiveness $u_{ki}(t)$ is multi-attribute and contains, besides other indicators of neighborhood quality, one or more types of accessibility indicators.

The advantage of accessibility-based location models is that by inserting different types of accessibility indicators into the utility functions of different types of locators, the great diversity of accessibility needs reflecting different lifestyles and preferences of households and different communication and transport needs of firms can be considered. Their disadvantage is that the actual travel and transport behavior, and hence actual travel times and transport cost, become known only in the next iteration of the associated transport model, but this may be acceptable because they change over time only gradually. The separation of the land-use and

transport parts of the model by the accessibility interface makes it easier to develop custom-tailored submodels of the location behavior of individual groups of actors, such as households looking for a dwelling, landlords looking for a tenant, developers considering upgrading of their housing stock or looking for vacant land for new residential buildings, or firms looking for vacant floorspace or for land to build new floorspace.

This has important implications for the software organization of the models. While spatial-interaction location models as described in the previous section tend to be “unified,” i.e., to consist of one single complex algorithm designed to achieve general equilibrium, the accessibility-based models described in this section tend to be “composite,” i.e., to consist of several interlinked modules each serving a specific purpose, modeling the behavior of a particular group of actors and using the accessibility indicators most appropriate for that.

39.4 Current Debates

The urban models sketched so far represent the main model types coexisting until the end of the 1990s. However, from then on, the urban modeling scene has become increasingly fragmented along two dividing lines. The first divide runs between equilibrium modeling approaches and models that attempt to capture the dynamics of urban processes. The second more recent divide runs between aggregate macro-analytic approaches and new microscopic agent-based models.

39.4.1 Equilibrium or Dynamics

The first urban models were static equilibrium models, such as the Lowry model which generated an “instant metropolis” at a point in time in the future. This tradition was maintained and is still strong in urban-economics models based on the notion that all markets, including urban housing, real estate, and transport markets, tend to move toward equilibrium between demand and supply and that therefore the equilibrium state is the most appropriate guidance for urban planning.

In contrast to this view, a different movement in urban modeling has become more interested in the adjustment processes going on in cities that may lead to equilibrium but more frequently do not. The proponents of this movement, influenced by systems theory and complexity theory, argue that cities have evolved over a long time and display a strong inertia which resists sudden changes toward a desired optimum or equilibrium (see ► [Chap. 69, “Spatial Dynamics and Space-Time Data Analysis”](#)). Following this view, urban change processes can be classified as slow, medium speed, and fast (Wegener et al. 1986):

- **Slow Processes: *Construction*.** Urban transport, communications, and utility *networks* are the most permanent elements of the physical structure of cities. The *land-use* distribution is equally stable; it changes only incrementally.

Buildings have a life-span of up to 100 years and take several years from planning to completion.

- **Medium-Speed Processes: *Economic, Demographic, and Technological Change.*** The most significant kind of *economic* change are changes in the number and sectoral composition of employment. *Demographic* changes affect population through births, ageing, and death and households through household formation and dissolution. *Technological* change affects all aspects of urban life, in particular transport and communication. These changes do not affect the physical structure of the city but the way it is used.
- **Fast Processes: *Mobility.*** There are even more rapid processes that are planned and completed in less than a year's time. They refer to the mobility of people, goods, and information within and between given buildings and communication facilities. These changes range from job relocations and residential moves to the daily pattern of trips and messages.

The advocates of dynamic models argue that in order to make realistic forecasts, it is necessary to explicitly take account of the different speeds of processes. In particular, they criticize the implicit assumption of spatial-interaction location models that households and firms are perfectly elastic in their location behavior and change to the equilibrium spatial configuration as if there were no transaction costs of moving.

In contrast, dynamic urban models make the evolution of the urban system through time explicit. Early dynamic urban models (Harris and Wilson 1978; Allen et al. 1981) treated time as a continuum. Today the most common form are recursive or quasi-dynamic models in which the end state of one simulation period serves as the initial state of the subsequent period. The length of the simulation period, usually 1 year, is the implicit time lag of the model, as changes occurring in one simulation period affect other changes only in the next simulation period. By using results from earlier simulation periods, the modeler can implement longer delays and feedbacks. For instance, if it is assumed that it typically takes 3 years to plan and build a house, a delay of 3 years between residential investment decisions and the new dwellings appearing on the market would be appropriate. Similar delays between investment decision and completion allow to model the typical cycles of over- and undersupply of office space.

Most current dynamic urban models are composite models, i.e., operate with a combination of custom-tailored submodels for different urban change processes. By selecting the sequence in which these submodels are processed during a simulation period, the modeler can give certain processes priority access to scarce resources. It is no coincidence that most dynamic land-use models are accessibility-based location models, i.e., use accessibility indicators as link between transport and land use and so take advantage of the possibility to select different types of accessibility for different types of development.

Most existing equilibrium urban models, however, are unified, i.e., apply one algorithm to all its parts, such as spatial-interaction location in the case of MEPLAN, TRANUS, and PECAS, or bid-rent location in the case of MUSSA,

because they aim at general equilibrium between supply and demand, which is easier to achieve in a unified model. However, the growing success of dynamic or quasi-dynamic models has had its effects on equilibrium models. Some spatial-interaction location models, such as MEPLAN and PECAS, have been made recursive, i.e., they are processed not only for a distant target year but for years in between and have been complemented by developer submodels producing residential, commercial, and industrial floorspace that serve as constraints for the allocation of households and economic activity in the equilibration of the subsequent simulation period.

39.4.2 Macro or Micro

The second major divide appearing in the urban modeling scene concerns the debate about the most appropriate level of spatial and substantive disaggregation.

The first urban models were zone-based like the travel models of the time, as the data required by both types of models were available only for relatively large statistical areas. However, in the 1990s, the growth in computing power and the availability of GIS-based disaggregate data fuelled by non-modeling applications, such as data capture, mapping, spatial analysis, and visualization, has had its impact on urban modeling. New modeling techniques, such as cellular automata (CA) and agent-based models developed and applied in the environmental sciences, were proposed for modeling land-use changes of high-resolution grid cells (see ► [Chap. 62, “Cellular Automata and Agent-Based Models”](#)). In transport planning, activity-based models modeling no longer trips but activity-related multi-stop tours have become the state of the art (see ► [Chap. 37, “Activity-Based Analysis”](#)). The impact of these developments on urban modeling has been a massive and still continuing trend toward disaggregation to the individual level or microsimulation.

There are important conceptual reasons for microsimulation, such as improved theories and growing knowledge about human cognition, preferences, behavior under uncertainty and constraints, and interactions between individuals in households, groups, and social networks (see ► [Chap. 38, “Social Network Analysis”](#)), a growing potential for individualization; the choice of diversified lifestyles and hence mobility and location patterns. Disaggregate models of individual behavior are better suited to capture this heterogeneity.

Microsimulation was first used in the social sciences by Orcutt et al. (1961). Early applications with a spatial dimension covered a wide range of processes, such as spatial diffusion and urban expansion (see ► [Chap. 63, “Spatial Microsimulation”](#)). Since the 1980s, several microsimulation models of urban land use and transport have been developed, such as the pioneering ILUTE (Salvini and Miller 2005). Stimulated by the technical and conceptual advances discussed above, agent-based microsimulation urban models are proliferating all over the world, including microsimulation versions of originally aggregate models, such as IRPUD, DELTA, and UrbanSim.

However, not all disaggregate urban modeling projects have been successful (see, for instance, Wagner and Wegener 2007; Nguyen-Luong 2008). Many large modeling projects had to reduce their too ambitious targets. The reasons for these failures are partly practical, such as large data requirements and long computing times, but partly also conceptual.

The most important conceptual problem is the lack of stability of microsimulation models due to stochastic variation. Stochastic variation, also called microsimulation or Monte Carlo error, is the variation in model results between simulation runs with different random number seeds (see ► Chap. 63, “Spatial Microsimulation”). In agent-based models of choice behavior, the magnitude of stochastic variation is a function of the ratio between the number of choices and the number of alternatives and the selectivity of the choosing agents (the β parameter in the equations of this chapter). The stochastic variation is small when a large number of agents with clear preferences choose between few alternatives, e.g., travel modes. It is large when a small number of agents with less pronounced preferences choose between a large number of alternatives, e.g., locations, such as grid cells, parcels, or zones, as in the case of residential or business location. In that case, the stochastic noise may be larger than the differences between competing planning alternatives under investigation, and the results may convey an illusionary sense of precision (Wegener 2011b).

There are several ways to overcome this dilemma, such as averaging the results to a higher spatial level or to artificially increasing the number of choices in the model. The most frequently recommended method is to run the model several times and to average across the results of the different runs, something rarely done because of the already long computation times of microsimulation models.

In conclusion, the microsimulation community has yet to find a proper answer to the stochastic variation problem. The optimum level of disaggregation may not be the most disaggregate one. What is needed is a theory of multilevel urban models to identify the appropriate level of conceptual, spatial, and temporal resolution for each modeling task.

39.5 Future Challenges

The world is changing fast, and so are the problems of urban planning. The first land-use transport models were growth-oriented and mainly addressed technical problems, such as the reduction of urban sprawl and traffic congestion. The second generation of models increasingly considered equity aspects, such as social and ethnic segregation, accessibility of public facilities, and distributive issues, such as who gains and who loses if certain policies are implemented. Today the third generation of models tries to take account of the observed individualization of lifestyles and preferences by ever greater spatial, temporal, and substantial disaggregation.

However, today new challenges are becoming visible that cannot be handled by many of the urban land-use transport models existing today.

The first challenge is to extend the models from land-use transport interaction models to land-use transport environment models. Today only few urban models are linked to environmental models to show the impacts of planning policies on greenhouse gas emissions, air quality, traffic noise, and open space (Lautso et al. 2004). As environmental submodels predicting air quality or noise propagation require high-resolution grid cell data, this model extension may give a new twist to the macro versus micro debate toward multilevel models using different spatial levels with different resolutions and upward and downward feedbacks. Even fewer models are able to model the reverse relationship, the impact of environmental quality, such as air quality or traffic noise, on location.

The second challenge is the transition from population growth to population decline already observed and foreseeable in many European cities. With small population decline and moderate economic growth, there is still demand for new housing because of decreasing household size and increasing floorspace per capita. The same is true for work places due to growing floorspace demand per worker. However, if the losses of population and employment become larger than the growth in floorspace demand per capita or per worker, the task is no longer the allocation of growth but the management of decline by new types of policies, such as rehabilitation of neighborhoods, upgrading of rundown housing, or conversion or demolition of derelict or vacant buildings. Only few current urban models are able to handle this.

The third and greatest challenge arises from the possibility of future energy crises and the requirements of climate protection. Both causes are likely to make mobility significantly more expensive. For model design, it does not matter whether car trips become more expensive through higher prices of fossil fuels on the world market or through government policies to meet greenhouse gas reduction targets. What matters is that these targets cannot be achieved without rigorous changes in the framework conditions of land use and transport in urban areas, in particular without significant increases in the price of fossil fuels.

Most current urban models are not prepared for this. Many of them are not able to model transport policies, such as carbon taxes, emissions trading, road pricing, or alternative vehicles and fuels, or land-use policies, such as strict development controls, improvement of the energy efficiency of buildings, or decentralized energy generation. Even fewer models are able to identify population groups or neighborhoods most affected by such policies or possible problems with access to basic services, such as schools or health facilities, or participation in social and cultural life in low-density suburban or rural areas.

Many current transport models cannot correctly predict the impacts of substantial fuel price increases. Many do not consider travel costs in modeling car ownership, trip generation, trip distribution, and modal choice. Many do not forecast induced or suppressed trips. Many use price elasticities estimated in times of cheap energy. Many do not consider household budgets for housing and travel.

Action space theory with explicit travel time and travel cost budgets permits to predict what will happen if speed and cost of travel are changed by environment-oriented planning policies. Acceleration and cost reduction in transport lead to

more, faster, and longer trips; speed limits and higher costs to fewer, slower, and shorter trips. In the long run, this has effects on the spatial structure. Longer trips make more dispersed locations and a higher degree of spatial division of labor possible; shorter trips require a better spatial coordination of locations. However, making travel slower and more expensive does not necessarily lead to a reconcentration of land uses back to the historical city center. In many urban regions, population has already decentralized so much that further deconcentration of employment would be more effective in achieving shorter trips than reconcentration of population.

That plausible forecasts of the impacts of substantial energy price increases can be made with land-use transport models based on action space theory was demonstrated by the results of the EU project *Scenarios for the Transport System and Energy Supply and their Potential Effects* (STEPs). They show that with appropriate combinations of transport and land-use policies, significant reductions in greenhouse gas emissions can be achieved without unacceptable loss of quality of life (Fiorello et al. 2006).

39.6 Conclusions

After half a century of development, there exists today a broad spectrum of mathematical models to predict the spatial evolution of cities subject to exogenous trends and land-use and transport policies. These models build on a range of theories from transport planning, urban economics, and social geography to explain the complex two-way interaction between urban land use and transport, i.e., the location of households and firms and the resulting mobility patterns in urban regions subject to concurrent economic, demographic, and technological developments. Stimulated by advances in data availability, theory development and computing technology, these models have reached an impressive level of sophistication and operational applicability.

However, the urban modeling field has recently become divided into camps with different modeling philosophies. In particular, two dividing lines are becoming visible: One is the divide between equilibrium approaches which assume that cities are essentially markets moving toward equilibrium between demand and supply and dynamic approaches focusing on adjustment processes of different speeds. The other is the divide between macro approaches dealing with statistical aggregates at the level of zones and micro approaches modeling individual households and firms at the level of grid cells or parcels. In each of the two debates, the advantages and disadvantages of the competing approaches are obvious, but what is missing is an open and honest assessment of their relevance for the validity and robustness of the results of the models. Collaborative research projects in which different models are applied to identical problems and their results compared by meta-analyses are still the exception.

A second issue regarding the future of urban models is the new challenges for urban planning. The growing importance of environmental impacts of land-use and transport policies has not yet fully been embraced by most urban models.

Neither has the transition from population growth to population decline already observed or foreseeable in many cities, a great challenge for some models originally designed for allocating growth. But the greatest challenge for urban models will be how to cope with the combined effects of future energy scarcity and the imperatives of climate change. During and after the energy transition, energy for transport and building heating will no longer be abundant and cheap but scarce and expensive. This will have fundamental consequences for mobility and location. Land-use transport models which are calibrated on behavior observed in times of cheap energy and do not consider the costs of travel and location in relation to household income cannot adequately forecast these consequences. To deal with significantly rising energy costs, land-use transport models must consider the basic needs of households which can be assumed to remain relatively constant over time, such as shelter and security at home, accessibility of work, education, retail and necessary services, and the constraints on housing and travel expenditures by disposable household incomes.

To avoid the danger that the models, as in the 1970s, are again rejected by the planning practice, they must give up some long-standing traditions and be prepared to adopt new modeling principles: less extrapolation of past trends but more openness to fundamental change, less reliance on observed behavior but more theory on needs, less consideration of preferences and choices but more taking account of constraints, and less effort on detail but more focus on basic essentials.

Abstract

Methods for the analysis and prediction of travel conforming to macroscopic assumptions about choices of the urban population cut a broad swath through the field of regional science: economic behavior, spatial analysis, optimization methods, parameter estimation techniques, computational algorithms, network equilibria, and plan evaluation and analysis. This chapter seeks to expose one approach to the construction of models of urban travel choices and implicitly location choices. Beginning with the simple route choice problem faced by vehicle operators in a congested urban road network, exogenous constants are

e-mail: dboyce@uic.edu

relaxed and replaced with additional assumptions and fewer constants, leading toward a more general forecasting method. The approach, and examples based upon it, reflects the author's research experience of 40 years with the formulation, implementation, and solution of such models.

40.1 Introduction

Journey times and costs are important variables in determining the wide range of choices available to individual travelers. To predict personal travel choices on congested urban road and public transport systems, journey times must be endogenous to the model. This statement is axiomatic. Otherwise, the representation of user congestion, a principal causative agent of urban travel and location choices, is not possible. This axiom provided the foundation for the original formulation of the road traffic network equilibrium model by Martin Beckmann (Beckmann et al. 1956). This seminal contribution, on which the entire field of urban travel choice modeling is implicitly based, was then overlooked for more than a decade. By the time it was rediscovered, a sequential, four-step paradigm had taken hold, consisting of (a) trip generation: the total amount of travel per time period (hour, day) that begins and ends at each location; (b) trip distribution: the amount of travel from every origin to every destination; (c) mode split: the proportion of trips by private cars, trains, buses, cycles, walking, and other modes of travel; and (d) traffic assignment: allocation of modal trip matrices to shortest routes to determine road link and transit line flows. Researchers then began to ask how to combine these steps into a more internally consistent method, only to arrive at Beckmann's original formulation and its extensions. Because of this irony of history, this literature became known as "combined models."

The objective of this chapter is to introduce one type of transportation network user-equilibrium model that originated from Beckmann's formulation: multi-class, multimodal, static models of origin-destination, mode, and route choices. Multi-class refers to models that consider two or more classes of travelers with different behavioral or choice characteristics. Multimodal refers to the consideration of all modes, such as public transport systems, but also including cycling and walking, in addition to motor vehicles on the road network. Static refers to models of constant flows over a congested period, such as the weekday morning or afternoon commuting period, possibly divided into intervals as short as 60 min.

This focus stems from an interest in models that are useful for decision-making about long-range transportation investments as well as short-range demand management. The era of building large-scale urban transportation infrastructure in developed urban economies has largely passed. Now these urban areas are focused on demand management issues, such as road pricing, as well as incremental additions to their road, public transport, and cycle-walkway systems. In contrast, rapidly developing urban economies, especially in Asia, are presently engaged in infrastructure development. Effective and efficient decisions for these systems' investment and management require an advanced evaluation framework to provide

information on the distribution of impacts on residents, employers, and public agencies. Travel forecasts are central to such a framework.

A conviction that travel forecasting models have the potential to be substantially superior to current travel forecasting practice, described by Ortúzar and Willumsen (2011), is one motivation for this chapter. Following a brief historical overview, formulations of several models are offered, beginning with a basic model of route choice on a road network. Assumptions about what is exogenous to that model are then relaxed, enabling a more general model to emerge. Solution algorithms for these models are described, including the issue of the uniqueness of route flows and multi-class link flows. A brief discussion of future research and practice concludes the chapter. References emphasize seminal works in the field and syntheses useful to newcomers.

40.2 Historical Overview

The historical development of this field is complex, in part because separate strands of research and practice provide a variety of approaches. An extensive historical account and mathematically rigorous synthesis of the field with over 1,000 references was prepared by Patriksson (1994). Marcotte and Patriksson (2007) updated and substantially extended that earlier synthesis. Sheffi (1985) synthesized his own contributions on stochastic route choice, as well as integrating some findings of others. Oppenheim (1995) set out to write a textbook on travel demand models, and in addition, offered several theoretical advances to origin-destination-mode-route choice models based on random utility theory. Florian and Hearn (1995) synthesized the network equilibrium literature from the viewpoint of operations research. Bell and Iida (1997) articulated their view of transportation network analysis, including chapters on reliability and design. Nagurney (1999) explored the application of variational inequalities to a variety of network-related problems. A review of implemented combined models was offered by Boyce and Bar-Gera (2004).

This overview is organized by groups of academic researchers working along similar lines. Beckmann did not follow up on his innovation. Instead, research extending Beckmann's model was undertaken by Stella Dafermos and her contemporaries. From her 1968 Ph. D. thesis until her death in 1990, Dafermos established a wide-ranging theory of traffic network equilibrium, including contributions to models with variable and fixed demand, treatment of multiple user classes and asymmetric cost functions, and perhaps most importantly extensions and applications of the theory of variational inequalities to transportation network equilibria. From the late 1970s, Michael Smith independently pursued a similar line of inquiry, focused on traffic equilibrium, traffic signal timing, and road pricing. Patriksson (1994) lists 19 references by Dafermos and 14 references by Smith.

The Centre for Research on Transportation at the University of Montreal, founded in 1972, embarked on theoretical research, model implementation, and testing. Initially led by Michael Florian (2008), successive generations of faculty and students made sustained contributions to network equilibrium modeling. Contributions to solving the transportation network equilibrium problem with variable demand,

including mode choice, were made by Florian and Nguyen during the 1970s. Subsequently, several of these methods were implemented in EMME (www.inro.ca), an interactive-graphic multimodal urban transportation planning system.

In the United Kingdom in the mid-1960s, John Murchland sought to devise an alternative to the sequential paradigm, but it was Suzanne Evans (1976) who devised a way to combine trip distribution and traffic assignment models into a single formulation, an optimization problem consisting of two parts, one related to route choice as in Beckmann's formulation and the other related to trip distribution, as suggested by Wilson (1970). Evans extensively explored the mathematical properties of her formulation and proposed a solution algorithm; see Sect. 40.4.1.

Boyce began to implement the formulation and algorithm of Evans in 1976. Over the next 25 years, he and his students, in separate collaborations with LeBlanc and Lundqvist, implemented a single-class, two-mode combined model on aggregated networks of Chicago and Stockholm. Model parameters were borrowed from other studies at first, but later estimated in a way that is self-consistent with the model solution. Boyce and Bar-Gera (2003) and several collaborators implemented, estimated, and validated a two-class, two-mode combined model at the same level of detail used by transportation planning professionals for the Chicago region.

In 1986, researchers in Chile began to implement multi-class combined models emphasizing route choices in the congested public transport network with several submodes found in Santiago (De Cea et al. 2005). This effort led to the development of ESTRAUS (www.mctsoft.com) which has been applied to Santiago and other Chilean cities. Aashtiani and Magnanti formulated a combined mode choice and traffic assignment model based on nonlinear complementarity theory, and Safwat and Magnanti extended this formulation to include trip generation as well as trip distribution; see Patriksson (1994) for references. Abrahamsson and Lundqvist (1999) extended a model of the Stockholm region to include parameter estimation methods and tested alternative specifications of nested travel choice functions.

The author submits there are different views of how to model urban travel, which are often mutually stimulating to research and practice. For example, another view poses separate travel demand and network cost models, which are solved jointly with an iterative equilibration procedure. From this perspective, there is less emphasis on model integration and more focus on model structure, parameter estimation, and solution procedures for the separate demand and network models. This approach may offer more flexibility to innovative modelers, who indeed often describe themselves as either demand modelers or network modelers, but seldom both. However, it offers fewer opportunities to analyze the properties of the entire model structure and to insure the consistency of the overall approach.

40.3 Model Formulations

Formulations and analyses of combined models of travel choice on congested urban transportation networks based on constrained optimization methods are introduced here, articulating one way to derive models of varying degrees of scope and

complexity. Detailed statements of model properties are omitted, but may be identified using standard techniques for deriving the optimality conditions for a convex function with equality and inequality constraints, as stated in Sect. 40.3.2. The model formulations represent the conventional (traditional) way of describing urban travel, known as trip-based, which originated in the United States in the 1950s. Activity-based or tour-based models, which are more representative of actual travel choices, are the subject of current research and advanced practice, but are not considered here.

40.3.1 Definitions and Assumptions

The following assumptions are briefly stated in agreement with current practice:

1. An urban region is divided into small, relatively homogeneous zones. Zone size varies with the density of development, so that activity levels per zone are relatively similar.
2. Urban activities in zones are described in terms of (a) residential population and households; (b) employment, education (primary, secondary, higher), and day care; (c) shopping, personal and business services, recreation, etc.
3. Facilities for urban activities consist of land and buildings: (a) residences, (b) workplaces, (c) schools, (d) shopping and service centers, and (e) parks and recreational facilities.
4. Travel occurs on two types of transportation systems or modes: (a) private vehicles/ways for driving-cycling-walking/traffic control system and (b) bus or train/roadway or railway/operations plan. Trucks also use the roadway system, depicted in car equivalent units. Transportation systems are represented as networks of nodes, links, link attributes, and for public transport, routes of scheduled services. Service characteristics of links depend on fixed parameters related to physical roadways and vehicle characteristics: (a) length, number, and width of lanes by type, including cycleways and walkways and grade; (b) public transport station spacing and vehicle performance; (c) control and operations plans: speed limits, signal settings, and road tolls; and (d) service frequencies, operating speeds, and public transport fares.
5. Other variables related to travel flows (demand) also determine service characteristics: (a) flows of cars, trucks, cycles, and pedestrians and (b) public transport boardings and alightings at stops per unit time. Taken together, these variables determine the performance characteristics of individual links:

link travel time = $f(\text{flows}|\text{fixed vehicle/way characteristics, and operations plans})$

Such cost performance functions are sometimes confused with supply functions. In a supply function, specific aspects of the vehicle-way-operations plan are not fixed, but are decision variables representing the operator or supplier of services. In contrast, in a travel forecast for a given scenario based on performance functions, optimal values of supply parameters are generally not represented. For example, traffic signal timings and public transport service frequencies are not optimized in response to the travel forecast.

6. Travel between daily activities (residing, working, eating, shopping, schooling, recreating) may be described in terms of pairs of activities linked by trips: (a) home-work, (b) work-eat meal, (c) work-shop, (d) shop-home, etc. Over the 24 h week-day, travel related to several activities makes up a sequence of trips connecting various purposes, or tour. The duration of the activities and the times required for travel determine the daily geographic range. In the trip-based approach, individual trips are aggregated by purpose and forecast as separate groups. Whether travel occurs by private car, either alone or with others, by public transport, cycle, or walking, depends on the availability of modes, their relative service times and monetary costs, as well as intangible factors like comfort and convenience. The timing of travel during the day also depends on constraints imposed by activity schedules, and the travel conditions on the private and public networks.
7. Travel occurs during a given period of the 24 h weekday, such as the morning peak commuting period. To represent observed trips, with their specific departure and arrival times, as flows (persons/unit time), a transformation is required, such as (a) all travelers departing from home for work during 6–9 a.m. are counted as flows in persons/hour, and (b) all travelers arriving at work from home during 6–9 a.m. are counted as flows in persons/hour.

For transportation systems planning, facility design, operations planning, or conformance with air quality regulations, forecasts of the following variables are required for each transportation system/activity pattern scenario:

1. Flows of private cars, trucks, cycles, pedestrians, and public transport vehicles on the road network by morning and evening peak commuting periods and for longer periods when travel conditions are relatively stable
2. Flows of persons on the public transport network by submode by time period
3. Flows of persons from origin zone to destination zone by private vehicles and public transport by time period

A capability to examine changes in these flows in response to changes in network layout, capacity and service attributes, monetary costs (e.g., fuel, tolls, fares, parking fees), and changes in zonal activity levels is required.

40.3.2 Methodological Approach

Travel choice models may be formulated and analyzed using several methods for solving optimization and equilibrium problems. These problems include convex optimization, nonlinear complementarity, variational inequality, geometric optimality, and fixed point, roughly in increasing order of generality. Each of these methods has been applied in the formulation of travel choice models. This brief introduction is limited to minimization of a convex function subject to inequality constraints, which is suitable for derivations in this chapter and based on the classic Karush-Kuhn-Tucker theorem (Kuhn and Tucker 1951):

$$\min_{(\mathbf{x})} f(\mathbf{x}) \quad (40.1)$$

$$\text{st: } h_i(\mathbf{x}) \leq 0, \quad i = 1 \dots, m \quad (40.2)$$

where \mathbf{x} is an unknown vector of length n , $f(\cdot)$ is a strictly convex function, and $h_i(\mathbf{x}) \leq 0$, $i = 1 \dots, m$, is a set of linear constraints. The necessary conditions for $f(\mathbf{x}^*)$ to be a local minimum are

$$\begin{aligned} \frac{\partial f(\mathbf{x}^*)}{\partial x_j} + \sum_{i=1}^m \lambda_i \left(\frac{\partial h_i(\mathbf{x}^*)}{\partial x_j} \right) &\geq 0, \quad j = 1 \dots, n \\ h_i(\mathbf{x}^*) &\leq 0, \quad i = 1 \dots, m \\ \lambda_i h_i(\mathbf{x}^*) &= 0, \quad i = 1 \dots, m \\ \lambda_i &\geq 0, \quad i = 1 \dots, m \end{aligned} \quad (40.3)$$

where λ_i is a dual variable associated with the constraint $h_i(\mathbf{x}^*) \leq 0$. If the inequality constraints include nonnegativity conditions, $\mathbf{x} \geq \mathbf{0}$, then the optimality condition can be written in a more compact and transparent manner, as follows:

$$\frac{\partial f(\mathbf{x}^*)}{\partial x_j} - \sum_{i=1}^m \lambda_i \left(\frac{\partial h_i(\mathbf{x}^*)}{\partial x_j} \right) \geq 0, \quad j = 1 \dots, n \quad (40.4)$$

$$x_j \left(\frac{\partial f(\mathbf{x}^*)}{\partial x_j} - \sum_{i=1}^m \lambda_i \left(\frac{\partial h_i(\mathbf{x}^*)}{\partial x_j} \right) \right) = 0, \quad j = 1 \dots, n \quad (40.5)$$

$$h_i(\mathbf{x}^*) \geq 0, \quad i = 1 \dots, m \quad (40.6)$$

$$\lambda_i h_i(\mathbf{x}^*) = 0, \quad i = 1 \dots, m \quad (40.7)$$

$$x_j \geq 0, \quad j = 1 \dots, n \quad (40.8)$$

$$\lambda_i \geq 0, \quad i = 1 \dots, m \quad (40.9)$$

Equations (40.5) are complementary slackness conditions, which state that either $x_j = 0$, or $\frac{\partial f(\mathbf{x}^*)}{\partial x_j} - \sum_{i=1}^m \lambda_i \left(\frac{\partial h_i(\mathbf{x}^*)}{\partial x_j} \right) = 0$, or both. As shown below, these conditions are needed for deriving the equilibrium conditions on route flows.

40.3.3 Deterministic Route Choice over a Road Network

In 1952, John Wardrop, a British traffic scientist, proposed the following criterion to describe traffic flows on a route:

The journey times on all routes actually used are equal, and less than those which would be experienced by a single vehicle on any unused route. . . (this) criterion is quite a likely one

in practice, since it might be assumed that traffic will tend to settle down into an equilibrium situation in which no driver can reduce his journey time by choosing a new route. (Patriksson 1994, p. 31)

The first sentence is now known as Wardrop's first principle of network user equilibrium (UE).

Beckmann et al. (1956, p. 59), working at the Cowles Commission for Research in Economics at the University of Chicago during 1951–1954, described the concept of equilibrium more generally:

Demand refers to trips and capacity refers to flows on roads. The connecting link is found in the distribution of trips over the network according to the principle that traffic follows shortest routes in terms of average cost. The idea of equilibrium in a network can then be described as follows. The prevailing demand for transportation, that is, the existing pattern of originations and terminations, gives rise to traffic conditions that will maintain that same demand. Or, starting at the other end, the existing traffic conditions are such as to call forth the demand that will sustain the flows that create these conditions.

Then, they described their concept of route equilibrium as follows (p. 60):

... the principle of traffic distribution among alternative routes in equilibrium. (1) If between a given origin and a given destination more than one route is actually traveled, the cost of transportation to the average road user, as indicated by the average-cost capacity curves, must be equal on all these routes. (2) Since the routes used are the "shortest" ones under prevailing traffic conditions, average cost on all other possible routes cannot be less than that on the route or routes traveled. (3) The amount of traffic originated per unit of time must equal the demand for transportation at the trip cost which prevails.

Note that these statements reflect Beckmann's view that origin–destination demand is variable, whereas Wardrop considered fixed flows (p. 344). McGuire stated they were not aware of Wardrop's paper at the time, although he became aware of it later (personal interview, 1999).

By "routes actually used," Wardrop meant the routes used from a given origin to a given destination, which may be defined as zones. If routes consist of sequences of links, then route costs may be defined as the sum of the link costs along the route. Since link costs depend on link flows, through the cost performance function, and each link serves (possibly) many routes, then identifying the route costs which satisfy Wardrop's principle involves solving the route choice problem simultaneously for a system of zones and a network.

Link flows have units of vehicles/hour (vph), so route flows and origin–destination (O-D) flows also have units of vehicles/hour or persons/hour. The resulting route choice model is a steady-state flow model in which no individual travels from an origin to a destination. Rather, O-D-route flows occur with corresponding flows on the links of each used route. This formulation leads in a relatively simple concept of congestion, with no bottlenecks or traffic jams, but only steadily flowing vehicles traveling at speeds determined by cost performance functions.

The user-equilibrium link flows and costs, and a set of route flows, corresponding to fixed O-D flows may be determined by solving the following constrained optimization problem:

$$\begin{aligned}
\min_{(\mathbf{h})} z(\mathbf{h}) &= \sum_{a \in A} \int_0^{f_a} c_a(x) dx \\
\text{st: } \sum_{r \in R_{pq}} h_r &= \bar{d}_{pq}, \quad p \in P; q \in Q \\
h_r &\geq 0, \quad r \in R_{pq}, p \in P; q \in Q \\
\text{where } f_a &\equiv \sum_{pq} \sum_{r \in R_{pq}} h_r \delta_{ar}, a \in A
\end{aligned} \tag{40.10}$$

f_a = flow of all vehicles on link a (vph)

$c_a(f_a)$ = generalized travel cost function for link a , a nondecreasing function of link flow f_a

h_r = flow of vehicles on route r of the set of routes R_{pq} connecting zone p to zone q (vph)

\bar{d}_{pq} = exogenous flow of vehicles from zone p to zone q (vph)

$\delta_{ar} = 1$, if link a belongs to route r from zone p to zone q and 0 otherwise

P, Q = sets of origin and destination zones, respectively

A = set of links in the network

The unknown variables are vehicle route flows $\mathbf{h} = (h_r)$; vehicle link flows (f_a) are defined in terms of the route flows. The link-route correspondence matrix (δ_{ar}) is exogenous. To simplify the derivation, truck flows are included in the single O-D matrix (\bar{d}_{pq}).

The optimality conditions for the above problem may be stated as follows:

$$\begin{aligned}
\sum_{a \in A} c_a(f_a) \delta_{ar} - u_{pq} &\geq 0, \quad r \in R_{pq}, p \in P, q \in Q \\
h_r \left(\sum_{a \in A} c_a(f_a) \delta_{ar} - u_{pq} \right) &= 0, \quad r \in R_{pq}, p \in P, q \in Q \\
\left(\sum_{r \in R_{pq}} h_r - \bar{d}_{pq} \right) &\geq 0, \quad p \in P, q \in Q \\
u_{pq} \left(\sum_{r \in R_{pq}} h_r - \bar{d}_{pq} \right) &= 0, \quad p \in P, q \in Q \\
h_r \geq 0, r \in R_{pq}, u_{pq} \geq 0, & \quad p \in P, q \in Q
\end{aligned} \tag{40.11}$$

where u_{pq} is a dual variable associated with the conservation of flow constraint defined on the exogenous O-D flow \bar{d}_{pq} . Conditions (40.11) may be interpreted as follows for O-D pair pq :

1. Assume $h_r > 0$; then, $\left(\sum_{a \in A} c_a(f_a) \delta_{ar} - u_{pq} \right) = 0$, or $C_r \equiv \sum_{a \in A} c_a(f_a) \delta_{ar} = u_{pq}$

Table 40.1 Deterministic models

Choice	Equilibrium conditions
Route	$h_r > 0 \Rightarrow C_r = u_{pq}; h_s = 0 \Rightarrow C_s \geq u_{pq}; C_t > u_{pq} \Rightarrow h_t = 0;$ $C_r \equiv \sum_{a \in A} c_a(f_a) \delta_{ar}, r \in R_{pq}, \sum_{r \in R_{pq}} h_r = \bar{d}_{pq}, p \in P, q \in Q$
Mode and route	$h_r^c > 0 \Rightarrow C_r^c = u_{pq}^c; h_r^c = 0 \Rightarrow C_r^c \geq u_{pq}^c; \sum_{r \in R_{pq}} h_r^c = d_{pq}^c$ $C_r^c > u_{pq}^c \Rightarrow h_r^c = 0; C_r^c \equiv \sum_{a \in A} c_a(f_a) \delta_{ar}, r \in R_{pq}^c$ $d_{pq}^c > 0 \Rightarrow u_{pq}^c = \kappa_{pq}; d_{pq}^c = 0 \Rightarrow u_{pq}^c \geq \kappa_{pq}$ $u_{pq}^c > \kappa_{pq} \Rightarrow d_{pq}^c = 0$ $d_{pq}^n > 0 \Rightarrow C_{pq}^n = \kappa_{pq}; d_{pq}^n = 0 \Rightarrow C_{pq}^n \geq \kappa_{pq}$ $C_{pq}^n > \kappa_{pq} \Rightarrow d_{pq}^n = 0, n \in N$
O-D, mode, and route	Deterministic equilibrium conditions for O-D flows correspond to the solution of a cost-minimizing allocation of origins to destinations, known as the classical transportation problem of linear programming (Evans 1973). The solution corresponds to a deterministic model for $\eta \rightarrow \infty$ in the case of the O-D-mode model and the mode-O-D model. Based on empirical studies of origin-destination flows, such solutions are considered to be unrealistic for urban travel choices
Mode, O-D, and route	

2. Assume $h_s = 0$; then, $\left(\sum_{a \in A} c_a(f_a) \delta_{as} - u_{pq} \right) \geq 0$, or $C_s \geq u_{pq}$.

3. Assume $C_t > u_{pq}$; then $h_t = 0$.

where C_r is the travel cost on route r , the sum of the costs of the links comprising route r . Hence, every used route connecting zone p to zone q has a generalized travel cost equal to u_{pq} , and no unused route has a lower travel cost. Thus, this formulation corresponds to Wardrop's first principle. These conditions are shown in Table 40.1 in the first row.

In the above formulation, identical and rational travelers are assumed to know accurately their travel times over alternative routes from their origins to destinations. The source of this information can only be described as being from their experience. Modern in-vehicle navigation systems may offer travel time information over one route at some point in time, but generally not over several alternative routes. Moreover, the model formulation applies to a relatively long time period, such as the morning peak period, during which actual route travel times may vary widely. This assumption implies that the model solution corresponds to a deterministic user equilibrium (DUE) and is relaxed somewhat in the next subsection.

If the generalized cost functions are strictly increasing with link flows, then the objective function is strictly convex guaranteeing that the solution is unique in the link flows. The solution is not unique in the route flows, or class link flows in the case that two or more demand classes are specified, however, since the total link flows are linear functions of the route flows. Therefore, the objective function is not strictly convex in the route flows, as required for uniqueness. The above

formulation applies to the case in which each link performance function depends only on the link's own flow, which is called separable. In a more general case, called symmetric, each link performance function depends on a specified vector of link flows such that the effect of a change in link a 's flow on link b equals the effect of a change in link b 's flow on link a for all links specified in the cost function. An example of such a vector of link flows is the links entering an intersection. Generally, intersection delays are not symmetric, so this requirement is not met. Models not exhibiting such symmetries are called asymmetric and may be formulated variational inequality problems (Patriksson 1994, pp. 74–77).

In contrast to the above model, the conventional approach to modeling route choice on a public transport network is relatively simple:

1. Represent all submodes (bus, rapid transit, commuter rail, express bus) in one network.
2. Find a minimal generalized travel cost route from origin zone p to destination zone q considering access, waiting, boarding, in-vehicle, and transfer times as well as fares; congestion at boarding and alighting are not considered.
3. Assign all public transport trips from zone p to zone q to a single minimal cost route, which is called all-or-nothing assignment.

Even if all-or-nothing assignment to minimal cost routes is considered adequate, representing public transport networks is more complex than road networks. The use of only one route between each O-D pair is simplistic if several public transport options are offered. Methods for modeling public transport route choice are found in Ortúzar and Willumsen (2011, pp. 373–80).

40.3.4 Stochastic Route Choice over a Road Network

A way to relax the deterministic route choice model, and possibly make it more realistic, is to introduce an additional constraint. The role of this constraint is to soften or blur the deterministic character of the above model by allowing some portion of each O-D flow to choose routes with higher costs. Before exploring this idea, it is appropriate to ask how many routes are used by each O-D pair in the deterministic solution. To answer this question, a moderately congested car O-D matrix was computed for the 1790 zone system of the Chicago region, and added to a truck O-D matrix obtained from the region's planning organization; see Bar-Gera and Boyce (2007). The total vehicle flow of 1,349,000 vph between 3,174,000 zone pairs was assigned to the Chicago regional network. The total number of UE routes in a very precise solution was 8,573,000, or 2.70 routes per O-D pair.

Of these O-D pairs, about 55 % have only one route, which seems surprising since many of these routes are very long. About 90 % of O-D pairs have five or fewer routes, and 99 % have 20 or fewer routes. However, one O-D pair has 1920 routes, the maximum in this solution. Figure 40.1 shows the number of O-D pairs on the y-axis versus the number of routes per O-D pair on the x-axis. The cumulative number of O-D pairs is shown starting at 1.0 at the upper left, decreasing to 1E-7 (0.0000001) at the lower right. Note where the line crosses the second horizontal

Fig. 40.1 Number of O-D pairs versus number of routes per O-D pair

line labeled 0.10 on the right y-axis; the five dots to the left of this intersection account for 90 % of all O-D pairs. In a more congested solution, the number of routes is much larger.

If one wished to distribute some O-D flow to higher cost routes, how might this be accomplished? Such a redistribution may be considered to be a “dispersion” of choices from the cost-minimizing UE routes to higher cost routes. A function depicting such a dispersion of proportions of route flow is available for this purpose. Known as the entropy function (Erlander and Stewart 1990, pp. 21–25), it has a one-to-one correspondence with the well-known logit function.

A constraint can be formed to represent such a dispersion. Travelers strictly take the least cost route in the deterministic solution, so it is the least dispersed feasible solution to problem (40.10). By constraining the route choices to be greater than this minimum level, some choices are shifted to higher cost routes. The form of the constraint is

$$-\sum_{p \in P} \sum_{q \in Q} \sum_{r \in R_{pq}} h_r \ln(h_r) > S_{UE} \tag{40.12}$$

where S_{UE} represents the dispersion of the choices in the DUE solution. Since there are unlikely to be any data at present on the dispersion of routes in a large network, a route dispersion constraint is simply a conceptual device. Modifying conditions (40.11) to include the effect of the dispersion constraint, one may obtain

$$\begin{aligned}
& \sum_{a \in A} c_a(f_a) \delta_{ar} + \frac{1}{\theta} (\ln h_r + 1) - u_{pq} \geq 0, \quad r \in R_{pq}, p \in P, q \in Q \\
& h_r \left(\sum_{a \in A} c_a(f_a) \delta_{ar} + \frac{1}{\theta} (\ln h_r + 1) - u_{pq} \right) = 0, \quad r \in R_{pq}, p \in P, q \in Q \\
& \left(\sum_{r \in R_{pq}} h_r - \bar{d}_{pq} \right) \geq 0, \quad p \in P, q \in Q \\
& u_{pq} \left(\sum_{r \in R_{pq}} h_r - \bar{d}_{pq} \right) = 0, \quad p \in P, q \in Q \\
& S + \sum_{p \in P} \sum_{q \in Q} \sum_{r \in R_{pq}} h_r \ln(h_r) \geq 0 \\
& \frac{1}{\theta} \left(S + \sum_{p \in P} \sum_{q \in Q} \sum_{r \in R_{pq}} h_r \ln(h_r) \right) = 0 \\
& h_r \geq 0, r \in R_{pq}, u_{pq} \geq 0, p \in P, q \in Q, \frac{1}{\theta} > 0
\end{aligned} \tag{40.13}$$

where $S > S_{UE}$ is the dispersion of an entropy-constrained solution, and $1/\theta$ is the dual variable corresponding to the entropy constraint. The reason that it is defined as a reciprocal will become clear shortly. Because the route flow h_r appears as the argument of the natural logarithm, it cannot take on a value of zero. Hence, all route flows are positive. Solving the complementarity slackness condition for $h_r > 0$, the following optimality conditions may be obtained:

$$\begin{aligned}
& \ln h_r = \theta (u_{pq} - C_r) - 1, \text{ so} \\
& h_r = \exp(\theta u_{pq} - 1 - \theta C_r), \text{ where } C_r \equiv \sum_{a \in A} c_a(f_a) \delta_{ar}
\end{aligned} \tag{40.14}$$

Apply the conservation of route flow constraint to this expression for h_r to obtain

$$\sum_{r \in R_{pq}} h_r = \bar{d}_{pq} = \exp(\theta u_{pq} - 1) \sum_{r \in R_{pq}} \exp(-\theta C_r) \tag{40.15}$$

$$\exp(\theta u_{pq} - 1) = \frac{\bar{d}_{pq}}{\sum_{r \in R_{pq}} \exp(-\theta C_r)} \tag{40.16}$$

Substituting this expression into the equation for h_r yields the logit route choice function:

$$h_r = \bar{d}_{pq} \frac{\exp(-\theta C_r)}{\sum_{r \in R_{pq}} \exp(-\theta C_r)} \tag{40.17}$$

These conditions are shown in the first row of [Table 40.2](#). Examination of these conditions reveals the structure of the stochastic user-equilibrium (SUE) model as well as raising several issues. Corresponding to the dispersion constraint, a logit

Table 40.2 Stochastic and mixed stochastic-deterministic models

Choices	Functions and equilibrium conditions
Route	Stochastic route choice: $C_r \leq C_r^{\max} \Rightarrow h_r > 0; C_r > C_r^{\max} \Rightarrow h_r = 0$ $h_r = \bar{d}_{pq} \frac{\exp(-\theta C_r)}{\sum_{r \in R_{pq}} \exp(-\theta C_r)}, \quad \theta < \infty$
Mode and route	Stochastic mode choice with deterministic route choice: $\theta \rightarrow \infty \Rightarrow C_{pq}^c \equiv u_{pq}^c$ $d_{pq}^m = \bar{d}_{pq} \frac{\exp(-\mu C_{pq}^m)}{\sum_{m \in M} \exp(-\mu C_{pq}^m)}, \quad m \in M$
	Stochastic mode choice with stochastic route choice: $\theta < \infty \Rightarrow \tilde{C}_{pq}^c \equiv -\frac{1}{\theta} \ln \sum_{r \in R_{pq}} \exp(-\theta C_r)$ $h_r^c = \bar{d}_{pq} \frac{\exp(-\mu \tilde{C}_{pq}^c)}{\sum_{m \in M} \exp(-\mu C_{pq}^m)} \frac{\exp(-\theta C_r)}{\sum_{r \in R_{pq}} \exp(-\theta C_r)}, \quad \mu < \theta < \infty$
O-D, mode, and route	$\mu < \infty \Rightarrow \tilde{C}_{pq} = -\frac{1}{\mu} \sum_{m \in M} \exp(-\mu C_{pq}^m)$ $d_{pq} = A_p \bar{O}_p B_q \bar{D}_q \exp(-\eta \tilde{C}_{pq})$, where $A_p \Rightarrow \sum_{q \in Q} \sum_{m \in M} d_{pq}^m = \bar{O}_p; B_q \Rightarrow \sum_{p \in P} \sum_{m \in M} d_{pq}^m = \bar{D}_q$ $d_{pq}^m = A_p \bar{O}_p B_q \bar{D}_q \exp(-\eta \tilde{C}_{pq}) \frac{\exp(-\mu C_{pq}^m)}{\sum_{m \in M} \exp(-\mu C_{pq}^m)}, \quad \eta < \mu < \infty$
Mode, O-D, and route	$\eta < \infty \Rightarrow \hat{C}_p^m = -\frac{1}{\eta} \ln \sum_{q \in Q} D_q B_q \exp(-\eta C_{pq}^m)$ $d_{pq}^m = \bar{O}_p \frac{B_q \bar{D}_q \exp(-\eta C_{pq}^m)}{\sum_q B_q \bar{D}_q \exp(-\eta C_{pq}^m)}$, where $B_q \Rightarrow \sum_{p \in P} \sum_{m \in M} d_{pq}^m = D_q$ $d_{pq}^m = \bar{O}_p \frac{\exp(-\mu \hat{C}_p^m)}{\sum_{m \in M} \exp(-\mu C_p^m)} \frac{B_q \bar{D}_q \exp(-\eta C_{pq}^m)}{\sum_q B_q \bar{D}_q \exp(-\eta C_{pq}^m)}, \quad \mu < \eta < \infty$

route choice function is obtained. The logit function allocates some portion of the O-D flow \bar{d}_{pq} to every route connecting p to q . Of course, as $C_r \Rightarrow +\infty$, $\exp(-\theta C_r) \Rightarrow 0$. For small values of θ , including 0, this limit could be ineffective. Therefore, a limit may need to be placed on the definition of routes and the maximum value of C_r . One possibility is that in traversing each link of a route, a driver must travel farther in cost from the origin and closer to the destination. However, the equilibrium travel costs are not available for the purpose of defining these route costs, so a fixed link cost, such as the free-flow time, might be used. Another option is to place an upper limit on the travel cost for each O-D pair, which could be related to the deterministic travel cost: $C_r^{SUE} \leq C_r^{\max} \equiv k C_r^{DUE}, r \in R_{pq}, k > 1$.

Another problem with the logit route choice function is that the SUE routes are often not distinct alternatives. Rather, routes may have substantial overlapping segments in an urban application. As Patriksson (1994, p. 65) noted, O-D flows are over allocated to overlapping routes. Consequently, the logit model may yield overly large flows. This anomaly results from the inability of the logit model to account for the correlation between the costs of alternative routes, which stems from its independence from irrelevant alternatives property. Another problem is that the route choice probabilities are based solely on route cost differences, and do not take their magnitudes into account. For additional discussion of SUE models, see Patriksson (1994, pp. 60–65) and Sheffi (1985).

40.3.5 Mode and Route Choice over Road and Fixed Cost Networks

If travel choices are viewed as a hierarchy, then route choice would seem to fall naturally at the lowest level. Route choices are specific to each transportation mode and may vary with every trip in response to current travel conditions. The choice of mode may be hypothesized to be the next higher choice in this hierarchy. Mode choices may be made on a daily basis, assuming a car is available. Choice of cycle and walking may also be considered, if available as options. Note the representation of choices as a hierarchy does not imply that choices are made sequentially.

To begin, the deterministic car route choice model is extended to include choice of mode to serve as a bridge to the consideration of stochastic models of mode as well as route choice. Denote mode by the superscript $m = \{c, n\}$ where c represents the car mode and $n \in N$ represents the subset of other modes (public transport, cycle, and walk), assumed to have fixed travel costs and not to affect the congestion of the car mode. The addition of superscript c to the demand for O-D pair pq denotes person flows per hour from zone p to zone q by car; likewise, n denotes person flows per hour by other modes. Route flows by car h_r^c are now redefined as persons per hour, whereas link flows f_a are defined as vehicles per hour, the conversion from persons to vehicles occurring in the definitional equation for link flows.

Consider the following generalization of the deterministic car route choice problem:

$$\begin{aligned}
 \min_{(\mathbf{h}^c, \mathbf{d})} z(\mathbf{h}^c, \mathbf{d}) &= v \sum_{a \in A} \int_0^{f_a} c_a(x) dx + \sum_{pq} \sum_{n \in N} C_{pq}^n d_{pq}^n \\
 \text{st: } \sum_{r \in R_{pq}^c} h_r^c &= d_{pq}^c, \quad p \in P; q \in Q \\
 \sum_{m \in M} d_{pq}^m &= \bar{d}_{pq}, \quad p \in P; q \in Q \\
 h_r^c &\geq 0, \quad r \in R_{pq}^c \quad p \in P; q \in Q \\
 d_{pq}^m &\geq 0, \quad m \in M, \quad p \in P; q \in Q \\
 \text{where } f_a &\equiv \sum_{pq} \sum_{r \in R_{pq}^c} h_r^c \delta_{ar} / v, \quad a \in A
 \end{aligned}
 \tag{40.18}$$

C_{pq}^n = fixed generalized cost of travel per person by fixed cost mode n from zone p to zone q

d_{pq}^c = flow of persons from zone p to zone q by the car mode c

d_{pq}^n = flow of persons from zone p to zone q by a fixed cost mode n , and

$$\mathbf{d} = \left(d_{pq}^m \right)$$

v = mean car occupancy, the ratio of all car occupants to all cars (persons per vehicle)

Note the following additions and changes in model formulation (40.18):

1. A parameter v is inserted in the first term of the objective function, and the definition of link flows, enabling the units of persons and vehicles to be represented consistently.
2. A second term is added to the objective function defining the total costs of fixed cost modes.
3. A new constraint requires the O-D-mode flows to sum to the exogenous O-D flow \bar{d}_{pq} .
4. The set of routes by car is redefined as R_{pq}^c .

This formulation seeks to find the allocation of exogenous O-D flows to the several modes, and within the car mode to routes, so as to minimize a function of total generalized cost. Because car route flows should be UE, the total cost of car travel is not minimized; rather, the sum of the integrals of the links cost functions is retained. The derivation of the optimality conditions with respect to h_r^c , d_{pq}^c , and d_{pq}^n is left as an exercise for the reader; their interpretation is presented in the second row of Table 40.1, where u_{pq}^c is a dual variable associated with the car route flow conservation constraints, and κ_{pq} is a new dual variable associated with the O-D flow conservation constraints.

To interpret these conditions, consider the case of $h_r^c > 0$, for an O-D pair pq . The UE route travel cost is $C_r^c \equiv \sum_{a \in A} c_a(f_a) \delta_{ar} = u_{pq}^c$, as is true for all used car routes from zone p to zone q . If $h_r^c > 0$, then $d_{pq}^c > 0$, and $u_{pq}^c = \kappa_{pq}$, the equilibrium modal O-D cost from zone p to zone q . If $\kappa_{pq} = C_{pq}^n$, for one or more of the fixed cost modes $n \in N$, then $d_{pq}^n \geq 0$; otherwise, $C_{pq}^n > \kappa_{pq}$, and $d_{pq}^n = 0$. The following conclusions may be drawn for this deterministic formulation:

1. If O-D flows occur by car, then all used routes have equal cost, and no unused route has a lower cost.
2. The UE costs of the used car routes not only determine the O-D cost but also determine whether any of the fixed cost modes (public transport, cycle, and walk) have sufficiently low costs to be used: if $u_{pq}^c < C_{pq}^n$, then $d_{pq}^n = 0$ (no one uses mode n). If $u_{pq}^c = C_{pq}^n$, then the O-D cost of fixed cost mode n and car are equal, and use of mode n may occur. If $u_{pq}^c > C_{pq}^n = \kappa_{pq}$, then all O-D flow occurs by one or more fixed cost modes, such as public transport from an outer suburb to the CBD, and no one uses car. That is, either there is no fixed cost mode flow or the fixed mode cost sets a maximum level for the car costs for each O-D pair. Hence, the solution is “all-or-nothing” with respect to mode.

3. If the car occupancy v were not added to the first term of the objective function, and to the definition of link flow, then the car O-D cost would be different from the O-D equilibrium cost by a factor equal to v . For consistency of the formulation, then, the parameter v is needed in the objective function.

One often observes travel by two or more modes (car, public transport, cycle, or walk) between many O-D pairs in survey data. Therefore, the formulation of the mode and car route choice model as a deterministic cost minimization problem, while instructive, is unrealistic. The relaxation of this deterministic formulation is proposed through the addition of a modal dispersion constraint, as in the stochastic route choice model. A function representing modal dispersion may be imposed to make mode choices more dispersed than the DUE minimum level; that is, some choices are allocated to higher cost modes. The form of the constraint is

$$-\sum_{pq} \sum_{m \in M} d_{pq}^m \ln(d_{pq}^m) \geq S \quad (40.19)$$

where S represents the level of dispersion of the choices to higher cost modes. Note: S cannot be observed except in very simple cases in which all of the observed choices are enumerated. S cannot be determined from sample data because a sample by its nature is less dispersed (more clustered) than the population. Let this constraint be added to the mode and route problem (40.18) above. The analysis of the optimality conditions is shown in the Mode and Route row of Table 40.2.

Let $1/\mu$ be the dual variable associated with the dispersion constraint. Then, in the same way as the logit route choice function was derived in Sect. 40.3.4, a logit mode choice function may be derived, as shown in the upper panel of the Mode and Route row of Table 40.2. This choice function includes the fixed cost modes (public transport, cycle, and walk), as well as car with its endogenous deterministic route costs. Together with the same UE conditions for car route costs, the function depicts the equilibrium conditions for stochastic mode and deterministic route choice. By replacing the car deterministic route conditions with the stochastic route choice function, a combined stochastic mode and route choice function may be obtained, as shown in the lower panel of the Mode and Route row of Table 40.2. Here the O-D cost of the car mode is the “composite cost” derived from the denominator of the logit route choice function. This composite cost replaces the equal route costs of each O-D pair governed by the deterministic conditions. The derivation of such a composite cost is given in the next section.

40.3.6 O-D, Mode, and Route Choice over Road and Fixed Cost Networks

The combined mode and route choice formulation can be further extended to include an origin–destination dispersion function in the same manner as described above for mode choice. In the version presented here, constraints are added to the mode and route choice formulation to derive a model corresponding to the classical

trip distribution function (Wilson 1970, pp. 15–17). These constraints consist of origin and destination constraints and another dispersion function representing dispersion of trips to higher cost destinations, separately from the modal dispersion constraint. In the following development, the relationship of these two constraints is explored. This formulation may be stated as follows, by further augmenting problem (40.18):

$$\begin{aligned}
 \min_{(\mathbf{h}^c, \mathbf{d})} z(\mathbf{h}^c, \mathbf{d}) &= v \sum_{a \in A} \int_0^{f_a} c_a(x) dx + \sum_{pq} \sum_{n \in N} C_{pq}^n d_{pq}^n \\
 \text{st: } \sum_{r \in R_{pq}^c} h_r^c &= d_{pq}^c, \quad p \in P, q \in Q \\
 \sum_m d_{pq}^m &= d_{pq}, \quad p \in P, q \in Q \\
 - \sum_{pqm} d_{pq}^m \ln \left(\frac{d_{pq}^m}{d_{pq}} \right) &\geq S^M \\
 \sum_q d_{pq} &= \bar{O}_p, \quad p \in P \\
 \sum_p d_{pq} &= \bar{D}_q, \quad q \in Q \\
 - \sum_{pq} d_{pq} \ln(d_{pq}) &\geq S^{PQ} \\
 h_r^c &\geq 0, \quad r \in R_{pq}^c, p \in P, q \in Q \\
 d_{pq}^m &> 0, \quad m \in M, p \in P, q \in Q \\
 d_{pq} &> 0, \quad p \in P, q \in Q, \\
 \text{where } f_a &\equiv \sum_{pq} \sum_{r \in R_{pq}^c} h_r^c \delta_{ar} / v, \quad a \in A
 \end{aligned} \tag{40.20}$$

The O-D-mode flow d_{pq}^m is assumed to be conditional on the O-D flow d_{pq} through its insertion into the denominator of the mode dispersion constraint as an a priori flow. The modal flows d_{pq}^m are constrained to sum to the O-D flow by the mode conservation of flow constraint. The origin–destination dispersion constraint is defined on S^{PQ} , and the O-D flows are constrained by the exogenous origin and destination totals, \bar{O}_p and \bar{D}_q .

Analysis of the UE conditions for car proceeds in the same way as in the mode and route choice models with regard to UE car cost C_{pq}^c . Consider the optimality conditions for d_{pq}^m and d_{pq} :

$$\begin{aligned}
 \ln \left(\frac{d_{pq}^m}{d_{pq}} \right) &= \mu \left(\kappa_{pq} - C_{pq}^m \right) - 1 \\
 \ln(d_{pq}) &= \eta \left(\alpha_p + \beta_q - \kappa_{pq} - \frac{1}{\mu} \right) - 1
 \end{aligned} \tag{40.21}$$

where $1/\eta$ is the dual variable for the O-D dispersion constraint and α_p and β_q are respectively the dual variables for the origin and destination constraints. Solving the first condition for d_{pq}^m , and applying the mode conservation of flow constraint, yields

$$d_{pq}^m = d_{pq} \exp(\mu \kappa_{pq} - 1) \exp(-\mu C_{pq}^m) \quad (40.22)$$

$$\sum_{m \in M} d_{pq}^m = d_{pq} = d_{pq} \exp(\mu \kappa_{pq} - 1) \sum_{m \in M} \exp(-\mu C_{pq}^m) \quad (40.23)$$

Solving for the exponential function containing κ_{pq} ,

$$\exp(\mu \kappa_{pq} - 1) = 1 / \sum_{m \in M} \exp(-\mu C_{pq}^m) \quad (40.24)$$

which can then be substituted into Eq. (40.22) to yield for the case of the car mode:

$$d_{pq}^c = d_{pq} \frac{\exp(-\mu C_{pq}^c)}{\sum_{m \in M} \exp(-\mu C_{pq}^m)} \quad (40.25)$$

This result expresses the O-D-car flow as the O-D flow times a logit function based on the UE cost for car C_{pq}^c and the costs of the fixed costs modes C_{pq}^n . A similar expression may be derived for the fixed cost modes. Now define $\exp(-\mu \tilde{C}_{pq}) \equiv \sum_{m \in M} \exp(-\mu C_{pq}^m)$; taking logs and solving for \tilde{C}_{pq} gives the modal composite cost from zone p to zone q ,

$$\tilde{C}_{pq} = -\frac{1}{\mu} \ln \sum_{n \in M} \exp(-\mu c_{pqn}) \quad (40.26)$$

Note that Eq. (40.24) can be rearranged as $\exp(-\mu(\kappa_{pq} + \frac{1}{\mu})) = \sum_{m \in M} \exp(-\mu C_{pq}^m)$. Therefore,

$$\tilde{C}_{pq} = \left(\kappa_{pq} + \frac{1}{\mu} \right) \quad (40.27)$$

An expression for the O-D flow d_{pq} can then be derived from optimality condition (40.21):

$$d_{pq} = \exp(\alpha_p + \beta_q - 1) \exp\left(-\eta\left(\kappa_{pq} + \frac{1}{\mu}\right)\right) = \exp(\alpha_p + \beta_q - 1) \exp(-\eta \tilde{C}_{pq}) \quad (40.28)$$

By applying the origin and destination constraints, a more compact expression may be obtained:

$$d_{pq} = A_p \bar{O}_p B_q \bar{D}_q \exp(-\eta \tilde{C}_{pq}) = \frac{\bar{O}_p \bar{D}_q \exp(-\eta C_{pq})}{\sum_q B_q \bar{D}_q \exp(-\eta C_{pq}) \sum_p A_p \bar{O}_p \exp(-\eta C_{pq})} \quad (40.29)$$

where A_p and B_q are balancing factors defined by Eq. (40.29) that insure that \bar{O}_p , the exogenous originating flow from zone p , and \bar{D}_q , the exogenous terminating flow at zone q , are satisfied (Wilson 1970, pp. 22–25). By substituting the O-D function for d_{pq} into the O-D-mode function for d_{pq}^m , the combined O-D-mode function may be stated as

$$d_{pq}^m = A_p \bar{O}_p B_q \bar{D}_q \exp(-\eta \tilde{C}_{pq}) \frac{\exp(-\mu C_{pq}^m)}{\sum_{m \in M} \exp(-\mu C_{pq}^m)} \quad (40.30)$$

This model may be extended further to include stochastic route choice, as described in Sect. 40.3.4. According to one hierarchy hypothesized to motivate the dispersion constraints, route choices are deterministic cost-minimizing functions of car travel costs, mode choices tend to be cost minimizing with some dispersion to the higher cost mode, and O-D choices are even less cost minimizing. By this rationale, the cost sensitivity parameters estimated from survey data for the logit functions should have numerical values such that $\eta \leq \mu$; a larger value of the parameter means that travelers are more sensitive to the fixed transport costs and UE car costs than for a smaller parameter value. For an interpretation of these coefficients based on the utilities of the choices, see Williams (1977, pp. 330–336) and Oppenheim (1995, pp. 198–205).

These values have additional implications in the logit function context. The cross elasticities of flow (demand) with respect to mode choice may be negative if $\eta > \mu$, meaning that an increase in the cost c' of a mode m' would lead to a decrease in the demand for traffic on the competing mode m'' , contradicting what intuitively would be expected from the transportation system (Abrahamsson and Lundqvist 1999, p. 93). An implication of estimated parameter values that violate this condition is that the hypothesis of the model is incorrect and that mode choice is less cost minimizing than O-D choice or, equivalently, that O-D choice should be conditional on mode choice. This situation led Abrahamsson and Lundqvist (1999, pp. 86–87) to hypothesize the “reverse nested combined model,” shown in the fourth row of Table 40.2. For this hypothesis, mode choice is less cost minimizing than O-D choice. If the cost of the modes are very different (low for car and high for public transport), a very small value of μ could be required for the estimated model to predict the sample choices correctly.

Boyce and Bar-Gera (2003) found that the parameter size condition was violated for other travel (not home-to-work travel) during the morning peak period for the Chicago area in 1990. Formulation and solution of such models for forecasting and scenario analysis is only meaningful if travel is segmented into several homogeneous classes, and implemented for time periods during the day with relatively stable levels of congestion.

40.4 Model Solution and Implementation

The solution and implementation of combined models of urban travel choice proceeded slowly in comparison with the sequential procedure in travel forecasting practice. Even so, combined models have provided a framework and basis for evaluating solution methods used in practice. This section briefly traces the evolution of solution methods for combined models, and describes a few notable efforts regarding their implementation and validation, concluding with a discussion of a new traffic assignment method for finding unique route flows and multi-class link flows.

40.4.1 Solution Algorithms

When the formulation of a model of variable demand and route choice on a network was first proposed by Beckmann et al. (1956), no solution algorithm was offered. Despite the needs of transportation planning studies in the United States, 1955–1975, and the United Kingdom, 1960–1975, to forecast urban travel for congested conditions, the potential contribution of Beckmann’s formulation was not recognized. By the late 1960s, several Ph.D. students had rediscovered Beckmann’s formulation and began to propose solution algorithms. Among these, the algorithm of Suzanne Evans was the most detailed and promising (Evans 1976). Evans proposed an iterative, convergent algorithm for trip distribution and traffic assignment (O-D and road route choice) that linearized the objective function only as necessary, and otherwise used the O-D choice functions directly. Her algorithm may be summarized as follows:

- Step 1 Find an initial solution: for free-flow link travel costs by road, find the least cost car routes between all zone pairs, compute an initial car O-D matrix with the travel choice function, and assign it to the least cost routes, resulting in an initial link flow vector; these arrays define a current feasible solution.
- Step 2 For the travel costs corresponding to the current road link flow vector, find the least cost car routes, compute a new O-D matrix with the travel choice function, and assign the car O-D matrix to the least cost routes, resulting in a new link flow vector.
- Step 3 Find weights $(1 - \lambda)$ and λ , $0 \leq \lambda \leq 1$, when used to compute a weighted average of the current and new O-D matrices and link flow vectors, minimizes

the objective function of the formulation augmented by the nonlinear dispersion function times its dual variable.

Step 4 Compute a convergence measure for the updated O-D matrix and link flow vector; if the solution has not converged to the target level, update the current solution and return to step 2; otherwise, stop.

The above algorithm is a partial linearization method for solving a convex optimization problem (Patriksson 1994, pp. 104–111). Although convergent, and useful for solutions on mainframe computers of the 1970–1980s era, the method converges slowly after the first several iterations. At that time, computer resources were generally insufficient to permit more than a few iterations for implementations of several hundred zones and a few thousand links typical of that period. A related algorithm, now known as the Frank-Wolfe method, began to be used from the mid-1970s to solve the road traffic assignment problem with fixed O-D flows.

Combined models of travel choices were implemented and estimated since the early 1980s. To be realistic for practice, such models should represent two or more classes of travelers plus trucks. An early multi-class model was implemented and estimated by Lam and Huang (1992). A model implementation similar in scale to those used in practice was undertaken by Boyce and Bar-Gera (2003) for the morning peak period of the Chicago region. Extensive estimation studies were undertaken; the model was validated with travel-to-work data from the 1990 US Census, contributing new methods for model validation as well as model estimation. That model was solved with the Evans algorithm, the state of the art at that time.

As computers expanded in size and speed during the 1980s with the introduction of supercomputers, engineering workstations and personal computers of similar memory and speed, algorithms for solving the traffic assignment problem with more precision and speed were proposed (Bar-Gera 2002; Dial 2006). These algorithms were origin-based, in contrast to the link-based assignment algorithm based on the full linearization of the objective function. Bar-Gera and Boyce (2003) applied Bar-Gera's origin-based traffic assignment algorithm to devise a solution method for the origin-destination, mode, and car route choice problem that achieved more precise convergence than is possible with the Evans algorithm for large-scale problems. This algorithm replaced the link-based assignment in step 2 with an origin-based procedure to update the solution of the assignment problem. Then the O-D matrices are updated followed by another assignment update, continuing until the convergence criterion is met. Unlike the Evans algorithm, a line search and averaging of solutions are not required.

De Cea et al. (2005) implemented and estimated a combined model for Santiago, Chile. A software system for solving the model, ESTRAUS, was created and applied in the redesign of the public transport system of Santiago (<http://en.wikipedia.org/wiki/Transantiago>). STGO, a software application in EMME, was created to implement a closely related model (Florian et al. 2002). These two systems represent two further implementations of combined models that are used by practitioners. CUBE (www.citilabs.com), TransCAD (www.caliper.com), and VISUM (www.ptv.de) also have the possibility to serve as platforms for

implementing combined models. However, such implementations require substantial knowledge and programming skills.

Solution of the stochastic route choice problem for large networks at a level of precision similar to DUE remains a work in progress. Lee et al. (2010) provided a detailed literature review, proposed two new algorithms, and reported computational results for a problem of moderate size. The use of a method proposed by Bell to find routes avoids the use of a maximum route length. Other problems remain, however, including overlapping routes, as discussed in Sect. 40.3.4.

40.4.2 Unique Route Flows and Multi-class Link Flows

For project evaluation and scenario analyses, total link flows and class O-D flows may suffice. More detailed analyses, however, require O-D-route flows or class link flows. Neither is uniquely determined by the solution of the standard traffic assignment formulation. Computed route flows and class link flows may be quite arbitrary. A simple example in Bar-Gera et al. (2012) illustrates this dilemma, which is well known to researchers and advanced practitioners.

To choose among the infinite possibilities of route flow solutions for a UE model, an additional behavioral assumption is required. One plausible assumption is proportionality, namely, that the proportion of O-D flows assigned to each of two alternative route segments with precisely equal costs should be the same regardless of their origin or their destination. Proportionality also determines class link flows uniquely in multi-class assignments.

The fixed demand traffic assignment with proportionality can be solved in two ways. First, the standard assignment problem can be solved with an origin-based algorithm to a precise level of convergence, such as a relative gap equal to $1E-7$. Then the route flows can be adjusted with a post-processing procedure to achieve the same proportions for each O-D flow over each pair of alternative segments, leaving the link flows unchanged. This procedure is now available in the TransCAD and VISUM software systems. Second, the proportionality condition can be used to design a new algorithm to solve the assignment problem. This approach was the basis for TAPAS (Bar-Gera 2010). Comparisons of solutions with TAPAS versus link-based and route-based tools for the Chicago regional road network were presented in Bar-Gera et al. (2012).

An example of route flows over a pair of alternative segments in the road network of the Chicago region is considered next. Two O-D matrices representing cars and trucks were assigned with TAPAS to the Chicago network by imposing the user-equilibrium principle with proportionality. The total flow of vehicles per hour in the matrices is 984,717 cars and 445,185 trucks in car equivalent units. The matrices were assigned to two networks: (a) an unrestricted network in which trucks can use any link and (b) a restricted network in which trucks are prohibited from using 563 car-only links (car-only lanes of two freeways, the Lake Shore Drive, and boulevards and other roads with truck prohibitions). According to the proportionality condition, class O-D flows using a pair of alternative segments should have the same proportion

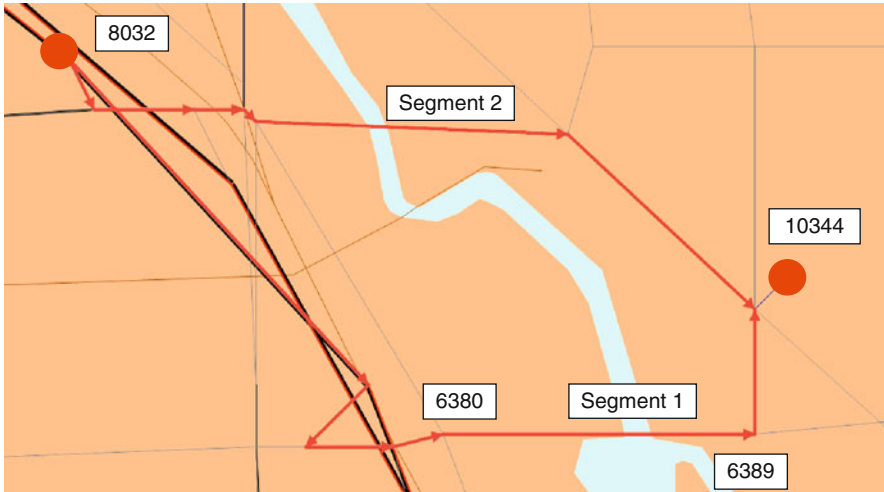

Fig. 40.2 Pair of alternative segments in the Chicago road network

on each segment for each assignment. Since the generalized cost variable is defined to be travel time, the same proportions should be observed for cars and trucks over a pair of segments with no truck restrictions. A pair of segments connecting nodes 8032 and 10344, shown in Fig. 40.2, was selected for this example.

Figure 40.3 compares the total O-D-segment flows on Segment 2 (y-axis) with the total O-D-segment flows on Segment 1 (x-axis). These flows lie on a straight line, showing that the condition of proportionality is imposed. The slopes of the lines are slightly different, indicating only a small change in the proportions between the solutions for the restricted and unrestricted networks. Although the alternative segments have precisely equal travel times in each of the two solutions, the total flows are somewhat different, as shown at the top of the figure for the two solutions. Figure 4 shows the car flows for segments 1 and 2. Note the slopes in Fig. 40.4 are the same as in Fig. 40.3. The truck flows, the differences between the flows in Figs. 40.3 and 40.4, are not shown, but have the same slopes.

The application of the condition of proportionality provides a meaningful and practical solution to the problem of nonuniqueness of route flows and multi-class link flows. TAPAS offers a method for rapidly and precisely solving the traffic assignment problem with proportionality.

40.5 Conclusions

Despite 60 years of research on urban transportation network equilibrium, many problems remain unsolved, and practice lags increasingly behind research knowledge. Research problems may be broadly classified according to travel choices, network representation, network design, and solution procedures, among others.

Fig. 40.3 Total route flows over two networks: (a) 683 segment pairs on unrestricted network (*squares*); (b) 678 segment pairs on restricted network (*triangles*)

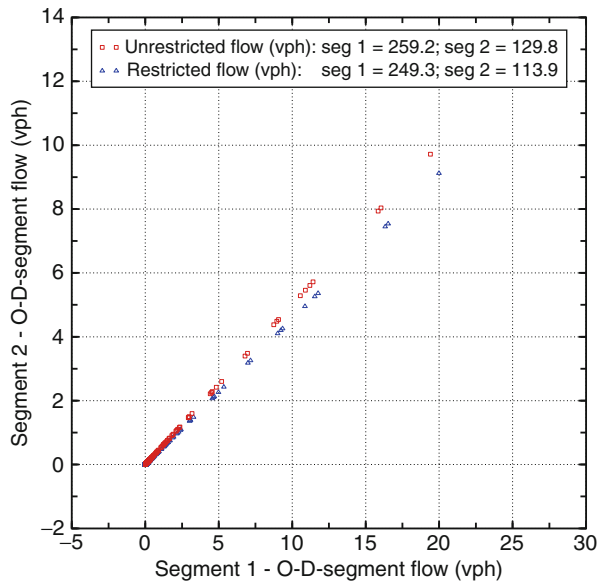

Fig. 40.4 Car route flows over two networks: (a) 680 segment pairs on unrestricted network (*squares*); (b) 670 segment pairs on restricted network (*triangles*)

a. Until now, the modeling of travel choices has mainly followed the trip-based paradigm. Increasingly, travel demand modelers view travel in terms of daily tours or daily activities. Generally, prediction of tours or activities has been approached from a micro-simulation point of view. To the author’s knowledge,

the stability of such simulations has generally not been examined, such as by generating a sufficiently large sample of simulations and analyzing their variation. Model formulations of aggregate tour-based travel using concepts similar to those described in this chapter have been studied, but more investigation is needed (Bernardin et al. 2009).

- b. The representation of travel cost functions in network equilibrium models has advanced little beyond the original separable formulation of Beckmann. Although asymmetric models can be formulated as variational inequalities, the apparent lack of uniqueness of solutions has discouraged serious efforts to investigate this approach further. For example, the side-constrained method of Patriksson (1994, pp. 66–70) has not been investigated with large networks. Solution methods have generally not advanced beyond the so-called diagonalization (relaxation) method (Marcotte and Patriksson 2007, pp. 671–673).
- c. Another problem that has received very little attention is transportation network design. In a combinatorial sense, the network design problem is intractable because of its large size. Other approaches are possible, however, such as the spacing of freeways in a grid, as was considered early in the history of this field. A new approach to this problem might be to develop methods to generate and evaluate scenarios in a systematic and semiautomated manner. Such a method would require an ability to distinguish among the merits of closely related scenarios. Given the precision of solutions to network models now possible, this capability may now be achievable.
- d. Although practitioners are required by government regulations in the USA to solve their sequential travel forecasting procedures in a way that achieves an internal consistency of travel costs, there is no general agreement on how this should be done. No practitioner or software developer has described, tested, and demonstrated that one procedure is best among alternatives for complex models applied in practice. Moreover, the errors introduced in forecasts that do not achieve consistency remain unknown. This relatively straightforward research problem should be tackled.
- e. Academic interest in the solution of combined model formulations of travel choice has influenced travel forecasting practice, but only to a limited extent. Except for Santiago, Chile, combined models have rarely been applied in practice. The formulation of a combined model clearly enhances the understanding of the challenges facing the practitioner in solving the model sequence. Few practitioners, however, seem equipped by their training or mathematical ability to gain from insights from these formulation. Moreover, software developers have not incorporated tools in their software systems to facilitate the application of this approach. Based upon past experience, they will not do so until interest among practitioners strongly induces them to proceed.

Pursuit of this research agenda requires a knowledge of optimization methods, computer skills, data, and perseverance. Many similar problems could be identified, especially from the viewpoint of other perspectives. For those so inclined, the journey will be challenging, but always interesting, and hopefully rewarding.

Acknowledgments Professor Huw Williams, Cardiff University, offered many useful comments on earlier drafts of this chapter. Dr. Hillel Bar-Gera, Ben-Gurion University of the Negev, has offered many stimulating insights and contributions to my thinking on combined network equilibrium models during the past 15 years. Dr. Yu (Marco) Nie, Northwestern University, has been a stimulating colleague during my renewed association with my undergraduate alma mater.

Their contributions are greatly appreciated. Remaining errors are my responsibility.

Abstract

We overview some of the major advances in supply chains and transportation networks, with a focus on their common theoretical frameworks and underlying behavioral principles. We emphasize that the foundations of supply chains as network systems can be found in the regional science and spatial economics literature. In addition, transportation network concepts, models, and accompanying methodologies have enabled the advancement of supply chain network models from a system-wide and holistic perspective.

We discuss how the concepts of system optimization and user optimization have underpinned transportation network models and how they have evolved to enable the formulation of supply chain network problems operating (and

e-mail: nagurney@isenberg.umass.edu

managed) under centralized or decentralized, that is, competitive, decision-making behavior.

We highlighted some of the principal methodologies, including variational inequality theory, that have enabled the development of advanced transportation network equilibrium models as well as supply chain network equilibrium models.

41.1 Introduction

Supply chains are networks of suppliers, manufacturers, transportation service providers, storage facility managers, retailers, and consumers at the demand markets. Supply chains are the backbones of our globalized network economy and provide the infrastructure for the production, storage, and distribution of goods and associated services as varied as food products, pharmaceuticals, vehicles, computers, and other high-tech equipment, building materials, furniture, clothing, toys, and even electricity.

Supply chains may operate (and be managed) in a centralized or decentralized manner and be underpinned not only by multimodal transportation and logistical networks but also by telecommunication as well as financial networks. In a centralized supply chain, there is a central entity or decision-maker, such as a firm, that controls the various supply chain network activities, whereas in a decentralized supply chain, there are multiple economic decision-makers, and the governing paradigm is that of competitive behavior among the relevant stakeholders, with different degrees of cooperation. For example, in a vertically integrated supply chain, the same firm may be responsible for production, storage, and distribution of its products. On the other hand, certain industry supply chain network structures may consist of competitive manufacturers, competitive distributors, as well as competing retailers. Nevertheless, the stakeholders involved in supply chains must cooperate to the extent that the products be received and processed as they move downstream in the supply chain (Nagurney 2006).

The complexity and interconnectivity of some of today's product supply chains have been vividly illustrated through the effects of recent natural disasters, including earthquakes, tsunamis, and even hurricanes, which have severed critical nodes and/or links and have disrupted the production and transportation of products, with major economic implications. Indeed, when supply chain disruptions occur, whether due to natural disasters, human error, attacks, or even market failure, the ramifications can propagate and impact the health and well-being of the citizenry thousands of miles away from the initially affected location (cf. Nagurney and Qiang 2009).

Since supply chains are network systems, any formalism that seeks to model supply chains and to provide quantifiable insights and measures must be a system-wide one and network based. Such crucial issues as the stability and resiliency of supply chains, as well as their adaptability and responsiveness to events in a global

environment of increasing risk and uncertainty, can only be rigorously examined from the view of supply chains as network systems (Nagurney 2006).

Supply chains share many of the same characteristics as other network systems, including a large-scale nature and complexity of network topology; congestion; which leads to nonlinearities; alternative behavior of users of the networks, which may lead to paradoxical phenomena (recall the well-known Braess paradox in which the addition of a new road may increase the travel time for all); possibly conflicting criteria associated with optimization (the minimization of time for delivery, e.g., may result in higher emissions); interactions among the underlying networks themselves, such as the Internet with electric power networks, financial networks, and transportation and logistical networks; and the growing recognition of their fragility and vulnerability. Moreover, policies surrounding supply chain networks today may have major implications not only economically but also socially, politically, and security-wise.

Although, historically, supply chain activities of manufacturing, transportation/distribution, as well as inventorying/storage have each, independently, received a lot of attention from both researchers and practitioners, the framework of supply chains views the various activities of production, transportation, and consumption in an integrated, holistic manner. Indeed, without the critical transportation links, what is manufactured cannot be delivered to points of demand. Moreover, needed inputs into the production processes/manufacturing links cannot be secured.

While, beginning in the 1980s (cf. Handfield and Nichols 1999), supply chains have captured wide interest among practitioners as well as researchers, it may be argued that the foundations of supply chain networks can be found in regional science and spatial economics, dating to the classical spatial price equilibrium models of Samuelson (1952) and Takayama and Judge (1971) with additional insights as to production processes, transportation, and distribution provided by Beckmann et al. (1956). For example, in spatial price equilibrium models, not only is production of the commodity in question considered at multiple locations or supply markets, with appropriate underlying functions, but also the consumption of the commodity at the demand markets, subject to appropriate functions (either demand or demand price) as well as the cost associated with transporting the commodity between pairs of the spatially separated supply and demand markets. Spatial price equilibrium models have evolved to include multiple commodities and multiple modes of transportation and may even include general underlying transportation networks. Moreover, with advances in theoretical frameworks, including, for example, the theory of variational inequalities (Nagurney 1999), one can now formulate and solve complex spatial price equilibrium problems with asymmetric supply price, demand price, and unit transportation/transaction cost functions (for which an optimization reformulation of the governing spatial price equilibrium conditions does not hold).

In addition, versions of spatial equilibrium models that capture oligopolistic behavior under imperfect, as opposed to perfect, competition serve as some of the basic supply chain network models in which competition is included, but, at the

same time, the important demand/consumption side is also captured (see Nagurney (1999) and the references therein).

Interestingly, spatial price equilibrium problems can be reformulated and solved as transportation network equilibrium problems with elastic demands over appropriately constructed abstract networks or supernetworks (see Nagurney and Dong 2002). Hence, the plethora of algorithms that have been developed for transportation networks (cf. Sheffi 1985; Patriksson 1994; Nagurney 1999; Ran and Boyce 1996) can also be applied to compute solutions to spatial price equilibrium problems. It is worth noting that Beckmann, McGuire, and Winsten in their classical 1956 book, *Studies in the Economics of Transportation*, formulated transportation network equilibrium problems with elastic demands. They proved that under the assumed user link cost functional forms and the travel disutility functional forms associated with the origin/destination pairs of nodes that the governing equilibrium conditions (now known as user-optimized conditions) in which no traveler has any incentive to alter his route of travel, given that the behavior of others is fixed, could be reformulated and solved as an associated optimization problem. In their book, they also hypothesized that electric power generation and distribution networks, or in today's terminology, electric power supply chains, could be transformed into transportation network equilibrium problems. This has now been established (cf. Nagurney (2006) and the references therein).

Today, the behavior of travelers on transportation networks is assumed to follow one of Wardrop's (1952) two principles of travel behavior, now renamed, according to Dafermos and Sparrow (1969), as user-optimized (selfish or decentralized) or system-optimized (unselfish or centralized). The former concept captures individuals' route-taking decision-making behavior, whereas the latter assumes a central controller that routes the flow on the network so as to minimize the total cost.

Moreover, a plethora of supply chain network equilibrium models, originated by Nagurney et al. (2002), have been developed in order to address competition among decision-makers in a tier of a supply chain whether among the manufacturers, the distributors, the retailers, and/or even the consumers at the demand markets. Such models capture the behavior of the individual economic decision-makers, as in the case, for example, of profit maximization, and acknowledge that consumers also take transaction/transportation costs into consideration in making their purchasing decisions. Prices for the product associated with each decision-maker at each tier are obtained once the entire supply chain network equilibrium problem is solved, yielding also the equilibrium flows of the product on the links of the supply chain network. Such supply chain network equilibrium models also possess (as spatial price equilibrium problems highlighted above) a transportation network equilibrium reformulation.

Supply chain network models have been generalized to include electronic commerce options, multiple products, as well as risk and uncertainty on the demand-side as well as on the supply side (cf. Nagurney (2006) and the referenced therein). In addition, and, this is product-specific, supply chain network models have also been constructed to handle time-sensitive products (fast fashion, holiday based, and even critical needs as in disasters) as well as perishable products (such as

food, cut flowers, certain vaccines and medicines, etc.) using multicriteria decision-making formalisms for the former and generalized networks for the latter (see Masoumi et al. 2012). Both static as well as dynamic supply chain network models, including multiperiod ones with inventorying, have been formulated, solved, and applied.

It is important to note that not all supply chains are commercial, and, in fact, given that the number of disasters is growing, as is the number of people affected by them, humanitarian supply chains have emerged as essential elements in disaster recovery. Unlike commercial or corporate supply chains, humanitarian supply chains are not managed using profit maximization as a decision-making criterion (since donors, e.g., would not approve), but rather cost minimization subject to demand satisfaction under uncertainty is relevant (see Nagurney and Qiang 2009). In addition, such supply chains may need to be constructed quickly and with the cognizant decision-makers working under conditions of damaged, if not destroyed, infrastructure and limited information.

Supply chain decision-making occurs at different levels – at the strategic, tactical, and operational levels. Strategic decisions may involve where to locate manufacturing facilities and distribution centers, whereas tactical decisions may include with which suppliers to partner and which transportation service providers (carriers) to use. Decisions associated with operational supply chain decision-making would involve how much of the product to produce at which manufacturing plants, which storage facilities to use and how much to store where, as well as how much of the product should be supplied to the different retailers or points of demand. In addition, because of globalization, supply chain decision-making may now involve outsourcing decisions as well as the accompanying risk management.

Today, it has been argued that, increasingly, in the network economy it is not only competition within a product supply chain that is taking place but, rather, supply chain versus supply chain competition. Zhang et al. (2003) generalized Wardrop's first principle of travel behavior to formulate competition among supply chains.

Location-based decisions are fundamental to supply chain decision-making, design, and management. Furthermore, such decisions affect spatial competition as well as trade, with Ohlin (1933) and Isard (1954) noting the need to integrate industrial location and international trade in a common framework.

Nagurney (2010) constructed a system-optimization model that can be applied to the design or redesign of a supply chain network and has as endogenous variables both the capacities associated with the links (corresponding to manufacturing, transportation, and storage) as well as the operational flows of the product in order to meet the demands. The model has been extended in various directions to handle oligopolistic competition as well as product perishability in specific applications (cf. Masoumi et al. (2012) and the references therein).

At the same time that supply chains have become increasingly globalized, environmental concerns due to global warming and associated risks have drawn the attention of numerous constituencies. Firms are increasingly being held accountable not only for their own performance in terms of their environmental performance but also for that of their suppliers, subcontractors, joint venture

partners, distribution outlets, and, ultimately, even for the disposal of their products. Consequently, poor environmental performance at any stage of the supply chain may damage the most important asset that a company has, which is its reputation. Hence, the topic of sustainable supply chain network modeling and analysis has emerged as an essential area for research, practice, as well as for policy analysis (see Boone et al. 2012).

41.2 Fundamental Decision-Making Concepts and Models

In this section of this chapter, we interweave fundamental concepts in transportation that have been used successfully and with wide application in supply chain network modeling, analysis, operations management, and design. Our goal is to provide the necessary background from which additional explorations and advances can be made using a readable and accessible format.

As noted in the introduction, over half a century ago, Wardrop (1952) considered alternative possible behaviors of users of transportation networks, notably, urban transportation networks, and stated two principles, which are named after him:

First principle: The journey times of all routes actually used are equal and less than those which would be experienced by a single vehicle on any unused route.

Second principle: The average journey time is minimal.

The first principle corresponds to the behavioral principle in which travelers seek to (unilaterally) determine their minimal costs of travel; the second principle corresponds to the behavioral principle in which the total cost in the network is minimal.

Beckmann et al. (1956) were the first to rigorously formulate these conditions mathematically and proved the equivalence between the *transportation network equilibrium* conditions, which state that all used paths connecting an origin/destination (O/D) pair will have equal and minimal travel times (or costs) (corresponding to Wardrop's first principle), and the Kuhn-Tucker conditions of an appropriately constructed optimization problem, under a symmetry assumption on the underlying functions. Hence, in this case, the equilibrium link and path flows could be obtained as the solution of a mathematical programming problem. Their fundamental result made the formulation, analysis, and subsequent computation of solutions to transportation network problems based on actual transportation networks realizable.

Dafermos and Sparrow (1969) coined the terms *user-optimized* (U-O) and *system-optimized* (S-O) transportation networks to distinguish between two distinct situations in which, respectively, travelers act unilaterally, in their own self-interest, in selecting their routes and in which travelers choose routes/paths according to what is optimal from a societal point of view, in that the total cost in the network system is minimized. In the latter problem, marginal total costs rather than average costs are equilibrated. As noted in the introduction, the former problem coincides with Wardrop's first principle and the latter with Wardrop's second principle. Table 41.1 highlights the two distinct behavioral principles underlying transportation networks.

Table 41.1 Distinct behavior on transportation networks

<i>User optimization</i>	<i>System optimization</i>
↓	↓
<i>User equilibrium principle</i>	<i>System-optimality principle</i>
User travel costs on used paths for each O/D pair are equalized and minimal	Marginals of the total travel cost on used paths for each O/D pair are equalized and minimal

The concept of “system optimization” is also relevant to other types of “routing models” in transportation, including those concerned with the routing of freight. Dafermos and Sparrow (1969) also provided explicit computational procedures, that is, *algorithms*, to compute the solutions to such network problems in the case where the user travel cost on a link was an increasing (in order to handle congestion) function of the flow on the particular link and linear. Today, the concepts of user optimization versus system optimization also capture, respectively, decentralized versus centralized decision-making on supply chain networks after the proper identifications are made (Boyce et al. 2005; Nagurney 2006).

In this section, the basic transportation network models are first recalled, under distinct assumptions as to their operation and the underlying behavior of the users of the network. The models are classical and are due to Beckmann et al. (1956) and Dafermos and Sparrow (1969). In subsequent sections, we present more general models in which the user link cost functions are no longer separable but, rather, are asymmetric. For such models, we also provide the variational inequality formulations of the governing equilibrium conditions, since, in such cases, the governing equilibrium conditions can no longer be reformulated as the Kuhn-Tucker conditions of a convex optimization problem. The presentation follows that in Nagurney (2007) with addition of material on supply chains with synthesis.

For easy accessibility, we recall the classical user-optimized network model in Sect. 41.2.1 and then the classical system-optimized network model in Sect. 41.2.2. The Braess (1968) paradox is, subsequently, highlighted in Sect. 41.2.3.

41.2.1 The User-Optimized Problem

The user-optimized network problem is also commonly referred to in the transportation literature as the *traffic assignment* problem or the *traffic network equilibrium* problem.

Consider a general network $\mathcal{G} = [\mathcal{N}, \mathcal{L}]$, where \mathcal{N} denotes the set of nodes and \mathcal{L} the set of directed links. Links connect pairs of nodes in the network and are denoted by a, b , etc. Let p denote a path consisting of a sequence of links connecting an origin/destination (O/D) pair of nodes. Paths are assumed to be acyclic and are denoted by p, q , etc. In transportation networks, nodes correspond to origins and destinations, as well as to intersections. Links, on the other hand, correspond to

roads/streets in the case of urban transportation networks and to railroad segments in the case of train networks. A path in its most basic setting, thus, is a sequence of “roads” which comprise a route from an origin to a destination. In the supply chain network context, links correspond to supply chain activities (with appropriate associated cost functions) and represent manufacturing, transportation/shipment, storage, etc. In addition, links can correspond to outsourcing links (see Nagurney 2006).

Here we consider *paths*, rather than *routes*, since the former subsumes the latter. The network concepts presented here are sufficiently general to abstract not only transportation decision-making but also combined/integrated location-transportation decision-making as well as a spectrum of supply chain decisions. In addition, in the setting of *supernetworks*, that is, abstract networks, in which nodes need to correspond to locations in space (see Nagurney and Dong 2002), a path is viewed more broadly and need not be limited to a route-type decision but may, in fact, correspond to not only transportation but also to manufacturing and inventorying/storage decision-making.

Let P_ω denote the set of paths connecting the origin/destination (O/D) pair of nodes ω . Let P denote the set of all paths in the network and assume that there are J origin/destination pairs of nodes in the set Ω . Let x_p represent the nonnegative flow on path p and let f_a denote the flow on link a . All vectors here are assumed to be column vectors. The path flows on the network are grouped into the vector $x \in R_+^{n_p}$, where n_p denotes the number of paths in the network. The link flows, in turn, are grouped into the vector $f \in R_+^{n_L}$, where n_L denotes the number of links in the network.

Assume, as given, the demand associated with each O/D pair ω , which is denoted by d_ω , for $\omega \in \Omega$. In the network, the following conservation of flow equations must hold:

$$d_\omega = \sum_{p \in P_\omega} x_p, \quad \forall \omega \in \Omega \quad (41.1)$$

where $x_p \geq 0$ and $\forall p \in P$; that is, the sum of all the path flows between an origin/destination pair ω must be equal to the given demand d_ω .

In addition, the following conservation of flow equations must also hold:

$$f_a = \sum_{p \in P} x_p \delta_{ap}, \quad \forall a \in \mathcal{L} \quad (41.2)$$

where $\delta_{ap} = 1$, if link a is contained in path p , and 0, otherwise. Expression (41.2) states that the flow on link a is equal to the sum of all the path flows on paths p that contain (traverse) link a .

Equations (41.1) and (41.2) guarantee that the flows in the network (be they travelers, products, etc.) are conserved, that is, do not disappear (or are lost) in the network and arrive at the designated destinations from the origins.

Let c_a denote the user link cost associated with traversing link a , and let C_p denote the user cost associated with traversing the path p . Assume that the user link cost function is given by the *separable* function in which the cost on a link depends only on the flow on the link, that is,

$$c_a = c_a(f_a), \quad \forall a \in \mathcal{L} \quad (41.3)$$

where c_a is assumed to be continuous and an increasing function of the link flow f_a in order to model the effect of the link flow on the cost and, in particular, congestion.

The cost on a path is equal to the sum of the costs on the links that make up that path, that is,

$$C_p = \sum_{a \in \mathcal{L}} c_a(f_a) \delta_{ap}, \quad \forall p \in P \quad (41.4)$$

41.2.1.1 Transportation Network Equilibrium Conditions

In the case of the user-optimization (U-O) problem, one seeks to determine the path flow pattern x^* (and the corresponding link flow pattern f^*) which satisfies the conservation of flow Eqs. (41.1) and (41.2) and the nonnegativity assumption on the path flows and which also satisfies the transportation network equilibrium conditions given by the following statement. For each O/D pair $\omega \in \Omega$ and each path $p \in P_\omega$,

$$C_p \begin{cases} = \lambda_\omega, & \text{if } x_p^* > 0 \\ \geq \lambda_\omega, & \text{if } x_p^* = 0 \end{cases} \quad (41.5)$$

In the user-optimization problem, there is no explicit optimization criterion, since users of the transportation network system act independently, in a noncooperative manner, until they cannot improve on their situations unilaterally and, thus, an equilibrium is achieved, governed by the above equilibrium conditions. Conditions (41.5) are simply a restatement of Wardrop's (1952) first principle mathematically and mean that only those paths connecting an O/D pair will be used which have equal and minimal user costs. In Eq. (41.5) the minimal cost for O/D pair ω is denoted by λ_ω , and its value is obtained once the equilibrium flow pattern is determined. Otherwise, a user of the network could improve upon his situation by switching to a path with lower cost.

Beckmann et al. (1956) established that the solution to the network equilibrium problem, in the case of user link cost functions of the form Eq. (41.3), in which the cost on a link only depends on the flow on that link and is assumed to be continuous and an increasing function of the flow, could be obtained by solving the following optimization problem:

$$\text{Minimize} \quad \sum_{a \in \mathcal{L}} \int_0^{f_a} c_a(y) dy \quad (41.6)$$

Fig. 41.1 The multitiered network structure of the supply chain

subject to

$$\sum_{p \in P_\omega} x_p = d_\omega, \quad \forall \omega \in \Omega \tag{41.7}$$

$$f_a = \sum_{p \in P} x_p \delta_{ap}, \quad \forall a \in \mathcal{L} \tag{41.8}$$

$$x_p \geq 0, \quad \forall p \in P \tag{41.9}$$

The objective function given by Eq. (41.6) is simply a device constructed to obtain a solution using general purpose convex programming algorithms. It does not possess the economic meaning of the objective function encountered in the system-optimization problem which will be recalled below. Note that in the case of separable, as well as nonseparable, but symmetric (which we come back to later) user link cost functions, the λ_ω term in Eq. (41.5) corresponds to the Lagrange multiplier associated with the constraint (41.7) for that O/D pair ω . However, in the case of nonseparable and asymmetric functions, there is no optimization reformulation of the transportation network equilibrium conditions (41.5), and the λ_ω term simply reflects the minimum user cost associated with the O/D pair ω at the equilibrium. As noted as early as Dafermos and Sparrow (1969), the above network equilibrium conditions also correspond to a Nash equilibrium (see Nash 1951). The equilibrium link flow pattern is unique for problem (41.6), subject to Eqs. (41.7)–(41.9), if the objective function (41.6) is strictly convex (for additional background on optimization theory).

It has also been established (cf. Nagurney (2006) and the references therein) that multitiered supply chain network problems in which decision-makers (manufacturers, retailers, and even consumers) compete across a tier of the supply chain network but cooperate between tiers, as depicted in Fig. 41.1, could be transformed

Fig. 41.2 The supernetwork representation of supply chain network equilibrium

into a transportation network equilibrium problem using a supernetwork transformation, as in Fig. 41.2. In Fig. 41.2, the activities of manufacturing and retailer handling/storage are associated with the topmost and the third sets of links, respectively. The second and fourth sets of links from the top in Fig. 41.2 are the transportation links (as is the case with the links in Fig. 41.1). This connection provides us with a path flow efficiency interpretation of supply chain network equilibria. She utilized variational inequality theory (see below) to establish the equivalence.

41.2.2 The System-Optimized Problem

We now recall the system-optimized problem. As in the user-optimized problem of Section 41.2.1, the network $\mathcal{G} = [\mathcal{N}, \mathcal{L}]$, the demands associated with the origin/destination pairs, and the user link cost functions are assumed as given. In the system-optimized problem, there is a central controller who routes the flows in an optimal manner so as to minimize the total cost in the network. This problem has direct relevance to the management of operations of a supply chain.

The total cost on link a , denoted by $\hat{c}_a(f_a)$, is given by

$$\hat{c}_a(f_a) = c_a(f_a) \times f_a, \quad \forall a \in \mathcal{L} \tag{41.10}$$

that is, the total cost on a link is equal to the user link cost on the link times the flow on the link. As noted earlier, in the system-optimized problem, there exists a central

controller who seeks to minimize the total cost in the network system, which can correspond to a supply chain, where the total cost is expressed as

$$\sum_{a \in \mathcal{L}} \hat{c}_a(f_a) \quad (41.11)$$

and the total cost on a link is given by expression (41.10).

The system-optimization (S-O) problem is, thus, given by

$$\text{Minimize } \sum_{a \in \mathcal{L}} \hat{c}_a(f_a) \quad (41.12)$$

subject to the same conservation of flow equations as for the user-optimized problem as well as the nonnegativity assumption of the path flows; that is, constraints (41.7), (41.8), and (41.9) must also be satisfied for the system-optimized problem.

The total cost on a path, denoted by \hat{C}_p , is the user cost on a path times the flow on a path, that is,

$$\hat{C}_p = C_p x_p, \quad \forall p \in P \quad (41.13)$$

where the user cost on a path, C_p , is given by the sum of the user costs on the links that comprise the path (as in Eq. (41.4)), that is,

$$C_p = \sum_{a \in \mathcal{L}} c_a(f_a) \delta_{ap}, \quad \forall a \in \mathcal{L} \quad (41.14)$$

In view of Eqs. (41.2), (41.3), and (41.4), one may express the cost on a path p as a function of the path flow variables, and, hence, an alternative version of the above system-optimization problem with objective function (41.12) can be stated in path flow variables only, where one has now the problem

$$\text{Minimize } \sum_{p \in P} C_p(x) x_p \quad (41.15)$$

subject to constraints (41.7) and (41.9).

41.2.2.1 System-Optimality Conditions

Under the assumption of increasing user link cost functions, the objective function (41.12) in the S-O problem is convex, and the feasible set consisting of the linear constraints (41.7)–(41.9) is also convex. Therefore, the optimality conditions, that is, the Kuhn-Tucker conditions, are as follows: for each O/D pair $\omega \in \Omega$ and each path $p \in P_\omega$, the flow pattern x (and corresponding link flow pattern f) satisfying Eqs. (41.7)–(41.9) must satisfy

Fig. 41.3 Case 0: firms *A* and *B* premerger

$$\hat{C}_p \begin{cases} = \mu_w, & \text{if } x_p > 0 \\ \geq \mu_w, & \text{if } x_p = 0 \end{cases} \tag{41.16}$$

where \hat{C}_p denotes the marginal of the total cost on path p , given by

$$\hat{C}_p = \sum_{a \in \mathcal{L}} \frac{\partial \hat{c}_a(f_a)}{\partial f_a} \delta_{ap} \tag{41.17}$$

evaluated in Eq. (41.16) at the solution and μ_w is the Lagrange multiplier associated with constraint (41.7) for that O/D pair w .

The system-optimization approach has been applied to supply chain networks in order to assess synergy associated with a possible merger or acquisition before such a decision, which may be very costly, is made. Nagurney and Qiang (2009) overview such an approach, which assesses the total cost prior to the merger and post.

The premerger supply chains corresponding to the individual firms, prior to the merger, are depicted in Fig. 41.3, whereas the post-merger supply chain network is given in Fig. 41.4. The topmost links correspond to the manufacturing links in Fig. 41.3, followed by the transportation links ending in the storage/distribution facility links and followed by additional shipment links to the demand markets. In Fig. 41.4, on the other hand, the topmost links represent the merger/acquisition with appropriate total cost functions assigned to those links.

41.2.3 The Braess Paradox

In order to illustrate the difference between user optimization and system optimization in a concrete example and to reinforce the above concepts, we now recall the well-known Braess (1968) paradox (see also Braess et al. 2005). Assume a network

Fig. 41.4 Post-merger network

Fig. 41.5 The Braess network example

as the first network depicted in Fig. 41.5 in which there are four nodes: 1, 2, 3, 4; four links: a, b, c, d ; and a single O/D pair $\omega_1 = (1, 4)$. There are, hence, two paths available to travelers between this O/D pair: $p_1 = (a, c)$ and $p_2 = (b, d)$.

The user link travel cost functions are

$$c_a(f_a) = 10f_a, \quad c_b(f_b) = f_b + 50, \quad c_c(f_c) = f_c + 50, \quad c_d(f_d) = 10f_d$$

Assume a fixed travel demand $d_{\omega_1} = 6$.

It is easy to verify that the equilibrium path flows are $x_{p_1}^* = 3$ and $x_{p_2}^* = 3$ and the equilibrium link flows are $f_a^* = 3, f_b^* = 3, f_c^* = 3, f_d^* = 3$, with associated equilibrium path travel costs: $C_{p_1} = c_a + c_c = 83$ and $C_{p_2} = c_b + c_d = 83$.

Assume now that, as depicted in Fig. 41.5, a new link “ e ,” joining node 2 to node 3, is added to the original network, with user link cost function $c_e(f_e) = f_e + 10$. The addition of this link creates a new path $p_3 = (a, e, d)$ that is available to the travelers. The travel demand d_{ω_1} remains at 6 units of flow. The original flow pattern $x_{p_1} = 3$ and $x_{p_2} = 3$ is no longer an equilibrium pattern, since, at this level of

flow, the user cost on path p_3 , $C_{p_3} = c_a + c_e + c_d = 70$. Hence, users on paths p_1 and p_2 would switch to path p_3 .

The equilibrium flow pattern on the new network is $x_{p_1}^* = 2$, $x_{p_2}^* = 2$, and $x_{p_3}^* = 2$, with equilibrium link flows $f_a^* = 4$, $f_b^* = 2$, $f_c^* = 2$, $f_e^* = 2$, and $f_d^* = 4$ and with associated equilibrium user path travel costs $C_{p_1} = 92$ and $C_{p_2} = 92$. Indeed, one can verify that any reallocation of the path flows would yield a higher travel cost on a path.

Note that the travel cost increased for every user of the network from 83 to 92 without a change in the travel demand!

The system-optimizing solution, on the other hand, for the first network in Fig. 41.5 is $x_{p_1} = x_{p_2} = 3$, with marginal total path costs given by $\hat{C}'_{p_1} = \hat{C}'_{p_2} = 116$. This would remain the system-optimizing solution, even after the addition of link e , since the marginal cost of path p_3 , \hat{C}'_{p_3} , at this feasible flow pattern is equal to 130.

The addition of a new link to a network cannot increase the total cost of the network system but can, of course, increase a user's cost since travelers act individually.

41.3 Models with Asymmetric Link Costs

In this section, we consider network models in which the user cost on a link is no longer dependent solely on the flow on that link. We present a fixed demand transportation network equilibrium model in Sect. 41.3.1 and an elastic demand one in Sect. 41.3.2.

We note that fixed demand supply chain network problems are relevant to applications in which there are good estimates of the demand as would be the case in certain healthcare applications. Elastic demand supply chain network problems can capture price sensitivity associated with the product and are used in profit-maximizing settings (cf. Nagurney 2006). Asymmetric link costs are relevant also in the case of competitive supply chain network equilibrium problems.

Assume that user link cost functions are now of a general form, that is, the cost on a link may depend not only on the flow on the link but on other link flows on the network, that is,

$$c_a = c_a(f), \quad \forall a \in \mathcal{L} \quad (41.18)$$

In the case where the symmetry assumption exists, that is, $\frac{\partial c_a(f)}{\partial f_b} = \frac{\partial c_b(f)}{\partial f_a}$, for all links $a, b \in \mathcal{L}$, one can still reformulate the solution to the network equilibrium problem satisfying equilibrium conditions (41.5) as the solution to an optimization problem, albeit, again, with an objective function that is artificial and simply a mathematical device. However, when the symmetry assumption is no longer satisfied, such an optimization reformulation no longer exists, and one must appeal to *variational inequality theory* (cf. Nagurney (1999) and the references therein).

Models of supply chains and transportation networks with asymmetric cost functions are important since they allow for the formulation, qualitative analysis, and, ultimately, solution to problems in which the cost on a link may depend on the flow on another link in a different way than the cost on the other link depends on that link's flow.

It was in the domain of such network equilibrium problems that the theory of finite-dimensional variational inequalities realized its earliest success, beginning with the contributions of Smith (1979) and Dafermos (1980). For an introduction to the subject, as well as applications ranging from transportation network and spatial price equilibrium problems to financial equilibrium problems, see the book by Nagurney (1999). Below we present variational inequality formulations of both fixed demand and elastic demand network equilibrium problems.

The system-optimization problem, in turn, in the case of nonseparable (cf. Eq. (41.18)) user link cost functions becomes (see also Eq. (41.12))

$$\text{Minimize } \sum_{a \in \mathcal{L}} \hat{c}_a(f) \quad (41.19)$$

subject to Eqs. (41.7)–(41.9), where $\hat{c}_a(f) = c_a(f) \times f_a$ and $\forall a \in \mathcal{L}$.

The system-optimality conditions remain as in Eq. (41.16), but now the marginal of the total cost on a path becomes, in this more general case,

$$\hat{C}'_p = \sum_{a,b \in \mathcal{L}} \frac{\partial \hat{c}_b(f)}{\partial f_a} \delta_{ap}, \quad \forall p \in P \quad (41.20)$$

41.3.1 Variational Inequality Formulations of Fixed Demand Problems

As mentioned earlier, in the case where the user link cost functions are no longer symmetric, one cannot compute the solution to the U-O, that is, to the network equilibrium, problem using standard optimization algorithms. We emphasize, again, that such general cost functions are very important from an application standpoint since they allow for asymmetric interactions on the network. For example, allowing for asymmetric cost functions permits one to handle the situation when the flow on a particular link affects the cost on another link in a different way than the cost on the particular link is affected by the flow on the other link.

First, the definition of a variational inequality problem is recalled. For further background, theoretical formulations, derivations, and the proofs of the results below, see the books by Nagurney (1999) and by Nagurney and Dong (2002) and the references therein. We provide the variational inequality of the network equilibrium conditions in path flows as well as in link flows since different formulations suggest different computational methods for solution.

Fig. 41.6 Geometric interpretation of VI (F, \mathcal{K})

Specifically, the variational inequality problem (finite-dimensional) is defined as follows:

Definition 1: Variational Inequality Problem

The finite-dimensional variational inequality problem, VI (F, \mathcal{K}) , is to determine a vector $X^* \in \mathcal{K}$ such that

$$\langle F(X^*)^T, X - X^* \rangle \geq 0, \quad \forall X \in \mathcal{K} \tag{41.21}$$

where F is a given continuous function from \mathcal{K} to R^N , \mathcal{K} is a given closed convex set, and $\langle \cdot, \cdot \rangle$ denotes the inner product in R^N .

Variational inequality Eq. (41.21) is referred to as being in *standard form*. Hence, for a given problem, typically an *equilibrium* problem, one must determine the function F that enters the variational inequality problem, the vector of variables X , as well as the feasible set \mathcal{K} .

The variational inequality problem contains, as special cases, such well-known problems as systems of equations, optimization problems, and complementarity problems. Thus, it is a powerful unifying methodology for equilibrium analysis and computation and continues to be utilized for the formulation, analysis, and solution of a spectrum of supply chain network problems (cf. Nagurney 2006).

A geometric interpretation of the variational inequality problem VI (F, \mathcal{K}) is given in Fig. 41.6. Specifically, $F(X^*)$ is “orthogonal” to the feasible set \mathcal{K} at the point X^* .

Theorem 1: Variational Inequality Formulation of Network Equilibrium with Fixed Demands: Path Flow Version

A vector $x^* \in K^1$ is a network equilibrium path flow pattern, that is, it satisfies equilibrium conditions (41.5) if and only if it satisfies the variational inequality problem:

$$\sum_{\omega \in \Omega} \sum_{p \in P_{\omega}} C_p(x^*) \times (x - x^*) \geq 0, \quad \forall x \in K^1 \quad (41.22)$$

or, in vector form,

$$\langle C(x^*)^T, x - x^* \rangle \geq 0, \quad \forall x \in K^1 \quad (41.23)$$

where C is the n_P -dimensional vector of path user costs and K^1 is defined as $K^1 \equiv \{x \geq 0, \text{ such that Eq. (41.7) holds}\}$.

Theorem 2: Variational Inequality Formulation of Network Equilibrium with Fixed Demands: Link Flow Version

A vector $f^* \in K^2$ is a network equilibrium link flow pattern if and only if it satisfies the variational inequality problem:

$$\sum_{a \in \mathcal{L}} c_a(f^*) \times (f_a - f_a^*) \geq 0, \quad \forall f \in K^2 \quad (41.24)$$

or, in vector form,

$$\langle c(f^*)^T, f - f^* \rangle \geq 0, \quad \forall f \in K^2 \quad (41.25)$$

where c is the n_L -dimensional vector of link user costs and K^2 is defined as $K^2 \equiv \{f \mid \text{there exists an } x \geq 0 \text{ and satisfying Eqs. (41.7) and (41.8)}\}$.

One may put variational inequality Eq. (41.23) into standard form Eq. (41.21) by letting $F \equiv C$, $X \equiv x$, and $K \equiv K^1$. One may also put variational inequality Eq. (41.25) into standard form where now $F \equiv c$, $X \equiv f$, and $K \equiv K^2$. Hence, fixed demand transportation network equilibrium problems in the case of asymmetric user link cost functions can be solved as variational inequality problems, as given above.

The theory of variational inequalities (see Kinderlehrer and Stampacchia 1980; Nagurney 1999) allows one to qualitatively analyze the equilibrium patterns in terms of existence, uniqueness, as well as sensitivity and stability of solutions and to apply rigorous algorithms for the numerical computation of the equilibrium patterns. Variational inequality algorithms usually resolve the variational inequality problem into series of simpler subproblems, which, in turn, are often optimization problems, which can then be effectively solved using a variety of algorithms.

We emphasize that the above network equilibrium framework is sufficiently general to also formalize the entire transportation planning process (consisting

of origin selection, or destination selection, or both, in addition to route selection, in an optimal fashion) as path choices over an appropriately constructed *abstract* network or supernetwork. Further discussion can be found in the books by Nagurney (1999, 2000) and Nagurney and Dong (2002) who also developed more general models in which the costs (as described above) need not be separable nor asymmetric.

41.3.2 Variational Inequality Formulations of Elastic Demand Problems

We now describe a general network equilibrium model with elastic demands due to Dafermos (1982), but we present the single-modal version for simplicity. It is assumed that one has associated with each O/D pair ω in the network a travel disutility function λ_ω , where here the general case is considered in which the disutility may depend upon the entire vector of demands, which are no longer fixed, but are now variables, that is,

$$\lambda_\omega = \lambda_\omega(d), \quad \forall \omega \in \Omega \quad (41.26)$$

where d is the J -dimensional vector of the demands.

The notation is as described earlier, except that here we also consider user link cost functions which are general, that is, of the form Eq. (41.18). The conservation of flow equations (see also Eqs. (41.1) and (41.2)), in turn, is given by

$$f_a = \sum_{p \in P} x_p \delta_{ap}, \quad \forall a \in \mathcal{L} \quad (41.27)$$

$$d_\omega = \sum_{p \in P_\omega} x_p, \quad \forall \omega \in \Omega \quad (41.28)$$

$$x_p \geq 0, \quad \forall p \in P \quad (41.29)$$

In the elastic demand case, the demands in expression (41.28) are variables and no longer given, in contrast to the fixed demand expression in Eq. (41.1).

The network equilibrium conditions (see also Eq. (41.5)) take on in the elastic demand case the following form. For every O/D pair $\omega \in \Omega$ and each path $p \in P_\omega$, a vector of path flows and demands (x^*, d^*) satisfying Eqs. (41.28) and (41.29) (which induces a link flow pattern f^* through Eq. (41.27)) is a network equilibrium pattern if it satisfies

$$C_p(x^*) \begin{cases} = \lambda_\omega(d^*), & \text{if } x_p^* > 0 \\ \geq \lambda_\omega(d^*), & \text{if } x_p^* = 0 \end{cases} \quad (41.30)$$

Equilibrium conditions (41.30) state that the costs on used paths for each O/D pair are equal and minimal and equal to the disutility associated with that O/D pair. Costs on unutilized paths can exceed the disutility. Observe that in the elastic demand model users of the network can forego travel altogether for a given O/D pair if the user costs on the connecting paths exceed the travel disutility associated with that O/D pair. This model, hence, allows one to ascertain the attractiveness of different O/D pairs based on the ultimate equilibrium demand associated with the O/D pairs. In addition, this model can handle such situations as the equilibrium determination of employment location and route selection, or residential location and route selection, or residential and employment selection as well as route selection through the appropriate transformations via the addition of links and nodes and given, respectively, functions associated with the residential locations, the employment locations, and the network overall (cf. Nagurney 1999; Nagurney and Dong 2002).

In the next two theorems, both the path flow version and the link flow version of the variational inequality formulations of the network equilibrium conditions (41.30) are presented. These are analogues of the formulations Eqs. (41.22) and (41.23) and (41.24) and (41.25), respectively, for the fixed demand model and are due to Dafermos (1982).

Theorem 3: Variational Inequality Formulation of Network Equilibrium with Elastic Demands: Path Flow Version

A vector $(x^, d^*) \in K^3$ is a network equilibrium path flow pattern, that is, it satisfies equilibrium conditions (41.30) if and only if it satisfies the variational inequality problem:*

$$\sum_{\omega \in \Omega} \sum_{p \in P_{\omega}} C_p(x^*) \times (x - x^*) - \sum_{\omega \in \Omega} \lambda_{\omega}(d^*) \times (d_{\omega} - d_{\omega}^*) \geq 0 \quad (41.31)$$

$$\forall (x, d) \in K^3,$$

or, in vector form,

$$\langle C(x^*)^T, x - x^* \rangle - \langle \lambda(d^*)^T, d - d^* \rangle \geq 0, \quad \forall (x, d) \in K^3 \quad (41.32)$$

where λ is the J -dimensional vector of disutilities and K^3 is defined as $K^3 \equiv \{x \geq 0, \text{ such that Eq. (41.28) holds}\}$.

Theorem 4: Variational Inequality Formulation of Network Equilibrium with Elastic Demands: Link Flow Version

A vector $(f^*, d^*) \in K^4$ is a network equilibrium link flow pattern if and only if it satisfies the variational inequality problem:

$$\sum_{a \in \mathcal{L}} c_a(f^*) \times (f_a - f_a^*) - \sum_{\omega \in \Omega} \lambda_\omega(d^*) \times (d_\omega - d_\omega^*) \geq 0 \quad (41.33)$$

$$\forall (f, d) \in K^4,$$

or, in vector form,

$$\langle c(f^*)^T, f - f^* \rangle - \langle \lambda(d^*)^T, d - d^* \rangle \geq 0, \quad \forall (f, d) \in K^4 \quad (41.34)$$

where $K^4 \equiv \{(f, d), \text{ such that there exists an } x \geq 0 \text{ satisfying Eqs. (41.27), (41.28)}\}$.

Under the symmetry assumption on the disutility functions, that is, if $\frac{\partial \lambda_w}{\partial d_\omega} = \frac{\partial \lambda_\omega}{\partial d_w}$, for all w, ω , in addition to such an assumption on the user link cost functions (see following Eq. (41.18)), one can obtain (see Beckmann et al. 1956) an optimization reformulation of the network equilibrium conditions (41.30), which in the case of separable user link cost functions and disutility functions is given by

$$\text{Minimize} \quad \sum_{a \in \mathcal{L}} \int_0^{f_a} c_a(y) dy - \sum_{\omega \in \Omega} \int_0^{d_\omega} \lambda_\omega(z) dz \quad (41.35)$$

subject to Eqs. (41.27)–(41.29).

Variational inequality theory has become a fundamental methodological framework for the formulation and solution of competitive supply chain problems in which the governing concept is that of Nash equilibrium (see, e.g., Masoumi et al. 2012).

In Fig. 41.7, a competitive supply chain network is depicted in which the firms have vertically integrated supply chains but compete in common demand markets. The topmost links represent manufacturing activities at different plants with different such links denoting alternative manufacturing technologies. The second set of links from the top reflects transportation, and alternative links depict the possibility of alternative modes of transportation. The next set of links corresponds to storage at the distribution centers and the final set of links the transportation to the demand markets. Here we also use multiple links to denote alternative technologies

Fig. 41.7 The competitive supply chain network topology

and transportation modes, respectively. The costs on the links can be separable or not and asymmetric, depending on the specific product application. Product differentiation and branding has also been incorporated into such supply chain networks using variational inequality theory. Observe that in the supply chain network depicted in Fig. 41.7, direct shipments from the manufacturing plants to the demand points/retailers are allowed and depicted by the corresponding links.

Finally, it is important to emphasize that the dynamics of the underlying interactions can be formulated and has been done so using projected dynamical systems (Nagurney and Zhang 1996).

41.4 Conclusions

In this chapter, we have highlighted some of the major advances in supply chains and transportation networks, with a focus on the common elements as to the theoretical frameworks and underlying behavioral principles. We have also argued that the foundations of supply chains as network systems can be found in the regional science and spatial economics literature.

Specifically, we have discussed how the concepts of system optimization and user optimization have underpinned transportation network models and, more recently, have evolved to enable the formulation of supply chain network problems operating (and managed) under centralized or decentralized, that is, competitive, decision-making behavior.

We have also highlighted some of the principal methodologies, including variational inequality theory, that have enabled the development not only of advanced transportation network equilibrium models but also supply chain network equilibrium models.

We have aimed to include both primary references as well as tertiary references; the interested reader can delve further, at his/her convenience and according to interest.

In conclusion, transportation network concepts, models, and accompanying methodologies have enabled the advancement of supply chain network models from a system-wide and holistic perspective.

Abstract

The modern spatial economy has a global “networked” character that is generating important socioeconomic and political changes. In this respect, new forms of connectivity play a significant role through their dynamic and complex interplay with the economic and political driving forces behind globalization. In analyzing such impacts, it is useful to consider the tools and models that have been adopted in regional economics as well as in other disciplines. In this

context, it is also necessary to reflect on complexity theory and on the models able to map out the complex interconnected spatial networks.

This chapter begins with a concise review of the most important definitions of complexity, in the light of their relations with spatial networks. There follows an exploration of the main findings from two “close” disciplines, that is, spatial economics and network science, with reference to their associated approaches and modeling tools which are able to grasp complexity from, respectively, the behavioral and the network structure viewpoint. The emerging discussion – with reference to both static and dynamic frameworks through the lens of complexity issues – indicates that (i) a formal correspondence between the fundamental spatial economic models and network models exists and (ii) this correspondence highlights the “simplicity” of the laws underlying complex spatial networks.

42.1 Introduction

The structure and the development of spatial networks, that is, networks where space – in the form of distance friction and/or transportation/communication costs/utilities – assumes a fundamental role in the economic activities, are currently experiencing unpredictable changes and following diverse paths. These uncertainties are mainly the result of the increasing connectivity, at all scale levels, of information and communication – and in general of economic – systems in our society.

In this complex and heterogeneous landscape, a central issue of research is the adoption and validation of approaches and methodologies able to grasp these aspects of economic uncertainty and discontinuity and overcome the current difficulties of carrying out reliable forecasts. In this vein, concepts, such as dynamics, complexity, connectivity, emergence and self-organization, vulnerability, and resilience – which have received a great deal of attention in recent decades – have been shown to provide scientists with a powerful framework for viewing the complex spatial economic transformation processes.

In this chapter, we discuss some of these issues, by focusing on the main modeling tools which have been adopted in the scientific literature in order to investigate the complex dynamics of this networked space economy. This concise chapter will be based on the exploration of the main findings from two “close” fields: spatial economics and network science. First, [Sect. 42.2](#) outlines the essential points concerning the definition of complexity, in order to provide a historical and conceptual background to the subsequent analyses. The fundamental models in spatial economic analysis, that is, the main static and dynamic models able to grasp complexity from the behavioral viewpoint, are then presented in [Sects. 42.3](#) and [42.4](#), in order to identify the similarities and synergies with the tools employed in network analysis (from the network structure viewpoint), in the light of their simplicity. The network models are then examined in [Sect. 42.5](#), while this dual analysis (spatial economics vs. network analysis) will be dealt with briefly in [Sect. 42.6](#), with reference to the central concepts of complexity, namely, connectivity, emergence, and resilience. Finally, [Sect. 42.7](#) concludes the chapter with

suggestions for new paths in future research: mainly the necessity for a blend of advanced theories and approaches belonging to regional economics and complex network theory, with the final aim of assessing such models for possible use in an operational setting.

42.2 Complexity and Spatial Networks

“Complexity has turned out to be very difficult to define. The dozens of definitions that have been offered all fall short in one respect or another, classifying something as complex which we intuitively would see as simple, or denying an obviously complex phenomenon the label of complexity” (Heylighen 1996, p. 1). As Heylighen argued, defining complexity is fraught with difficulties. Horgan, in his 1996 article entitled “From Complexity to Perplexity,” mentions 31 definitions of complexity and associated concepts (Reggiani 2004). Given this wide arena and production of works on the meaning of complexity, it is worth examining the etymology of the term “complexity.” As Heylighen (1996) has noted, the original Latin word *complexus* means “entwined,” “twisted together”; furthermore, the Oxford English Dictionary defines something as “complex” if it is “made of (usually several) closely connected parts.” From these definitions it is clear that the term “complexity” embeds both the assemblage of different units in a system and their intertwined dynamics. In other words, the term “complexity” is strictly related to the concept of networks.

Several definitions also exist concerning the term “network.” Let us then also consider the etymology of the term “network.” Literally, the notion of network refers to “operations via nets.” In this context, Nijkamp and Reggiani (1998) argue that spatial networks may be interpreted as an ordered connectivity structure for spatial communication and transportation which is characterized by the existence of main nodes which act as receivers or senders (push and pull centers) and which are connected by means of corridors and edges. The relevance of the dynamic function of the (spatial) network via organized linkage patterns is embedded in this definition. Here, it is interesting to recall the simple definition by Barthélemy (2010, p. 3): “Loosely speaking, spatial networks are networks for which the nodes are located in a space equipped with a metric.”

The relationship between complexity and (spatial) networks can be structured in the following way, on the basis of Casti’s (1979) classification of complexity:

- *Static complexity*: refers to the network configuration, where the components are put together in an interrelated and intricate way. Network configuration concerns, for example, the number and type of hierarchical structures, the type of the connectivity patterns, the variety of components, and the strength of the interactions. Clearly, static complexity can be roughly measured by the above-mentioned variables.
- *Dynamic complexity*: concerns the dynamic network behavior governed by nonlinearities in the interacting components. Here, two rough measures can be the computational complexity and the evolutionary complexity. The latter

measure can be carried out by means of appropriate nonlinear models, like chaos models, in particular, and evolutionary models in general, which are able to map out the dynamic (random) network patterns.

If we consider the synthetic, but exhaustive, definition of a complex system formulated by Simon (1962, p. 468) as a “large number of parts that interact in a nonsimple way” vs. Casti’s (1979, p. 97) definition of complexity: “The primary idea of complexity concerns the mapping of a system’s non-intuitive behaviour, particularly the evolutionary patterns of connections among interacting components of a system whose long-run behaviour is hard to predict,” we can extract a further important element which – in addition to the network concept – characterizes complexity, namely, the (random) dynamic behavior, which is difficult to predict.

It should be noted that a previous interesting classification of complexity was provided by Weaver in 1948, in his article “Science and Complexity,” as follows:

- *Disorganized complexity*: concerns a situation in which the number of interacting variables is very large and in which each of the many variables has a behavior which is individually erratic or perhaps totally unknown. For this type of problem, the statistical methods hold the key. In this context, Weaver provides the examples of a large telephone exchange, the financial stability of a life insurance company, and the motion of the atoms and stars, which suggest a “whole array of practical applications and statistical techniques based on disorganized complexity” (Weaver 1948, p. 538).
- *Organized complexity*: concerns a situation in which the number of variables is moderate and their interrelationships cannot fully be captured in probabilistic statistics. Weaver considers here the “middle” regions, where the number of variables is moderate: large compared to two but small compared to the number of atoms. For example, the reproduction mechanism or the chemical reactions, as well as some macroeconomic relationships (e.g., on which variable the price of wheat depends), are problems “which involve dealing simultaneously with a sizable number of factors which are interrelated into an organic whole” (Weaver 1948, p. 539).

The concepts of networks and erratic behavior are encapsulated in Weaver’s two definitions, where, in addition, the concept of simplicity can be identified as follows: (a) statistical methods are a way of “decoding” the disorganized complexity and (b) the “organic wholes,” with their parts in close interrelation, represent another type of simplicity approach. In other words, already in Weaver, as also later on in Casti, the simplicity concept appears to be intrinsically related to the concept of complexity, since it seems the only way of “governing” complexity from the scientific viewpoint. The issue of harnessing complexity has also been tackled by Axelrod and Cohen (2000), with reference to the difficult task of making predictions in complex settings and thus to the necessity of providing a device for channeling the complexity of a system into desirable change.

Even though the above classifications can help in the discussion on how to define and tackle complexity, the objective of identifying a unified theory of complexity is still open. On the one hand, both systems and network theory may help in defining analytical, and hence measurable, complexity, although it remains difficult to

capture inherent behavioral complexity. On the other hand, both systems and economic theory may help in trying to understand the dynamic complexity of spatial economic phenomena, by analyzing appropriate dynamic models. The idea of dynamic systems with complex landscapes has been advocated by Krugman (1994), as a unifying theme in a number of research fields in the last decades. In other words, an interdisciplinary approach, able to fill the gap between socioeconomic and physical science, might grasp the common universal principles which can create a kind of unified science of complexity. A first step in this respect is to look at complexity in terms of two interrelated approaches: spatial economic analysis (Sects. 42.3 and 42.4) and network analysis (Sect. 42.5).

42.3 Static Complexity and Models

42.3.1 Preface

Spatial economics seeks to identify the factors governing the distribution/location of economic activity over space; thus, the space economy can be interpreted as a well-functioning economic system enriched with the element of space. Here, the complex evolution of interrelated spatial economic networks (e.g., transport and communication networks, industrial and financial networks, socioeconomic and organizational networks) plays a crucial role in the economic growth of regions/countries and in the related forecasting analyses. The contrast between slow (e.g., the evolution of physical infrastructure networks) and fast dynamics (e.g., the evolution of digital communication networks) points out the unpredictable (dynamic) character of such spatial interconnected networks and calls for a complexity approach able to understand the underlying forces and emerging processes.

In this landscape of multifaceted developments of spatial economic systems, a fascinating scientific question is whether the models which have been formed on the basis of the spatial economic analysis are still useful and in what respect, with reference to these new concepts of complexity and networks. A concise review of the fundamental models in spatial economic analysis, with reference to static complexity, is provided next in Sect. 42.3. The related dynamic framework through the lens of complexity issues will be discussed in Sect. 42.4.

42.3.2 Static Complexity and Static Models in Spatial Economic Analysis

By considering a *static framework*, some fundamental models in spatial economics can be summarized in their historical evolution as follows:

- (a) The rank-size rule/Zipf's law (Zipf 1949)
- (b) Gravity models (Isard 1956)
- (c) Spatial interaction models (Wilson 1970)
- (d) Discrete choice models (McFadden 1974)

These four types of models are all static models, with very simple formulations. Their common characteristic is to be *spatial models* (where space is (generally) represented in the form of a system of discrete locations (zones) at a certain level of resolution), at the aggregate level for models (a), (b), and (c) and at the disaggregate level for model (d). It is well known that we can observe an *analytical compatibility* between the spatial interaction model (SIM) and all the other models (a), (b), and (d) (Batty 2010; Reggiani 2004; Reggiani and Nijkamp 2009).

The general form of a (doubly-constrained) SIM reads as follows:

$$F_{ij} = A_i B_j O_i D_j f(\beta, c_{ij}), \quad i = 1, \dots, I \quad j = 1, \dots, J \quad (42.1)$$

where F_{ij} represents the total number of flows (physical or virtual) between the origin i and the destination j ; O_i and D_j are the stock variables (e.g., population size, workplaces) in the places of origin and destination; c_{ij} are the generalized interaction costs; the term $f(\beta, c_{ij})$ is the impedance function, measuring separation effects between i and j ; and β is the cost-sensitivity parameter. It should be noted that different types of impedance functions can be used, according to the type of spatial structure under analysis (e.g., the negative exponential for homogeneous centers/nodes in the spatial network, the negative power in the presence of large agglomerations/metropolitan areas, etc.: for a review, see Fotheringham and O'Kelly 1989; Reggiani and Nijkamp 2009). The terms A_i and B_j are balancing factors, equal to:

$$A_i = 1 / \sum_j B_j D_j f(\beta, c_{ij}), \quad B_j = 1 / \sum_i A_i O_i f(\beta, c_{ij}) \quad (42.2)$$

both derived from the respective additivity conditions:

$$\sum_j F_{ij} = O_i, \quad \sum_i F_{ij} = D_j \quad (42.3)$$

Model (42.1) can be derived as a probabilistic approach based on statistical equilibrium concepts (Wilson 1970). Wilson, in fact, demonstrated that SIM (42.1) can be derived from a mathematical optimization problem, by maximizing an entropy function, and can thus be seen as an optimum systems solution. The SIM (42.1) can be then perceived as the equilibrium state solution in the network of erratic movements. This approach provided a macrobehavioral context to SIMs, given that entropy can be interpreted in terms of a generalized cost function for spatial interaction behavior (Nijkamp and Reggiani 1992).

Consequently, the SIM (42.1) appears to be a suitable instrument/model able to deal with static complexity (e.g., in the presence of a high number of (origin/destination) cells in the network), that is, when the dynamic complex network is in equilibrium.

Interestingly, the SIM (42.1) appears to be the focal "model" among the others, since it emerges from different theoretical roots. In particular, the SIM is linked to:

- The gravity principle (Newton's law) (Isard 1956) and to the rank-size rule (Reggiani and Nijkamp 2009)

- Statistical information principles and entropy maximization (Wilson 1970)
- The logit model and thus to microeconomic theory (stochastic utility maximization) (Anas 1983).

Concerning the first methodological link, that is, the SIM and gravity model/rank-size rule, let us consider the unconstrained version of the SIM:

$$F_{ij} = KO_i D_j f(\beta, c_{ij}) \quad (42.4)$$

where K is a scaling factor, which has to be calibrated.

Model (42.4) clearly reflects Newton's gravity law, in the network of the cost/distance relations $f(\beta, c_{ij})$ between the masses (in our case populations O_i and workplaces D_j) (see, among others, Sen and Smith 1995).

Let us then examine the rank-size formulation, which reads as follows:

$$P_j = GR_j^{-q} \quad (j = 1, \dots, J) \quad (42.5)$$

where P_j is a given size of a city population j , R_j is the related rank of the city j , q is the elasticity parameter, and G is a positive constant (usually the population of the biggest city). In the particular case of $q = 1$, the rank-size rule boils down to the well-known Zipf's law (Zipf 1949) and thus to a perfect equilateral hyperbola where the agglomeration/centripetal forces (influencing the masses or population P_j in the network) are in equilibrium with the opposing diversification/centrifugal forces (influencing the rank R_j).

Furthermore, the SIM (42.4) can be formulated as follows:

$$F_{ij}/O_i D_j = Kf(\beta, c_{ij}) \quad (42.6)$$

by showing its link to the rank-size rule (42.5) (see also Batty 2010). The rank-size rule (42.5), in fact, appears to be compatible with the spatial/gravity interaction (Eq. (42.6)), since, like the SIM, it can be derived from an entropy maximization approach, in particular by maximizing the most likely combination of population stocks P_j from among a very large number of realizations of independent microlevel outcomes. In this interpretation, entropy essentially refers to the maximum probability of decentralization among random population centers, and the rank R_j can assume an economic value, being interpreted as the shadow cost. In other words, entropy can be considered as an indicator of the static network complexity, whereas the SIM (42.1) and the rank-size rule (42.5) represent the optimal equilibrium solutions. It is interesting to note that Zipf had already provided a form of "cost/distance" interpretation of the rank R_j , by arguing: "In other words, and in general, the most frequently used good services tend to be the cheapest and the nearest, and the reverse" (Zipf 1949 p. 371).

In addition, the rank-size rule (42.5) can be written as:

$$G = P_j R_j^q \quad (j = 1, \dots, J) \quad (42.7)$$

Surprisingly, Eq. (42.7) resembles Einstein's law (1905):

$$E = mc^2 \quad (42.8)$$

In Einstein's expression (42.8), E is energy, m is mass, and c is the speed of light, which – like the rank R_j – may clearly have an economic value; here the coefficient of c assumes the value 2 (Newton's value). The population P_j in Eq. (42.7) (and thus in Eq. (42.5)) may then be interpreted as mass m and the constant G as energy E . Also in this framework, the rank R_j may assume a cost interpretation. It should be noted that Isard (1971) also interpreted Einstein's law in spatial economic theory; however, in his view, the variable c represents flux or movement rather than a relative cost (or benefit) factor.

All in all, the compatibility between models (42.4) and (42.8) is fascinating. It seems that – by dealing with the complex network of masses (planets, cities, population, etc.) – the constancy of Newton's and Einstein's law persists, being captured by the SIM (42.4) and consequently by its general spatial formulation (42.1) or by its particular form, the rank-size rule (42.5).

From the theoretical viewpoint, as previously anticipated, the SIM is not only a “simple” model describing the spatial interaction between masses but is also the equilibrium solution of an entropy maximization approach. In addition, the SIM can be analytically linked to microeconomic theory, by means of the logit model, which emerged from random utility maximization (McFadden 1974). Compatibility between the SIM and the logit model has been demonstrated (Anas 1983; Sen and Smith 1995; Nijkamp and Reggiani 1992). The SIM can be interpreted in a behavioral context with an economic meaning, by considering the SIM to be an aggregate model of human behavior.

In summary, the above considerations highlight:

- The simplicity of the SIM
- The “constancy” of the SIM, with reference also to other disciplines and related laws, such as Newton's and Einstein's law
- The theoretical strength of the SIM, being connected to entropy maximization and to microeconomic theory

The SIM seems, therefore, to be the most simple and suitable model able to map out the static complexity of a network, from different angles (aggregate/disaggregate level) and from different spatial scales, by dealing also with a great number of origin/destination nodes. The issue of the SIM as an equilibrium “state” in a complex network evolution is examined next in Sect. 42.4.

42.4 Dynamic Complexity and Models

42.4.1 Simple Models vs. Dynamic Complexity

In this section we show that, by considering the dynamic setting of a spatial economic system, we find the same “constancy” of the spatial interaction form and that, in

particular, the SIM reflected in Eq. (42.1) – and hence the related models (a), (b), and (d) (in Sect. 42.3) – represents the steady state of network evolution.

By considering a *dynamic framework*, we have to keep in mind that the only mathematical instruments available which are able to model dynamic (un)stable and complicated patterns are the difference or differential equations. The most simple – and interesting – dynamic model is certainly the May model, usually called the “logistic” (or Pearl-Verhulst) map, namely, the nonlinear first-order difference Eq., which reads as follows (Gandolfo 1996):

$$x_{t+1} = ax_t(1 - x_t) \quad x \in [0, 1] \quad a \in [0, 4] \quad (42.9)$$

Equation (42.9) originally stems from biology: the time-dependent value x_t represents the observation of the variable x (biological population) at time t , and the parameter a represents the growth parameter that reflects the maximum per capita rate of x_t . May’s logistic Eq. (42.9) is a nonlinear model, which is very simple in its formulation, since it contains only one variable (x) and only one parameter (a). However, it can show chaotic and irregular movements, according to particular values of the parameter a and initial conditions. More specifically, cyclical behavior for the values $3 < a \leq 3.824\dots$ or unstable/chaotic movements for $3.824\dots < a \leq 4$ occur. At the bifurcation value $a = 3.824\dots$, a period of cycle 3 appears, giving rise – according to Li and Yorke’s theorem “Period Three Implies Chaos” – to the chaotic situation, where an uncountable number of aperiodic and periodic trajectories occur. It should be noted here that we define chaotic systems as the deterministic, nonlinear, dynamic systems which are able to produce *complex motions* of such a nature that sometimes seem completely random (Gandolfo 1996; Nijkamp and Reggiani 1992). Thus, the dynamic complexity previously defined, with its inherent impossibility to predict, is a clear feature of the chaotic systems.

Consequently, May’s logistic Eq. (42.9) turns out to be a fundamental example of “dynamic complexity,” emerging from a “noncomplicated” network. In other words, static complexity according to Casti’s definition is not satisfied here, showing that the various measures of static complexity are not necessary conditions for reaching dynamic complexity. Also disorganized complexity in the spirit of Weaver is not satisfied here, since Eq. (42.9) does not deal with a large number of variables (see Sect. 42.2). We can then conclude that May’s model is the first “simple” example of dynamic complexity.

In May’s formulation (42.9), x_t varies between 0 and 1, and thus, it may denote – in the spatial economics field – the dynamic probability of choosing a certain discrete alternative (transport mode, market product, etc.).

In contrast, the differential version of Eq. (42.9), that is, the following logistic equation in continuous time:

$$\dot{x} = bx(1 - x) \quad (42.10)$$

does not lead to any type of instability, independently of the values of the parameter b , as established by the Poincaré-Bendixson theorem. In fact, according to this

theorem, chaotic behavior can only arise in continuous dynamic systems with three or more dimensions (for a review, see Nijkamp and Reggiani 1992). Therefore, the “ability” of the analyst to correctly interpret and model the spatial system under investigation is a crucial issue. This is because the choice of the difference vs. the differential equation in one dimension leads to completely different dynamic trajectories in the presence of high values of the parameters a and b , that is, unstable vs. stable trajectories, respectively, with clear implications for prediction purposes.

A final reflection concerns the relevance – in practical terms – of the parameter a in Eq. (42.9), since the related high values, in particular values greater than three, induce cyclical/chaotic behavior. In other words, one might argue whether these high values of a are common in the dynamics of spatial economic systems. The answer is that high values of a – which are connected to the growth rates of the variable x at time t – might occur either in those systems which are characterized by fast dynamics, such as the financial and Internet networks, or in particular space-temporal windows of “less fast” systems, such as the traffic or technological networks. Consequently, the use of May’s logistic model (42.9) in detecting complex dynamic behavior seems unsuitable for the systems which display slow dynamics, such as the demography and physical infrastructure system, where the growth parameter a usually does not assume high values. However, this possibility might occur in some links or nodes of these slow systems in a certain time interval. In this case, an interesting issue is the dynamic relationship between the whole stable system and the corridor/center which is unstable: will the stable system be able to stabilize the unstable subsystem, or will it be destabilized by this unstable area? There are many examples in this respect, for example, a train crash which can destabilize the whole rail network and a terrorist attack on a central node. Analytically, it seems that the destabilization of the whole system might occur under particular interrelated conditions of the carrying capacities and parameter values (Nijkamp and Reggiani 1992, 1998).

The analysis of the relationship “stable vs. unstable system” implies an enlargement of our Eq. (42.9) to two or more dimensions. If x_t represents, for example, the dynamic production of a peripheral area, we need an additional variable y_t expressing the dynamic production of the metropolitan area, strictly linked to x_t , as well as additional terms expressing the dynamic interaction between x_t and y_t (and vice versa). Examples of dynamic Eqs in two and more dimensions will be provided in the subsequent Sect. 42.4.2.

Having said this, it is worth returning to the issue of the methodological “strength” of the SIM also in a dynamic setting. In this context, it can be shown that the logistic Eq. (42.9) is the dynamic version of a binary logit model and thus of a SIM (since a logit model is compatible with a SIM), under the condition that the utility function of x_t increases linearly with time through the fixed parameter a . In summary, a dynamic SIM might also exhibit complex behavior, since it is strictly connected to May’s equation of type (42.9) (Nijkamp and Reggiani 1992). In addition, the SIM appears to be the equilibrium solution of a dynamic entropy maximization approach, thus reinforcing the argument that a random complex network (like that expressed by a dynamic entropy) shows the SIM to be a simple model in its equilibrium.

It is then interesting to examine a multiple-choice situation, when the number of dynamic variables increases (Sect. 42.4.2).

42.4.2 Less Simple Models vs. Dynamic Complexity

In a multiple-choice dynamic situation, the logistic Eq. (42.9) shows the addition of the interacting terms, in the form of an ecologically based model, like the well-known prey–predator, competing, or symbiosis system. Let us consider, for example, a general competing system in two dimensions (in discrete time):

$$\begin{aligned}x_{t+1} &= x_t(H - hx_t - ey_t) \\y_{t+1} &= y_t(V - fx_t - vy_t)\end{aligned}\tag{42.11}$$

where x_t and y_t represent, respectively, the values of the variables x and y at time t ; H , V , h , and v are related to the endogenous variable dynamics of each corresponding variable; and the coefficients e and f reflect the interaction between the two dynamic variables x and y . System (42.11) is a general formulation which clearly interrelates two logistics of type Eq. (42.9): depending on the signs of the parameters, either the well-known prey–predator model developed by Lotka and Volterra, or the competition/symbiosis model emerging from Eq. (42.11) (Gandolfo 1996; Nijkamp and Reggiani 1992, 1998). Since system (42.11) is expressed in discrete time, unstable and chaotic/unpredictable trajectories may emerge, depending on the values of the parameters and initial conditions, according to the Poincaré-Bendixson theorem, previously outlined.

System (42.11) has frequently been utilized in spatial economic analysis as an “epidemic” model for describing technological innovation diffusion, urban growth, etc. (see Batty 2005; Fischer and Leung 2001; Nijkamp and Reggiani 1998). Interestingly, like the logistic Eq. (42.9), system (42.11) is very simple, although it can show complex and unpredictable patterns. In fact, by varying the parameters, simulation experiments concerning networks of form Eq. (42.11) exhibit a wide spectrum of ordered, irregular, and complex behavior.

From the empirical viewpoint, such results raise the problem of the prediction and control of complex systems and, hence, the necessity to collecting quasi-dynamic or panel data on spatial networks, in order to test the model coefficients and mostly their speed of change.

A generalization of Eq. (42.11) is the niche model, which expresses the phenomenon of interspecies competition and dynamic resource utilization. The niche model can also be interpreted in an economic framework, by considering the interaction between species as production functions (Nijkamp and Reggiani 1998). Formally, the logistically defined niche system (in continuous terms) is:

$$\dot{z}_i = z_i(Z_i - \sum_{j=1}^N d_{ij}z_j)\tag{42.12}$$

Fig. 42.1 The visualization of Eq. (42.12) for three populations (z_1), (z_2), and (z_3). Here the logistic niche (z_1) is occupied successively by a new niche of increasing effectiveness (z_2); analogously, the logistic niche (z_2) is occupied successively by a new niche of increasing effectiveness (z_3)

where z_i is the population of species i (e.g., transport mode or market product $i = 1, 2, \dots, N$), \dot{z}_i is the rate of change of z over time, Z_i is the carrying capacity for species i , and the coefficients d_{ij} are the interaction/competition coefficients measuring the niche overlapping. The logistic niches can be visualized in Fig. 42.1 for three populations (z_1, z_2 , and z_3). A positive network evolution occurs when a new species (z_2) replaces, in the short or long run, the old one (z_1), by exploiting new network capacities; analogously, the logistic niche (z_2) is occupied successively by a new niche of increasing effectiveness (z_3) (Nicolis and Prigogine 1977). The dynamic processes of the substitution/introduction of innovations in technology, transport, and market goods, as well as the development of new patterns of urban growth, can be modeled by means of the niche chain (Eq. (42.12)).

Interestingly, system (42.12), even though expressed in continuous time, may exhibit chaotic and complex behavior, for $i > 3$, that is, in the presence of three or more species of population, again according to the Poincaré-Bendixson theorem. It should be noted that the capacities Z_i and the coefficients d_{ij} may also embed dynamic functions, by modeling what are called “multilayer niche dynamics,” where the interaction exists not only among niche species but also among the niche capacities and/or the niche growth rates. However, by increasing the number of dynamic variables and parameters in model (42.12), very often the model fails in its analytical potential, by showing that a multilayer complicated model can hardly display complex behavior.

In other words, if we increase the analytical complexity of the network (by increasing, e.g., the number of variables, the multilayer/multilevel configurations) in order to replicate the real world, surprisingly the complex motions very often tend to explode or disappear: we reach the stage of “mathematical undecidability,” where no suitable information can be extracted (Reggiani 2004). In short, an inverse relationship between analytical complexity and dynamic complexity seems to emerge.

42.4.3 Concluding Remarks

In this section, we have pointed out that the SIM represents the steady state of network evolution, by maximizing a dynamic entropy. Moreover, the dynamic

version of the logit model (compatible with the SIM) leads, under particular assumptions, to the well-known (May/Pearl-Verhulst) logistic function, which can lead to unstable and unpredictable behavior of a chaotic type. In other words, the simple models (a)–(d), and in particular SIMs, appear to be the fundamental (conceptual and operational) instruments able to *decode* the complexity of the space-time phenomena concerned (Reggiani 2004; Reggiani and Nijkamp 2009).

From the methodological viewpoint, the lack of predictability of future events – for complicated systems – is still the main issue in the research concerning complexity in spatial economic analysis. A contribution in this respect might be provided by the exploration of network analysis. It is interesting to note the following: if the search for a “hidden” order/simplicity seems to have governed the scientific arena in spatial economics as an instrument able to “decode” and harness complexity, then network analysis, which aims to study complex network representations of physical, biological, and social phenomena, again reveals these “simplicity laws.” This issue will be discussed next in [Sect. 42.5](#).

42.5 Complexity and Network Analysis

42.5.1 Preface

In [Sect. 42.2](#), we indicated that complex systems evolve in different ways, depending on the type of interdependencies among the components. Thus, connectivity, that is, the ability to make and maintain a connection between two or more points in a spatial system, is one of the essential elements that characterizes complex networks. The connectivity issue has been strongly emphasized in recent years, especially in social network analysis, with consequent impacts and developments in other fields.

“A social network is a set of actors (individuals or social groups) and relationships of different kinds (friendship, kinship, status, sexual, business or political) among them” (Boccaletti et al. 2006, p. 251). In this chapter, we do not deal with social networks, since our attention is focused on complexity and spatial networks. However, it is useful to recall that some fundamental concepts and tools, which are now used in network analysis, such as connectivity, node centrality, and clustering index, have their origin in sociometry (Boccaletti et al. 2006). For a review on social network analysis, see, among others, Scott (2000). It is also interesting to recall here that the fast development of communication systems (Internet, cellular phones, etc.) has created new (virtual) forms of social contacts and cooperation, which can be modeled by means of network analysis (see, e.g., the analysis of community structures in the context of R&D Cooperation in Europe, by Barber et al. 2011).

In spatial economics, the connectivity concept has hardly been formalized, since it has been encapsulated in the strength of the network interaction and thus embedded in the values of the variables concerning the models previously mentioned, essentially in the cost matrix c_{ij} . In this context, connectivity has been

strictly linked to the concept of accessibility, since accessibility weights the network connectivity structure – embedded in the cost matrix c_{ij} – by means of the socioeconomic activities in j (for a review on the link between accessibility and connectivity, see Reggiani 2012). Connectivity is now receiving more attention, thanks to the popularity of social and network analysis. An interesting related issue is the relevance of the topological network structure, particularly considering the often conflicting relationship between distance/cost and topology. For example, two spatially close neighborhoods may not display any significant interaction if they are separated by a strong barrier (e.g., a highway).

In addition, networks often show common behavior, based on their topological characteristics; consequently, the identification of the network architecture/topology cannot be ignored without missing a crucial ingredient of the complex phenomena concerned (Vega-Redondo 2007). The topology issue implies a focus on the network configuration and its properties, in order to analyze the related impact on the behavioral dynamics of the network itself.

Starting from this issue, that is, the relevance of connectivity and topology in complex networks, in this section we show how network analysis deals with it, in particular by highlighting two focal network models (random and scale-free networks) which are strictly linked to the aforementioned models (see Sect. 42.3) conceived and applied in spatial economic analysis.

42.5.2 Simple Network Models: Random and Scale-Free Networks

In network science, a rigorous framework for the description and analysis of networks is found in graph theory. We can refer, first, to 1736, which marked the birth of this discipline, when Leonhard Euler published the solution to the Königsberg problem, and then to the 1920s, which witnessed the early beginnings of social network analysis that focuses on the complex relationships between social entities. In the last few decades, there has been renewed interest in the study of complex networks by means of graph theory, thanks essentially to the works by Watts and Strogatz on small-world networks and by Barabási and his group on scale-free networks (for a comprehensive review, see Boccaletti et al. 2006).

It is interesting to observe how complexity is defined in network science. For example, Caldarelli and Vespignani (2007), p.15 argue that “a definition of complexity may involve two main features: (i) the system exhibits complications and heterogeneity that extend virtually on all scales allowed by the physical size of the system; (ii) these features are the spontaneous outcome of the interactions among the many constituent units of the system, i.e. we are in the presence of an emergent phenomenon.” These authors add that examples of this are the WWW, the Internet, the airline airport networks, and all the social and biological networks which grow in time by following complicated dynamic rules and without global supervision. Moreover, “All these networks are self-organizing systems, which at the end of the evolution show an emergent architecture with unexpected properties and regularities” (Caldarelli and Vespignani 2007, p. 15).

Two new interesting characteristics of complex networks were introduced by Caldarelli and Vespignani: (a) emergence and (b) self-organization. Complexity is “decoded” here by means of the “emergence” level, which results from the self-organized, spontaneous, process coming out from the complicated or complex interaction of the units at the lower levels. Caldarelli and Vespignani continue their discussion on complexity by pointing out that heavy tails and heterogeneity appear to be the common features of a large number of these complex networks. In other words, the emergence concept highlights a final state of the complex system which can be identified and mapped out, thanks to its “regular” properties.

In particular, the network topology seems to be crucial in determining the emergence of this “collective” dynamic behavior (such as synchronization of activities, habits, fashions, ideas) or in governing the main features of relevant processes (such as the spreading of information, epidemics, rumors, new ideas) (Boccaletti et al. 2006). In this context, one of the most surprising findings in social network analysis is that real networks behave very differently from conventional hypotheses about them. Traditionally, real networks were conceived to have a majority of nodes with about the same number of connections around an average. These are called “random networks” (Erdős and R enyi 1959), which display homogeneous, diffuse patterns, without cluster characteristics. In a random network with n ($n = 1, \dots, N$) nodes and k links, the degree (number of links k per node n) distribution $P(k)$ is well approximated by a Poisson distribution, as follows:

$$P(k) = e^{-\langle k \rangle} \frac{\langle k \rangle^k}{k!} \quad (42.13)$$

where $P(k)$ is the probability that a node n chosen uniformly at random has degree k and $\langle k \rangle$ is the average degree. Eq. (42.13) identifies the random network as a homogeneous network. Homogeneity, in the interaction structure, means that all the nodes are topologically equivalent, and thus, each link is present with equal probability.

However, a variety of different social, natural, economic, and technological networks significantly deviate from the Poisson distribution (42.13), since they show high clustering characteristics, degree correlations, and the presence of motifs (patterns of interconnections) and community structures (subgroups or clusters tightly connected). All these common features make these real networks completely different from random graphs: they display fat-tailed shapes in their degree distributions (Boccaletti et al. 2006). In summary: in all these situations, the associated graph presents a universal feature of some elements with many connections (hubs) and many with only a few. This is expressed by a power-form-shaped degree distribution, as follows:

$$P(k) \sim k^{-\gamma} \quad (42.14)$$

where γ is the degree exponent and \sim indicates “proportional to.”

The networks which display a power form of type (Eq. (42.14)) have been called “scale-free networks” by Barabási and his group, because power distributions display the same functional characteristics at all scales. The value of the exponent γ depends on the attributes of the single systems and is crucial to detect the exact network topology. As Barabási and Oltvai (2004) point out, the value of γ determines many properties of the system. The smaller the value of γ , the more important the role of the hubs is in the network. In particular, for $2 < \gamma < 3$, there is a hierarchy of hubs, with the most connected hub being in contact with a small fraction of all nodes, and for $\gamma = 2$, a hub-and-spoke network emerges, with the largest hub being in contact with a large fraction of all nodes. In general, the properties of scale-free networks are valid only for $\gamma < 3$. For $\gamma \geq 3$, the hubs are not relevant, and in many respects, the scale-free network behaves like a random one.

Clear empirical examples concerning random networks and scale-free networks can be found in spatial economic systems. For example, in air transport, random networks are useful to map point-to-point connections, as is the case for low-cost airlines. In the ideal point-to-point network, all airports are connected to each other so that passengers can fly from one airport to any other directly without stopping in any hub to change flights. The same applies to any other type of network which can be seen as a homogeneous system which gives accessibility to the majority of the nodes in the same way.

In contrast, the Internet, the WWW, the high-speed train, the air transport system with full-service carriers, scientific coauthors, company directors, and any other socioeconomic network typified by what is called a hub-and-spoke structure (where central nodes (hubs) have a high number of links (spokes) to the majority of the other nodes), all exhibit this clustering nature, which is also reflected in the associated socioeconomic activities. It should also be noted that the scale-free network was introduced by Barabási in order to incorporate two mechanisms upon which many real networks have proved to be based: *growth* and *preferential attachment*. The former indicates the dynamic character of networks, which grow by the addition of new nodes and new vertices; the latter explains how new nodes enter the network, namely, by connecting themselves to the nodes which have the highest number of links.

42.5.3 Concluding Remarks

In the previous section, we briefly delineated two main types of complex networks, namely, random and scale-free networks, both of which have recently received a great deal of attention in the literature on complex networks, especially in social network analysis.

In this framework, the value of the coefficient γ in the connectivity degree distribution (42.14) appears to be crucial in the identification of the random/scale-free network and thus of related homogeneity/heterogeneity characteristics of the associated network. Other network topology indicators, like centrality, closeness, betweenness, and cluster coefficients, can also help in the network pattern recognition

(for a definition of these indicators, see, among others, Barthélemy 2010; Boccaletti et al. 2006). In addition, if we want to detect the network configuration (random vs. scale-free), we need to understand to what extent these networks are concentrated, because the existence of hubs implies a high degree of concentration. Thus, the network concentration indices, such as the Gini concentration index, the Freeman centrality index, and the entropy indicator, can be useful in this respect.

In summary, these interesting studies on random vs. scale-free networks have revealed, on the one hand, the importance of the topological characteristics in a complex network for the detection of homogeneity/heterogeneity features and, on the other hand, that these topological characteristics are captured by very simple indicators, as we can see by examining Eq. (42.13), identifying random networks, and Eq. (42.14), identifying scale-free networks. Basically, the essential element which leads to this topological diversification (random vs. scale-free network) is the type of connectivity. This issue will be examined in the next section, also with reference to spatial economic analysis.

42.6 Spatial Economics and Network Analysis: Connectivity, Emergence, and Resilience

Our debate on complexity in Sect. 42.3 mainly focused on dynamic complexity. In particular, the complex network's characteristic of high levels of interdependence through nonlinearities drew attention to the fundamental feature that the outcome is not obvious from the simple building blocks. In Sect. 42.4 we saw how complexity can be conceived as the result of a complex (and possibly evolving) network of connections among the different units involved. Hence, connectivity assumes a fundamental role in detecting complexity.

Interestingly, if we carry out a dual analysis, that is, spatial economic analysis vs. network analysis, we find that the homogeneity and heterogeneity of the economic centers in spatial economic analysis fit the homogeneity and heterogeneity of the topological structures (random vs. scale-free networks) in network analysis. For example, the rank-size rule and Zipf's law, which model the urban hierarchy (see Sect. 42.3), were conceived in a historical period (the 1950s) when the physical and virtual connectivity between cities was not so evident and strong as it is today. However, the cities are connected, and in fact, it has been recently demonstrated that the value of the coefficient q , which can be interpreted as the elasticity parameter in the rank-size rule (42.5), thus identifying the type of hierarchical spatial structures in spatial economics, is strictly related to the degree exponent γ , which emerges from the connectivity distribution (42.14) in the associated graph. In other words, the coefficients q and γ appear to be two sides of the same coin; more precisely, the q -coefficient identifies the population (in)equalities from the viewpoint of spatial economics, and at the same time, it is linked to γ by this simple analytical transformation (Adamic 2000):

$$\gamma = 1 + (1/q) \tag{42.15}$$

which can be crucial in the identification of the associated random/scale-free network and thus of the homogeneity/heterogeneity network connectivity characteristics. In particular, by considering Eq. (42.15), we can find the following correspondence:

- For $q \leq 0.5$ (urban homogeneity), $\gamma \geq 3$ (random network) emerges.
- For $q > 0.5$ (urban heterogeneity), $\gamma < 3$ (scale-free network) emerges.

This connectivity interpretation of the rank-size coefficient q reinforces the argument on the relevance of the connectivity element in the spatial economic networks, which was somehow neglected in the models based on the SIM and also mentioned earlier in Sect. 42.3. As a consequence, the emergence concept assumes a new “network” meaning. As previously anticipated in Sect. 42.4.2, the emergent phenomenon is the “state” of the network expressing collective behavior, that is, a self-organized structure which is the result of the continuous dynamic interplay between the macro- and the microelements of a network. Emergence tells us that an economic system of interacting agents (like traffic commuters or traders in a financial market) can spontaneously develop collective properties that are not at all obvious from our knowledge of each of the agents individually. Emergence signifies order despite change (Reggiani 2004). However, this interplay between the dynamic behavior of the agents at the microlevel is only possible by means of connectivity. The emergent mesostructures can, therefore, also be identified as random, scale-free, or intermediate networks. For example, if we consider the logistic niche, as in Eq. (42.12) and Fig. 42.1, the envelopes z_1 , z_2 , and z_3 , representing the emerging network structures resulting from the interaction between the dynamic behavior of SIM structures at the microlevel, can also be classified as random/scale-free or intermediate networks, according to their connectivity structures.

Consequently, the connectivity and emergence concepts emphasize the evolutionary aspect of organized complexity, in contrast to disorganized complexity (Sect. 42.2). These two ingredients reinforce the perspective of order in complexity.

A final issue, related to the previous ones, which is worth mentioning, is the fragility/resilience aspect of a complex network. An important feature of the scale-free network highlighted by Barabási and his coauthors is a high degree of robustness in the face of accidental node failures. In other words, in the case of a random attack on nodes, the scale-free network will show high resistance, because a random attack will probably damage nodes that have only a few connections (which are the majority). In contrast, random networks are weak against a random attack which will cause a rupture of the network.

However, in the case of an oriented attack against the hubs, the network will easily be fragmented, because of the high connectivity of the hubs with the majority of the nodes. Consequently, we might also talk of the “vulnerability/permeability” of the scale-free network in its hubs: if certain information or a virus is dispersed in the hubs, it is diffused all over the network, if the connective configuration is completely accessible. Accessibility then turns out to be a driving force for the formation of the scale-free network and the related dynamic functionality. Therefore, the identification of the random/scale-free characteristics, together with the

associated accessibility patterns, appears to be essential for understanding the dynamics of network function and behavior in the light of policy/planning interventions (Reggiani 2012).

The issue of the relationship between network stability and complexity thus opens new perspectives, essentially based on the concepts of connectivity, emergence, and fragility/resilience. In general, a dynamic fragile system can be defined as a system that will tend to collapse under perturbations to its parameters or population values (as in the case of the scale-free networks attacked in its hubs). In this framework, the concept of resilience appears to offer interesting ground for investigating the stability structure of a complex network. Resilience refers to the capacity of a system to retain its organizational structure following the perturbation of some state variable from a given value, but not only, since resilience also reflects the capacity of the network to adapt itself to new states; thus, evolution is formed by the switch of these resilient networks from one equilibrium state to another (for a review on resilience applied to spatial systems, see, among others, Rose 2009).

Resilience reveals a framework that goes beyond the usual stability concept, since, in principle, a complex system can be unstable but resilient (Reggiani 2004). In other words, resilience can overcome the conventional debate “unstable/stable node vs. stable/unstable network” – outlined in Sect. 42.2 – by allowing unstable paths toward different equilibrium states in the complex network (as in the case of scale-free networks, if attacked in the majority of the nodes which are not the hubs).

42.7 Conclusions

This chapter has aimed to review briefly the complex relationship “complexity and spatial networks.” The argument is so vast that it is impossible to tackle this issue from all the perspectives of analysis. We focused, therefore, only on the main models used in the regional/spatial economic literature as well as in network analysis, in order to compare and investigate similarities and differences.

The following main conclusions can be drawn: a formal correspondence between the rank-size rule (42.5) and network connectivity analysis expressed by Eq. (42.14) does exist, thanks to the behavioral interpretation of the q -coefficient and to its related connectivity γ -coefficient. Thus, the rank-size model (42.5), and hence the SIM (42.1), is able to (i) grasp the homogeneity/heterogeneity of the network concerned (at an aggregate level, by means of its q -coefficient, expressed in Eq. (42.5)) and (ii) represent the associated connectivity infrastructure or socio-economic network/constellation of complex spaces, by means of its associated γ -coefficient, as in Eqs. (42.14) and (42.15).

From the spatial economic viewpoint, Eq. (42.5) is conventionally formulated according to a power form. However, it has been demonstrated that Eq. (42.5) can theoretically embed different functional forms, such as exponential and lognormal, all of them capable of capturing the socioeconomic spatial characteristics of the network under analysis. In summary, the power form in Eq. (42.5) with a q -coefficient > 0.5 is suitable to detect the presence of agglomeration economies,

that is, hierarchies in the spatial economic structure of the variable concerned. As is well known, Eq. (42.5) could also map out different variables other than population, such as GDP and inflows. Thus, both the simple rank-size model (42.5) and the SIM (42.1) certainly represent a useful instrument in grasping the “emergent” features of the spatial economic networks.

From the network viewpoint, formulation (42.14) has reinforced the argument that complex phenomena can exhibit unexpected similarities, as well as increasing the interest in researching what is called the “heavy tail” in the probability distribution of a certain quantity, and thus heterogeneity in the number of connections per node.

Thus, analytically, the power form seems to be “ubiquitous” from different perspectives, expressing the aforementioned inequality characteristics. However, some caution is necessary here, with reference to (a) the estimation analysis of the coefficients which should be statistically correct and (b) the theory behind formulation (42.14), which so far seems to be derived from empirical experiments.

This latter issue necessitates some reflections on data. An alternative way of detecting complex behavior is the use of techniques able to extrapolate, from data, nonlinear network interactions. It should be noted that in chaos and complexity analysis (Sect. 42.4), many applications lack empirical content. A solution could be the adoption of techniques generally used for proving the existence of chaotic behavior – and thus the inherent dynamic complexity – in panel data. Detecting complexity from data requires the use of conventional established techniques, such as the Brock-Dechert-Scheinkman statistic, the method of the largest Lyapunov exponent, or the artificial neural network tool, belonging to the biocomputing models. In this context, it is interesting to mention works that address the compatibility between artificial neural networks and SIMs (e.g., Reggiani 2004).

Finally, some simulation tools, for example, cellular automata (based on a fixed spatial framework) and agent-based modeling (where agents can be mobile with respect to space), should be mentioned here, on account of their potential in detecting emerging patterns. Cellular automata and agent-based modeling are complementary modeling strategies. They can be integrated into a common geographic automata system where some agents are fixed, while others are mobile (Batty 2005).

New research paths should then consider, in a multidisciplinary way, a very rich agenda, which mostly tries to join these two disciplines, spatial economics and network science, from all the perspectives: theory, methodology, empirics, and policy analysis.

Currently, network analysis appears to be extremely full of new contributions which aim to deepen the first findings of Barabási and his coauthors: the elaboration of new network metrics, as well as of new dimensions of shock propagation (e.g., depth, width, strength), has recently come to the fore. All this shows the efforts that have been made in approaching spatial science and its modeling. On the other hand, an increasing number of studies in regional science are now adopting the models of network analysis in order to analyze the space-time dynamics of economic phenomena.

This endeavor involves a synthesis of knowledge from the different scientific traditions, where the traditional concept of prediction needs to be revisited, in the presence of a complex network sensitive to initial conditions and perturbations. Mostly, new developments in theory are necessary, for example, new theories of stochastic dynamics or path-dependent dynamics, in the presence of large networks, given the current rich amount of data available in telecommunications and the powerful computation tools.

Finally, a further effort, in the form of a blend of advanced theories and approaches belonging to regional economics and complex network theory, is required to bridge the gap between science and policy, in order to provide an integrated framework able to manage the multilayer-multilevel complex spatial networks also from an operational viewpoint.

Acknowledgment The author wishes to thank two referees for their valuable comments.

Abstract

Location theory has traditionally been based on equilibrium concepts. Dynamics have been introduced mainly to ascertain whether there are paths leading to the equilibrium states. The modeling of dynamics has been very simple yet involving both locational changes and price changes. Notions of market areas and competition between firms have been at the core of location analysis. Although the classical location theory was developed in a regional context, the models have found a number of recent applications in urban analysis where interdependencies and dynamics are central elements. The theoretical contributions of Hotelling, Hoover, and Palander form cornerstones for the discussion in the current chapter. In this chapter, we will mainly dwell in the Hotelling tradition and use the theories of Hoover and Palander as introductory and complementary inputs. The chapter presents a series of behavioral models in the spirit of the classical Hotelling location game involving the spatial location

of suppliers (sellers) and consumers (customers) in an urban context. The models have been established within a cellular automata framework. The location models studied assume fixed prices. The location of sellers is determined by the relative accessibility to customers and the competition between sellers for customers. Using the techniques of cellular automata, a set of simulations will be performed to discuss equilibrium states of customer-seller systems. The discussion will serve to illustrate some elements of location theory under different levels of complexity.

43.1 Introduction

Some scientific articles have become classics in their field. This is the case with the theoretical contributions of Hotelling, Hoover, and Palander. Their works form one of the cornerstones for the discussion in the current chapter. We will focus mainly on the Hotelling tradition and use the theories of Hoover and Palander as introductory and complementary inputs. Techniques of cellular automata are used to investigate how fundamental principles of dynamics and evolution which replicate the theoretical results of locational analysis can be applied also in more complex spatial arrangements. This type of analysis has been demonstrated useful in studying a wide range of dynamic systems, including spatial urban systems (White and Engelen 1997; Semboloni 2000), political systems (Downs 1957), and innovation systems (see, e.g., Rasmusen 1989; Leydersdorff 2002).

It is common to consider industrial location within conventional general equilibrium theory, in which everything is assumed to happen at one point in space. Two fundamental questions have to be distinguished: Where will production take place? And given the place of production, the competitive conditions, factory costs, and transportation rates, how does price affect the extent of the area in which a certain producer can sell his goods?

One of the fundamental research issues in location theory is the boundary of the market areas of spatially located firms. The simple case of two firms making the same product for linear markets, where consumers are uniformly distributed on a line or along a street, was developed among others by Palander (1935).

Palander argues that the price charged at a certain location (the delivered price) is the plant cost measured as the price charged for the product at source plus the necessary cost of transportation to the fixed location from the plant. This is illustrated in Fig. 43.1. The boundary of the two markets will be the point where the delivered price from both producers is equal. This is the point where customers will be indifferent as to which firm they buy from. The size of the market area influences the profit. With the cost of production and profit per unit of output given, total profits become a function of the distance from the plant that a firm can extend its market.

The assumption of perfect competition was also used by Hoover (1938, 1948). Using the same setting as developed by Palander and introducing the condition of diminishing returns to scale in the production function of the firm, Hoover arrives at

Fig. 43.1 The classical result of Palander's market area theory

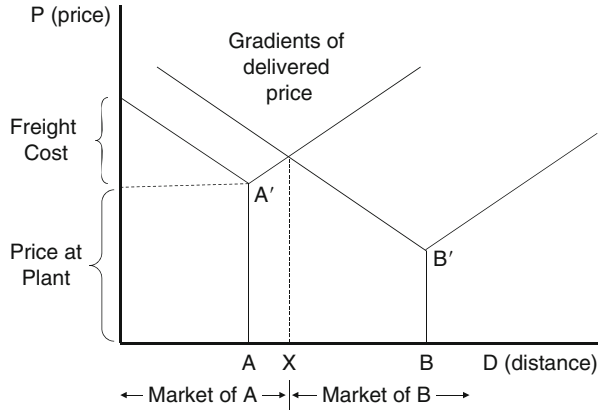

Fig. 43.2 The classical result of the Hoover location theory

the conclusion that in the absence of production cost differences, the best location will be at the point of minimum transport costs (see Fig. 43.2). Market area boundaries between different producers arise from areal variations in production costs and delivered prices.

In the early literature, market areas were separated from each other for firms having a fixed set of locations. The early location theorists found the problem of optimum location for the individual firm intractable. As soon as the interdependence of firms is accepted with the possibility that the action of one firm in locating itself can require the relocation of existing firms, the problem became too complex for mathematical formulations.

The third tradition from the classical location theory was the spatial competition analysis put forward by Hotelling (1929). That analysis differed in at least two respects from the other theorists. The first was that location was not given but a matter of competition. The other was that the analysis was dynamic or could at least be interpreted in a dynamic way. The analysis was aimed at providing a theory

which would apply to industries which would choose their location to compete for the best position.

The problem of location of interdependent firms in space was formulated and solved in strict theoretical terms by Koopmans and Beckmann (1957). They also showed that there was no price system which would sustain the equilibrium location in their quadratic assignment problem. It was shown by Heffley (1972) and Snickars (1978) that the reason for this complexity was the non-convexity of the quadratic assignment matrix. The nature of transportation costs implied that the matrices representing the assignment parameters, in essence, would never be diagonal dominant.

The following discussion will build on the tradition of Hotelling (1929) and combine it with game theory and the theory of cellular automata to address the question of spatial competition involving many competitors and several different demand schemes and competitive conditions. One reason for this choice of approach is that it is important to follow the dynamics of the system and thus to frame the classical theories in a modern theoretical and computational context.

43.2 Theoretical Background

Location theory has traditionally been based on equilibrium concepts. Dynamics have been introduced mainly to ascertain whether there are paths leading to the equilibrium states. The modeling of dynamics has been simple yet involving both locational changes and price changes. The current cellular automata framework is based on the assumption that complex spatially defined phenomena can be modeled by treating dynamics explicitly. Complexity will arise from the interaction among actors rather than from the behavioral assumptions for each actor. Cellular automata use a grid of cells to describe the spatial dimensions of the system and an incremental stepwise analysis of all cells to approximate the temporal dimension. This type of analysis has been demonstrated to be useful in a wide range of dynamic systems, but only recently the concepts are being applied to urban systems.

This contribution presents a series of behavioral models in the spirit of the classical Hotelling location game involving the spatial location of suppliers (sellers) and consumers (customers) in an urban systems context.

The location models in this chapter assume fixed prices at the factory gate. This does not preclude the possibility that these prices will vary among plants. Obviously, it will be beneficial for a firm to have lower production costs which will be reflected in the prices at the factory gate. The location of sellers is determined by the relative accessibility to customers and the competition between sellers for customers. The cellular automata approach used to investigate how fundamental principles of dynamics and evolution which replicate the theoretical results of locational analysis can be applied also in more complex spatial arrangements; see [Fig. 43.3](#) for an example of two-dimensional location-theoretical results.

The dynamic simulations may also be used for predictive purposes to determine the equilibrium states of a customer-seller system at some future point in time. They

Fig. 43.3 Classical picture of the development of market areas in two dimensions

may also provide an insight into the dynamic behavior of customer-seller systems approaching the spatial complexity of real urban areas. Usually, these processes proceed concurrently and may, or may not, be directly related to one another. The speed of the processes will differ as will the spatial extension of impacts among agents involved in them.

It is difficult to provide a single approach for exploring the fundamental issues in the dynamics and spatial evolution of the urban system. A wide range of different approaches is emerging derived from the use of artificial intelligence, multi-agent-based models, cellular automata, network analysis, dynamic programming, queuing theory, game theory, stochastic simulation, and several other mathematical modeling techniques useful for urban analysis (see also Wegener 2004 and Batty 2008).

In the model treated, the simulation process operates on urban activities using sets of rules for spatial interaction among these activities, including environmental and other constraints. The set of urban activities (workplaces, residential districts, green areas, water surfaces) will vary in different investigations, depending upon the research goals, the level of aggregation required, and what interacting mechanisms of change among agents to be considered. The set of rules and constraints for spatial interaction may be more or less well defined and will be modeled using nonlinear system methods, differential equations, or procedural knowledge.

The processes will need to be spatially and temporally defined to model the inherent dynamics of multi-agent urban systems. In this chapter, these methods are used to develop a class of dynamic land-use models (see also Anas 1987; White and Engelen 1993; Roy and Snickars 1996, 1998; Wegener 2004; Batty 2008). Specifically, we will be examining a customer-seller problem in the spirit of the classical Hotelling location game to demonstrate these principles.

In the cellular automata approach adopted in the chapter, the spatial dimension is represented by a set of cells covering the region to be studied. These cells are often based on a regular grid, and while this is not a fundamental requirement, it does simplify computations involving distance and adjacency. The dynamic state of each cell is determined by its initial state and the dynamics of the states in neighborhood cells. Many of the properties of the cellular automata will be determined by the scope of the neighborhood and the rules of interaction among neighboring cells.

In addition to the rules of interaction among neighboring cells, there will be system-wide constraints and changes imposed by externalities outside the scope of the urban system itself. The constraints will often be employed to introduce different types of public policies to address the externalities caused by the interaction among urban agents. It is also possible to introduce agglomeration factors in the framework by increasing the attractiveness of clustering spatial location elements around already existing clusters.

The resulting modeling framework is rather simple and can be readily modified to add new interaction mechanisms while maintaining the same model structure. We still need to be concerned about the integrity of the modeling process to ensure that it adequately represents the interaction mechanisms we wish to include. The chapter is concerned with attempting to show, for the case of simple models, that we can obtain results consistent with classical theories. We will then extend the analysis with the help of our model to more complex situations where theoretical analysis will not be able to give closed-form results. A further ambition is to compare the equilibrium outcomes in a cellular automata framework to the ones derived from static equilibrium theory.

Similar land-use models based on cellular automata have been proposed by, for instance, Roy and Snickars (1996), White and Engelen (1993, 1997), Semboloni (2000), and Liu (2009). Most of them are intended for investigation of basic questions of emergent urban form rather than to provide simulations of the spatial development of particular cities. The contributions suggest different behavioral processes for the representation of urban activities. The common principles for all models are that the spatial structure of urban land-use is approximated by a regular grid of cells, each cell representing a single type of land use.

According to specified sets of transformation rules, the models convert cells from one state to another and so produce fractal or bi-fractal land-use structures for the urbanized area and for each land-use type. Transformation rules are generally simple and yet can produce highly organized, complex, evolving structures. The set of rules may be divided into those that permit an unused cell to be set to a certain state and those permitting cells to become locked in a particular state or to allow displacement of one land use by another. A set of weighting parameters is used to

represent the relative competitiveness of various land-use activities. These weighting parameters control the spatial and sectoral patterns of interaction. The choice of weighting factors is thus a part of the research investigation: to discover where and when particular values have significant influences on system behavior.

The simulation process begins from a predefined initial state for the land-use pattern and through a series of transformations that evolve into new states. The transformation rules for cells can be written quite generally, but they typically rely on the present state and the activities in neighboring cells to determine the subsequent state of the cell. The neighborhood concept may not necessarily be based on geographical proximity. It can also relate to linkages in relation to economic clusters of sectors of the economy or clusters in the sense of industrial districts. The model suggested by Roy and Snickars (1996) is more general in its approach to the simulation of urban system dynamics because it does not impose restrictions on the character of neighborhood bounds. Furthermore, it does not impose a predetermined development cycle where one land-use type has externally determined predominance to another.

43.3 Theoretical Modeling of Location Choices

As mentioned earlier, the model of location choice of sellers in an urban system is inspired by the classical article by Hotelling (1929). The topic has been treated extensively in later location theory work, see e.g., Gabszewich et al. (1986), Thisse et al. (1996), Fujita et al. (1999) and Nickel and Puerto (2005). A seminal contribution was made by d'Aspremont et al. (1979) where results were proved for general customer-seller configurations using methods from game theory. The Hotelling location analysis addressed the question of competition in space by letting sellers compete for customers both with their choice of location and with their product price. The question was what would be the equilibrium location and price configuration for different assumptions about customer behavior and schemes of cooperation among sellers.

In the Hotelling location game, prices are fixed and the firms choose the most appropriate locations for their activities. Consumers or customers are distributed along the interval $[0,1]$ with a uniform density equal to one. The prices equal one, and production costs are zero. The players in the Hotelling game are sellers, say a , who simultaneously choose locations $x(a) \in [0,1]$. They are ordered by their location $x(1) < x(2) < \dots < x(n)$, $x(0) = 0$ and $x(n+1) = 1$. Seller number, a , attracts half of the customers on the gaps on each side of him so that his payoff is $(x(a) - x(a-1))/2 + (x(a+1) - x(a))/2$.

The existence of an equilibrium in the Hotelling location game was investigated for homogeneous and discriminate pricing, elastic and inelastic demand, independent and interacting products and bundles of products, non-differentiated and differentiated consumers, various distributions of consumers, different models of distance, and different numbers of sellers (see Gabszewicz et al. 1986 for an overview of results). Eaton and Lipsey (1975) proved the existence of equilibrium in pure strategies with more than three sellers. Dasgupta and Maskin (1986a, b) and

Simon (1987) investigated equilibrium properties in mixed strategies for any number of sellers in a space of any dimension. The main results are that there exist equilibria for a wide variety of assumptions. The case of three sellers seems to be an exception. In that particular case, there was a game of musical chairs in which there was always an incentive for a seller to change location among a limited set of cells.

In this chapter, we investigate a number of related modeling frameworks to illustrate the complexities of the Hotelling location game. The different models can be related to the classical questions in location theory formulated by Palander (1935), Hoover (1948), and others. Essentially, the setup means that space is subdivided into discrete cells. In the framework of the Hotelling classical ice-cream vendor problem, we think of a beach with people assigned to predetermined chairs or sunshades. In the game theory framework, the problems we will primarily address are what will happen when new sellers arrive at the marketplace, i.e., at the linear beach:

- Will there be a single stable equilibrium, or will there exist cycles with sellers roaming the beach in search of ice-cream buyers?
- What patterns will emerge in a situation when some sellers are fixed in space and others are mobile?
- What patterns will emerge under different assumptions about the mechanisms of interaction among sellers?

There will be homogeneous sellers and buyers, and the products will not be differentiated. Generalizations are not pursued here as they would cloud the results of the behaviors we are trying to model. We illustrate how spatial patterns emerge from different assumptions with the help of a specifically developed model; see Roy, Snickars, and Zaitseva (2000) for a full description of the analyses. Our basic problem concerns the operation of a market with multiple sellers and customers where the behavior of the sellers (e.g., ice-cream vendors) is driven by the objective to maximize market share and the behavior of the customers (e.g., visitors of the beach) is to maximize accessibility to purchase the product for sale (i.e., ice creams).

Since the behavior of sellers and customers is not complementary, we will consider a total of six frameworks, each one intended to model a particular behavioral paradigm. There are two different market types and three optimization strategies. The first optimization strategy will take a seller perspective, specifically optimizing for the last seller to enter the market (sellers do not cooperate). The second takes the customer perspective thus optimizing the total benefit to all customers. For the first market type, customers are assumed to only use the most accessible (or closest) seller. We will call this a closed market. In the second case, customers will share their purchasing among all sellers in proportion to their relative accessibility. We will call this an open market. The relationships between customer and seller behavior are shown in [Table 43.1](#).

In Model 1, sellers are locating to maximize their market share and do not cooperate in sharing the market. The market share for a new seller is determined by maximizing the number of customers who are closer to the new seller than to each of the other sellers. We assume that a new seller entering the market has only the

Table 43.1 The considered location models and market types

	Seller perspective Noncooperative game	Customer perspective Welfare maximization
Closed market		
Customers use nearest seller only	Model 1	Model 2
Open market		
Customers use accessible sellers	Model 3	Model 4

choice of location to maximize the market share; no other mechanisms are possible (e.g., price or product differentiation). In Model 2, sellers are locating to maximize the (total) accessibility to all customers, with each customer choosing to use the nearest seller only. From the customers' view, a seller which is closer offers additional benefit. The accessibility is estimated by a negative exponential distance decay function.

In Model 3, sellers locate to optimize their market share but do not cooperate in sharing the market. The market share is being determined by the accessibility of sellers to customers. It is assumed that sellers can attract a proportion of all customers, depending on the relative accessibility of sellers to customers. In Model 4, sellers locate to maximize the total benefit to all customers. Customers will share their purchasing with all sellers in proportion to their relative accessibility as measured by a negative exponential distance decay function.

In the context of cellular automata, we will consider our market to be defined over a grid of cells, each occupied by a seller or customer (or being empty). From some initial state, we will examine how the system evolves as more sellers are added to the system. There are thus two cases to consider. The first assumes that once located sellers do not relocate. This framework attempts to model urban systems in a development phase or systems in which some seller units are fixed and others mobile. The second case assumes that after the addition of a new seller, there is some time period during which the urban system adjusts toward an equilibrium state which is facilitated by allowing all sellers to change location to improve their relative payoffs.

While these modeling frameworks represent just a small sample of possible options and behavioral assumptions, they will permit us to see how the cellular automata handle the different situations. Our objective is to demonstrate that a cellular automata approach can produce results consistent with what we should expect from classical theory or intuitively from a behavioral analysis.

43.4 Basic Modeling Principles and Assumptions

As the basis for modeling, we take a spatial framework based on a regular grid of cells, (see also Roy et al. 2000). Each cell represents a unit of space which may contain some particular urban activity. The spatial arrangement of cells reflects the spatial organization of a seller-customer system. One might consider two basic spatial arrangements. One is a classical one-dimensional model where the customers are

located along a line and the other is a two-dimensional problem with a square array of customers. The analysis permits a range of cell types and the specification of several operational parameters (e.g., accessibility indices, competition factors, allocation sequences, clustering mechanisms, and distance metrics). Each cell will only be allocated to one seller, but a seller may be located in the same cell as a customer. The assumptions we will make for the purpose of comparability are as follows:

- Distances are Euclidean and measured from cell center to cell center.
- The negative exponential distance attenuation parameter is taken as 1.0.
- In the one dimension, sellers locate along the edge of a line of customers.
- In two dimensions, sellers may overlay customers within occupied cells.

We begin with some general definitions:

A is the set of sellers, a being any seller, and b a new seller; $a, b \in A$.

S is the set of customers, s being any customer, $s \in S$.

a , b , and s represent locations, $x(a)$, $x(b)$, and $x(s)$.

$d(s, a)$ represents the distance from a customer at cell s to a seller at cell a .

$W(a)$ represents the attractiveness of cell a for a new seller.

W is the attractiveness summed over all cells of the total system.

Model 1: Closed market, seller perspective and noncooperative game

Given that a system exists with a number of sellers and customers, an additional seller will locate at cell a when this cell maximizes the market share for the new seller. Sellers do not cooperate in any way. The market share is determined from the number of customers closer to k than any other seller. Hence a will be chosen as follows:

$$\begin{aligned}
 W &= \max W(a), \text{ across all } a \\
 W(a) &= \sum \underline{d}(s, a), \text{ across all } s \\
 \underline{d}(s, a) &= 1, \text{ if } d(s, a) < \min d(s, b), \text{ across all } b \text{ other than } a \\
 \underline{d}(s, a) &= 0, \text{ otherwise}
 \end{aligned} \tag{43.1}$$

The new seller adopts a selfish view, attempting to claim as much of the market share as possible, knowing that if she locates so that the cell is closer to a customer than any other seller, then she will claim all the purchases of that customer. Naturally, the other sellers will not be content with the situation and, if possible, attempt to relocate to reclaim some of their lost market shares.

Model 2: Closed market, customer perspective and welfare maximization

This model takes the customer perspective. The location of a new seller is taken to maximize the accessibility of customers to sellers. Customers do not care which seller they use, but they will choose the closest and will (collectively) be more satisfied if the total accessibility is maximized. The attractiveness W is defined as follows (μ is a distance attenuation parameter):

$$\begin{aligned}
 W &= \max W(a), \text{ across all } a \\
 W(a) &= \sum (\exp(-\mu \underline{d}(s, a))), \text{ across all } s \\
 \underline{d}(s, a) &= \min d(s, b), \text{ across all } b
 \end{aligned} \tag{43.2}$$

This implies that the new seller will be located at cell a , which results in the total accessibility for all customers being maximized. Each customer chooses the closest seller exclusively for their purchases. Allowing existing sellers to relocate in response to this new seller entering the system may result in further improvements to the collective payoff to customers. Sellers placed closer to customers are considered more beneficial in accordance with the posited distance attenuation function.

Model 3: Open market, seller perspective and noncooperative game

Here we assume that customers are prepared to share their custom over all sellers in proportion to their relative accessibility to sellers. When a new seller locates (at cell a), he/she can count on capturing a proportion of all customers' business and so attempts to maximize this share. The proportion is assumed to be based on the relative accessibility of sellers to customers as computed from a standard distance-based accessibility measure. The new seller is thus located at cell a so that

$$W = \max W(a), \text{ across all } a \quad (43.3)$$

$$W(a) = \frac{\sum(\exp(-\mu d(s, a)))}{\sum(\exp(-\mu d(s, b)))}, \text{ across all } b \text{ and } s$$

As with Model 1, the location of a new seller will most probably reduce the market share of the remaining sellers, who may then wish to relocate in an attempt to minimize this loss. In the accessibility case, the total purchases from the customers will depend on the number of sellers unlike in the closed market case when the total demand in the system will stay the same irrespective of the total number of sellers and their locations.

Model 4: Open market, customer perspective and welfare maximization

In this final model, the location of the new seller is taken to maximize the collective payoff to all customers assuming that customers will share their purchasing power with all sellers in proportion to the relative accessibility of sellers to customers. In this case, we have, therefore, the new seller being located at cell a so that

$$\max W(a) = \sum(\exp(-\mu d(s, a))), \text{ across all } s \quad (43.4)$$

As with the previous models, if existing sellers are permitted to relocate, further improvements in total customer payoffs may be possible.

43.5 Experimenting with the Hotelling Model

To study the behavior of these models, an experimental test bed will be established. It may be, for instance, that the end result is path-dependent and thus influenced by the initial spatial distribution of the sellers. There could also be deviations between theory and practice because of our decision to use discrete cells rather than a continuum of possible locations (see also Puu 2003).

We are interested in comparing the cellular automata results with the classical theories as described earlier in the chapter. Our linear region must be of finite size to be computationally manageable. This fact will naturally introduce some edge effects due to the size of the system. We expect these will not cause fundamental problems, providing the models are sufficiently large (i.e., have a large enough number of cells) relative to the number of sellers added to the system. The likely effect of a small-size sample in this case will be that occasionally payoffs will not vary across location cells. We will therefore expect there to emerge several equilibrium patterns of location. This is also confirmed from performing theoretical experiments with the models in the framework of game theory. In these experiments which have been done for the one-dimensional case, the result is that the best-response functions of the sellers will contain sets of locations with equal payoffs; see the theoretical considerations in, for instance, Rasmusen (1989).

A best-response function reveals the best response of one seller given the locations of all other sellers. Since these best responses are set valued, it is to be expected that the simulations will indicate the existence of several possible equilibrium situations or situations in which sellers cycle between different locations. An analysis has been performed to compute the equilibrium state in mixed strategies for some simple cases of the model. They show that already in the case of two sellers, the classical Hotelling solution will not always appear simply as a result of the existence of several best-response locations under the metric used.

The linear model consists of a line of 20 customer cells, with (initially) one seller located at the fourth cell from the left (see the sequence of figures below). Three more sellers are then allocated to the system. The displays show the location of sellers, assuming all other cells are housing customers. We consider two cases, one where sellers are fixed and cannot relocate once making an initial decision and one where they can and, indeed, generally do relocate. As a sensitivity test, simulations are performed also for other initial positions of the first seller.

In the first case, a single seller is placed in the fourth slot, and the positions for the second and subsequent allocations are computed for the given system state. In the second case, the initial position for the new seller is computed and the seller allocated. Then the positions of each seller are reviewed (in turn), and the sellers are relocated if better positions can be found. This relocation process is repeated iteratively until an equilibrium is obtained (i.e., no locational changes for any sellers can improve his/her individual payoffs). In some cases, a unique equilibrium is not obtained as the allocation pattern cycles through a sequence of cells.

In Figs. 43.4–43.7, the seller positions are shown shaded. Where a final stable equilibrium state is not found, the sellers tend to cycle through a number of states, the range of which is shown by the more lightly shaded cells. The darker shaded cells show a typical (but no equilibrium) state. The lack of convergence is not unexpected as we are dealing with a system with discrete spatial positions and a relatively limited number of customers compared to sellers.

Fig. 43.7 Open market, customer perspective and welfare maximization (Model 4): (a) sellers fixed after initial allocation and (b) sellers reallocated after new seller entered. The vertical dimension represents end situation after additional sellers have entered

43.6 Analysis of the Simulation Results

We will now discuss the results in relation to a set of figures showing the end result of a number of simulations. The figures are organized so that each row represents the end state of the system with one, two, three, and four sellers. Note also that the market is represented by a one-dimensional array of 20 cells, each one of which can house one seller at a time.

Model 1 represents a selfish strategy for each new seller, implying that sellers do not cooperate to share the market. This can be seen in [Fig. 43.4a](#). Each new seller takes a position immediately to the right of the previously allocated seller, thus claiming the market for all customers to her right. The other sellers naturally lose market share, and when allowed to relocate, as shown in [Fig. 43.4b](#), they cluster at the center of the line. The second row shows the classical Hotelling result. The states for three or more sellers do not build up to a stable equilibrium since one, or more, of the sellers will always see a way of improving their market share (there are no relocation costs in our model). This is in line with the theoretical developments offered by, e.g., d'Aspremont et al. (1979).

It may be noted that the cycling in the fourth row will keep the four sellers as close to one another as possible in the middle of the market. The simulation shows, however, that the outermost spatial position will be challenged leading to some likelihood that this cell will also be occupied.

Model 2 takes the customer perspective, and thus we would expect to see the distribution of sellers optimized to suit the customers. This result can be seen in [Fig. 43.5](#). When sellers do not relocate, [Fig. 43.5a](#), the new seller locates in a way to split the longest line of sellers in half (approximately, of course). This is more clearly seen in [Fig. 43.5b](#) when sellers are allowed to relocate. This model gives results which seem to be directly following from the Hotelling problem. The welfare maximizing spatial pattern is such that the sellers cover the market rather than crowding toward the center of the joint market. The ultimate spacing is, of course, influenced by the fact that the market covers exactly 20 cells. It is to be noted that no instabilities occur in this model.

Model 3 takes a seller perspective, but this time opening the market so that we assume that customers will share their purchasing power among all sellers, but in accordance to their relative accessibility to each. The sellers do not cooperate to share the market. The result is shown in [Fig. 43.6](#). The results are similar to the closed market case (Model 1) but with the sellers being more spatially distributed. This is to be expected as the sellers share the customers' market, making the choice of location less sensitive to claiming customers from existing sellers. The sellers can take customers from each other without piggybacking each other at the middle of the market.

Model 4 takes the customer perspective with the open market strategy. In the one-dimensional market case shown in [Fig. 43.7](#), the results are quite clear. Sellers locate to maximize the total accessibility to customers. Since, from the customers view, the sellers are not competing with each other, the sellers tend to congregate toward the center of the linear system space. If one compares the end result for the

closed market case with the open market one, one can observe that the spatial patterns seem to be more concentrated out in the open market case than in the closed market one where sellers one access the nearest customers. The result will be sensitive to the choice of distance decay parameter to illustrate the attenuation of demand.

The simulation results above have been developed for the case of a linear market. Let us assume that the spatial competition takes place on a square with 10 cells in each direction and that the first seller is placed in cell (1,1). The end point for the noncooperative case in which sellers cannot relocate will be that late-coming sellers will take over the market by placing themselves on the diagonal from that corner. If the sellers are allowed to be relocated, they will cycle around the central cell (5,5). Thus, they will not be placed only in the middle area made up by the most central cells. One reason for this is the fact that the total market is limited in all directions.

In the case of welfare maximization, again starting with a seller in cell (1,1), the end result in the relocation case will be as expected that each seller will create a local monopoly at each of the four corners. In the case of fixed locations, the result is similar although influenced by the starting location of the first seller. The end results in the open market case are spatially more complex with cycles occurring.

A general conclusion from the experiments is that in simple cases, the theoretical results will be replicated. However, when complexity increases, the classical theories will lose some of their predictive power. The end results will be path-dependent, i.e., be different depending on the starting position of the first seller. The resulting patterns of spatial competition are not always stable, but sellers seem to cycle between a limited set of cells. This indicates the complexity of spatial competition and makes it necessary to develop more complex urban simulation models to attain further predictive power.

43.7 Conclusions

The modeling process by which the above results have been generated is quite simple. At the same time, the results are closely related to the classical problems of location theory posed by Hotelling, Hoover, and Palander. What we have illustrated is that we can replicate these results with good precision and efficiency using modern computational techniques. We have also demonstrated that modern theoretical work can get a substantial support for combining strict mathematical modeling with computer simulations. Finally, we have demonstrated the capacity to add complexity stepwise to show how further introduction of behavioral realism will affect the results both in terms of end-point equilibria and in terms of development paths in spatially competitive settings. It is also possible to use these methods to illustrate in a pedagogical way how different parameter settings will change the resulting spatial patterns.

The process of integrating different modeling frameworks into the cellular automata context is straightforward. We need to define the appropriate accessibility

function and the proper selection criteria for location choice of subsequent sellers. This function is applied to all cells (or at least to a sufficiently large number) to cover the region of interest. The state of the cell meeting the selection criteria is then designated to be a seller location. While the cellular automata framework facilitates a whole range of more complex analyses that might affect the choice of location, we have not included these here. For example, it is straightforward to introduce issues of price competition, cost of relocation, policy restrictions, clustering, and other nonmarket factors (e.g., collusion among a subset of sellers). The recent literature abounds with examples of such attempts as showed, for instance, by the reviews of Wegener (2004) and Batty (2008).

As a result of our modeling framework, we gain an immediate impression of the emerging spatial and temporal organization of the spatial competition system. We can observe the changes as they are computed and quite readily see if the behavior is in line with what might be intuitively expected. As a result, we can create an opportunity to explore a range of initial states and to evaluate the sensitivities of various modeling parameters on the simulation outcomes. Such a capability is a useful addition to available tools for the analysis of the dynamics of complex urban and regional systems.

It appears from our studies that cellular automata can produce results which seem plausible and demonstrate behaviors that we might have expected under classical theoretical assumptions. They also replicate the theoretical results in cases where strict comparisons can be made. This might be of value in studying the dynamics of complex processes and learning more about how they impact on the form and composition of urban regions. The cellular automata are conceptual tool that can be used in teaching or in visualizing behavioral dynamics. In this mode of use, the method will accompany theoretical analyses of urban systems, strengthening the theoretical insight about the behavior of urban agents.

The computations require information about the temporal state of cells and the ability to compute properties about neighboring cells. Such computations, as well as the graphical display of the cells with their properties, are generally well handled in geographic information systems which contain the spatial information. A limiting factor to treat different dynamic processes interdependently will be the computational speed available. Accessibility computations like those used here are very sensitive to the number of active cells in the system. Implementations will thus require some care to optimize computational processes even with modern computing speeds.

Abstract

This chapter introduces into the theory of labor and capital movements between regions or countries. Movements of other mobile factors, in particular knowledge, are not dealt. After an introduction defining terms, it explains the basic factor mobility model assuming perfect competition and full factor price flexibility. Particular emphasis is given to the welfare results: Who are the winners and losers if factors are allowed to move and under what conditions does free mobility increase overall efficiency? We show how factor allocations deviate from an efficient outcome if the markets do not work perfectly. After studying factor mobility in a static framework, we extend the analysis to a dynamic framework. It is needed because investment decisions are forward looking. Investors compare present expenditures with present values of future returns. The same holds true for migration because migrants invest into human capital when they expend migration cost today in order to

e-mail: broecker@economics.uni-kiel.de

earn a higher income in the future. In a final section, we study the role of factor mobility in New Economic Geography. A concluding section points to further topics not dealt with in this chapter.

44.1 Introduction

Factor mobility means that factors of production move across geographical space in the course of time. Labor, capital, and knowledge are the factors that are mobile, at least in principle. There are numerous obstacles to mobility that may go that far that factor mobility is completely prevented. If the factor is labor, its movement across space is called labor migration. Migration is a wider notion covering the change of peoples' place of residence, be they workers, nonworking family members, or other persons not in the labor force like students or pensioners (for a review of migration research, see Greenwood (2007)). Modern democratic societies grant citizens the right to freely choose the place of residence within the country or to leave the country, but restrict the right to freely enter the country and may restrict the free choice of residential location of persons who are not citizens of the country. In the European Union free mobility is, after a transition period, extended to the entire area of the union.

People either freely choose to change residential location because they expect better living conditions in the destination regions than where they hitherto have lived or they are violently forced. In the latter case they are classified as refugees or displaced persons and typically not called migrants, but there is no sharp borderline between migrants and refugees. About ten million people in the world are officially counted as refugees by the United Nations (UNHCR 2010). Regarding movement of persons, this chapter is confined to labor migration. We do not deal with migration of persons not in the labor force and exclude issues like displacement or fleeing from war or terror.

Capital mobility has aspects in common with labor mobility, but there are also important conceptual differences. While workers physically relocate, this is only exceptionally the case for capital. Reparations after the war are such an exceptional example. Though physical relocation is an exception rather than a rule, we nevertheless treat capital mobility in the simplest models as if capital was physically relocated. When treating capital mobility in a dynamic framework, however, we distinguish between real and financial capital. Financial capital is highly mobile in most parts of today's world, but real capital like buildings, fabrics, stocks of goods, and goods in process only relocates steadily through higher investment in one place and lower investment – including net disinvestment due to depreciation – in another place. In other words, real capital does not literally relocate, but its spatial distribution changes due to differential real capital growth.

An important subcategory of investment is foreign direct investment (FDI) meaning that some agent from country i (typically a firm) invests into another country j . This is to be distinguished from a capital flow in the way that an agent in country j invests, obtaining the financial means through the financial capital market, for example, by issuing bonds or selling shares of an incorporation. In the latter the

creditor has no role other than providing the financial means, while in the former the investment also benefits from nonfinancial resources of the investor like management capabilities, knowledge about products, technologies, and markets. The literature on motives and consequences of FDI has exploded during the last decades and is too wide to be dealt with here.

The third mobile factor mentioned above is knowledge. Partly it flows between regions carried in the brain of people, but knowledge flows have many other forms like learning and copying, trade in patents and blueprints, and trade in research and development services. Knowledge as a production factor is very different from other factors and can therefore not be dealt with by the same theories. Different from labor or capital, it is a non-rival input meaning that its use by one agent does not hinder its use by others. Furthermore, it is often difficult to privatize returns from investment into knowledge; others can copy without paying. Finally, investment into knowledge is usually much more risky than investing into other factors. An appropriate treatment of knowledge mobility would thus lead us into completely different realms of theory, in particular into endogenous growth theory, which is beyond the coverage of this chapter (see Acemoglu (2009) for a modern treatment).

44.2 Basics

Figure 44.1 illustrates the basics in factor mobility theory (see Borjas (1994, 2008) for an introduction). Consider a world of two regions, 1 and 2, both producing a single homogenous output freely tradable across regions. It is taken as the numéraire; its price is one. All factors but one, labor say, are immobile. Competition is perfect. Factor prices thus equal their respective marginal products. Let initially the total world stock of labor be distributed among the two regions such that the wage in region 1, w_1^0 , minus migration cost m exceeds the wage in region 2. In the figure, L_1^0 and L_2^0 denote initial factor endowments of regions 1 and 2, respectively. The width of the figure is the total stock of labor. Labor in region 1 (2) is measured from the left (right). The two curves are the marginal productivities of the two regions. They are at the same time the labor demand curves, falling with increasing labor employed in the respective region.

If labor is allowed to migrate, M_{21} workers move from 2 to 1 until the wage in region 1 net of migration cost just equals the wage in region 2, $w_1 - m = w_2$. Who will gain, who will lose? First, migrants obviously win $C + D = (w_2 - w_2^0)M_{21}$; otherwise they would not move. Workers staying behind gain the same per worker, that is, E in total; otherwise they would also move or, if they won more than the migrants, migrants would have stayed. Owners of immobile factors in region 2 lose E which is the income share shifted from other factor owners to the workers staying home. But they lose more, also D , because migrants contributed more than what they got paid when they worked in region 2. A worker got paid the contribution of the marginal worker, but intramarginal workers contributed more than the marginal worker due to decreasing marginal productivity. Taking the region of origin (called the “origin” in the following, for short) as a whole (workers plus other factor owners), it suffers the net loss D .

Fig. 44.1 Basics of factor migration theory: Given initial stocks of labor L_1^0 and L_2^0 in regions 1 and 2, respectively, the wage w_1^0 in region 1, net of migration cost m , exceeds the wage w_2^0 in region 2. After M_{21} workers moved from region 2 to region 1, the wage rate in region 1, net of migration cost, $w_1 - m$, equals the wage w_2 in region 2. The destination region 1 gains B , the origin region 2 loses D , and migrants gain C plus D

For the destination region (called the “destination” in the following, for short), the story is similar, with signs reversed. Workers lose A and other factor owners win $A + B$. Thus, the destination’s net gain is B . Summing up, the world society gains $B + C$:

$B + C = -A$	loss of workers in 1
$+ A + B$	gain of other factor owners in 1
$+ E$	gain of workers in 2
$- (E + D)$	loss of other factor owners in 2
$+ C + D$	gain of migrants.

$B + C$ is the integral of marginal productivity gains, net of migration cost, over migrants.

Workers staying behind and workers already residing in the destination before are the factors competing with the migrants; the other factors are jointly complementary to migrants. We can thus summarize what we found as follows: *If factors move, competing factors in the destination lose and in the origin win, complementary factors in the destination win and in the origin lose, destinations as a whole win, origins as a whole lose, migrants win, and the world society as a whole wins.* While this result is derived for labor mobility, it also holds for capital if capital rather than labor is the mobile factor.

Two assumptions are vital for this result: (i) factor demand curves are falling, and (ii) factor price differentials are the only migration motive. Assumption (i) makes sure that factor flows are self-defeating: The more workers or capital move, the lesser becomes the incentive to move. Agglomeration theory tells that this needs not be so if the basic neoclassical assumptions (constant returns to scale, perfect competition) are given up. We return to this issue in Sect. 44.7.

Assumption (ii) is obviously extreme, in particular as far as labor migration is concerned. For labor migration we therefore now take a second look at this assumption. Empirical research on migration uncovers many motives beyond (expected) income differentials. Still, there is unanimity among reviewers of empirical migration research that, after controlling for other variables, income differentials are among the most relevant migration incentives; possibly they are the one most relevant migration incentive. But there is also ample evidence of persisting wage differentials between regions, controlling for skill differentials, despite free labor mobility. Several reasons account for this observation:

- (a) *Amenities*: Workers are willing to accept lower-paid jobs if they get compensated by favorable living conditions such as provision of public goods, nature, and safety. This is easily incorporated into the above approach by shifting the labor demand curves upward or downward such that w does not represent just wage, but a wage corrected for the willingness to pay for amenities. All welfare results go through as stated.
- (b) *Consumer price differentials*, in particular land price differentials: These are also easily incorporated by correcting labor demand for consumer prices such that real instead of nominal wages appear on the vertical axis. Note, however, that, while workers care about real wages, the demand decision of firms depends on nominal wages. Land prices are endogenous. They are increasing in the number of workers entering the region. The real wage curve is thus steeper than the nominal wage curve. If scarcity of residential land is taken into account, the welfare gain in the destination does not only end up in the pockets of complementary production factors owners but also in those of residential landowners. Similarly, the welfare loss in the origin is partly passed on to the residential landowners. But apart from this modification, welfare results remain intact.
- (c) *Unemployment*: If labor markets do not clear, potential migrants weigh the income they could earn on a job in a destination with the probability of obtaining or keeping it. There is a wide literature claiming this to be the main explanation of persistent big wage differentials between rural and urban regions in less developed countries (Harris-Todaro hypothesis (Harris and Todaro 1970)). These countries are typically characterized by a dual labor market. In rural areas people are either self-employed or low-paid farm hands, and the wage is downward flexible such that there is little or no unemployment. In the cities there is a formal sector paying comparatively high wages that are not (fully) downward flexible. There is also an informal urban sector with low pay. Downward wage rigidity in the formal urban sector can have different reasons, minimum wage laws, state-owned firms with regulated wages, union power, or efficiency wages. The latter means that firms have an incentive to pay a higher-than-market-clearing wage in order to maintain the threat of a job loss as a disciplinary device to prevent workers from shirking or to force them to work harder. In this situation the migration equilibrium is different from what we have seen so far. Workers leave the rural region as long as the *expected* income y_j^e in city j ,

Fig. 44.2 Rural–urban migration in the Harris-Todaro model: Given initial stocks of labor L_1^{i0} in the informal urban sector and L_2^0 in the urban region, respectively, the expected urban income y_1^e exceeds the rural wage w_2^0 . After M_{21} workers moved from region 2 to region 1, both coincide. In addition to the wage w_1^i in the informal sector, the expected urban income also takes the chance to get a higher-paid job in the formal urban sector into account. There can be a total welfare loss if B is greater than A

$$y_j^e = p_j w_j + (1 - p_j) y_j^u$$

exceeds the rural income. w_j denotes wage in the formal sector; y_j^u is income of an unemployed (wage w_j^i in the informal sector plus transfer income, if there is any). p_j is the probability of having a job in the formal sector. It is decreasing in the rate of unemployment u_j . In particular, $p_j = (1 - u_j)$ if workers are randomly assigned to jobs.

Regarding the welfare impact, the gains and losses of owners of complementary and competing factors in the origin and destination have the same signs as before. But the country as a whole may lose rather than win, as illustrated in Fig. 44.2. Region 1 is the urban, region 2 the rural region. For the urban region only the informal labor market is shown with employment L_1^i and wage rate w_1^i . No changes need to be taken into account for the formal sector because wages and employment in that sector are unaffected by assumption. What is affected, however, is who happens to belong to the formal sector’s labor force; migrants (though not all of them) enter it, but at the same time the same number of residents leave it. This affects individual but not total welfare.

For the sake of simplicity, Figure 44.2 is drawn for the case of zero migration cost. Rural–urban migration continues until the expected urban income y_1^e equals the rural wage w_2 . Thus, in equilibrium the urban wage in the informal sector is $w_1^i < w_2$. In the figure, w_1^i is larger than w_2^0 . But this is not necessarily the case. It may be smaller such that, without transfers, migrants not getting a job in the formal urban sector are actually worse off than if they had stayed home.

Still, they move because they expect having a chance to get a job in the formal sector, or because social benefits make them better off, or a combination of both. The total net welfare gain is $A - B$, which may be positive or negative. In any case the level of rural–urban migration is inefficiently excessive. The higher the urban wage in the formal sector and the larger the transfer income paid to an urban unemployed, the more the urban-rural migration exceeds its efficient level. Obviously, full wage flexibility in the formal sector is the first best solution of the problem. But this solution is typically not available, and countries therefore try to restrict rural–urban migration by other means such as China’s Hukou (household registration) system.

- (d) *Learning*: Jobs may offer non-visible benefits to workers letting them accept a lower real wage in the destination. Most important is the chance to learn on the job. It explains why people with higher education degrees but little experience on the job accept low real incomes in dynamic cities. They regard the income foregone a worthwhile human capital investment (Glaeser 1999).

44.3 Labor with Different Skills

The conclusion regarding the impact of immigration on workers’ welfare obtained so far is however too pessimistic. Immigrants are typically not perfect substitutes of residents. Often they are less educated or have acquired professional skills that the destination region is short of. Immigrants can be substitutes for residents, though not perfect substitutes. Depending on the degree of substitutability between labor and capital and between different kinds of labor as well as on input costs shares, wages of residents may either rise or fall as a response to immigration. To disentangle the parameter profiles leading to either an increase or decrease of residential wages, we extend the previous analysis to one with three factors, capital K , residential labor L_r (“residents,” for short), and labor L_i of immigrants (“immigrants,” for short). The respective wages are denoted w_r and w_i . The stocks of capital and residents are fixed, markets are perfectly competitive, and prices are perfectly flexible. The three factors are used for producing a single homogenous output taken as the numéraire (see Borjas (2003) for a more general analysis along these lines).

We assume a nested production function as illustrated in Fig. 44.3. Each node represents a quantity (output x , composite labor L , and the two kinds of labor, residents L_r and immigrants L_i) with associated prices (output price p , composite labor price w , and wages w_r and w_i for the two kinds of labor, respectively). For producing the output quantity x , capital K and composite labor L are combined in the upper nest, and composite labor is in turn composed of the two kinds of labor in the lower nest. The output price (equal to one by convention) is the minimal expenditure for capital and composite labor needed per unit of output. The composite labor price w is the minimal expenditure for the two kinds of labor needed per unit of composite labor.

Fig. 44.3 Nested production function: Output x , sold at price p , is produced with capital K , rented at rate r , and composite labor L hired at composite wage w . L is a composite of labor supplied by residents (L_r) and immigrants (L_i), hired at wages w_r and w_i , respectively

Table 44.1 Elasticities with respect to the stock of immigrants

	Variable	Elasticities	
r	Rental rate	$S_i S_L / \sigma$	> 0
w	Composite wage	$-S_i S_K / \sigma$	< 0
w_r	Resident's wage	$S_i (1/\eta - S_K / \sigma)$	$?$
w_i	Immigrant's wage	$-S_i S_K / \sigma - S_r / \eta$	< 0
x	Output	$S_i S_L$	> 0
L	Composite labor	S_i	> 0

Table 43.1 shows how the endogenous variables respond to immigration. The entries in the table are elasticities of the respective endogenous variables with respect to the stock of immigrants. $S_K > 0$ and $S_L > 0$ are the shares of capital and labor cost in the cost of the final output, respectively ($S_K + S_L = 1$). Similarly, $S_r > 0$ and $S_i > 0$ are the shares of residential and immigrating labor in the cost of composite labor, respectively ($S_r + S_i = 1$). Furthermore, σ is the elasticity of substitution between capital and composite labor; η is the elasticity of substitution between the two kinds of labor. The former measures the percentage increase of the labor to capital ratio as a response to a one percent increase in the ratio of the rental rate to composite wage (similarly for the latter). For example, the first entry $S_i S_L / \sigma$ in the table is the elasticity of the rental rate with respect to the stock of immigrants, that is, the percentage response of the rental rate to a one percent increase in the stock of immigrants.

To derive these elasticities, we use the following facts on cost minimization of a competitive firm with output $x = f(z_1, z_2)$, inputs z_1 and z_2 , output price p , input prices w_1, w_2 , and linear-homogenous production function f :

- (i) $\hat{p} = S_1 \hat{w}_1 + S_2 \hat{w}_2$ with expenditure shares $S_1 \geq 0, S_2 \geq 0, S_1 + S_2 = 1$.
- (ii) $z_i = \hat{x} + \sigma(\hat{p} - \hat{w}_i), i = 1, 2$, with elasticity of substitution σ .

$\hat{p} = dp/p = d \log(p)$ denotes the relative change of p (similarly for the other variables). Both facts are intuitive: (i) states that the percentage change of output price is the weighted average of the percentage changes of the input prizes, with

weights equal to the respective cost shares. (ii) states that the percentage change of the input equals the percentage change of the output corrected for the effect of the relative input price. The larger the elasticity of substitution, the stronger is the price effect. Rule (i) holds generally, for any functional form. While rule (ii) is typically derived assuming a CES (constant elasticity of substitution) form, it generally holds in the two-input case.

Writing the equilibrium as a total differential in logs (i.e., in relative changes) yields

$$\hat{p} = S_K \hat{r} + S_L \hat{w} \quad (44.1)$$

$$\hat{w} = S_r \hat{w}_r + S_i \hat{w}_i \quad (44.2)$$

$$\hat{K} = \hat{x} + \sigma(\hat{p} - \hat{r}) \quad (44.3)$$

$$\hat{L} = \hat{x} + \sigma(\hat{p} - \hat{w}) \quad (44.4)$$

$$\hat{L}_r = \hat{L} + \eta(\hat{w} - \hat{w}_r) \quad (44.5)$$

$$\hat{L}_i = \hat{L} + \eta(\hat{w} - \hat{w}_i) \quad (44.6)$$

Rule (i) is applied in Eqs. (44.1) and (44.2), rule (ii) in the other equations. Setting $\hat{p} = \hat{K} = \hat{L}_r = 0$, we solve for the entries in Table 44.1: \hat{r}/\hat{L}_i , \hat{w}/\hat{L}_i , and so forth.

All signs but one are unambiguous: The rental rate, output, and composite labor go up; the immigrants' wage and the composite wage go down with immigration. Quantity effects just depend on the respective input shares. The smaller the elasticities, the bigger are the price effects. Smaller elasticities require large price changes for the economy to adapt to changing input stocks.

Regarding the welfare effect for immigrants on the one hand and the collective of the other factor owners on the other hand, Figure 44.1 still applies. Immigrants compete with immigrants (their perfect substitutes). The more they are, the lower their wage. The collective of other factor owners gains because the average extra output generated by the immigrants exceeds the marginal output which is paid to them as their wage. Among the other factors, capital owners are sure to gain, but residents may gain or lose. They gain if and only if $\sigma/\eta - S_K > 0$. In particular, they always gain if $\sigma > \eta$, that is, if labor and capital are more substitutable than the two kinds of labor. They also gain if capital has a low share in factor costs.

All we have found so far holds, with all signs reversed, in the emigration region: Workers who are perfect substitutes of the emigrants gain, capital owners lose, and workers of a different type than those emigrating either gain or lose. The more complementary to the emigrants they are, the more they lose.

44.4 Inefficient Migration

We have seen that rural–urban migration is inefficiently large if the formal urban sector pays a downward nonflexible wage. But in a perfectly competitive world with flexible factor prices, free factor mobility brings about an efficient factor allocation across regions, though not everyone is made better off. Why do we not observe free mobility, in particular no free labor migration across national borders, and why do governments try to prevent big migration waves, for example, in Germany after unification or in the European Union after Eastern expansion? One obvious reason is the political economy induced by the distribution effects explained above. Workers competing with immigrants are many, while owners of complementary factors are few. In a democratic society the former are the majority of voters, opting for parties pursuing restrictive immigration policies.

Another reason is the aim to avoid excessive migration beyond the level that is welfare enhancing. Besides by unemployment, inefficiency of migration can be caused by external effects. If immigrants exert negative external effects as, for example, congestion of public infrastructure or social conflict in the destination, then restricting the number of immigrants is socially efficient. In addition, there may also be negative external effects of outmigration for the origin, as, for example, the loss of knowledge spillovers if educated workers leave the region. This strengthens the argument for restrictive migration policies.

This argument is however questionable for two reasons. First, there are also positive external effects for the destination. Immigrants may as taxpayers contribute more to the provision of public goods than is required to compensate residents for increased congestion. The more likely this is, the less public goods are subject to users' rivalry. Another positive externality in the immigration region is related to the brain drain. High-skilled workers are supposed to marginally contribute more than their respective gross wage to output because of knowledge spillovers, which favor residents without them having to pay for.

Second, there are also external effects in the region of origin. For example, while residents in the destination suffer from increased congestion (if not compensated by taxes of the immigrants), suggesting migration to be inefficiently large, the opposite happens in the origin, per se suggesting migration to be too small. It is therefore impossible to come to an a priori unambiguous conclusion as to whether and to what extent migration leads to inefficient labor allocation across regions or countries. An empirical assessment of external effects is needed for the concrete case.

44.5 Two-Way Migration

So far, migration seems to be a one-way road from a low-wage to a high-wage region. In some historical periods migration was in fact predominantly one way, from European countries to North America in the nineteenth century, from southern to northern Europe in the 1960s and early 1970s of the twentieth century or the East–West migration since the ending of the 1980s of the twentieth century. These

big waves fit well with the picture revealed by the model of the previous sections. They represent responses to severe regional or national disparities in expected lifetime incomes after removal of migration barriers.

Considerable migration flows are however also observed under conditions of moderate disparities and without any previous barriers having been lifted. Such flows are typically more balanced, going from one region to another as well as in the reverse direction.

The obvious explanation of this phenomenon is heterogeneity of workers regarding their respective preferences for different types of jobs. Consider an economy with n regions. Region i is the location of N_i firms with identical technologies. Each firm's labor demand is $l_i = Aw_i^{-\varepsilon}$. Initially, L_i^0 workers reside in region i . They migrate to the most attractive destination within the period considered. Workers have heterogeneous preferences regarding the attractiveness of jobs in the different firms. They are willing to accept lower payments, if they find a job more attractive. The attractiveness of a job in firm f compared to firm g , say, is quantified by the wage reduction a worker is willing to accept when choosing a job in firm f rather than firm g . For destination choice, migration cost is also taken into account. Both, migration costs and attractiveness are measured as a percentage of the destination wage. Let m_{ij} denote the share of migration costs for moving from i to j in region j 's wage rate. Furthermore, let e_{fh} be the share in the wage rate representing the attractiveness of a job in firm f for worker h . Thus, the wage plus attractiveness term minus migration cost is $(1 - m_{ij})w_j(1 + e_{fh}) \approx (1 - m_{ij})w_j \exp(e_{fh})$, if worker h initially resides in region i and the firm's location is j . One can show that, if e_{fh} is a Gumbel-distributed random variable, independently and identically distributed across all worker-job pairs, then we obtain the expected migration flow from i to j as

$$M_{ij} = L_i^0 \frac{N_j \mu_{ij} w_j^\lambda}{\sum_k N_k \mu_{ik} w_k^\lambda} \tag{44.7}$$

where $1/\lambda$ is the standard deviation of e times $\sqrt{6}/\pi$ and $\mu_{ij} = (1 - m_{ij})^\lambda < 1$. Note that i and j are allowed to be the same. Thus, M_{ii} denotes the number of workers residing initially in i and staying there. In equilibrium the labor market clears. Hence,

$$\sum_i M_{ij} = N_j A w_j^{-\varepsilon} \tag{44.8}$$

Equations (44.7) and (44.8) jointly determine the migration flows and the wage rates, given the parameters, initial number of workers, and number of firms in the regions. Another way to write the model is

$$M_{ij} = L_i^0 a_i \mu_{ij} N_j b_j \tag{44.9}$$

with constrains

$$\sum_j M_{ij} = L_i^0$$

and

$$\sum_i M_{ij} = AN_j b_j^{-\varepsilon/\lambda}$$

with $b_j = w_j^\lambda$.

This form shows the equilibrium to be described by a constrained gravity model. L_i^0 and N_j are the masses, μ_{ij} is the resistance term, and a_i and b_j are the balancing factors relating to the regions of origin and destination, respectively. The gravity model is constrained on both sides, inelastically so on the origin side and elastically constrained on the destination side.

The formal structure of this model turns out to be a special case of a general interaction model suggested by Alonso (1978), called “A Theory of Movements” after the title of Alonso’s original contribution. Alonso introduces exogenous characteristic variables of origins and destinations corresponding to our masses L_i^0 and N_j , endogenous multipliers associated with origins and destinations, respectively, and elasticity parameters controlling the response of flows to these multipliers. Our model emerges if the elasticities on the origin side are set equal to zero. Alonso’s multipliers associated with the destinations – paraphrased vaguely as “competition, crowding, congestion” variables in his original paper – turn out to be increasing transforms of the wages. Introducing wages and the labor market equilibrium provides a theoretical underpinning of Alonso’s interpretations of the multipliers.¹

Gravity models are the workhorses of econometric migration research. Taking logs in Eq. (44.9) and adding a random term lead to a linear regression. Adding a time dimension allows for applying panel methods. Origin and destination characteristics that are constant over time can be represented by fixed effects. Instead of taking logs one can stick to the nonlinear logit form. A well-specified logit model for bilateral migration flows clearly shows the positive impact of wages and the negative impact of unemployment on destination choice (Davies et al. 2001).

Two extreme cases of the equilibrium are of special interest: If (for finite λ) ε goes to infinity, the labor demand curve is horizontal. This implies a fixed b and no demand constraint. If ε is zero, the labor demand curve is vertical. The equilibrium

¹To be precise, Alonso’s multiplier c_j is $c_j = w_j^{\lambda+\varepsilon}$, and his elasticity β is $\beta = \lambda/(\lambda + \varepsilon)$. Hence $c_j^\beta = w_j^\lambda$ and $c_j^{\beta-1} = w_j^{-\varepsilon}$.

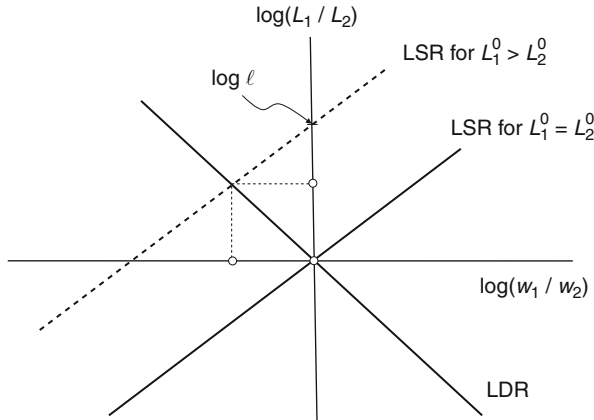

Fig. 44.4 Two-way migration: The equilibrium distribution of labor between the two regions (L_1/L_2) is attained where the *LSR* (labor supply ratio) and *LDR* (labor demand ratio) lines cut. *Solid and dashed LSR lines* refer to symmetrical and asymmetrical initial distributions of labor, respectively. *LSR* is increasing; *LDR* is decreasing in the wage ratio w_1/w_2 . In the symmetrical case, equal flows of migrants move both ways. In the asymmetrical case more workers move from 1 to 2 than the other way, but migration in one period does not fully equalize labor distribution and wages among the two regions

stock of labor in each region is thus fixed; the model is equivalent to the so-called doubly constrained gravity model in this case.

Let us work out the model for a world with two regions, covering the same number of firms each. Firms are identical, except for the fact that workers value jobs differently, as described above. Changing jobs within a region is costless, while migration to the respective other region incurs costs equal to m times the destination's wage. Then the number of jobs offered in region 1 relative to region 2 is

$$L_1^d/L_2^d = (w_1/w_2)^{-\varepsilon}$$

while labor supply in region 1 relative to region 2 is

$$\frac{L_1^s}{L_2^s} = \frac{M_{11} + M_{21}}{M_{12} + M_{22}} \tag{44.10}$$

with

$$M_{ij} = L_i^0 \frac{\mu_{ij} w_j^\lambda}{\sum_{k=1}^2 \mu_{ik} w_k^\lambda}, \quad \mu_{ij} = \begin{cases} 1 & \text{if } i = j \\ (1 - m)^\lambda < 1 & \text{else} \end{cases}$$

Figure 44.4 depicts the equilibrium. Axes are in log scale. The labor demand ratio (*LDR*) L_1^d/L_2^d is decreasing, and the labor supply ratio (*LSR*) L_1^s/L_2^s is increasing in

w_1/w_2 . Furthermore, as LDR goes to infinity (zero) and LSR goes to zero (infinity) if w_1/w_2 goes to zero (infinity), there is unique equilibrium. In particular, if $L_1^0 = L_2^0$ (solid LSR curve), then the equilibrium is the origin in the graph. It is symmetrical: $w_1 = w_2$, $L_1 = L_2$, $M_{11} = M_{22}$, $M_{12} = M_{21}$, and the out-migration rates are

$$\frac{M_{12}}{L_1^0} = \frac{M_{21}}{L_2^0} = \frac{\mu}{1 + \mu} \quad (44.11)$$

Clearly, the higher the migration cost and the more homogenous the job preferences, that is, the larger λ , the smaller are the outmigration rates.

The figure also shows an equilibrium for an initially unequal distribution of labor, $L_1^0 > L_2^0$ (dashed LSR curve). The LSR curve cuts the abscissa at $\log \ell$. ℓ denotes the LSR for $w_1 = w_2$:

$$\frac{L_1^0}{L_2^0} > \ell = \frac{L_1^0 + \mu L_2^0}{\mu L_1^0 + L_2^0} > 1$$

It follows that in the equilibrium, indicated by dotted lines, we find

$$L_1^0/L_2^0 > L_1/L_2 > 1 \text{ and } w_1 < w_2$$

Migration leads to a more equal, though not perfectly equal, distribution of labor. The distribution remains unchanged if m goes to one, of course, and it becomes equal if m goes to zero. The lower the migration cost is, the more migration tends to equalize the distribution of labor between the two regions. One can apply the model iteratively, period by period, such that the equilibrium in the first period becomes the initial distribution in the second and so forth. Then, period by period, the distribution equalizes more and more. In the limit we come back to the symmetrical equilibrium with migration rates as given by Eq. (44.11).

44.6 Dynamics of Factor Mobility

In the previous sections we studied factor movements as if the economy existed for only one period. In the beginning of the period, the distribution of factors across regions differs from what it would be if factor owners could freely decide where to locate their respective factors, labor of certain skills or capital. Then mobility restrictions are lifted or reduced, and factors jump to the place where they earn the highest real return net of migration cost. This kind of story is a shortcut to the long-run steady-state impact uncovered by a more sophisticated dynamic analysis.

Hence, let us extend the foregoing analysis to a dynamic framework (see Barro and Sala-I-Martin (1995, Sect. 9.1 and 3.5) for a textbook treatment of dynamic factor mobility). We begin with labor migration. To simplify, we abstract from land as consumption good and all kinds of market imperfections. Consider a small open region facing a fixed world wage rate \bar{w} . Capital is perfectly mobile such that the

interest rate in the region is the same as in the rest of the world, \bar{r} . It is constant from the region's point of view. Labor is mobile between the region and the rest of the world. At least one other factor (land) is immobile. Labor may be just a segment of the entire labor force.

Sjaastad (1962) introduced the idea that the decision to migrate is a decision to invest into human capital. Migrants compare migration cost with future returns. A potential migrant from the rest of the world enters the region at time t if the present value of the wage differential as of time t between the region and the rest of the world,

$$B(t) = \int_t^{\infty} (w(L(\tau)) - \bar{w}) \exp[\bar{r}(t - \tau)] d\tau \quad (44.12)$$

exceeds the migration cost $m(t)$. While we confine the discussion to the immigration process starting in a world where $w(t_0) > \bar{w}$, outmigration can be studied in a similar way if $w(t_0) < \bar{w}$ at start point t_0 . For the sake of simplicity, we assume the potential migrant to take wage differentials through the infinite future into consideration. One justification is that this reflects the fact that migrants not just care about their own but also their decedents' well-being. Another is that the approach implies that migrants move early in life, because the earlier they move, the longer they reap the benefits from a wage differential. For a young migrant the difference between an infinite and an end of active-life horizon is small.

If we assumed fixed migration cost m at all times, we would still observe migrants to jump in instantaneously and stay forever. The equilibrium labor force L^* would be obtained from the steady-state condition:

$$B = \frac{w(L^*) - \bar{w}}{\bar{r}} = m$$

As this had to hold forever, the time argument is dropped. We may rewrite this as

$$w(L^*) = \bar{w} + \bar{r}m \quad (44.13)$$

bringing us back to the static-migration model in Sect. 44.2. The only difference is that migration costs would now be a per annum flow, namely, the perpetuity equivalent to the one-off cost m . The immigration would be $L^* - L_0$, where L_0 is the stock of labor at the start point t_0 .

Why do we observe a continuous migration flow rather than jumps in the regional stock of labor? One obvious reason is that new generations enter the pool of potential migrants only gradually. Still, also within a cohort reaching the age to look at the first job, not everyone moves at the same time. Some move as early as they are allowed to, others move later, and many do not move at all. Partly, the lack of information or the time needed to decide can explain this phenomenon. Another explanation is adjustment cost. If everyone expecting a gain moves at the

Fig. 44.5 Dynamic migration theory: In the course of time, the present value B of immigration benefits and labor L in the region move along the saddle path until B is down at the lower bound \underline{m} of migration cost, and immigration ceases. As indicated by the arrows pointing into the direction of movement, the saddle path is the only path leading to the long-run equilibrium

same moment, the region’s labor market, housing market, etc. have to adapt instantaneously. This burdens migrants with costs. The more people move at the same time, the higher are these costs. It is thus reasonable to assume migration costs to be increasing in M/L :

$$m(t) = c(M(t)/L(t)) \tag{44.14}$$

$c(\cdot)$ is increasing and assumed to go to a lower bound $\underline{m} > 0$ if M/L goes to zero. Even if there is no other migrant, an infinitesimal migrant is facing strictly positive migration cost. She will stay if $B < \underline{m}$.

Noting that $M(t) = \dot{L}(t)$, where dotted variables denote time derivatives, Eqs. (44.12) and (44.14) can be written as a dynamic system in B and L :

$$\dot{B} = \bar{r}B - (w(L) - \bar{w}), \quad \dot{L} = Lc^{-1}(B)$$

The first equation is the time derivative of Eq. (44.12); the second is the solution of Eq. (44.14) for $M = \dot{L}$, using the equilibrium condition $m(t) = B(t)$ to substitute B for m .

Figure 44.5 illustrates the dynamics in a phase diagram. Arrows point into the direction of movement of B (vertical) and L (horizontal), respectively. Along the ($\dot{B} = 0$) isocline, B does not change, that is, $B = (w(L) - \bar{w})/\bar{r}$. The isocline is decreasing because of decreasing marginal productivity. It cuts the ($B = \underline{m}$) line at the stationary state where condition (44.13) holds. In the dynamic transition B and L move along the saddle path asymptotically toward the steady state. If, starting at $L_0 = L^*$, regional productivity goes up due to an exogenous shock, then the ($\dot{B} = 0$) isocline as well as the saddle path shift upward; B jumps up to the new saddle path and workers start moving into the region until the stock of labor has asymptotically adjusted to the new higher stationary state.

A similar theory, called Tobin's q -theory, explains why capital does not jump to a place of higher marginal returns but adjusts by a smooth growth of the capital stock in the destination. Consider a small open region with capital stock K and marginal capital productivity $f(K)$, $f(\cdot)$ positive and decreasing in K .² Financial capital is perfectly mobile. The uniform world interest rate is \bar{r} . The increase of the capital stock per unit of time \dot{K} is gross investment I minus depreciation δK :

$$\dot{K} = I - \delta K \quad (44.15)$$

The cost of investment is assumed to depend on the volume of investment as well as the rate of capital growth. The latter is due to adjustment cost: The faster capital grows, the more expensive is a given investment. A standard specification is a quadratic function for investment cost C :

$$C = I(1 + bI/K) \quad (44.16)$$

Parameter b measures the importance of adjustment costs. If investment per unit of capital goes to zero, goods are transformed into investment one to one, without adjustment cost.

Firms choose the level of investment at any moment such that the marginal investment cost equals the market stock price of capital q (so-called Tobin's q):

$$q = 1 + 2bI/K$$

Solving for I and inserting into Eq. (44.15) yields

$$\dot{K} = \begin{cases} K \left(\frac{q-1}{2b} - \delta \right) & \text{if } q \geq 1 \\ -\delta K & \text{else} \end{cases} \quad (44.17)$$

The stock price of capital q is the present value of future capital returns, similar as B in the dynamic migration model. Its dynamics follow from the non-arbitrage condition

$$\bar{r}q = \dot{q} - \delta q + f(K) + \frac{(q-1)^2}{4b} \quad (44.18)$$

In capital market equilibrium the interest on the market value of one unit of capital must equal the revaluation \dot{q} minus depreciation δq plus marginal productivity $f(K)$

²In a growth model with technical progress, f is increasing in time. For the sake of simplicity, we assume it to be time independent such that the long-term equilibrium is stationary.

Fig. 44.6 Tobin’s q-theory of investment: In the course of time, the capital K and its stock price q in the region move along the saddle path until q is down at the stationary stock price q^* , and capital inflow ceases. As indicated by the *arrows* pointing into the direction of movement, the saddle path is the only path leading to the long-run equilibrium

plus the marginal contribution of capital to investment cost reduction according to Eq. (44.16).

With Eq. (44.18), solved for \dot{q} , and Eq. (44.15), we have two differential equations in the two variables K and q . Figure 44.6 depicts the dynamics in a phase diagram. The ($\dot{q} = 0$) line is downward sloping for $q < \bar{q} = 1 + 2b(\bar{r} + \delta)$. The stationary state is (K^*, q^*) with

$$q^* = 1 + 2b\delta$$

and

$$K^* = f^{-1} \left((\bar{r} + \delta)q^* - \frac{(q^* - 1)^2}{4b} \right)$$

Note that, without adjustment costs ($b = 0$), we are back at the equilibrium condition with perfect real capital mobility:

$$\bar{r} = f(K^*) - \delta$$

If K_0 is smaller than K^* as in the figure, then $q(t_0) > q^*$. This induces positive net investment; capital grows and q steadily declines. If, due to some exogenous shock, the marginal productivity of capital goes up, the instantaneous response is not a capital “jump in,” but a “jump up” of the stock price q . This in turn lets investment instantaneously jump up and the capital starts growing steadily.

If $K_0 = K^*$ and, due to an exogenous shock, marginal productivity falls, then q falls below q^* . Hence, gross investment falls short of depreciation and the capital stock shrinks. If the downward shock is drastic enough, q even falls below one; investment ceases and capital declines at the depreciation rate δ .

44.7 Migration and Agglomeration

As mentioned, the assumption leading to the stabilizing role of factor migration is the neoclassical idea of decreasing marginal productivity. The so-called New Economic Geography (NEG) forcefully made the argument that this assumption cannot generally be true in a spatial economy (Krugman 1991). Otherwise it is impossible to explain the self-organization of the spatial economy such that agglomerations endogenously emerge on the one hand and sparsely populated areas on the other. If economies of scale in modern production sectors are strong enough and transportation costs small enough, then factor mobility does not lead to a uniform factor distribution in isotropic space, but on the contrary: If, in a thought experiment, obstacles to factor mobility are removed, a circular cumulative causation process sets in ending with the concentration of mobile factors at small spots that we call cities.

The emerging spatial structure is an equilibrium of centripetal and centrifugal forces. The former tend to make places with higher spatial concentration of mobile factors even more attractive for these factors. Two linkage effects generate the centripetal force: The *backward linkage effect* is due to the fact that factor movements to one region increase the size of the market in that region because the owners of the factors – provided they move with the factors – buy consumer goods. Firms and thus factors tend to follow the market because they want to save transport costs. Input and investment demand of firms also contribute to the backward linkage effect. The *forward linkage effect* is due to the fact that more factors in a region and thus higher supply available with low transport cost imply a lower price level in that region making it a more attractive location for even more factors to follow.

The centrifugal force is the *competition* or *crowding effect*. It is due to the fact that at least one factor is immobile. In Krugman's original center-periphery model, farmers are the immobile factor. As farmers are also consumers, the farmers' share in consumer demand has to be delivered to the farmers' location that is fixed and assumed to be distributed evenly across space. Firms thus also have an incentive not to be too far from the farmers' consumption demand.

To understand the role of factor mobility in NEG models we look at the so-called wiggle diagram in Fig. 44.7. It plots, for a NEG model with two symmetrical regions, the real wage difference (percentage deviation between region 1 and 2) over the distribution of the only mobile factor (labor in the nonfarm sector, called the "modern" sector) across the two regions. The basic assumptions of the model that the curve is derived from are the following:

- There are two regions (1 and 2) and 2 sectors, agriculture and "modern."
- Agricultural goods are produced by immobile farmers under constant returns to scale.
- Modern goods are produced by mobile workers under increasing returns to scale.
- In the eyes of consumers, modern goods varieties are imperfect substitutes.
- Modern goods trade between regions is burdened with transport cost; agricultural goods trade is not. (The latter assumption is not essential, but made for the sake of tractability.)

Fig. 44.7 Wiggle diagram for the center-periphery model: Workers are attracted by higher real wages. The *solid* and *dotted* lines refer to low and high transport costs, respectively. The half-and-half distribution of labor across regions is stable (unstable) for high (low) transportation cost

The figure depicts two curves, the hump-shaped dotted curve for high, the solid monotone curve for low transport costs in the modern sector. For low transport costs the centripetal forces can be shown to dominate. The larger the share of the mobile factor in one region, the higher the wage in comparison to the other region. For high transport costs it is the other way round. The role of factor mobility is thus entirely different, depending on whether the economy is under the low transport cost or high transport cost regime. Assume labor is initially evenly distributed and now allowed to move. Under the high transport cost regime, nothing happens, while under the low transport cost regime, a slight random variation of the distribution makes the region with more workers more attractive. Hence, workers start moving to that region making it even relatively more attractive, until all workers reside in only one of the two regions, the endogenously emerging center. Which one of the two initially identical regions is going to become the center is a matter of historical coincidence.

While in Krugman's original model there is only one factor redistribution, from dispersed to concentrated, if transport costs decline from high to low, there are extended model versions with a second shift, back from concentrated to dispersed, if transport costs become low enough. The reason is a further immobile factor that is either an input of the modern sector or a consumption good. The higher the concentration of the mobile factor, the more its real returns get depressed by the scarcity of the immobile factor. When transport cost are low enough, the excess of the linkage effects over the competition effect, though still positive, is getting too small to compensate the negative effect of the scarce immobile factor (Puga 1999).

Distributional implications are similar to what we have seen in the neoclassical framework: Migrants gain, owners of immobile factors left behind in the periphery (farmers in this case) lose because they must pay more transport costs for consumer goods, and owners of immobile factors in the center gain because they have the modern sector closer by. In the extended model with an additional immobile input

factor in the modern sector, this input factor also gains in the center and loses in the periphery.

Questions about overall welfare gains or losses are much harder to answer. Because of imperfect competition no solution is Pareto optimal, and different allocations are usually Pareto incomparable because there are always winners and losers. One needs compensation criteria or a social welfare function for a comparison. No wonder, results in the literature are therefore rather diverse (see Behrens and Robert-Nicoud 2011, for a survey). In the basic model one finds that for low transport costs agglomeration is both a welfare optimum and market equilibrium. Therefore, if mobile factors are initially equally distributed among two symmetrical regions and mobility barriers are lifted, then they move to one of the regions, and this is desirable from a welfare point of view. If transport costs are high, then the dispersed equilibrium is both optimum and equilibrium. Initially equally distributed factors would not move, even if they could, and this is a desirable outcome. If, however, transport costs pass the so-called breakpoint from above, the dispersed equilibrium is replaced by a concentrated equilibrium. Initially equally distributed mobile factors start moving to one of the regions, though a dispersed equilibrium is still preferable if transport costs are lower than but sufficiently close to the breakpoint. Unfortunately, this conclusion is not robust against extensions of the model. In a model version where the modern sector needs an immobile factor, the market may also generate too much dispersion. Introducing additional centripetal forces can also lead to a market equilibrium with too little rather than too much agglomeration.

44.8 Conclusions

The previous sections show that factors tend to move to places where factor owners expect the highest returns. Under ideal circumstances factor movements enhance overall efficiency but also lead to considerable income redistribution such that not everyone is better off with free mobility rather than under a regime of restricted factor mobility. Under conditions of decreasing marginal productivity, factor movements support a dispersed factor distribution across space, but with increasing returns to scale and sufficiently low transport costs, they lead to concentration.

Though these are fairly clear conclusions, they are based on rather simplified concepts of migration decisions and migration incentives. Important branches of migration theory could not be dealt with in the previous sections due to space limitation, but shall briefly be mentioned. Some authors focus on the fact that migration decisions are not individual but *family decisions*. Many families look for a residential location offering jobs for more than one family member in an acceptable commuting distance. In this case the decision depends on the expected family income, taking migration costs as well as commuting costs in the destination into account. Beyond expected income, costs of educating children are an important migration motive (Mincer 1978). Family members may have diverging interests.

Thus, game-theoretic approaches help to explain the outcome of a family decision regarding migration.

An important issue in migration theory is *uncertainty*. Risk-averse individuals down-weight expected destination income if it is uncertain. Uncertainty is typically larger with regard to the destination region than the home region, such that a worker may prefer staying home in spite a net income gain to be expected in another region. Uncertainty also explains why migrants postpone a migration decision even though a move seems favorable. The reason is the *option value of waiting*. Potential migrants are facing a trade-off: An early move allows for reaping the benefit for a longer time but possibly lets the migrant miss the chance of staying or choosing a different destination after more information has become available. Finally, uncertainty is also among the factors explaining *destination clustering*. Cross-border migrants from one region of origin often cluster together in one region of destination. Closeness of friends and relatives or people with same language or culture eases information access. Sharing services like shops or cultural facilities also contributes to clustering.

Remittances are another important issue in international migration research. Remittances amount to more than 400 billion USD per annum and for some countries can be one third of GDP or more (World Bank 2012). The impact of remittances on the receiving countries is an active field of research beyond the scope of this chapter (Maimbo and Ratha 2005). Finally, migration and the welfare state have also only been touched upon above in the context of rural–urban migration. It is a wide field, also beyond the scope of this chapter.

Abstract

This chapter presents and critically evaluates the economic assumptions and applicability of a series of regional and interregional interindustry models. It begins with the demand-driven, single-region Leontief quantity model and its cost-push price dual. Then [Section 45.4](#) discusses the ideal, full information, interregional input–output model with interregional spillover and feedback effects at length, and compares it with the requirements and assumptions of more limited information, multiregional input–output models. [Section 45.5](#) discusses how to construct and add an interregional consumption function to obtain the type II interregional interindustry model. [Section 45.6](#) outlines further

extensions, all through to the most complex price-quantity interacting interregional demo-economic model LINE. Finally, an Appendix presents the microeconomic foundation for the Leontief model and compares it with the alternative supply-driven quantity model and its demand-pull price dual.

45.1 Introduction

The power of input–output (IO) analysis lies in its linking the sales of one industry, say agriculture, to the purchases of another industry, say the food industry. Interregional IO analysis adds a spatial dimension to this, for example, by linking the sales of the French agriculture to the purchases of the German food industry. In addition, input–output analysis places the data that describe these linkages into a single input–output table (IOT), such that it becomes directly clear that interregional IO analysis is based on a sectoral and regional disaggregation of the well-known macroeconomic equation for the gross regional or gross national product (GDP). With these data, a whole series of regional and interregional interindustry models may be built. This chapter discusses the assumptions of the basic version of these models, how these models can be solved, and what type of applications can be conducted with them.

We start in Sects. 45.2 and 45.3 with the basic IO quantity and the basic IO price model, developed by Wassily W. Leontief, who received the 1972 Nobel Prize for economics, especially for this work. In Sect. 45.4, we consider in more detail the ideal interregional IO model, developed by Walter Isard, the founding father of the Regional Science Association. In Sect. 45.5, the basic interregional IO model will be extended with an interregional consumption function. Section 45.6 will indicate how this model can be further extended and disaggregated, and how it can thus be used as a simple general equilibrium model, with prices and quantities interacting. Students with a strong theoretical interest will find the microeconomic foundation of the Leontief model, and a comparison with the alternative supply-driven IO model of Amica Ghosh (1958), in an Appendix.

45.2 Interindustry Relations: The Base IO Table and the Demand-Driven IO Quantity Model

Throughout this chapter, matrices are denoted by bold capitals, vectors by bold small types, and scalars by italics; \mathbf{x}' indicates the transpose of \mathbf{x} , $\hat{\mathbf{x}}$ a diagonal matrix of \mathbf{x} , \mathbf{i}' a summation row with ones, and $\mathbf{I} = \hat{\mathbf{1}}$ the identity matrix.

Figure 45.1 shows how the usual data in a national or regional input–output table are organized in four quadrants. The *first quadrant* contains the most salient data of the table, namely, the deliveries of intermediate products from industry i to industry j (indicated by z_{ij} , with $i, j = 1, \dots, N$). The *second quadrant* contains the deliveries of industry i to final demand category q (i.e., consumption, investments, government, and exports, indicated by y_{iq} , with $q = 1, \dots, Q$). The *third quadrant*

	Industry 1	Industry j	Industry N	Final demand	Total
Industry 1	.	<i>1st quadrant</i>	.	<i>2nd quadrant</i>	x_1
Industry i	.	z_{ij}	.	y_{iq}	x_i
Industry N	x_N
Imports	<i>3rd quadrant</i>			<i>4th quadrant</i>	M
Value added	.	v_{pj}	.	y_{pq}	Y
Total	x_1	x_j	x_N	$C \quad I \quad G \quad E$	

Fig. 45.1 Regional input–output table, with four quadrants and macroeconomic totals. Legend: z_{ij} , intermediate deliveries from industry i to industry j ; y_{iq} , final deliveries from industry i to final demand type q ; x_i , total output/input of industry i ; v_{pj} , primary input type p purchased by industry j ; y_{pq} , primary inputs type p purchased by final demand type q ; C , household consumption; I , investments; G , government expenditures; E , exports; M , imports; Y , gross value added at market prices

contains the primary inputs of category p (i.e., imports and the various components of gross value added at market prices) used by industry j (indicated by v_{pj} , with $p = 1, \dots, P$). The *fourth quadrant* contains the primary inputs of type p that are purchased by final demand category q (y_{pq}). The most important of these are the imports of consumption and investment goods.

The row totals of the first and second quadrant (x_i) equal total sales by industry i , which is made equal to total output by including *changes in stocks* as part of investments. Calculating percentages across these rows enables interesting analyses of the differences in market and *sales structure* of the industries distinguished. The column totals of the first and third quadrant (x_j) equal total cost of industry j , which is made equal to total output by including the *net operating surplus* as part of the gross value added in market prices. Calculating percentages across these columns allows for comparative analyses of the purchase and *cost structure* of various industries. Since these row and column totals are equal by industry, the overall total of the third and fourth quadrant ($M + Y$) and the overall total of the second and fourth quadrant ($C + I + G + E$) are also equal. The rearrangement of these totals shows that an IOT, in fact, represents a sectorally detailed view of the well-known *macroeconomic identity* for the gross regional or gross national product/income (GDP), namely, $Y = C + I + G + E - M$.

Besides descriptive statistical analyses of sales and cost structures, an input–output table also provides the data to specify a series of interindustry models. The accounting identities of these models are usually based on those of an IOT. Additionally, these models require behavioral and institutional assumptions, and assumptions about which variables are determined outside the model (called exogenous variables), and which are determined inside the model (called endogenous variables). We start our exposition of these models with the most simple and oldest of them (Leontief 1936).

This *demand-driven IO quantity model* is based on the accounting identities for the rows of an IOT for a *closed economy*, that is, for Fig. 45.1 without the import row and without the export column. This model has two core behavioral assumptions. The first stipulates that the supply of output of all industries, $i = 1, \dots, N$, follows the total of the intermediate demands z_{ij} and the total of the final demands f_{iq} for its products:

$$x_i = \sum_j z_{ij} + \sum_q y_{iq} \text{ for all } i \quad (45.1)$$

$$\text{or in matrix algebra : } \mathbf{x} = \mathbf{Z} \mathbf{i} + \mathbf{Y} \mathbf{i} = \mathbf{Z} \mathbf{i} + \mathbf{y}$$

where the N -by- N matrix \mathbf{Z} represents the first quadrant, the N -by- Q matrix \mathbf{Y} the second quadrant, and the N -column \mathbf{x} the row totals of the first plus second quadrant of Fig. 45.1. Note that these three types of quantities are all defined as unit quantities, with a constant price equal to one (not shown explicitly), such that they may be summed by row and column. Thus, Eq. (45.1) assumes that supply follows demand without any price change or stimulus. This means that each industry's supply is infinitely price elastic, which is a plausible assumption in short run situations with spare production capacity, or in long run situations in which the relative prices of the inputs on the supply side do not change.

The second behavioral assumption is that the demand for intermediate inputs z_{ij} and primary inputs v_{pj} is linearly and solely determined by the total output of purchasing industry j :

$$z_{ij} = a_{ij}x_j, \text{ for all } i, j \text{ or in matrix algebra : } \mathbf{Z} \mathbf{i} = \mathbf{A} \mathbf{x} \quad (45.2a)$$

$$v_{pj} = c_{pj}x_j, \text{ for all } p, j \text{ or in matrix algebra : } \mathbf{V} \mathbf{i} = \mathbf{C} \mathbf{x} \quad (45.2b)$$

where the P -by- N matrix \mathbf{V} represents the third quadrant of Fig. 45.1. Note that the assumption of constant prices equal to one, which is implicitly present in Eq. (45.2a, b), implies that the demand for intermediate and primary inputs has a price inelasticity of zero, whereas the supply of intermediate and primary inputs is perfectly price elastic. Taken together, these assumptions imply that there are no bottlenecks in the region's labor, land, or capital markets.

The *technical coefficients* a_{ij} and c_{pj} in Eq. (45.2a, b) indicate, respectively, the amount of intermediate inputs from industry i , and the amount of primary inputs of category p , needed per unit of output of industry j . When only one IOT is available, the matrices \mathbf{A} and \mathbf{C} are simply estimated by the column-wise division of each element of the intermediate inputs matrix \mathbf{Z} , and the primary inputs matrix \mathbf{V} , by the total of the corresponding column of the IOT. In such cases, $\mathbf{A} = \mathbf{Z} \hat{\mathbf{x}}^{-1}$ and $\mathbf{C} = \mathbf{V} \hat{\mathbf{x}}^{-1}$, with the overall column total of the technical coefficients being equal to one, that is, $\mathbf{i}' \mathbf{A} + \mathbf{i}' \mathbf{C} = \mathbf{i}'$. Note that this specification implies that there are *no* economies of scale, while all intermediate and primary inputs are mutually complementary.

Fig. 45.2 The causal structure of the basic IO quantity model

Figure 45.2 summarizes the causal structure of the basic IO quantity model. The symbols next to the arrows indicate the size of the *direct effect* along the direction of the arrow. The symbol **A**, for instance, indicates that a change in the total output vector ($\Delta\mathbf{x}$) leads to a direct change in intermediate input matrix **Z** that is equal to **A** times $\Delta\mathbf{x}$, while the arrows with the symbol **I** indicate a one-to-one backward impact of demand on the corresponding supply.

Figure 45.2 shows that the demand for final outputs \mathbf{y} is exogenous, as no arrows are coming in. Any change in \mathbf{y} will lead to an equally large direct change of $\mathbf{I} \Delta\mathbf{y}$ in total output \mathbf{x} . This change in total output, in its turn, will lead to *first round indirect effects* on the demand for intermediate and primary inputs of, respectively, $\mathbf{A} \Delta\mathbf{y}$ and $\mathbf{C} \Delta\mathbf{y}$. The 1st round effect on primary inputs will lead to *no* further changes in any of the endogenous variables, as no arrows go out. The 1st round effect on intermediate inputs, however, will lead to an equally large backward change in total output, indicated by **I**, which will lead to *second round indirect effects* on the demand for intermediate and primary inputs of, respectively, $\mathbf{A}^2 \Delta\mathbf{y}$ and $\mathbf{C} \mathbf{A} \Delta\mathbf{y}$. The third round indirect effects amount to, respectively, $\mathbf{A}^3 \Delta\mathbf{y}$ and $\mathbf{C} \mathbf{A}^2 \Delta\mathbf{y}$, and so on. Consequently, the equilibrium size of total output equals

$$\mathbf{x} = (\mathbf{I} + \mathbf{A} + \mathbf{A}^2 + \mathbf{A}^3 + \dots)\mathbf{y} = (\mathbf{I} - \mathbf{A})^{-1}\mathbf{y} = \mathbf{L}\mathbf{y} \tag{45.3}$$

If all column sums of **A** are smaller than one, which implies that value added is positive for each industry, the *Taylor expansion* of the **A** matrix converges to the so-called *Leontief inverse* $\mathbf{L} = (\mathbf{I} - \mathbf{A})^{-1}$ in Eq. (45.3). However, since the input–output model is a comparative static equilibrium model, it does not specify either the length or the nature of the equilibrium process. Most IO applications, in fact, work with year-to-year changes of one equilibrium to the next. When large shocks to the economy need to be modeled, it may be necessary to assume a longer period before the new equilibrium is reached.

The equilibrium solution for endogenous total output in Eq. (45.3) may also be found by substituting Eq. (45.2a) in Eq. (45.1), transferring $\mathbf{A} \mathbf{x}$ to the left-hand side, and pre-multiplying both sides by the Leontief inverse. The equilibrium solutions for endogenous intermediate and primary inputs, in their turn, are found by substituting Eq. (45.3) in Eqs. (45.2a) and (45.2b), respectively, yielding

$$\mathbf{Z} \mathbf{i} = \mathbf{A}(\mathbf{I} - \mathbf{A})^{-1}\mathbf{y} = \mathbf{A} \mathbf{L} \mathbf{y} \tag{45.4a}$$

$$\mathbf{v} = \mathbf{V} \mathbf{i} = \mathbf{C}(\mathbf{I} - \mathbf{A})^{-1}\mathbf{y} = \mathbf{C} \mathbf{L} \mathbf{y} \tag{45.4b}$$

with $\mathbf{v} = P$ -vector with the economy-wide total primary inputs of type p , that is, the row totals of the third quadrant of Fig. 45.1. Equations (45.3) and (45.4a, b) specify how the endogenous variables \mathbf{x} , \mathbf{Z} and \mathbf{v} depend on exogenous final demand \mathbf{f} through output, and intermediate and primary input multipliers, respectively.

The IO literature pays much attention to the *output multipliers* from the Leontief inverse $(\mathbf{I} - \mathbf{A})^{-1}$. Its typical element, l_{ij} , indicates the direct and indirect need for outputs of industry i per unit of final demand for products of industry j , while the column sums of the Leontief inverse indicate the economy-wide total output effect of the same unit of final demand. For policy purposes, however, the *employment multipliers* and the *income multipliers* from matrix $\mathbf{C} \mathbf{L}$ in Eq. (45.4b) are much more interesting. If p relates to the use of labor or total value added, its typical element, $cl_{pj} = \sum_i c_{pi} l_{ij}$, indicates the economy-wide direct and indirect employment or income per unit of final demand for products from industry j .

Such primary input multipliers are used in a whole array of applications. The most common of these are all kind of estimations of the income, employment, or CO₂ emissions embodied in, for example, consumption, investments, or exports. In the case of CO₂ emissions or energy use, the matrix \mathbf{V} is simply replaced with a single row of emission levels or energy use by industry, \mathbf{v}' , and the matrix \mathbf{C} is simply replaced with a row with CO₂ emission coefficients or energy use coefficients per unit of industry output, \mathbf{c}' . Input–output practitioners should be wary about the implications of the assumptions underlying, especially, the income and employment multipliers, as authorities and firms will press for large multipliers to serve their lobby needs. If, for instance, the regional labor market is tight, the impact of a demand shock may materialize in an increase of local wages, instead of the job growth that is predicted by the IO employment multiplier.

Policy makers have been fascinated by multipliers, but they often neglect differences in quality (e.g., skill levels) of jobs and focus instead on the size of the multipliers. Further, there is often confusion about the interpretation of an employment multiplier since the indirect effects may involve parts of many hundreds or thousands of jobs that when netted out generate only a modest number. This will typically be the case for *impact analysis* of short-term events; for example, participants in the Chicago Marathon usually stay 2–3 nights in the region. While there, they will spend money in restaurants generating part of the daily income to many hundreds of waiters – but only for the period in which they are in the region. The resulting multipliers might reveal 50 full-time equivalent jobs in the restaurant sector from the impacts of their spending, but in reality, hundreds of parts of jobs will have been affected.

Further, as transportation costs have decreased in real terms, interregional trade has increased sharply; this has resulted in a *hollowing out* of many regional economies as intra-regional purchases are replaced by interregional ones. The resulting intra-regional multipliers have often decreased, generating concern among policy makers that the region may be losing its competitiveness. Spurred on by the promise of cluster-based development strategies, underpinned by IO analyses of existing *clusters of industries*, there is a concomitant expectation that multipliers should increase over time. However, the competitiveness of each component of a supply

chain may see production systems having a much more extensive geographical imprint; thus, both the magnitude and composition (intra- versus interregional or feedback effects) of multipliers are likely to change over time.

45.3 Adding Prices Without Interaction: The Dual Cost-Push Price Model

As said above, prices do not play a role in the IO quantity model, but they assume center stage in the dual *cost-push IO price model* (Leontief 1951). The causal structure of that model is also shown in Fig. 45.2, but then the arrows should be imaged as running in the opposite, forward direction, while the boxes then refer to prices, and not to quantities.

This mirror image of Fig. 45.2 shows that the P prices of the primary inputs (p_p), along the rows of the third quadrant of Fig. 45.1, are the exogenous variables in the IO price model, as none of the reversed arrows is coming in. Any change in the P -column with these prices (\mathbf{p}_v) leads to a change in N -column with the output prices per industry (\mathbf{p}'), the size of which is determined by the P -by- N matrix with the *cost shares* of these primary inputs in total output (\mathbf{C}). Each change in a single output price, in its turn, is entirely passed on to all intermediate and final users of that output, as indicated by the \mathbf{I} matrix. In the case of the final users, this leads to no further changes, as no reversed arrows are going out. In the case of intermediate users (i.e., firms), however, any change in their intermediate input prices is passed on to the firms that use their outputs, as indicated by the \mathbf{I} matrix. This leads to a further forward change in output prices, the size of which is determined by matrix with the cost shares of the intermediate inputs in total output (\mathbf{A}). Hence, the IO price model is very suited to model forward, cost-push effects of primary input prices on final output prices.

The mathematics of the IO price model formalizes the above explanation. Its accounting identities are based on the columns of the IOT, instead of on its rows, as in the quantity model. Moreover, now prices are made explicit, whereas in the quantity model, they were implicit, held constant, and set equal to one. The accounting identities for the *values* of the columns of the IOT equal:

$$p_j x_j = \sum_i p_i z_{ij} + \sum_p p_p v_{pj}, \text{ for all } j \quad (45.5)$$

or in matrix algebra : $\mathbf{p}'\hat{\mathbf{x}} = \mathbf{p}'\mathbf{Z} + \mathbf{p}_v'\mathbf{V}$

Substitution of Eqs. (45.2a) and (45.2b) in Eq. (45.5), and post-multiplication with $\hat{\mathbf{x}}^{-1}$, reveals the accounting identities for the total output prices, which equal the sum of their intermediate and primary input prices weighted by their corresponding cost shares:

$$\mathbf{p}' = \mathbf{p}'\mathbf{A} + \mathbf{p}_v'\mathbf{C} \quad (45.6)$$

Adding the assumption that all price changes are entirely and precisely passed on to all users makes it possible to solve for the final output prices \mathbf{p}' as a function of the primary input prices \mathbf{p}_v' :

$$\mathbf{p}' = \mathbf{p}_v' \mathbf{C} (\mathbf{I} - \mathbf{A})^{-1} \quad (45.7)$$

Note that the *output price multipliers* of the primary input prices, $\mathbf{C} (\mathbf{I} - \mathbf{A})^{-1}$ in Eq. (45.7), are equal to the primary input multipliers of final demand in Eq. (45.4b). Also note that the column sum of these price multipliers is equal to one, as $\mathbf{i}'\mathbf{C} + \mathbf{i}'\mathbf{A} = \mathbf{i}'$ implying that $\mathbf{i}'\mathbf{C} = \mathbf{i}'(\mathbf{I} - \mathbf{A})$. Both observations make sense as both types of multiplier show the amount of primary inputs (capital, labor and land) embodied in final output.

This primal-dual model relationship becomes even more evident when Eq. (45.7) is post-multiplied with final demand \mathbf{y} , which provides the following expression:

$$\mathbf{p}'\mathbf{y} = \mathbf{p}_v' \mathbf{C} (\mathbf{I} - \mathbf{A})^{-1} \mathbf{y} = \mathbf{p}_v' \mathbf{v} \quad (45.8)$$

Equation (45.8) shows that the value of total final demand equals the value of total primary inputs, as already shown by $C + I + G + E = M + Y$ in Fig. 45.1. In the case of the IO quantity model, the focus of the model behind Eq. (45.8) is on the *backward causal impact* of any change in final demand on the, directly and indirectly, necessary primary inputs. In the case of the IO price model, the emphasis is on the *forward causal impact* of any change in primary input prices, both directly and indirectly, on the prices paid by the final users (consumers, investors, and government).

Typical applications of the IO price model inform policy makers on such questions as the impact of oil price hikes on consumer prices, or on the impact CO₂ taxes or production subsidies on the competitive price of exports. In a very early interregional application, Oosterhaven (1981a) used an interregional IO price model, with an endogenous instead of exogenous wage rate, to simulate the regionally different consumer price impacts of the increases in the oil and natural gas prices in the 1970s, in the case of the Netherlands. To be able to repeat such an analysis, we first have to add space and endogenous consumption to the standard IO price and quantity model, which is the topic of the next two sections.

45.4 Adding Trade: The Interregional IO Table and Model

Figure 45.3 shows the setup of the so-called “ideal” *interregional input–output table* (IRIOT), devised by Isard (1951), with the IO data for a national economy split-up into R regions and N industries. The first quadrant contains the NR -by- NR intermediate demand block matrix \mathbf{Z} , with \mathbf{Z}^{rs} as its typical square block showing the sales of the N industries in region r to their N sister industries in region s .

	Industry demand			Final demand				Total
	Region 1	...	Region R	Region 1	...	Region R	Foreign exports	
Region 1	Z^{11}	...	Z^{1R}	F^{11}	...	F^{1R}	e^1	x^1
⋮	⋮	Z^{rs}	⋮	⋮	F^{rs}	⋮	e^r	x^r
Region R	Z^{R1}	...	Z^{RR}	F^{R1}	...	F^{RR}	e^R	x^R
Foreign imports	Z^{m1}	...	Z^{mR}	F^{m1}	...	F^{mR}	Transit trade	M^{for}
Value added	V^1	...	V^R	Y^1	...	Y^R	0	Y^{nat}
Total	$x^{1'}$	$x^{s'}$	$x^{R'}$	$C^1 I^1 G^1$...	$C^R I^R G^R$	E^{for}	

Fig. 45.3 The “ideal” interregional input–output table for R regions. Legend: see Fig. 45.1. All double-superscripted matrices relate to interregional trade from the origin region (*first superscript*) to the destination region (*second superscript*)

The distinction between the diagonal and the off-diagonal blocks of Z is crucial. The diagonal blocks show the *intra-regional deliveries* of intermediate goods and services, z_{ij}^{rr} , whereas the off-diagonal blocks show the *interregional trade* in intermediate goods, z_{ij}^{rs} , from industry i in r (note: first indices = origin) to industry j in s (note: second indices = destination).

The second quadrant contains the final demand block matrix that consists of the domestic final demand block matrix F and a foreign export block column e . The typical N -by- Q rectangular block F^{rs} contains the sales of final goods and services by the N industries in region r to the consumers, investors, and government in region s . Again, the distinction between the diagonal and the off-diagonal blocks is important. The diagonal blocks show the intra-regional deliveries of final goods and services to demand category q within region r , f_{iq}^{rr} , whereas the off-diagonal blocks show the interregional trade of final goods from industries in r to consumers, investors, and government in s , f_{iq}^{rs} . As for the block column e , note that its typical column e^r contains the foreign exports of both *intermediate* goods, for the industries, and *final* goods, for the consumers, investors, and government, in the Rest of the World (RoW).

The third quadrant contains the primary input block matrix, which consist of the N -by- N square foreign import blocks Z^{ms} and the P -by- N rectangular value added blocks V^s . The foreign import blocks contain the imports of products from industry i in the RoW by the industries j in s (z_{ij}^{ms}). The value added blocks contain the usual components of gross value added at market prices (production taxes less subsidies, gross wages, employers’ contributions to social security, and the operating surplus) of industries j in s (v_{pj}^s). The fourth quadrant again contains the primary inputs of final demand.

As in the case of Fig. 45.1, the total output along the rows of Fig. 45.3 equals the total input along its columns. Consequently, total final demand

$(\sum_r C^r + \sum_r I^r + \sum_r G^r + E^{for})$ again equals total primary input ($Y^{nat} + M^{for}$). In Sect. 45.2, it was shown that a national IOT represents a sectoral disaggregation of the *macroeconomic identity*: $Y = C + I + G + E^{for} - M^{for}$. Here, it becomes clear that an interregional IOT represents an additional, regional disaggregation of the same identity. Moreover, the rearrangement of the elements of Fig. 45.3 shows that an IRIOT also includes all (but now much more detailed) identities for gross regional product/income:

$$\begin{aligned}
 Y^r &= \mathbf{i}'\mathbf{V}^r\mathbf{i} + \mathbf{i}'\mathbf{Y}^r\mathbf{i} = C^r + I^r + G^r \\
 &+ \left(\sum_{s \neq r} \mathbf{i}'\mathbf{Z}^{rs}\mathbf{i} + \sum_{s \neq r} \mathbf{i}'\mathbf{F}^{rs}\mathbf{i} + \mathbf{i}'\mathbf{e}^r \right) \\
 &- \left(\sum_{s \neq r} \mathbf{i}'\mathbf{Z}^{sr}\mathbf{i} + \sum_{s \neq r} \mathbf{i}'\mathbf{F}^{sr}\mathbf{i} \right) = C^r + I^r + G^r + E^r - M^r
 \end{aligned} \tag{45.9}$$

Note that the $\sum_{s \neq r}$ in Eq. (45.9) is needed to exclude the intra-regional transactions from total regional exports (the first term between brackets) as well as from total regional imports (the second term between brackets).

Calculating percentages across the rows of the IRIOT enables interesting comparative analyses of interregional sales structures of industries across different regions, whereas calculating percentages across the columns allows for an analysis of cost structures and interregional purchases structures of industries across regions. The main use of an IRIOT, however, is to supply the accounting identities of the various interregional IO models and the coefficients for the behavioral equations of such models.

The mathematics of the basic *interregional IO quantity model* is rather similar to that of the single-region IO model of Eqs. (45.1) and (45.2a, b). Written with all blocks separately, the interregional IO model for an open national economy reads as follows:

$$\mathbf{x} = \begin{bmatrix} \mathbf{x}^1 \\ \vdots \\ \mathbf{x}^r \\ \vdots \\ \mathbf{x}^R \end{bmatrix} = \begin{bmatrix} \mathbf{A}^{11} & \cdots & \mathbf{A}^{1R} \\ \vdots & \ddots & \vdots \\ \mathbf{A}^{R1} & \cdots & \mathbf{A}^{RR} \end{bmatrix} \begin{bmatrix} \mathbf{x}^1 \\ \vdots \\ \mathbf{x}^r \\ \vdots \\ \mathbf{x}^R \end{bmatrix} + \begin{bmatrix} \mathbf{F}^1\mathbf{i} \\ \vdots \\ \mathbf{F}^R\mathbf{i} \end{bmatrix} + \begin{bmatrix} \mathbf{e}^1 \\ \vdots \\ \mathbf{e}^R \end{bmatrix} \tag{45.10a}$$

$$\mathbf{v} = \begin{bmatrix} \mathbf{v}^1 \\ \vdots \\ \mathbf{v}^R \end{bmatrix} = \begin{bmatrix} \mathbf{c}^1 & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & \mathbf{c}^R \end{bmatrix} \begin{bmatrix} \mathbf{x}^1 \\ \vdots \\ \mathbf{x}^R \end{bmatrix} \tag{45.10b}$$

Using the block matrices of Fig. 45.3, its solution for total output and value added is similar to Eqs. (45.3) and (45.4):

$$\mathbf{x} = (\mathbf{I} - \mathbf{A})^{-1}(\mathbf{F}\mathbf{i} + \mathbf{e}) = \mathbf{L}^* (\mathbf{F}\mathbf{i} + \mathbf{e}) \tag{45.11a}$$

Fig. 45.4 The causal structure of the interregional IO model extension. Legend: y , vector with exogenous final demand of single-region IO model by sector of origin; f , vector with exogenous demand of interregional IO model by sector of origin; Z^{rs} , interindustry matrix with intermediate exports from region r to region s ; x , vector with total output by sector; V , matrix with value added by type, by sector

$$v = \hat{c}(I - A)^{-1}(F i + e) = \hat{c}L^*(F i + e) \tag{45.11b}$$

where the interregional input coefficient matrices A and \hat{c} may be derived from an IRIOT, like Fig. 45.3, by means of $A = Z \hat{x}^{-1}$ and $c' = v' \hat{x}^{-1}$, and where L^* denotes the *interregional Leontief inverse*, whose typical element, l_{ij}^{rs} , indicates the direct and indirect output from industry i in r needed per unit of final demand for the outputs of industry j in s . Analogously, the *interregional income multiplier* matrix $\hat{c}L^*$ has $c_i^{r,l_{ij}^{rs}}$ as its typical element, indicating the direct and indirect value added in industry i in r needed per unit of final demand for the product of industry j in s . Although the mathematical structure of the basic interregional IO model of Eq. (45.10a, b) is rather similar to that of the single-region model, its economic interpretation and behavioral implications are more complex.

To sharpen our insight, we first compare the causal structure of the interregional model with only two regions r and s with the single-region model, by means of Fig. 45.4. For reasons of simplicity, Fig. 45.4 assumes that the two regions r and s together form a *closed economy*, that is, there are no foreign imports or foreign exports. The bold lines and boxes show the casual structure of the two independent single-region models, that is, they represent a double version of Fig. 45.2. The dotted separation in the two top boxes indicates which part of the single-region's final demand remains exogenous, and which part is made endogenous by adding the two dotted interregional trade boxes that link the two independent single-region models into one interregional model.

From the viewpoint of region r , its formerly exogenous exports of intermediate goods to region s are now endogenously determined by the output levels of the purchasing industries in region s , that is, $Z^{rs}i = A^{rs}x^s$, while the formerly exogenous intermediate exports of s are now explained as imports of region r 's industries, that is, $Z^{sr}i = A^{sr}x^r$. Consequently, the exogenous demand for the outputs of both regions has shrunk. Their output levels, however, do not change.

The same reality is only modeled in a different way! Thus, the smaller size of exogenous demand has to be neutralized by larger multipliers. And, indeed, the multipliers of the interregional IO model are larger because they add the *interregional feedback effects*, from region r via region s back to region r , to the single-region model. Following the dotted arrows of Fig. 45.4 shows that the interregional feedback effects for region r , actually, consist of two *interregional spillover effects*, the first from r to s and the second back from s to r , enhanced by the *intra-regional multipliers* of region s . In more formal terms, the interregional feedback effects of region r 's final demand on its own output levels equal $\mathbf{A}^{rs}(\mathbf{I} - \mathbf{A}^{ss})^{-1}\mathbf{A}^{sr}$.

This interregional feedback formula may be derived mathematically, by writing out and solving the partitioned version of the *two-region IO model* of Fig. 45.4:

$$\mathbf{x}^r = \mathbf{Z}^{rr}\mathbf{i} + \mathbf{Z}^{rs}\mathbf{i} + \mathbf{f}^r = \mathbf{A}^{rr}\mathbf{x}^r + \mathbf{A}^{rs}\mathbf{x}^s + \mathbf{f}^r \quad (45.12a)$$

$$\mathbf{x}^s = \mathbf{Z}^{sr}\mathbf{i} + \mathbf{Z}^{ss}\mathbf{i} + \mathbf{f}^s = \mathbf{A}^{sr}\mathbf{x}^r + \mathbf{A}^{ss}\mathbf{x}^s + \mathbf{f}^s \quad (45.12b)$$

The first equalities of Eq. (45.12a, b) show the accounting identities across the rows of the underlying bi-regional IO table. The second equalities show how the intra- and interregional input coefficients together with the output levels of the purchasing industries determine the endogenous domestically produced inputs and the endogenous imported inputs. A step-by-step solution of Eq. (45.12a, b) gives the disaggregated solution of the two-region IO model:

$$\begin{aligned} \mathbf{x}^r &= \left[\mathbf{I} - \mathbf{A}^{rr} - \mathbf{A}^{rs}(\mathbf{I} - \mathbf{A}^{ss})^{-1}\mathbf{A}^{sr} \right]^{-1} \left[\mathbf{f}^r + \mathbf{A}^{rs}(\mathbf{I} - \mathbf{A}^{ss})^{-1}\mathbf{f}^s \right] \\ &= \mathbf{L}^{rr}\mathbf{f}^r + \mathbf{L}^{rs}\mathbf{f}^s \end{aligned} \quad (45.13a)$$

$$\begin{aligned} \mathbf{x}^s &= \left[\mathbf{I} - \mathbf{A}^{ss} - \mathbf{A}^{sr}(\mathbf{I} - \mathbf{A}^{rr})^{-1}\mathbf{A}^{rs} \right]^{-1} \left[\mathbf{f}^s + \mathbf{A}^{sr}(\mathbf{I} - \mathbf{A}^{rr})^{-1}\mathbf{f}^r \right] \\ &= \mathbf{L}^{sr}\mathbf{f}^r + \mathbf{L}^{ss}\mathbf{f}^s \end{aligned} \quad (45.13b)$$

Equations (45.13a) and (45.13b) may also be written with block matrices and vectors, which explicitly shows the structure of the interregional Leontief inverse \mathbf{L}^* for two regions:

$$\begin{aligned} \mathbf{x} &= \begin{bmatrix} \mathbf{x}^r \\ \mathbf{x}^s \end{bmatrix} \\ &= \begin{bmatrix} \left[\mathbf{I} - \mathbf{A}^{rr} - \mathbf{A}^{rs}(\mathbf{I} - \mathbf{A}^{ss})^{-1}\mathbf{A}^{sr} \right]^{-1} & \mathbf{L}^{rr}\mathbf{A}^{rs}(\mathbf{I} - \mathbf{A}^{ss})^{-1} \\ \mathbf{L}^{ss}\mathbf{A}^{sr}(\mathbf{I} - \mathbf{A}^{rr})^{-1} & \left[\mathbf{I} - \mathbf{A}^{ss} - \mathbf{A}^{sr}(\mathbf{I} - \mathbf{A}^{rr})^{-1}\mathbf{A}^{rs} \right]^{-1} \end{bmatrix} \begin{bmatrix} \mathbf{f}^r \\ \mathbf{f}^s \end{bmatrix} \\ &= \mathbf{L}^*\mathbf{f} \end{aligned} \quad (45.13)$$

Thus, total output of region r is determined by the exogenous part of its own final demand \mathbf{f}^r as well as by the exogenous part of the final demand of the other region \mathbf{f}^s .

There are two differences between the multipliers of a single-region IO model compared to those of an interregional IO model. The first difference shows up in the intra-regional impact of the own final demand \mathbf{f}^r on the own output \mathbf{x}^r . In the single-region model, it equals $(\mathbf{I} - \mathbf{A}^{rr})^{-1} \mathbf{f}^r$, whereas in the interregional model, the same effect equals $[\mathbf{I} - \mathbf{A}^{rr} - \mathbf{A}^{rs}(\mathbf{I} - \mathbf{A}^{ss})^{-1} \mathbf{A}^{sr}]^{-1} \mathbf{f}^r$. Clearly, the last impact is larger than the first, as it includes the *interregional feedbacks* of the own final demand via the own imports on the exports and output of the other region, and the subsequent effect of the imports of the other region back on the own region's exports. These larger intra-regional multipliers are, however, compensated by the smaller size of the exogenous demand in the interregional model ($\mathbf{f}^r = \mathbf{y}^r - \mathbf{Z}^{rs} \mathbf{i}$) compared to the single-region model (\mathbf{y}^r).

The empirical size of this first difference has been studied extensively (see Miller and Blair 2009). Unfortunately, it is almost always measured by dividing the interregional feedback effect by the total intra-regional effect, thus including the one-to-one direct effect of final demand on total output, as captured in the \mathbf{I} matrix of the Taylor expansion of the Leontief inverse in Eq. (45.3). However, neither the IO model nor any other model is needed to estimate this direct effect. Hence, the underestimation of the intra-regional impact should only be judged by the indirect part of the impact, as captured by the $(\mathbf{L} - \mathbf{I})$ matrix.

In the case of the Dutch economy in 1970, measured for the indirect impacts only, Oosterhaven (1981b) found an underestimation of the regional income effects of regional final demand of only 1.1 % for the relatively isolated rural Northern Netherlands and a small 3.4 % for the heavily urbanized greater Rotterdam region. When type II multipliers, with endogenous consumption expenditures, as discussed in the next section, were used, the neglect of interregional feedbacks led to a larger underestimation of the regional income impacts of 3.1 % and 6.6 %, respectively. The reason for the larger feedbacks was that interregional commuting and interregional shopping effects were included in the type II multipliers, whereas they are absent in the basic interregional IO model.

The second difference between the two models is hardly discussed in the literature but is at least as important. It shows up in the interregional spillover effect of the own final demand \mathbf{f}^r on the output of the other region \mathbf{x}^s . In the single-region IO model, the interregional spillover is measured by $\mathbf{A}^{sr}(\mathbf{I} - \mathbf{A}^{rr})^{-1}$, whereas it equals $\mathbf{L}^{ss} \mathbf{A}^{sr}(\mathbf{I} - \mathbf{A}^{rr})^{-1}$ in Eq. (45.13c). Hence, the *interregional spillovers* are also larger when estimated with the interregional IO model than when estimated with the single-region model. The difference being, of course, that the interregional model takes the intra-regional effects inside the other region into account, as shown by the added \mathbf{L}^{ss} , whereas the single-region model is unable to do so.

Recent research for the 27 members of the European Union (EU) analyzed the differences in the EU27 income effects of the EU27 exports to third countries, as estimated with 27 separate national IO models and as estimated with a single

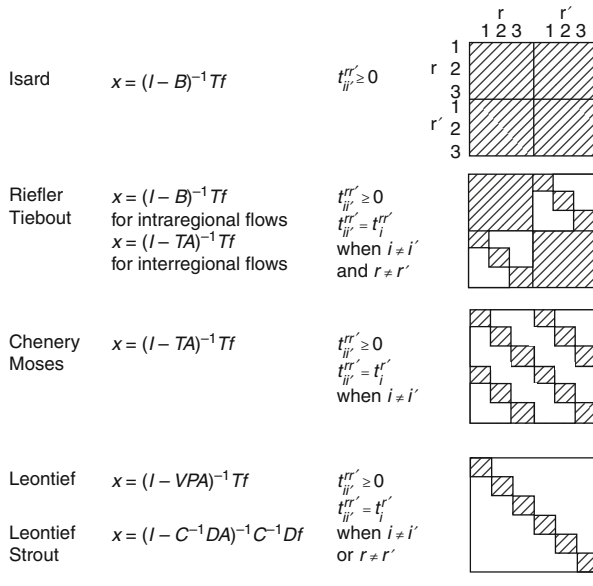

consolidated IO model for the EU27 as a whole (Bouwmeester, et al. 2012). It reports a weighted average *first round intra-EU income spillover* in the rest of the EU27, as calculated with the 27 single-country models, of 7.7 % of the domestic income effect of the country at hand. The additional *higher-order intra-EU income spillovers and feedback effects*, as calculated with the full EU27 model, appeared to be as large as 10.7 % of the weighted average domestic effect. The relatively large size of the higher-order effects, in this case, must be attributed to the fact that they relate to the interactions between as much as 27 countries. Hence, the underestimation of interregional spillover effects with a single-region IO model seems to be much more serious issue than the much discussed underestimation of the intra-regional effect.

One last theoretically important aspect of the basic interregional input–output (IRIO) model needs to be discussed, as it applies to all interregional IO models. In the closed economy model of Sect. 45.2, the input coefficients a_{ij} and c_{pj} may be termed *technical coefficients*, as they specify the amounts of technically necessary inputs per unit of total output of industry j . In the interregional IO model, however, the intra-regional and interregional intermediate *input coefficients*, a_{ij}^{rr} and a_{ij}^{rs} , may no longer be called “technical coefficients” as they actually are the product of a technical IO coefficient and a not-yet-discussed IO *trade coefficient*:

$$a_{ij}^{rr} = t_{ij}^{rr} a_{ij}^{\bullet r} \quad \text{and} \quad a_{ij}^{sr} = t_{ij}^{sr} a_{ij}^{\bullet r}, \quad \text{with} \quad \sum_s t_{ij}^{sr} = t_{ij}^{\bullet s} = 1 \quad (45.14)$$

where an \bullet indicates a summation over the corresponding index. The intra-regional trade coefficient or *self-sufficiency ratio*, t_{ij}^{rr} , is known in the literature as the *regional purchase coefficient* (RPC, Stevens and Trainer 1980). It indicates the share in the total demand for products i by industry j in r that is supplied by the domestic industry i . Note that the RPC is equal to one minus the sum of the interregional import coefficients, that is, $t_{ij}^{rr} = 1 - \sum_{s \neq r} t_{ij}^{sr}$.

Besides interregional IO tables, the literature also distinguishes various *multiregional IO tables* (MRIOTs) and multiregional input–output (MRIO) models that are based on these data (see Oosterhaven 1984; Batten and Boyce 1986). The difference between these two accounting frameworks is that MRIOTs do not contain full interregional trade matrices for intermediate and final demand, as the IRIOT of Fig. 45.3. Instead, the basic MRIOT, schematized under Chenery/Moses in Fig. 45.5, only contains $R \times R$ columns \mathbf{h}^{rs} , each with the total of the interregional sales of the N industries i in r to all customers in s . In terms of Fig. 45.3, these trade columns thus contain the combined row sum of the *bilateral* intermediate and final demand matrices \mathbf{Z}^{rs} and \mathbf{F}^{rs} (i.e., $\mathbf{h}^{rs} = \mathbf{Z}^{rs} \mathbf{i} + \mathbf{F}^{rs} \mathbf{i}$). In addition, the basic MRIOT contains R square N -by- N matrices with the technically necessary intermediate inputs by industry j and R rectangular N -by- Q matrices with final use of products from the *worldwide* industry i by category q (not shown in Fig. 45.5). In terms of Fig. 45.3, these matrices thus contain the aggregates $\mathbf{Z}^{\bullet s} = \sum_r \mathbf{Z}^{rs} + \mathbf{Z}^{\text{mr}}$ and $\mathbf{F}^{\bullet s} = \sum_r \mathbf{F}^{rs} + \mathbf{F}^{\text{mr}}$.

Notes: The compact notation is as follows:
B is the matrix of interregional input-output coefficients;
T is the matrix of trade share coefficients;
f is the vector of final regional demands;
A is the matrix of regional technical coefficients;
V is the share vector denoting proportions of total production from each region;
P is the pooling strategy of regional demand shares;
C is the share of regional production not pooled;
D is the share of total regional demand not imported from the pool.
 In general, if *I* is the number of sectors and *R* the number of regions, then the maximum number of different entries assumed in the *T* matrix is as follows:
 Isard model : $I^2 R^2$
 Riefler-Tiebout model : $IR(I+R-1)$
 Chenery-Moses model : IR^2
 Leontief pool models : IR

Fig. 45.5 Alternatives to the full information input-output framework (Source: Batten and Boyce (1986))

Hence, this basic multiregional IOT does contain the information to estimate the technical IO coefficients, a_{ij}^{r} , by means of $A^{r \bullet} = Z^{r \bullet} (\hat{x}^r)^{-1}$, but it does not contain the information on all t_{ij}^{rs} for intermediate goods, nor on all t_{iq}^{rs} for final goods. Consequently, instead of Eq. (45.14), the *multiregional IO model*¹ (Chenery 1953; Moses 1955) uses the following behavioral assumption:

$$a_{ij}^{rr} = t_{i \bullet}^{rr} a_{ij}^{r \bullet} \text{ and } a_{ij}^{sr} = t_{i \bullet}^{sr} a_{ij}^{r \bullet}, \text{ with } \sum_s t_{i \bullet}^{sr} = 1 \tag{45.15}$$

That is, it assumes that all RPCs and all import coefficients are identical across the rows of each intermediate and each final demand block of the IRIOT of Fig. 45.3. With Eq. (45.15) substituted in the right place, the solution of the MRIO model equals (see also Fig. 45.5)

$$\mathbf{x} = (\mathbf{I} - \mathbf{TA})^{-1} \mathbf{T} \mathbf{f} \quad (45.16)$$

where \mathbf{T} has the structure of the block matrix shown in Fig. 45.5 under Chenery/Moses, with on the diagonal of each block the N aggregate trade coefficients, $t_{i \cdot}^{r \cdot}$ or $t_{i \cdot}^{s \cdot}$, where \mathbf{A} is a diagonal block matrix with \mathbf{A}^{*r} on its diagonal blocks, and where \mathbf{f} is a R -block column with the stacked N -columns $\mathbf{F}^{*s} \mathbf{i}$.

As can be seen by comparing Eq. (45.16), the solution of the MRIO model, with Eq. (45.11a), the solution of the IRIO model, both models are able to calculate dimensionally the same employment, income, and CO₂ multipliers. Therefore, both models are able to answer the same type of income, employment, or CO₂ impact questions, be it with most likely a different degree of empirical reliability.

The initial framework proposed by Isard (1951) is often termed a *full information* IRIOT because it assumes that the flows from industry i in r to *all* industries j in s are known. The multiregional framework proposed by Chenery (1953) and Moses (1955) is often called a *limited information* MRIOT because their goal was to estimate the proportion of exports from sector i in region r that would move to region s . An intermediate variant was specified by Riefler and Tiebout (1970). They worked with full information for the important intra-regional transactions and with limited information on interregional trade (see Fig. 45.5). Leontief and Strout (1963) moved in the other direction. They further simplified the multiregional data requirements by introducing the notion of *supply and demand pools* in both the regions of origin and destination. The interregional components were estimated using a *gravity model*. Subsequent research has proposed a variety of alternative estimation techniques; perhaps the most widely used now is the *maximum entropy* formulation originally proposed by Wilson (1970).

As regards the availability of input–output data, increasingly, national accounting agencies are issuing input–output data in the form of the *supply and use table* (SUT) accounting *framework*. In this system, a supply table has industries on the left axis and commodities across the top; following across the row would provide information on the number of different commodities produced by the industry at the left. With greater disaggregation, the matrix would tend to be diagonally dominant; off-diagonal entries would indicate what are termed *secondary products*. The use table has a commodity-by-industry matrix in which each column provides information on the commodities used in production by the industry at the top of the column. Through matrix manipulation, it is possible to obtain either an industry-by-industry matrix or a commodity-by-commodity matrix (see ten Raa and Rueda-Cantuche 2003, for an overview).

The advantage of the SUT framework is its greater flexibility – one can usually provide information on a much larger set of commodities than industries. Further, sales to final demand are of commodities thus facilitating easier linkage with consumption modeling and links with commodity flow information. Oosterhaven (1984) gives an overview of both families of interregional square IO frameworks and interregional rectangular SUT frameworks and corresponding models, and Jackson (1998) discussed methods of regionalizing national SUTs.

45.5 Adding Endogenous Consumption to the Interregional Model

Although important from a methodological point of view, the above interregional extension of the single-region IO model still leaves the most important component of local final demand, namely, private household consumption, unexplained. Investments and government expenditures may be endogenized in a similar way, but note that there is a danger in endogenizing more and more components of final demand. In the extreme case, this may lead to zero exogenous final demand with infinitely large multipliers (see Oosterhaven 2000, for a conclusion of an interesting debate on this issue).

Here we only discuss how to endogenize that part of local consumption demand that can directly be tied to the value added per local industry. Figure 45.6 shows the nature of this extension. The bold lines and boxes duplicate the basic interregional IO model from Fig. 45.4. The dotted separation in the two top boxes again indicates which part of regional final demand remains exogenous and which part now becomes endogenous by adding the four dotted boxes and arrows in the lower part of Fig. 45.6. This extension of the interregional IO model results in a so-called *type II interregional IO model*.

To distinguish the *indirect* effects of the type I models from the effects through consumption demand that are added in the corresponding type II models, the latter impacts are often referred to as *induced* effects. Figure 45.6 shows the three types of induced effects that are added in type II models. First, each of the two type II single-region models adds *intra-regional induced effects* to their own intra-regional indirect effects, by making the intra-regional sales of consumption goods (\mathbf{c}^{r^r} and \mathbf{c}^{s^s}) dependent on the own region's value added, and thus on the own region's total output. Secondly, the type II interregional model adds *induced spillover effects* to the indirect spillover effects, by making the exports of consumption goods by region r and s (\mathbf{c}^{rs} and \mathbf{c}^{sr}), and thus the output of the exporting regions, dependent on the value added of the purchasing region s and r . Finally, combining these two induced spillover effects, and enhancing the product with the intra-regional induced effects, the interregional type II model adds *induced feedback effects* to the indirect feedback effects of type I model.

Next, we discuss the nature of the induced effects in more detail. In the type I interregional IO model, all consumption demand of households living in region r is exogenous. The same holds for the consumption of households in s . Some part of private consumption, however, will directly depend on the size and growth of the own regional value added. Some other part will only be influenced indirectly, that is, after the *interregional redistribution* of regionally generated value added through interregional commuting, interregional capital income flows, and central government's social security and taxation schemes. (The empirical specification of these relations requires the information that would be available in interregional Social Accounting Matrices (SAMs; see Pyat and Round (1979), for the original national SAM). SAMs usually distinguish between the supply of products and the use of them by industries and final demand by incorporating a SUT. Besides a SUT,

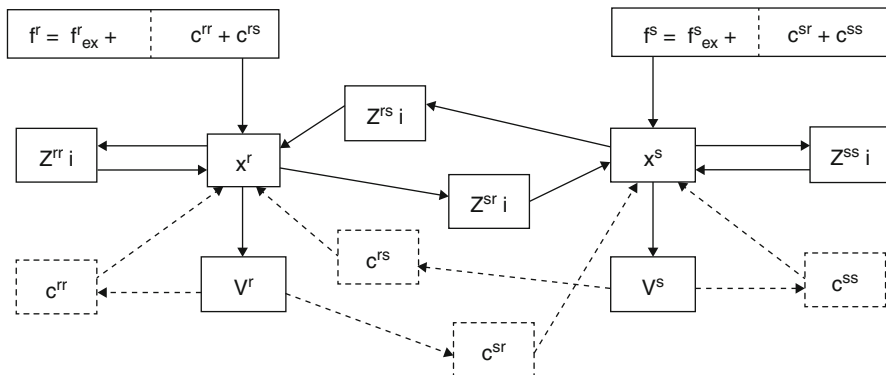

Fig. 45.6 The causal structure of the endogenous consumption extension. Legend: see Fig. 45.4. In addition: f_{ex}^r , vector with remaining exogenous final demand of the type II interregional IO model; c^{rs} , vector with the endogenous delivery of consumption goods by sectors i in region r to households in region s

a SAM usually contains extensive information on the generation and redistribution of all kind of income, directly and through government taxes and social security programs, mostly for a series of different types of households. There are, however, few interregional SAMs.) Here, we only add a simple direct relation between regional value added (v^r) and that part of the own region’s private consumption that is directly depending on it (c^{rr} and c^{sr}). A comparable relation is added for the other region’s private consumption (c^{ss} and c^{rs} ; see Fig. 45.6).

To better understand the nature of this addition, we first discuss the determination of the endogenous part of the consumption of *households living in r* in normal algebra:

$$c_{ij}^{rr} = q_{ij}^{rr} x_j^r = t_{ic}^{rr} a_{ic}^{*r} (1 - s^r)(1 - t^r) w_j^{rr} x_j^r, \text{ for all } i, j \tag{45.17a}$$

$$c_{ij}^{sr} = q_{ij}^{sr} x_j^s = t_{ic}^{sr} a_{ic}^{*r} (1 - s^r)(1 - t^r) w_j^{rr} x_j^r, \text{ for all } i, j \tag{45.17b}$$

The typical coefficient q_{ij}^{rr} of Eq. (45.17a) indicates the amount of goods and services produced by industry i in r that is consumed by households living in r and earning their income in industry j in r , per unit of output of that industry.

This *consumption demand coefficient* is built up from a series of separate coefficients. Working backward in the formula, but along the chain of cause and effect, the *labor income coefficient* w_j^{rr} indicates the gross labor income earned by households living in r per unit of output of industry j in r . The *regional tax rate* t^r determines which part of that income is disposable for consumption. The *regional savings ratio* s^r determines which part of that disposable income is actually consumed. The regional *consumption package coefficient* a_{ic}^{*r} indicate which part of total consumption in r is spent on products of the worldwide industry i .

Finally, *consumption self-sufficiency ratio* t_{ic}^{rr} indicate which part of the total consumption of products i originates from the own region r .

The consumption demand coefficient q_{ij}^{sr} of Eq. (45.17b) indicates the imports of consumption goods from industry i in s for households in r earning a labor income in industry j in r , per unit of industry j 's output. Its built-up is the same as that of q_{ij}^{rr} , except for the self-sufficiency ratio t_{ic}^{rr} that are replaced with the import coefficients t_{ic}^{sr} . The comparable consumption demand coefficient, q_{ij}^{ss} and q_{ij}^{rs} , for households living in region s , are constructed in the same way as Eq. (45.17a, b).

Combining these four sets of consumption demand coefficients, one can summarize the endogenous part of private consumption by households in matrix algebra:

$$\begin{bmatrix} \mathbf{c}^{rr} \\ \mathbf{c}^{sr} \end{bmatrix} + \begin{bmatrix} \mathbf{c}^{rs} \\ \mathbf{c}^{ss} \end{bmatrix} = \begin{bmatrix} \mathbf{q}^{rr} \\ \mathbf{q}^{sr} \end{bmatrix} \mathbf{x}^r + \begin{bmatrix} \mathbf{q}^{rs} \\ \mathbf{q}^{ss} \end{bmatrix} \mathbf{x}^s = \begin{bmatrix} \mathbf{q}^{rr} & \mathbf{q}^{rs} \\ \mathbf{q}^{sr} & \mathbf{q}^{ss} \end{bmatrix} \begin{bmatrix} \mathbf{x}^r \\ \mathbf{x}^s \end{bmatrix} = \mathbf{Q} \mathbf{x} \quad (45.18)$$

The mathematical solution of the type II interregional IO model is simple, but first, the final demand from the accounting identity of the type I model of Eq. (45.12a, b) needs to be split up into the endogenous consumption demand of Eq. (45.18) and remaining exogenous final demand \mathbf{f}^{ex} (see also Fig. 45.6):

$$\begin{bmatrix} \mathbf{x}^r \\ \mathbf{x}^s \end{bmatrix} = \begin{bmatrix} \mathbf{Z}^{rr} & \mathbf{Z}^{rs} \\ \mathbf{Z}^{sr} & \mathbf{Z}^{ss} \end{bmatrix} \begin{bmatrix} \mathbf{i} \\ \mathbf{i} \end{bmatrix} + \begin{bmatrix} \mathbf{f}^r \\ \mathbf{f}^s \end{bmatrix} = \mathbf{Z} \mathbf{i} + \begin{bmatrix} \mathbf{c}^{rr} \\ \mathbf{c}^{sr} \end{bmatrix} + \begin{bmatrix} \mathbf{c}^{rs} \\ \mathbf{c}^{ss} \end{bmatrix} + \begin{bmatrix} \mathbf{f}^r \\ \mathbf{f}^s \end{bmatrix}^{\text{ex}} \quad (45.19)$$

Then, substitution of $\mathbf{Z} \mathbf{i} = \mathbf{A} \mathbf{x}$ and Eq. (45.18) in Eq. (45.19), transfer of $\mathbf{A} \mathbf{x}$ and $\mathbf{Q} \mathbf{x}$ to the left-hand side, and pre-multiplication of both sides with $(\mathbf{I} - \mathbf{A} - \mathbf{Q})^{-1}$ provide the type II model's solution for endogenous output:

$$\mathbf{x} = (\mathbf{I} - \mathbf{A} - \mathbf{Q})^{-1} \mathbf{f}^{\text{ex}} = \mathbf{L}^{**} \mathbf{f}^{\text{ex}} \quad (45.20)$$

In Eq. (45.20), \mathbf{L}^{**} represents the *type II interregional Leontief inverse*, indicating the direct, indirect, and *induced* interregional impacts of any change in the remaining exogenous demand \mathbf{f}^{ex} in region r or s . Naturally, each type II output, employment, or income multiplier is larger than its type I equivalent, but, as before, this is compensated by a smaller exogenous demand \mathbf{f}^{ex} compared to the type I exogenous demand \mathbf{f} , as shown in Eq. (45.19) and Fig. 45.6. And, consequently, endogenous output, employment, and income are the same in both models.

This means that essentially the same type of applications that are done with type I interregional IO models may also be done with a type II model. The same holds for the type II price dual that has a causal structure and interpretation that runs along arrows in directions opposite to those of the type II quantity model shown in Fig. 45.6 (as explained in Sect. 45.3). Its main difference with the type I price model is that regional wage rates in a type II price model are endogenous and not exogenous. This allows for the analysis of interregional, interindustry price/wage/price inflationary processes (cf. Oosterhaven 1981a).

45.6 Further Demo-economic Extensions of the Interregional IO Model

The size of the intra-regional type II multipliers, and especially the interregional type II spillovers, would again be larger if the interregional redistribution of labor incomes through commuting and cross-border shopping trips would be incorporated in the \mathbf{Q} matrix in Eq. (45.18). There is, in fact, a whole family of demo-economic extensions of the basic type I model into type II, III, etc., single-region IO models (see Batey 1985).

This literature makes a distinction between (i) increases in labor incomes accruing to resident workers (*intensive income growth*), (ii) new labor incomes accruing to migrants and unemployed (*extensive income growth*), (iii) and the loss of benefits of formally unemployed (*redistributive income growth*). To estimate the induced consumption effects, (i) *intensive* income growth requires the use of marginal instead of average consumption demand coefficients, (ii) *extensive* income growth of migrants can be handled with the average consumption demand coefficients as in Eq. (45.17a, b), while (iii) *redistributive* income growth of unemployed requires using the difference between the average consumption coefficients of workers and unemployed. Hence, these three types of income change can only be modeled properly if levels of economic activity are explicitly distinguished from changes therein.

With levels and changes in levels distinguished, the interregional *type III demo-economic IO model* solution for, for example, endogenous employment becomes

$$\begin{aligned}\Delta \mathbf{v} &\equiv \hat{\mathbf{c}}\Delta \mathbf{x} + \Delta \hat{\mathbf{c}} \mathbf{x}_{-1} = \hat{\mathbf{c}}(\mathbf{I} - \mathbf{A} - \mathbf{Q}_w + \mathbf{Q}_u)^{-1} \Delta \mathbf{f} + \Delta \hat{\mathbf{c}} \mathbf{x}_{-1} \\ &= \hat{\mathbf{c}}\mathbf{L}^{***} \Delta \mathbf{f} + \Delta \hat{\mathbf{c}} \mathbf{x}_{-1}\end{aligned}\quad (45.21)$$

where $\Delta \mathbf{v}$ = interregional *NR*-vector with the employment change by industry, by region, $\Delta \hat{\mathbf{c}}$ = decreases in employment coefficients due to *nominal labor productivity growth*, and \mathbf{x}_{-1} = output impact of the combined lagged endogenous and exogenous variables. Furthermore, \mathbf{Q}_w and \mathbf{Q}_u represent the *NR*-by-*NR* matrices with consumption demand coefficients, indicating the private consumption of products from industry i in r , respectively, per working resident and per unemployed resident previously working in industry j in s , per unit of output of industry j in s . Note the positive sign in front of \mathbf{Q}_u , which indicates the *negative feedback effect* of employment growth on *unemployment benefits* in this type III model.

Typically, \mathbf{Q}_w and \mathbf{Q}_u need to be jointly specified by an IO vacancy-chain sub-model, which determines which vacancies in industry j in s are filled by workers from industry i in r and which are filled by, for example, school-leavers and unemployed. With the unemployment benefits of the Netherlands, the intra-regional type III multipliers with vacancy chains $\hat{\mathbf{c}}(\mathbf{I} - \mathbf{A} - \mathbf{Q}_w + \mathbf{Q}_u)^{-1}$ move between 35 % and 60 % of the difference between the intra-regional type I multipliers $\hat{\mathbf{c}}(\mathbf{I} - \mathbf{A})^{-1}$ and intra-regional type II multipliers $\hat{\mathbf{c}}(\mathbf{I} - \mathbf{A} - \mathbf{Q}_w)^{-1}$ per industry (van Dijk and Oosterhaven 1986, the interregional IO software package IRIOS uses a generalization of Eq. (45.20); see Stelder et al. 2000).

To finish this introductory overview of interregional input–output modeling, Fig. 45.7 shows the structure of the state-of-the-art *demo-economic model LINE* of Denmark, with 12 industries, 20 commodities, 7 ages, 2 sexes, 5 education levels for labor, 4 household consumption types, 13 private and 8 public consumption need components, 10 capital/investment components, and 277 municipalities (Madsen and Jensen-Butler 2004). Besides this data hungry detail, LINE has commuting, shopping, and domestic and foreign tourism sub-models, which are all interregional, along with taxes, social security, and central and local government budget sub-models.

Its most interesting feature, however, is not shown in Fig. 45.7. Along with the quantity model that is shown in Fig. 45.7, LINE also has a price model, with its arrows running in the opposite direction (as explained in Sect. 45.3). Finally, in contrast to the explanation of the non-interaction between prices and quantities in Sect. 45.3, LINE uses nonzero price elasticities for exogenous final demand, mainly foreign exports, and finite elasticities for the supply of exogenous primary inputs, mainly foreign imports and the impact of investments on size of the capital stock. This creates a price–quantity interaction between the quantity model and its price dual, which is mathematically solved by means of iteration. This presents a good example of the flexibility of interregional IO analysis that is able to combine an amount of detail that is only tractable in *linear* demo-economic type of models, with the theoretical advantages of the mostly much smaller, but nonlinear computable general equilibrium (CGE) models.

45.7 Conclusion

One of the new challenges, both an accounting and a modeling one, for interregional input–output analysis, will be the growth of *Internet retail purchases*. Without the possibilities of retrieving survey data, it will be difficult to allocate the flows of funds and the concomitant transfer of a physical good or service across space. In addition, whereas a retail transaction in a household's home region may not involve the purchase of transportation costs (these would be part of the price mark up by the retailer), an Internet purchase of a good often is accompanied by mailing or delivery charges. As Internet retail sales increase in importance, tracing these flows and carefully allocating the components to appropriate locations will present new challenges for modelers.

With advances in computer software, modeling systems have become more sophisticated with the result that increasingly input–output components are nested within larger models. In many cases, the larger models represent a trajectory to make more activity endogenous and to embrace more received theory to help interpret the behavior of aggregates (e.g., household consumption) that were relegated to exogenous categories. However, there are times when a simple input–output system will suffice (e.g., the impact of a short-term event); whereas, in other cases, large multiregional CGE systems would be more appropriate, for example, to

study significant policy changes such as trade liberalization. Viewing the input–output system as part of a family of options is probably the most appropriate way to gauge its value and importance.

Perhaps, the most important challenge will be to embrace more detail in the household income and consumption components of these models. Households are becoming more mobile, intra- and internationally, they are changing in size and composition (e.g., the growth of two-earner households), and in almost all countries, the share of the population over 65 years of age is growing rapidly. These changes will generate important signals for the future composition of industry, the variety of goods and services produced, and the location of this production. As supply chains become geographically more dispersed, the sets of data contained in interregional input–output tables will become ever more valuable.

Acknowledgments The authors thank the editors, Piet Rietveld and Manfred Fischer, and Dirk Stelder for useful comments.

Appendix: The Microeconomic Foundation of the Leontief and the Ghosh IO model

The basic Leontief price and quantity model for a closed economy, introduced in Sects. 45.2 and 45.3, may be derived from microeconomics by assuming that all firms in each industry sell that industry’s single homogeneous output under full competition, while they minimize their cost at given prices under a *Walras-Leontief production function*:

$$x_j = \min(z_{ij}/a_{ij}, \forall i; v_{pj}/c_{pj}, \forall p) \quad (45.22)$$

This results in a perfectly elastic supply of that single homogeneous output and a perfectly inelastic demand for intermediate and primary inputs, z_{ij} and c_{pj} , under fixed input ratios, a_{ij} and c_{pj} . Consequently, any change in the exogenous primary input prices is entirely and precisely passed on to all intermediate and final markets for the output of that firm. The left-hand side of Fig. 45.8 summarizes these individual firm assumptions and adds the assumptions about what is determined exogenously and what follows endogenously for the economy as a whole.

The interregional model extension, introduced in Sect. 45.4, adds *trade coefficients* to the basic Leontief model for a closed economy. The theoretical foundation for assuming trade coefficients to be fixed is less convincing than that for the technical coefficients by means of Eq. (45.22). It may be assumed that the output of, for example, agriculture is a different product in each different region. The trade coefficients will then have a technical character and will be fixed for the same reason. As each cell then relates to different goods, this assumption fits best with the “ideal,” full information, interregional IO model. It may also be assumed that the products of, for example, agriculture in different regions are close substitutes for

each other. The trade coefficients will then be fixed only for as long as the relative prices of agricultural outputs from different regions remain unchanged. As relative prices will influence all trade coefficients along a row of the IO table in the same manner, this assumption fits best with the limited information, multiregional IO model.

The left-hand side of Fig. 45.9 shows the implications of the above assumptions for the working of, for example, an individual intermediate input market. The vertical demand for these inputs is determined by the Leontief quantity model, whereas the horizontal supply of these inputs is determined by the Leontief price model. Any change in the demand of the purchasers is matched exactly by a corresponding change in its supply, without any change in the price asked by the suppliers. Hence, *demand drives the quantity model*. On the other side of the market, any change in the price asked by the suppliers is accepted by its purchasers, without any effect on their demand for this input. Hence, *cost pushes the price model*. Clearly, in the short run, this is not a realistic model unless there is excess capacity on all relevant primary input markets, whereas, in the long run, this model is only realistic if the *relative* prices of the primary inputs do not change.

The obvious follow-up question is whether the alternative IO quantity model of Ghosh (1958), and its dual price model (Oosterhaven 1996), offers a more plausible alternative. Ghosh developed his alternative IO model for the essentially centrally planned Indian economy of that time. Here we interpret the Ghosh model as a model for a market economy. As such it represents the pure opposite of the Leontief model, as can be seen by comparing the right- and left-hand side of Figs. 45.8 and 45.9.

In the Ghosh quantity model, the homogeneity assumption is made for all inputs along the columns of the IOT, instead of for all outputs along the rows of the IOT, as in the Leontief model. This implies that all inputs are perfect substitutes for each other. Hence, factories may run without labor, and cars may run without gasoline. Next, the Ghosh model assumes perfect complementarity of the outputs along the rows of the IO table, which is technically plausible for chemical industries, but which has to be based on a marketing desire to service all markets with the same constant market share for other industries. This is only possible if this supply of outputs is confronted with a perfectly elastic demand for them. Hence, *supply drives the Ghosh quantity model*. See the right-hand side of Fig. 45.8 for the remaining assumptions.

The mathematics of the Ghosh quantity model is far simpler than its economics, if only because it is the pure opposite of the Leontief model. Its solution reads as follows (see Oosterhaven 1996 for details):

$$\mathbf{x}' = \mathbf{v}'(\mathbf{I} - \mathbf{B})^{-1} = \mathbf{v}'\mathbf{G} \quad \text{and} \quad \mathbf{i}'\mathbf{Y} = \mathbf{v}'\mathbf{G}\mathbf{D} \quad (45.23)$$

where $\mathbf{B} = N \times N$ -matrix of intermediate *output coefficients*, $\mathbf{D} = N \times Q$ -matrix of final output coefficients, and \mathbf{G} = the so-called *Ghosh inverse*. In contrast to the Leontief inverse, which may be used as a measure of the *backward linkages* of each

Demand-driven quantity & cost-push price model:	Supply-driven quantity & demand-pull price model:
<i>For the individual firm:</i>	
- given demand for its single homogeneous output, i.e. perfect substitution among all outputs	- given supply of its single homogeneous input, i.e. perfect substitution among all inputs
- full complementarity of all inputs (fixed input ratios)	- perfect jointness of all outputs (fixed output ratios)
- cost minimization at given input prices	- revenue maximization at given output prices
- full competition, i.e. passing on of all input price changes into the single output price	- full competition, i.e. passing on of all output price changes into the single input price
<i>For the economy as a whole:</i>	
- exogenous demand for final outputs per industry	- exogenous supply of primary inputs per industry
- endogenous demand for all inputs per industry	- endogenous supply of all outputs per industry
- perfectly elastic supply of all primary inputs, i.e. exogenous primary input prices	- perfectly elastic demand for all final outputs, i.e. exogenous final output prices
- endogenous total output prices and quantities	- endogenous total input prices and quantities

Fig. 45.8 Assumptions of the basic Leontief and Ghosh models for market economies

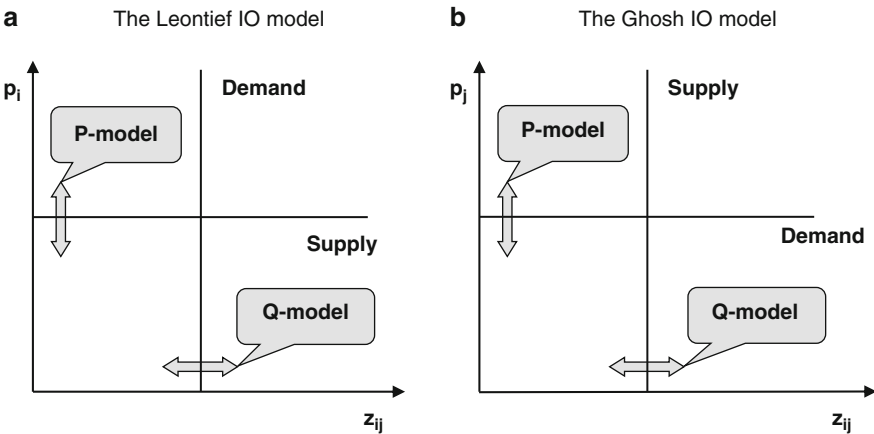

Fig. 45.9 The functioning of markets in the basic two input–output models. (a) The Leontief IO model, (b) The Ghosh IO model

sector with its direct and indirect suppliers along the columns of the IOT, the Ghosh inverse provides an indication of each sector’s direct and indirect *forward linkages* with its customers, along the rows of the IOT. When used to measure forward linkages, in causal terms, the Ghosh model is best interpreted as a cost-push IO price model measured in values, instead of in prices as in Sect. 45.3 (see Dietzenbacher 1997).

The price version of the Ghosh model, which is called the *demand-pull IO price model*, is the pure opposite of the Leontief price model. Its solution reads as (see Oosterhaven 1996 for details)

$$\mathbf{p} = (\mathbf{I} - \mathbf{B})^{-1} \mathbf{D} \mathbf{p}_y = \mathbf{G} \mathbf{D} \mathbf{p}_y \quad (45.24)$$

where $\mathbf{p}_y = Q$ -vector of (index) prices for total final use per category. As opposed to the cost-push model, where \mathbf{p} refers to the price for each sector's single homogeneous output, \mathbf{p} in Eq. (45.24) relates to the price for each industry's single homogeneous *input*. Furthermore, as opposed to the cost-push model, where primary input was homogeneous across the rows, here final use is homogeneous across each column of the IO table. This assumption implies that not only firms but also consumers may drive cars without gasoline and run home appliances without electricity. See Fig. 45.8 for the remaining assumptions.

Finally, each IO market in the Ghosh model thus functions as in the right-hand side of Fig. 45.9. Prices and quantities move independently. Demand is perfectly price elastic. This means that there is infinite demand at the going market price, which is a good description of the functioning of the butter mountains and the milk lakes of the old common agricultural policy of the EU. Supply, on the other hand, is perfectly inelastic to price changes. Clearly, the Ghosh model does not offer a plausible alternative to the Leontief model, but studying it does enlarge our understanding of the nature of the Leontief model.

Abstract

Interregional trade has been relatively neglected by most trade analysts. A dearth of data has limited formal explorations of interregional trade but the magnitudes of the volumes revealed suggest that greater attention should be directed to this form of connectivity between economies. This chapter begins with a review of the theory and practice of international trade theory and its link to some of the ideas that form the basis of the New Economic Geography. Some alternative

approaches to the measurement of trade are examined, especially the role of intra-industry as opposed to interindustry trade, vertical specialization, trade overlap, and spatial production cycles. Thereafter, attention is addressed to the interregional impacts of international trade.

46.1 Introduction

A press release from the Illinois state government in March 2008 announced:

Gov. Rod R. Blagojevich today announced Illinois achieved record export growth for the third consecutive year. Illinois exports totaled more than \$48.73 billion worth of goods and services in 2007, an increase of 15.79 % from 2006, according to data released from WISER, the World Institute for Strategic Economic Research, who compiles its information from the US Census Bureau, Foreign Trade Division. This record growth maintains Illinois' place as the fifth largest exporting state in the nation, up from seventh in 2005. (<http://www.illinois.gov/pressreleases/ShowPressRelease.cfm?SubjectID=3&RecNum=6691>)

Apart from the significant growth rate, the most notable feature of the news release is the absence of any mention of the growth of *interstate* or *interregional* trade. In contrast to international trade data, which are often released on a monthly or quarterly basis, data on interregional trade are often not collected at all or issued only infrequently. Hence, Gov. Blagojevich and many others have come to interpret regional trade as regional *international* trade, i.e., flows of goods and services from a region in one country to other countries, with trade between regions within the same country being ignored.

This is surprising in view of the fact that interregional trade is free of many of the restrictions imposed on international trade. Within a country, there are likely to be smaller cultural differences, lower freight costs, a uniform currency, and similar institutions. Consequently, interregional trade is most likely relatively more important than international trade. This chapter will provide analyses of the importance, structure, and measurement of interregional trade.

The next section will provide a review of international trade theory with a focus on its relevance for regional trade, i.e., with a focus on the difference between trade with and without trade barriers. The following two sections will examine some analysis of the structure of interregional trade using a variety of methods for a variety of countries. The final section provides some summary comments and challenges.

46.2 Theories on Trade With and Without Barriers

It is clarifying to start an overview of traditional trade theory by comparing it with traditional growth theory. Both are based in neoclassical economics, which means that they assume flexible prices, full competition, and substitution between inputs. Growth theory explains regional time paths of output/capita based on regional growth of factor inputs, including net in- or outflows of capital, labor, and

technology, while it assumes regional sectoral specialization to be determined exogenously. Trade theory, however, explains regional specialization from technological and factor endowment differences, and concentrates on comparative static analyses of social welfare with and without trade barriers, but it does not generate time paths of per capita output. Besides traditional trade theory, we summarize the so-called new trade theory and show how New Economic Geography is a direct descendant of it.

46.2.1 Technological Differences: Comparative Advantage Instead of Absolute Advantage

There is a host of factors that is put forward to explain the commodity pattern of interregional and international trade. David Ricardo argued in the early nineteenth century against the conventional wisdom of that time, which said that *absolute advantages* in costs determined which commodities a country could export. In fact, he showed that even countries with an absolute disadvantage in terms of the unit production cost of all its tradeable products may profitably engage in international trade without needing to protect their high cost domestic industries. He argued that even such countries must have a comparative advantage in the production of at least some goods, where *comparative advantage* is defined as the lower amount of other goods that has to be forsaken, compared to other countries, if the country at hand specializes in the production of that good.

Figure 46.1 summarizes his argument in a neoclassical setting with two countries, East (E) and West (W); two products, Steel (S) and Textiles (T); one factor of production, labor (L); and constant returns to scale. Figure 46.1 considers the case in which both countries are equally large (i.e., E and W have the same amount of labor available) and both have the same consumer preferences for S and T , i.e., E and W have the same *social indifference curves* (SICs), indicated by the bold convex, nonlinear lines in Fig. 46.1. The falling slopes of these SICs indicate the amount of T that the consumers in East and West require to stay equally satisfied when losing one unit of S .

As there is only one factor of production that operates under constant returns to scale, the *production possibility frontiers* (PPFs) of both East and West are linear, as indicated by the bold straight lines in Fig. 46.1. For each country, the slope of its PPF indicates the amount of T that the producers are able to produce more if they produce one unit less of S . The PPF of West lies entirely above that of East, which indicates that West has an absolute advantage in the production of both S and T . The PPF of East, however, has a steeper slope, which indicates that it has a comparative advantage in the production of Textiles. The equilibrium is reached where the highest SIC just touches the PPF of the country at hand.

When there is no trade between East and West, the left-hand side of Fig. 46.1 shows that this set of assumptions leads to an *autarky equilibrium* with a higher level of consumption = production of both S and T in West, and thus to a higher level of welfare in West, as indicated by its higher equilibrium SIC. Also note that

Fig. 46.1 Ricardian analysis of technological differences under autarky and free trade

the form of the shaded consumption = production rectangles of East and West indicates that the consumers in East consume relatively more Textiles (i.e., $C_{TE}/C_{SE} > C_{TW}/C_{SW}$). The explanation is that East has a comparative advantage in producing Textiles, and thus a higher domestic price of Steel to price of Textiles ratio (P_S/P_T), indicated by the higher slope of its PPF.

Removing trade barriers, including transport cost, implies that East will start to export Textiles and West will start to export Steel until the domestic P_S/P_T ratios in East and West converge to a value in between the two *autarky price ratios* shown in the left part of Fig. 46.1. This uniform *free trade equilibrium price ratio* is shown by the slope of the two parallel dashed lines in the right part of Fig. 46.1. The lower of the two dashed lines indicates the equilibrium *consumption possibility frontier* (CPF) for East, which starts at the maximum possible production of Textiles by East (Y_{TE}). Given the equilibrium P_S/P_T slope of its CPF, East will consume C_{TE} of Textiles and export the remainder of its textiles production to West (i.e., $Y_{TE} - C_{TE} = X_{TE}$), which allows East to import the amount of steel it desires at this free trade P_S/P_T ratio.

The higher of the two dashed lines indicates the equilibrium CPF of West, which starts at its maximum possible production of Steel (Y_{SW}). Given its CPF, West will consume C_{SW} of Steel and export the remainder of its steel production to East (i.e., $Y_{SW} - C_{SW} = X_{SW}$). In this two-region case, the exports of East equal the imports of West and vice versa. Hence, the two shaded *trade triangles* have exactly the same size and form. Note that this free trade equilibrium leads to a higher level of welfare for both East and West, as argued by Ricardo, but West still has a higher level of welfare as it is able to consume absolutely more Steel and more Textiles.

One of the criticisms of the Ricardo model is that it presents no explanation for the productivity differences between East and West. A more serious criticism is that it seems to predict that each country will produce and export only one product and import the remaining products that it wishes to consume with the revenue of that single export. Reality, however, shows that most countries export a whole range of

products. This criticism is not entirely correct as the production capacity of many smaller countries is limited, which reduces the import possibilities of the larger countries, as indicated by the horizontal section of the higher of the two dashed CPFs in the right part of Fig. 46.1. Consequently, larger countries need to produce more tradeable products than the single one they export. In terms of Fig. 46.1, this will lead to a corner solution for West at the kink of its consumption possibility frontier.

Note that even in a free trade situation with no interregional differences in tastes, technology, or factor endowments, the existence of transportation cost with increasing returns to transportation may result in a commodity composition of interregional trades that is opposite to those predicted by the Ricardian model (see Cukrowski and Fischer 2000). Still also in that case, additional gains from trade may emerge from the reductions of transportation costs. See Krugman et al. (2011) for a further evaluation of the Ricardian model.

46.2.2 Trade Driven by Factor Endowment Differences: The Heckscher-Ohlin Model

Above, we have formulated the Ricardian model in terms of a neoclassical trade model, although it is usually considered to be part of the classical tradition in economics (e.g., van Marrewijk 2002). The real neoclassical trade model was developed by Heckscher and Ohlin in the 1920s (hereafter called the HO model; see Leamer [1995] for a review). It also has two countries, say E and W , and two products, say S and T , which are both produced under constant returns to scale. In contrast to the Ricardian model, the HO model assumes that production technologies are identical across countries and that production requires two factors, say capital (K) and labor (L), instead of just one. Both factors of production operate under diminishing marginal returns, which means that the production possibility frontiers of both East and West are concave, nonlinear curves, as shown in Fig. 46.2, instead of straight PPFs in Fig. 46.1.

The only difference between East and West in the HO model is that they are differently endowed with K and L . Assume that say West has relatively more capital available and East relatively more labor, and assume further that producing say Textiles requires relatively more labor, while Steel requires more capital. In that case, the PPF of East has a steeper slope than that of West at all amounts of Steel being produced, as shown in Fig. 46.2. Consequently, in the *autarky equilibrium*, labor-abundant East produces and consumes relatively more labor-intensive Textiles at a higher P_S/P_T ratio, whereas West does the opposite as indicated in the left part of Fig. 46.2. (Note that the higher welfare level of West, indicated by its higher equilibrium SIC, here is coincidental. It is not a consequence of any assumption made.)

When all trade barriers, including transportation cost, are removed, the difference in the domestic price ratios induces firms in East to start exporting Textiles and those in West to start exporting Steel until the domestic P_S/P_T ratios converge to

Fig. 46.2 HO analysis of factor endowment differences under autarky and free trade

a common *free trade equilibrium* price ratio. The two parallel dashed lines in the right part of Fig. 46.2 represent this equilibrium price ratio. In contrast with the Ricardian model in Fig. 46.1, the equilibrium consumption possibility frontiers (CPFs) of *E* and *W* of Fig. 46.2 do not start where the production possibility frontiers (PPFs) join the horizontal and vertical axes, but start where the PPFs equal the slope of the free trade price ratio. Consumers in East (West) consequently move away from consuming the formerly cheap Textiles (Steel) toward consuming more of the now cheaper, partly imported Steel (Textiles) until they end up at their highest indifference curve possible.

The right part of Fig. 46.2 shows that, under free trade, East exports the difference between its now larger production and smaller consumption of Textiles (i.e., $X_{TE} = Y_{TE} - C_{TE}$). Analogously, West exports the difference between its now larger production and smaller consumption of Steel (i.e., $X_{SW} = Y_{SW} - C_{SW}$; see the right part of Fig. 46.2). With these exports, *E* and *W* finance their import against the free trade price ratio of the two CPFs. This is indicated by the two shaded *trade triangles*. With only two regions, these have exactly the same size and form (like in Fig. 46.1). Again, both countries benefit from free trade, as indicated by reaching a higher social indifference curve (SIC) when moving from the left to the right part of Fig. 46.2.

In contrast to the Ricardian case, however, both countries still produce both goods, be it in different proportions than in the autarky case. This implies that both capital and labor, in both *E* and *W*, have to move from the sector that shrinks because of competing imports to the sector that grows as it becomes the exporting sector. This interindustry *production factor mobility*, of course, has consequences for the remuneration of both capital and labor (not shown in Fig. 46.2).

Under autarky, labor in the labor-abundant East will receive relatively low wages (P_L), whereas capital will receive a relatively high rate of return (P_K). The reverse will apply to West. Under free trade, relatively little labor comes free from the shrinking Steel sector of East, while relatively much is needed in its growing

Textiles sector. In contrast, relatively more capital comes free from its shrinking S , while relatively little is needed in its growing T . Consequently, in East P_L will increase, whereas P_K will decrease. As a reaction to this decrease in P_K/P_L , both the T and S sector in East will substitute away from using labor toward using relatively more capital, which partly counteracts the rising wages and declining P_K . Note that the decrease in the domestic P_K/P_L ratio in East is caused by the decrease in its domestic P_S/P_T ratio. Hence, the prices of the production factors move in the same direction as the prices of the products that use them intensively.

The reverse process in West will lead to a reverse result. Under free trade, its domestic P_S/P_T ratio will increase, which will draw both K and L from its T sector to its S sector, which will require its P_K/P_L ratio to rise too. Hence, relative product prices converge under free trade and relative factor prices follow. In fact, Paul Samuelson proved in the 1940s the *factor price equalization* (FPE) theorem: when under neoclassical conditions (i.e., identical technologies, concave PPFs, and convex SICs) both goods remain being produced in both countries, the complete equalization of product prices under free trade will lead to a complete equalization of factor returns (see van Marrewijk 2002, Chap. 5).

The Heckscher-Ohlin model of international and interregional trade is thus a full general equilibrium model that predicts sectoral production, consumption, imports and exports, and the prices of products and production factors. Its prediction of factor price equalization, however, only partly comes true in reality, whereas its prediction of the composition of exports (namely, that countries abundant with capital will export goods that use capital intensively) has been refuted many times. This outcome became known as the *Leontief paradox*, after Leontief who first used the input–output model to measure the *factor content of trade* (see Foster and Stehrer (2012) for an overview of these studies).

Leontief (1953) found that US exports embodied relatively more labor than US imports, whereas the USA was considered to be capital abundant. Trefler (1995) showed that part of the Leontief paradox may be explained by adding the Ricardian assumption of different technologies to the HO model. Others have shown that adding natural resources and different levels of human capital improves the prediction of the HO model. However, even the extended HO model still predicts far more embodied trade in the abundant factors than is found in reality. This became known as the *missing trade problem* (Trefler 1995).

Relaxing its restrictive assumptions thus improves the performance of the HO model. However, the core assumption of free trade does not hold in international trade. Even the trade between EU countries is still hampered by differences in legal systems, languages, and business cultures. The assumption of free trade, in fact, fits much better to the conditions under which *interregional trade* within one country operates. The same applies to the assumption of identical production technologies and consumer preferences, and the assumption of zero transport cost. Hence, it does not come as a surprise that extended versions of the HO model perform much better when tested on interregional trade (see Davis et al. (1997) for Japanese regions).

There is one core assumption of the HO model, however, that fits better to international than to interregional trade, namely, the immobility of factor

endowments between spatial units. The *interregional migration of production factors* K and L and the interregional mobility of products S and T have much in common. Both are motivated by price ratios (P_K/P_L and P_S/P_T) that move in the same direction when mobility barriers are removed. Both also reinforce each other's contribution to the *interregional FPE* of wages and capital returns (see Borts and Stein 1962). The HO model's prediction of sectoral specialization, however, is undermined by the interregional mobility of K and L , as it equalizes factor endowments across regions. This takes away the comparative advantage of the regions and thus undermines one of the driving forces behind what is known as *interindustry trade*, namely, why regions import and export different kinds of products.

46.2.3 New Trade Theory: Economies of Scale and Love of Variety

The Ricardian model and the HO model combined and extended, thus provide a good approach to understand interindustry trade. Both models, however, are of no help to understand why, especially, developed countries and regions import and export the same type of goods, i.e., why Germany exports as well as imports cars to and from Japan. This type of trade is known as *intra-industry trade*, and its explanation requires what is known as *new trade theory*.

The empirical importance of intra-industry trade became clear after the topical study of Grubel and Lloyd (1975). They measured the share of intra-industry trade of product i in the total trade of product i of any region r by means of the *Grubel-Lloyd index*:

$$GL_{ir} = 1 - |X_{ir} - M_{ir}| / (X_{ir} + M_{ir}) \quad (46.1)$$

where X_{ir} stands for the exports of product i by region r and M_{ir} for the imports of i by r . Brühlhart (2009) shows that the weighted average Grubel-Lloyd index for high income countries grew from 11 % in 1962 to almost 38 % in 2006, whereas it remained at a level of around 1 % for the poorest countries in that sample.

To explain this increasingly important phenomenon of intra-industry trade, two strongly related core assumptions of neoclassical economics have to be dropped, namely, that of constant returns to scale and that of full competition, while the assumption of homogeneous products has to be replaced with that of heterogeneous products and love of variety.

Introducing *increasing returns to scale* may simply be done by introducing fixed costs that are independent of the scale of production along with marginal cost (MC) that is constant per unit of output. This makes average cost (AC) a downward sloping, concave function of output, approaching MC at higher output levels, as shown in Fig. 46.3. Introducing *imperfect competition*, however, opens up a whole array of options, from pure monopoly via duopoly and oligopoly, either with or without collusion, all through to monopolistic competition. New trade theory, consequently, consists of a whole array of different models

Fig. 46.3 Monopoly under autarky turning into monopolistic competition under free trade

(see Krugman et al. (2011) for an overview). We will only use the two most extreme models and thus simply move from a pure monopoly under autarky to monopolistic competition with many varieties of the same product produced under free trade in many different countries.

To start, assume a single monopoly that operates in a fully protected market, say the Trabant car company in the former German Democratic Republic (GDR). Assume that Trabant was allowed to maximize its profits, then it would have increased its sales of cars by lowering its price until its dropping marginal revenue (MR) would just equal its constant marginal cost (MC), as indicated in left part of Fig. 46.3. This would generate a maximum monopoly profit, equal to the difference between the *monopoly price* ($P_M = AR$) and average cost (AC) multiplied with the number of Trabants sold at $MR = MC$ (i.e., Q_M). This maximum profit is indicated by the shaded rectangle in left part of Fig. 46.3. In the interest of its inhabitants, however, the GDR government most likely would have ordered Trabant to further decrease its price until it just equaled average cost ($P_S = AC = AR$), at which *social price* Trabant would not have made any monopoly profits, but would have been able to produce and sell many more cars (i.e., Q_S).

Next, consider the case in which East Germany joins the European Union. Then, Trabant would have been confronted with the competition of many more car producers from many more countries. Of course, some former East Germans would have continued to buy Trabants, because that was precisely the car they wanted to have anyhow, but the majority of them would have turned to different types of cars that better suited their taste. This means dropping the assumption of a single homogenous product for the assumption of *heterogeneous products with a love of variety*. Trabant would have lost a considerable amount of domestic sales, but at the same time, it could have expanded its production by selling to new customers in the Rest of the World. In terms of market forms, the former monopolist now has to operate in multiple markets with many competitors, each producing a different variety of car, i.e., it has to operate in a market characterized by *monopolistic competition*.

In that market, the demand for Trabants is much more elastic to price changes, as indicated by the rotation of the demand curve in the right part of Fig. 46.3. In the new *free trade equilibrium*, more Trabants might have been sold, but at a lower price, which would mimic the case in which the government would force the monopoly price P_M down to AC . The monopolistic competition model further assumes *free entry and exit of firms*, which will move the demand curve for Trabants down until $AC = AR$. In reality, we saw a closing down of the Trabant car factories, probably indicating that their average cost was too high for their new much more price-sensitive demand.

This raises the question whether the welfare benefits of free trade are always positive. The most frequently used model of monopolistic competition (Dixit and Stiglitz 1977) uses a constant elasticity of substitution (CES) function in which a consumer derives utility U_c from the consumption c_i of variety i over a total of N varieties:

$$U_c = \left(\sum_{i=1}^N c_i^\rho \right)^{1/\rho} = (Nc^\rho)^{1/\rho} = \left(N^{(1/\rho)-1} \right) (Nc) \quad (46.2)$$

= *love of variety* * *resource use*, $0 < \rho < 1$

The first two terms of Eq. (46.2) represent the CES utility function, with different c_i and a *love of variety* parameter ρ . To better understand the working of this love of variety, assume that all varieties i are consumed in the same amount $c = c_i$, i.e., this consumer buys multiple TVs that all have the same size 1.0 instead of multiple TVs that have sizes of say 1.1, 1.5, and 1.9. Then, the utility U_c from consuming TVs can be decomposed as indicated by the last two terms of Eq. (46.2). They show that the increase in utility is larger than the increase in resource use due to consuming more TVs. Mathematically, this reflects that a single TV that is chosen from a large variety of TVs delivers a larger satisfaction than when there is only a single type of TV for sale.

Equation (46.2) can be used to compute the main *welfare benefits of free trade* under monopolistic competition on the demand side of such markets. Further benefits occur on the supply side due to lower AC , because of the larger production volumes under free trade (compare the left with the right part of Fig. 46.3), and because of productivity gains and innovation due to competition. The closing down of some firms, like that of Trabant, however, shows that the economic and social cost of transition may be sizeable. Besides, several cases of less usual combinations of assumptions also lead to negative impacts of free trade, such as the case of the *infant industry argument* and comparable unfortunate *path dependencies* (see van Marrewijk (2002) and Krugman et al. (2011) for further discussion).

One last, major benefit of free trade has not been discussed yet. The love of variety effect of Eq. (46.2) not only applies to final goods but also applies to *intermediate goods* and services used by firms. In that case, Eq. (46.2) mathematically reflects that, say, having to buy with one local, general purpose public relations (PR) firm delivers a less effective advertisement campaign than when

the purchasing firm may choose between a host of local specialized PR firms, normally available in big urban agglomerations. These *matching benefits of thick markets* not only apply to intermediate input markets but also to thick local labor markets. Besides these matching effects, big urban agglomerations also benefit from pecuniary external economies of scale, such as the lower risks and lower cost of *outsourcing*, and pure technical *externalities*, such as the free exchange of, especially, tacit type of information leading to more innovation.

Not surprisingly, therefore, the above monopolistic competition variant of new trade theory may be considered as the forerunner of *New Economic Geography* (NEG). In fact, simplified to its bare essentials, the first core model of NEG (Krugman 1991) only adds the mobility of labor to this variant of new trade theory (Krugman 1979).

46.3 Interregional Trade: Alternative Approaches

The above theoretical expositions have been expanded to include additional dimensions of trade, such as the links between trade and *production chains*. Hummels et al. (1998) introduced the concept of *vertical specialization* of production (see the left side of Fig. 46.4) to explain at least part of the empirical finding that economies were becoming increasingly integrated. For vertical specialization to occur, Hummels et al. (1998) postulated three conditions: (i) the good must be produced in multiple, sequential stages; (ii) two or more countries must specialize in some but not all stages; and (iii) at least one good in its various processing stages must cross an international border more than once. In essence, consider a good produced in a country for export that uses an imported component. Translated to the interregional system, vertical specialization would be similar with an imported component from region r being used in the production of a good in region s that is exported to region q .

This concept feeds into several related issues: how is it linked to outsourcing, fragmentation, hollowing out, and spatial production cycles? *Outsourcing* can accompany vertical specialization when a firm that formerly used domestic inputs decides to source them from another country. However, the firm using the now imported inputs would have to export the good to qualify as being engaged in vertical specialization. *Fragmentation of production* (see Jones and Kierzkowski 2005) is a process that might be considered a necessary but not a sufficient condition for vertical specialization to take place.

Referring to Fig. 46.5, during an era of high transportation costs, firms organized production in such a way that a larger volume of products and intermediates were often produced within the same plant or within plants located in the same vicinity. As transportation costs decreased, firms were able to exploit economies of scale by fragmenting production into more specialized components that were associated with specific geographic locations. The production chain thus spread across many economies (states or countries); if the three characteristics of vertical specialization

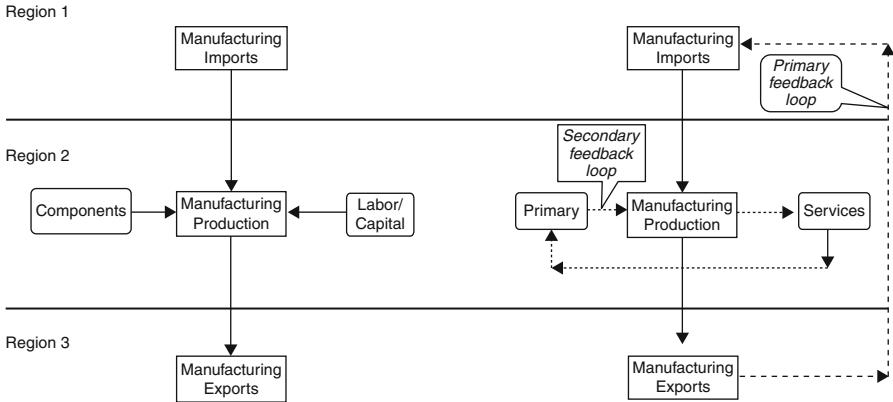

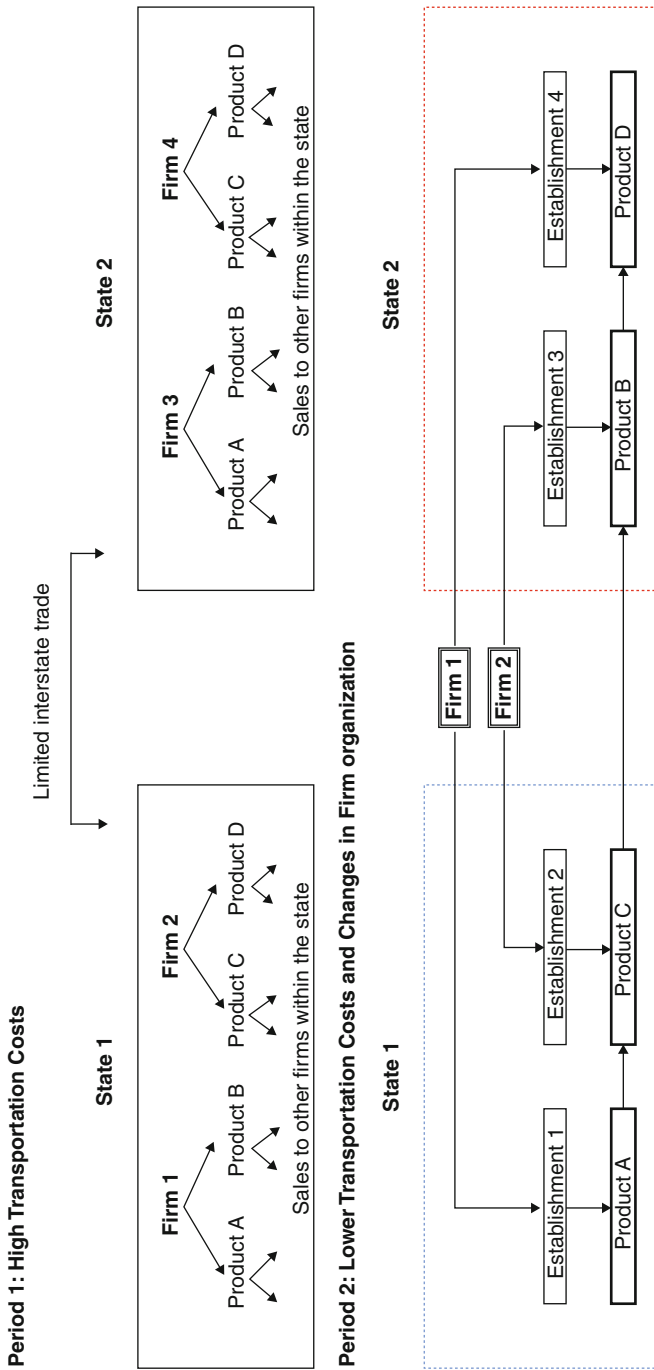

Fig. 46.4 Vertical specialization and spatial production cycles compared (Source: Sonis et al. (2002))

were met, then fragmentation would lead to vertical specialization and trade would come to be dominated by intra-industry trade.

In an economy such as Japan at the national level (Okazaki 1987) or Chicago at the regional level (Hewings et al. 1998), the process of fragmentation often accompanied the *hollowing out* of economies. This process implies that intra-economy dependence decreases and inter-economy dependence increases. The striking evidence for this are the ways in which both international and interregional trade have grown at rates exceeding domestic production. The final piece of the picture may be offered by the notion of *spatial production cycles*. Here, Sonis et al. (2002) expanded the notion of vertical specialization by exploiting the ideas of *feedback loops* (see Fig. 46.4) where the possibility that the exported good from the vertical specialization process may end up undergoing further processing until a finished good is produced that may be being exported to the country in which the whole process started.

46.3.1 Vertical Specialization and Trade Overlap

Although there have not been any attempts to measure the degree of vertical specialization in interregional trade, a companion approach by Munroe et al. (2007) attempted to measure the degree of intra-industry trade between the Mid-west states of the USA. While vertical specialization focuses on the import content of exports, an important subset of this trade would be accounted for by flows between firms in the same broad industrial category. In the traditional HO model of international trade described in Sect. 46.2, trade is driven by differing factor endowments between regions. The HO model cannot adequately explain the large degree of trade in similar goods taking place among similar economies. If intra-industry trade (hereafter, IIT) is at odds with the more traditional HO framework of comparative advantage, one must first grapple with the determinants of such trade.

Commodity chain of production has a higher probability of involving interstate trade

Fig. 46.5 Changing spatial structure of production (Source: Hewings and Parr (2009))

Stone (1997) separates the determinants of IIT into two categories: industry-based determinants and regional characteristics. The industry-based determinants include product differentiation, scale economies, industry specific cost structures, and transportation costs. Regional determinants include macroeconomic characteristics, such as income level and relative capital/labor ratios. It has been assumed that IIT will increase as income differences decrease because demand structures become more similar, with fewer differences in factor endowments and growing average incomes.

Within the IIT theoretical literature, there are differing assumptions regarding the type of product differentiation within an industry that leads to IIT. The three general types of differentiation include *horizontal product differentiation* (differences of variety), *vertical product differentiation* (differences of quality), and the *vertical integration of production process* itself (trade in intermediate goods). Krugman (1991) has championed the case for horizontal differentiation leading to increased IIT, using Eq. (46.2), the Dixit-Stiglitz equation; his contributions add the fact that consumer preferences become more diverse leading to greater product differentiation by type or variety. As each region specializes in a certain variety of a good, incentives for trade arise (see Fig. 46.5). This model is most applicable to the study of trade among highly developed economies, with a predominance of trade in capital-intensive goods and a high level of technology. Intra-industry trade between economies with dissimilar endowments and levels of technology, however, is most likely the consequence of the international fragmentation of value chains.

Thom and McDowell (1999) argued that intra-industry trade takes two forms: horizontal and vertical. *Horizontal intra-industry trade* is associated with economies of scale and occurs when products are differentiated and consumers express preferences for product variety, as in the Dixit-Stiglitz formula. *Vertical intra-industry trade*, on the other hand, is similar to interindustry trade in that it exploits comparative advantage and specialization, not between different industries as with interindustry trade but within the same industry as trade in different parts and components. Price (2001) noted two trends in the fragmentation process: trends in the spatial dimension associated with economies becoming more global (in part reflected by the hollowing out phenomenon noted earlier) and trends in the specialization dimension where firms (and particularly plants) are becoming more specialized because of the enlarged market created by global demands.

To provide a brief empirical illustration, an examination of US Midwest interregional trade was conducted using the *Grubel-Lloyd (GL) IIT index*, see Eq. (46.1), to measure the amount of *trade overlap*. A value of one would imply perfect trade overlap, and a value of zero would imply perfect specialization. Comparing GL indices for the five Midwestern states is a good point of departure for understanding trade flows within this region. Table 46.1 summarizes these findings. For each of the five states, five industries with the highest (trade overlap) and lowest (trade driven by industry specialization) GL indices are reported. In addition, the state of destination is reported, where RUS stands for “Rest of the United States.”

Table 46.1 Highest and lowest Grubel-Lloyd indices for the Midwest US states^a

	Most overlap	SIC	State of destination	Most specialization	SIC	State of destination
Illinois	Farm products	01	Indiana	Fresh fish	09	Indiana
	Lumber and wood prods	24	Indiana	Coal	11	RUS

Photographic, optical instr.	38	Illinois	Misc. freight equipment	41	Illinois

^aRUS = “Rest of the USA” (Source: Munroe et al. (2007))

As predicted by new trade theory, some of the more “high-tech” industries appear in the column with the highest trade overlap, e.g., fabricated metal, transportation equipment, machinery, and food and kindred products (agricultural processing). Conversely, in the column reporting the most specialized trade, some industries appear that are more natural resource based, or have lower levels of high-tech production methods, e.g., coal, textile mill products, pulp and paper products, metallic ores, and furniture and fixtures. However, these results are somewhat equivocal. In a few cases, an industry that exhibits a high level of trade overlap for one state is specialized in another state, e.g., photographic and optical instruments, leather and leather products, and clay, concrete glass, and stone. This finding perhaps points to the complexity of these trade flows; possibly, trade driven by both intra-industry specialization and competitive advantage occurs.

Another interesting finding is that for all states, most of the IIT is directed to other states in the Midwest. For Illinois, Ohio, and Wisconsin, more of their trade to the Midwest is driven by IIT, while their trade to states outside the Midwest is predominantly specialized. This observation underscores the importance and interdependence of trade flows among states within this region and further suggests that *agglomeration effects* are being manifested at the multistate level rather than for individual metropolitan or state economies.

It should be noted that several authors have addressed problems with the GL index. Nilsson (1997) presented two major problems with the measurement of IIT. The first is the inappropriate grouping of industry activities. He proposed an alternative measure, indicating that the volume of intra-industry trade between two countries r and s may be divided with the total number of products they trade with each other to yield a measure of the average level of intra-industry trade per product group. Further, a dynamic GL index was suggested by Brühlhart (2009) based on the concept of marginal IIT to address the problem of changes in the trade flows.

46.3.2 Spatial Production Cycles

The notion of *spatial production cycles* can be considered as a reworking of the ideas of feedback loops into a form that is compatible with the vertical specialization of production proposed by Hummels et al. (1998). Further details may be found

Table 46.2 Midwest interregional flows (1992 million US dollars)^a

in Sonis et al. (2002); the graphical structure is presented in the right-hand side of Fig. 46.4. The methodology exploits the properties of *block-permutation matrices* that enable the identification of hierarchies of spatial production cycles. For the Midwest US application, the analysis was conducted at three levels: at an aggregated level in which all sectors were collapsed into one, at the level of three sectors (primary, secondary, and tertiary), and at a six-sector level into which the previous three sectors were each divided into two.

Table 46.2 shows the geographical division of the trade between the Midwest states in 1992. From this table, it is easy to calculate that the global intensity of trade in the Midwest in 1992 reached \$3.9 trillion, while the interregional trade was \$894.9 million, which is 22.2 % of all US trade. 85.5 % of Midwest interregional trade includes export and import with the Rest of the USA; the remaining 15 % that flows among the Midwest states amounts to \$135 billion. (If flows to final demand accounts were included, the total Midwest interstate flow would be of the order of \$350–\$400 billion.) Without a detailed analysis of this table, it would be difficult to identify and interpret the dominant interregional and interactivity linkages.

This is accomplished in the following tables. On the most aggregated regional level of analysis, there is the decomposition of the Midwest trade flows into five feedback loops hierarchically ordered according to the intensity (sum of flows) of trade through this loop. Table 46.3 presents the two largest feedback loops connecting all the states of Midwest and the Rest of the USA. The larger of the

two includes 25.9 % of all interregional trade. It includes the largest export flow, from Illinois to the Rest of the USA, and the largest import flow, from the Rest of the USA to Michigan. The second of these two feedback loops accounts for 23.3 % of all interregional trade and includes the largest inner Midwest trade flow, from Ohio to Michigan. It is important to note that the spatial structure of these two loops is topologically identical; they differ only in the direction of flows. This means that the Midwest economy is well developed and bilaterally balanced: to each flow, there corresponds the equivalent counterflow.

These two feedback loops together account for 49.2 % of all Midwest interregional trade. They characterize the multilateral trade connections between all Midwest states. Some further amplification can be provided; these two multilateral feedback loops together can be presented with the help of another pair of feedback loops including only bilateral trade connections. A more detailed analysis of the structure of industry-based spatial production cycles can be found in Sonis et al. (2002).

46.4 Interregional Trade Impacts from International Trade

Finally, the relation between international and interregional trade is important. The promotion of first US-Canada Free Trade Agreement (FTA), and then NAFTA, was based on the premise that an enlarged market would provide mutual benefits to participant countries. Almost all the analysis and the presentation of the outcomes were considered at the national level, but what of the spatial impacts? Using a multiregional computable general equilibrium model, Gazel et al. (1996) estimated the regional (state-level) impacts of the US-Canada FTA to be of the order of 1–2 % in the Midwest states (which had the greatest volume of trade with Canada) and up to 5 % in states like Texas with more modest levels of trade. The analysis revealed that the relative regional gains from the FTA depend on factors other than export and import share of each region with Canada and their respective economic size. As Gazel et al. (1996) noted, the internal economic structure and the nature and volume of interregional trade played an important role in determining the outcome of the regional gains from trade.

The spatial impacts of NAFTA turn out to be much more complex; one major structural change generated by this trade agreement was the significant spatial restructuring of the supply chains of many automobile companies. As a result, the sectoral impacts were often much more varied than the spatial impacts. Andresen (2009) measured the impacts of NAFTA on Canadian provinces and found that the impact on interprovincial trade was more important than province-US trade; once again, the larger impact was on within-country trade. The US results were mixed; model specifications often fail to capture complex interplay between national and interregional trade, assuming somehow that the two are not connected.

Further, the impact of international trade changes on interregional trade is often significant and spatially concentrated (Hewings and Parr 2009). Table 46.4 provides an analysis of interregional trade focusing on the Midwest and the Rest of the USA for three selected years. First, the proportion of intraregional flows (those

Table 46.4 Analysis of interregional trade in the USA, 1980–2000^a

	1980	1990	2000
Total flow	4,688,314	4,964,328	5,933,438
Intraregional flow	83.2 %	82.4 %	80.8 %
Intra-activity	31.0 %	35.5 %	37.5 %
Interactivity	52.2 %	46.9 %	43.3 %

circulating within the Midwest or the Rest of the USA) declined over the two decades of the analysis, even while total flows increased. Secondly, intra-activity flows (those between the same sectors) increased while interactivity flows (between different sectors) decreased. Interregional flows accounted for an increasing share of total flows with, once again, intra-activity flows increasing and interactivity flows decreasing. Flows within the Midwest but between different states increased as did trade between the Midwest and the Rest of the USA (in both directions).

Table 46.5 provides assessment of the way in which changes in international trade differentially impact regions. Even though the macrostructures of the states of Indiana (IN), Michigan (MI), Ohio (OH), and Wisconsin (WI) are similar, a change

in international demand will generate different impacts – both internally and externally. Wisconsin is far more open – only 20 % of the indirect effects of a unit change in international trade from this state remain within the state, 17.2 % leaks out to the other Midwest states, and the remainder (51.9 %) to the Rest of the USA. In contrast, Michigan retains about 30.9 % of the indirect effects, but almost an equal percentage (28.9 %) spills over to the other Midwest states, and only 34 % finds its way to the Rest of the USA. Ohio is the least “generous” with other states, retaining over 50 % of the indirect effects within its borders. The strength of these interstate connections in the Midwest – in 1993 over 40 % of each constituent state’s imports and exports were derived from or destined for other Midwest states – means that changes in international trade will have a significantly concentrated effect.

A similar analysis with Spanish regions (Llano et al. 2010) revealed that while domestic (intra- and interregional) trade flows dominated, international imports and exports grew at much faster rates between 1995 and 2005, a period within which Spain became increasingly integrated into the European Union. There is a continuing debate about the related so-called *border effect* in dampening trade flows. When considering intranational trade flows, the question has been posed as to whether state borders have an impact that is comparable to that of national borders.

Hillberry and Hummels (2003, 2008) have explored some aspects of this problem. Taking as a challenge that state borders apparently impeded trade flows, they revealed that much of the apparent limitation on interstate flows could be explained by the dominance of wholesaling activity which, by its very nature, was focused on local markets (Hillberry and Hummels 2003). With greater access to individual establishment-level data, a more extensive analysis was conducted to examine the degree to which trade responded to geographic frictions (Hillberry and Hummels 2008). In addition, they complemented the earlier work by decomposing trade into *extensive* margins (the number of commodities involved) as opposed to *intensive* margins (the value per commodity). Having access to actual trade flows (with precise distances up to a tolerance of four miles) from individual establishments, they were able to show that spatial frictions reduce the extensive margins and that the so-called home bias was an artifact of geographic aggregation.

Among other findings, they found that value declined very rapidly with distance, “. . .dropping off almost an entire order of magnitude between 1 and 200 miles, and is nearly flat thereafter” (Hillberry and Hummels 2008, p. 533). Further, the number of unique shipments drops at about the same rate as value over distance, but value per shipment had no clear decline with distance. In essence, they conclude that spatial frictions have their greatest impact on the number of shipments rather than on the value per shipment. Shipments within a 5-digit zip code (about a four mile radius of the shipper) are three times higher than those outside the zip code; if the results had been estimated at a 3-digit (more extensive spatial unit) level, then intrastate flows dominate.

However, it is not clear how these spatial frictions manifest themselves since the nature of state barriers vis-a-vis national ones are several orders less intrusive. In addition, the limitations in the number of goods exported/imported may be attributed to the lack of demand and thus to variations in economic structure. One further

interesting finding from their work is that even at the five-digit level, intra-industry trade occurs – further verifying that the Jones and Kierzkowski (2005) ideas even operate at very small spatial scales.

46.5 Conclusions

The analysis presented in this chapter has drawn from research that has examined gross trade flows. Increasingly, research is now focusing on *trade in value-added*. For example, the completion of the World Input–output Database (www.wiod.org) in 2012 enabled analysis that revealed that EU’s trade deficit with China was 36 % smaller when the value of the separate stages of production was summed independently rather than focusing on the value of the end products shipped. Applications of such methodology at the regional level would provide the potential for some reconsideration of the nature of trade flows.

Further, the new approach might rekindle interest in Thirlwall’s (1980) proposition that regional problems are balance of payments problems, an issue recently reexplored by Ramos (2007). In addition, a related avenue of exploration is the degree to which trade in people (migration) and trade in goods and services are linked. Several studies have been directed at the impact that immigrants might have on opening markets between their current and former countries; in this sense, the role of interregional trade may also play a synergetic role in *interregional migration* flows.

Earlier analysis of regional policies promoting greater diversification of state and local economies, as opposed to exploiting existing competitive advantages, now have to be extended to the portfolio of export and import dependencies. Traditional *cluster-based development* strategies are now being challenged by the increasing hollowing out of regional economies and the continuing fragmentation of production. Simple dyadic trade exchange has been replaced by complex flows; the final origin for an import or the final destination of an export from any given region may hide the chains of interaction that contributed to the assembly of the import, and the ultimate destination of the export may be many further product transformations away and these transformations may occur in more than one location. Unraveling these complexities will require detailed databases and careful integration with other sources of information. While input–output and trade tables provide information on flows between sectors and countries, they reveal little about the ordering or sequencing of trade flows. Issues of risk and vulnerability will come to assume a more critical role as notions of dependency and interdependency are further elaborated and modified to account for much more extensive considerations of trade and its role in economic growth and development.

the evolution of the underlying natural systems or simply due to our poor understanding of these complex systems and their interactions with the exploitation policies. These interactions are of particular importance when the ecosystem response might involve irreversibility, so that unexpected undesirable outcomes cannot be undone after they are realized. In this chapter, we review the various sources of uncertainty, the methodologies developed to account for them, and the implications regarding the management of environmental and natural resources.

47.1 Introduction

Environmental and resource economics is the branch of economics in which human activities interact with natural processes, giving rise to complex dynamical systems. Since the natural processes that constrain the options open to resource managers evolve in ways that are often poorly understood, the responsible management of natural resources must account for the dynamical and uncertainty aspects of the combined human-natural systems. These two aspects make the central theme of this chapter.

The importance of uncertainty considerations in the design of environmental policies has long been recognized, and the literature dealing with this topic is vast (see Mangel (1985) and the recent reviews of Heal and Kriström (2002) and Pindyck (2007)). In this chapter, we consider this issue emphasizing the rich variety of forms in which uncertainty enters all components of the management problems. Uncertainty stems from two main sources: (a) our own limitations in understanding key natural and economic parameters and (b) genuine stochastic elements that govern the evolution of the systems under consideration. It can show up as unpredictable disturbances to the evolution of an ecosystem, either in the form of abrupt discrete occurrences (“catastrophic events”) or as an ongoing stream of small stochastic shocks which drive diffusion processes that need to be controlled.

Obviously, the diversity of uncertainty sources and types calls for a variety of methods to model and handle them as well as for various (often conflicting) policy measures to respond to their influence on the systems to be managed. Here we review various methods and approaches that have been considered in the literature for dealing with uncertainty in the context of natural resource management. We begin with a schematic (“canonical”) resource management model (Sect. 47.2) and proceed to show how the various types of uncertainty enter each of its elements (Sect. 47.3). In actual practice, resource managers may face more than a single type of uncertainty at the same time. We point out that the interaction between the various types can give rise to new complex effects.

In a more general setup, the management problem cannot be restricted to the resource sector but must be considered in a wider context, with various economy-wide variables both affecting and being affected by the environmental and natural

resource sectors. To account for such considerations, we describe a framework that integrates natural resources and aggregate economic growth and use it to discuss additional effects of uncertainty (Sect. 47.4). In Sect. 47.5, we direct attention to the concept of irreversibility characterizing many resource management situations. Irreversible outcomes are particularly relevant when coupled with uncertainty, because they can otherwise be anticipated and avoided when so desired. Finally, we discuss briefly the case of Knightian uncertainty (Sect. 47.6) under which the underlying structure of uncertainty (e.g., the specification of the underlying distribution) is incompletely known.

47.2 The Canonical Resource Management Model

In a typical resource management situation, an initial resource stock Q_0 is to be exploited over some planning horizon $t \in [0, T]$, t being the running time index and T is the end of the planning period which may or may not be predetermined. At any instant of time, the remaining stock $Q(t)$ is given, and the exploitation rate $q(t)$ generates the instantaneous benefit $u(Q(t), q(t), t)$ and changes $Q(t)$ according to

$$\dot{Q}(t) \equiv dQ(t)/dt = G(Q(t), q(t), t) \quad (47.1)$$

A simple example of a stock dynamic process is obtained from the specification $G(\cdot) = R(Q) - q$, where $R(\cdot)$ represents natural recharge (growth, replenishment). For nonrenewable resources, for example, minerals, R vanishes at all times and $G = -q$.

An exploitation policy $\{T, q(t), t \in [0, T]\}$ generates the payoff

$$\int_0^T u(Q(t), q(t), t) e^{-\rho t} dt + e^{-\rho T} v(Q(T)) \quad (47.2)$$

where ρ is the time rate of discount and $v(\cdot)$ is the post-planning value (the present value at time T of the benefit stream over the post-planning period $t > T$). The policy is feasible if it satisfies some given constraints on T and on $\{Q(t), q(t), t \in [0, T]\}$, for example, T is given or restricted to a certain range, the stock $Q(t)$ is positive or bounded in some range, and $q(t) \geq 0$ for all $t \in [0, T]$. We denote by Γ the set of all feasible policies.

The optimal policy is the feasible policy that maximizes Eq. (47.2) subject to Eq. (47.1) given $Q(0) = Q_0$. The value of Eq. (47.2) obtained under the optimal policy is denoted $V(Q_0; \Gamma)$ and is called the value function. For brevity, the argument Γ is often dropped, leaving the initial resource stock as the sole argument of the value function.

The formulation of the resource management problem in this way started with Hotelling (1931) who considered exhaustible (nonrenewable) resources and characterized optimal extraction policies in different market settings, using the calculus of variations to verify economic reasoning. The development of optimal control and dynamic programming methods opened the way for a wide range of extensions, including the incorporation of uncertainty of various kinds and forms.

In real-world situations, uncertainty is likely to be present in each of the components of the resource management problem: the planning horizon T , the instantaneous benefit $u(\cdot, \cdot, \cdot)$, the discount rate ρ , the post-planning value $v(\cdot, \cdot)$, the recharge process $R(\cdot, \cdot)$, the initial reserve Q_0 , as well as the specification of the feasibility constraints. In this chapter, we survey different approaches to deal with uncertainties often encountered in resource management problems.

Before delving into extensions involving uncertainty, it is expedient to summarize the salient properties of the optimal policy of the canonical management problem formulated above. Suppose that at some time t the resource owner is offered the opportunity to increase the remaining stock $Q(t)$ by a marginal unit. What is the maximal amount the owner will be willing to pay (at time t) to realize this opportunity? The answer, obviously, is the contribution of the added stock to the resource value at time t , that is, $V'(Q(t)) \equiv \partial V(Q)/\partial Q|_{Q=Q(t)}$. Let $\lambda(t)$ represent this opportunity cost at time t when the remaining stock is $Q(t)$. The variable $\lambda(\cdot)$ comes under various names, including costate, shadow price, scarcity or royalty rent, and in situ value. By definition, it embodies the economic implications of stock changes, such as increasing extraction costs as the resource dwindles and the price of scarcity when a nonrenewable resource is nearing depletion.

Exploitation at the rate $q(\cdot)$ bears two effects. First, it provides the instantaneous gratification $u(\cdot)$. Second, it changes the available stock via Eq. (47.1), hence the potential to enjoy future gratifications. The (current value) Hamiltonian,

$$H(Q, q, \lambda, t) \equiv u(Q, q, t) + \lambda G(Q, q, t)$$

balances these two effects such that the optimal exploitation rate maximizes it at each point of time. The economic interpretation of this “maximum principle” is readily seen under the specification $G(Q, q, t) = R(Q) - q$ and when the maximization admits an internal solution, in which case the optimal rate q satisfies $\partial u/\partial q = \lambda$: Along the optimal path, the marginal benefit from exploitation should equal the shadow price of the resource, that is, the marginal cost of exploitation.

Once the $\lambda(\cdot)$ process is given, the Hamiltonian maximization determines the optimal exploitation rate and, via Eq. (47.1), the ensuing stock process for the entire planning period $t \in [0, T]$. Solving the management problem, then, requires the determination of the shadow price process, for which optimal control and dynamic programming are two approaches.

In many cases, the optimal stock process $Q(\cdot)$ approaches a steady state (perhaps only asymptotically when $T = \infty$), where exploitation and natural recharge just balance each other out. This is the case, for example, in infinite horizon, autonomous problems (where the time argument enters explicitly only via discounting) involving a single stock. In such problems, it has been shown that the optimal stock process is monotonic, hence (when bounded) must eventually converge to a steady state. Deriving the steady state is relatively easy even for problems that do not admit analytic solutions for the full dynamic evolution. Comparing the steady states under different conditions (model specifications, parameter values) provides a simple way to study the effects of changes in the underlying conditions on the optimal policy.

The canonical resource management problem has been studied extensively, and the relevant literature is vast. For detailed treatments, we refer to Clark (1976) and Dasgupta and Heal (1979) who discussed resource management in a variety of situations, emphasizing renewable and nonrenewable resources, respectively.

47.3 Resource Management Under Uncertainty

As mentioned above, uncertainty abounds in resource management situations. It is important to distinguish at the outset between two types of uncertainty, depending on its origin. The first type is due to the participants' (resource owners, users, regulators, etc.) limited knowledge of certain parameters or functional relations characterizing the resource and the economic systems under consideration. The second type is due to genuine random elements often encountered when dealing with Mother Nature. We refer to the former type as *ignorance uncertainty* and to the latter as *exogenous uncertainty*. For example, the recharge or instantaneous benefit may undergo an abrupt shift when the stock process crosses some threshold, but the exact location of this threshold is a priori unknown. There is nothing inherently random in the threshold parameter, except that it is unknown to the resource manager; hence, the uncertainty is due to ignorance. If, however, the abrupt regime shift depends also on exogenous environmental factors such as weather variables affecting the outburst of a pollution-induced disease, then its occurrence is triggered by the confluence of environmental conditions which are genuinely stochastic, and the uncertainty regarding the abrupt shift is exogenous. How to handle a particular source of uncertainty depends to a large extent on its type.

We proceed now to discuss the incorporation of uncertainty, considering in turn each component of the above canonical resource management model.

47.3.1 Uncertain T

Some resource management problems do not admit a natural completion time, in which case the planning horizon becomes infinite ($T = \infty$). In other cases, extraction must cease at a finite date T , while the considerations related to later periods are summarized in the post-planning value $v(Q(T))$. For example, mine developers

may be permitted to extract the mineral only until some given date T when their concession expires. Moreover, the depletion of nonrenewable resources (or of renewable resources like fisheries that can be exploited to extinction) marks the end of the planning horizon, which depends on the extraction policy. In these cases, the planning horizon is either given exogenously or is a decision variable which can be determined for any extraction policy. In either case, its incorporation within the management problem involves no uncertainty and poses no particular difficulty.

In many situations, however, T is subject to uncertainty. A prominent example is that of an unknown initial stock – a situation studied initially by Kemp (1976). In such cases, T is a random variable whose realization marks the depletion of the resource, at which time management shifts to the post-planning period. A slight extension of the term “depletion” to include situations in which the resource can no longer be exploited or becomes obsolete allows to associate T with an uncertain date of nationalization (Long 1975) or with the uncertain arrival of a backstop substitute (Dasgupta and Heal 1974; Dasgupta and Stiglitz 1981). Cropper (1976) presented the problem in an environmental pollution context, identifying T with the random triggering of various environmental catastrophes.

While the uncertainty in the cake-eating problem of Kemp (1976) is solely due to ignorance, the uncertainty in political (nationalization) or economical (technological breakthrough) events often involves genuine stochastic elements and is therefore exogenous. The distinction between the two types of uncertainty plays out most pronouncedly via the specification of the hazard rate function, measuring the probability density of the event occurrence (the realization of T) in the next time instant. In all of these variants, the management problem seeks to maximize the *expected* value of the objective Eq. (47.2) with respect to the distribution of T , and the latter closely depends on the type of uncertainty.

47.3.1.1 Ignorance Uncertainty

A common ignorance-uncertainty situation involves a catastrophic event triggered by the stock falling below some unknown threshold. Examples, in addition to Kemp’s cake-eating problem, include seawater intrusion into coastal aquifers (Tsur and Zemel 1995) and global warming-induced catastrophes (Tsur and Zemel 1996; Nævdal 2006). The hazard rate in this case measures the probability of crossing the threshold during the next time instant. If the stock process does not decrease (e.g., extraction does not exceed the natural recharge) or if the stock process was in the past strictly lower than its current level, the hazard vanishes (it is certain that the threshold will not be crossed in the next time instant). In contrast, decreasing stock processes proceed under risk of occurrence. This feature complicates the formulation and solution of the management problem. The situation is greatly simplified if only monotonic stock processes are allowed. It turns out that in many cases of interest the *optimal* stock process is indeed monotonic.

The characterization of the optimal monotonic stock process proceeds along the following steps. Let \hat{Q}^c be the optimal steady state of the risk-free (canonical) problem. Consider an initial stock $Q_0 < \hat{Q}^c$. Since it is not optimal to decrease the stock further even without the risk of triggering a damaging event, it is obviously

not optimal to do so under the event risk. The optimal process under occurrence threat, then, coincides with the (increasing) risk-free process and approaches a steady state at \hat{Q}^c .

Suppose that $Q_0 > \hat{Q}^c$. Then, the optimal stock process cannot increase. For if it increases, the monotonicity property implies that it will never decrease, in which case the hazard vanishes at all times and the problem reduces to that of the risk-free problem. But without the occurrence risk, the optimal stock process converges to \hat{Q}^c – a contradiction. So when $Q_0 > \hat{Q}^c$, the optimal stock process is nonincreasing.

Let X denote the unknown threshold stock with the probability distribution $F(Q) \equiv Pr\{X \leq Q\}$ and the corresponding density $f(Q) = F'(Q)$. For a decreasing stock process, the distribution

$$F_T(t) \equiv Pr\{T \leq t\} = Pr\{X \geq Q(t)\} = 1 - F(Q(t))$$

and the density

$$f_T(t) = F'_T(t) = -f(Q(t))\dot{Q}(t)$$

of the random occurrence time T determine the expected payoff (the expectation of Eq. (47.2) with respect to T). This expected payoff defines the objective of a deterministic management problem, denoted the “auxiliary” problem, which also admits a monotonic optimal stock process that converges to a steady state $\hat{Q}^{aux} > \hat{Q}^c$. It turns out that the resource management problem under uncertain threshold splits into two distinct deterministic subproblems, depending on the initial stock: For $Q_0 < \hat{Q}^c$, the optimal stock process is the same as the increasing *risk-free* process, and the occurrence risk can be ignored; for $Q_0 > \hat{Q}^{aux}$, the optimal process coincides with the decreasing *auxiliary* process, and the occurrence risk is relevant. If $Q_0 \in [\hat{Q}^c, \hat{Q}^{aux}]$, the uncertainty process enters a steady state instantly (at the initial state Q_0) because any other policy is ruled out by the above considerations. The *steady state interval* $[\hat{Q}^c, \hat{Q}^{aux}]$ is a peculiar feature, unique to optimal behavior under ignorance uncertainty.

Note the prudence implications of this characterization: Decreasing stock processes turn on the occurrence risk and hence approach a higher (and safer) steady state than that obtained without occurrence risk. Another interesting observation relates to the role of learning in this model. Decreasing stock processes provide new information regarding the threshold location as these processes proceed. This information, however, is already accounted for by the auxiliary objective, and the resource owners have no reason to update the original policy (designed at $t = 0$) as the information accumulates, unless the process is interrupted at some time by the catastrophic occurrence.

47.3.1.2 Exogenous Uncertainty

Under exogenous uncertainty, the event is triggered by genuinely random conditions, and the probability of occurrence within the next time instant is measured by the hazard rate (Long 1975; Cropper 1976; Heal 1984). The hazard rate in this case

depends neither on the history of the process nor on its trend (increasing or decreasing); hence, the splitting of the uncertainty problem into two distinct sub-problems (that gave rise to the equilibrium interval under ignorance uncertainty) does not occur. The hazard rate can, however, depend on the current resource stock and exploitation rate, which allows the owners to affect, even if not avoid completely, the risk of future occurrence by adjusting the extraction policy. This type of events has been assumed in a variety of resource models, including Deshmukh and Pliska (1985) who studied exploitation and exploration of nonrenewable resources, Reed and Heras (1992) in the context of biological resources vulnerable to a catastrophic collapse, Clarke and Reed (1994) and Tsur and Zemel (1998) in the context of pollution control, Cropper (1976) and Aronsson et al. (1998) who considered the risk of nuclear accidents, and Gjerde et al. (1999) and Bahn et al. (2008) in the context of climate policies under risk of environmental catastrophes.

Given the stock process $Q(\cdot)$, the stock-dependent hazard process $h(\cdot)$ is related to the probability distribution and density of the event occurrence time, $F(t) = Pr\{T \leq t\}$ and $f(t) = F'(t)$, according to

$$h(Q(t))\Delta \equiv Pr\{T \in (t, t + \Delta) | T > t\} = \frac{f(t)}{1 - F(t)} \Delta$$

Thus, $h(Q(t)) = -d \ln(1 - F(t))/dt$; hence,

$$F(t) = 1 - e^{-\int_0^t h(Q(s))ds} \quad \text{and} \quad f(t) = h(Q(t))[1 - F(t)]$$

The expectation (with respect to T) of the objective Eq. (47.2) becomes

$$\int_0^\infty [u(Q(t), q(t), t) + h(Q(t))v(Q(t))]e^{-\int_0^t [\rho + h(Q(\tau))]d\tau} dt \quad (47.3)$$

The optimal policy is the feasible policy that maximizes the objective Eq. (47.3) subject to Eq. (47.1) and $Q(0) = Q_0$. In this way, the uncertainty problem is recast as a standard deterministic infinite horizon problem. Its optimal policy is relevant only as long as the event has not occurred. Once the event occurs, the optimal policy switches to that of the post-event problem (represented by the post-event value v).

The event occurrence risk affects the resource management problem via the hazard rate, which enters the objective Eq. (47.3) both in the discount rate and in the instantaneous benefit ($u + hv$). The discount rate increases from ρ to $\rho + h$ with two conflicting effects. First, the increased impatience (due to the higher discount rate) promotes aggressive exploitation (less conservation). Second, the discount rate $\rho + h(Q)$ turns endogenous through its dependence on the stock. The possibility to control the discount rate via the extraction policy typically encourages conservation, and the trade-offs associated with the discounting effect are represented by the hazard rate of change $h'(Q)/h(Q)$.

The other effect of the occurrence threat on the management problem comes through the $h(Q)v(Q)$ term, which is added to the instantaneous benefit in the objective Eq. (47.3). When this term depends on the stock, the resource owners can control the expected damage of the event by adjusting the extraction policy. The overall uncertainty effect results from balancing these conflicting trends. In a particularly simple example, the post-event value $v(\cdot)$ vanishes identically at all Q levels. This is the case, for example, when the event occurrence renders the resource obsolete with no further consequences or when it is possible to renormalize the instantaneous benefit in such a way that the post-event value vanishes (see, e.g., Tsur and Zemel 2009; Karp and Tsur 2011). In this case, only the discounting effects remain. When the hazard is independent of the stock, only the impatience effect is active, and the ensuing optimal policy entails more aggressive exploitation than its risk-free counterpart: If the world may come to an end tomorrow and there is nothing we can do about it, we may as well exploit the resource today while we can. However, if the hazard is sensitive to the resource stock, such that more exploitation increases the occurrence probability, then the endogeneity of the discount rate encourages conservation. Which of these effects dominates depends on $h'(Q)/h(Q)$ (see discussion in de Zeeuw and Zemel 2012).

A slightly more general formulation describes the post-event value $v(\cdot)$ in terms of a penalty inflicted upon occurrence. Tsur and Zemel (1998) distinguish between single occurrence and “recurrent” events. The latter entails multiple penalties inflicted each (random) time the event occurs. For penalty functions that decrease with the stock, both types of events imply more conservative exploitation vis-à-vis the risk-free policy. A prominent example of recurrent events is the case of forest fires which affect forest rotation management (see Reed 1984).

Events that impact ecosystems often entail abrupt changes in the system dynamics. The post-event value in such cases is the outcome of the (risk-free) post-occurrence optimization problem proceeding under the new regime. When the change in dynamics implies a loss (e.g., via reduced natural replenishment of the resource), the extraction policy under uncertainty is more conservative than its risk-free counterpart (see Polasky et al. 2011 and references they cite). In fact, the discrete regime shift is in many cases a simplified description of the actual complex non-convex dynamical processes which give rise to fast transitions among locally stable basins of attraction and to hysteresis phenomena. However, when our interest is focused on the economic implications of the shift (rather than on the exact dynamics driving it), this simplification can yield interesting insights.

Catastrophic events of global nature, such as those induced by global warming, are often exogenous to local decision units (countries, regions). In such cases, the occurrence hazard is taken parametrically by the decision maker. The damage inflicted by the event, however, may change across locations, with particular grave outcomes to some specific nations. A possible response by local governments to this state of affairs is to consider adaptation activities in order to reduce or eliminate the damage that will be inflicted by the event, should the mitigation efforts (via reduced exploitation) fail to avoid its occurrence. The adaptation activities entail some given costs, while the benefit (of reduced damage) will be

enjoyed only following the (uncertain) occurrence date. The optimal adaptation policy should balance these costs and benefits (see de Zeeuw and Zemel 2012 and references therein). When the occurrence probability can be affected by mitigation policies, the two policy measures interact strongly and must be considered simultaneously to obtain optimal outcomes. Indeed, the mere presence of the adaptation option can modify the extraction policy even prior to the actual implementation of this option.

Our discussion has focused on unfavorable events such as environmental catastrophes. Favorable events, for example, technological breakthroughs, can be modeled in a similar way. Early studies of the uncertain arrival of a backstop substitute for nonrenewable resources with R&D efforts include Dasgupta et al. (1977), Kamien and Schwartz (1978) and Davison (1978). Bahn et al. (2008) considered such events in a renewable resource context of a climate policy that includes R&D efforts to develop clean energy technologies.

47.3.2 Stochastic Stock Dynamics

The dynamics of resource stocks is often driven by stochastic elements. Examples include biomass growth subject to random shocks, the replenishment of groundwater aquifers under uncertain precipitations, atmospheric pollution decay varying with changing weather conditions, and oil and mineral reserves subject to uncertain discoveries. The random shocks can come in the form of an ongoing stream of small fluctuations or as abrupt and substantial discrete occurrences. The latter show up, for example, when the resource evolution process undergoes a regime shift which entails the uncertain T scenario discussed above. Here we consider the continuous flow of small fluctuations giving rise to a diffusion (or random walk) process. As before, uncertainty regarding the stock evolution may be due to genuine random environmental shocks (Reed 1979; Pindyck 1984) or due to incomplete information. For example, the resource owners may be unable to measure the current stock precisely or to follow exactly the optimal extraction rule, leading to errors in predicting the next period's stock (Clark and Kirkwood 1986).

Reed (1974, 1979) considered a biomass stock (e.g., fish population) Q_t following the discrete-time natural growth rule

$$Q_{t+1} = Z_t R(Q_t)$$

where $R(\cdot)$ is the *expected* stock recruitment and Z_t are independently and identically distributed unit-mean random variables representing stochastic shocks affecting the population growth in each reproduction season. The resource stock is revealed following the realization of Z_t , yet the future evolution of the stock process cannot be predicted. In general, the concept of a steady state must be replaced by that of steady state distribution. However, if the realizations of the random shocks are observed before harvest decisions are made, the optimal policy maintains a constant escapement (postharvest biomass), that is, the optimal steady state

distribution of escapement degenerates to a constant (Reed 1979). When additional sources of uncertainty (e.g., errors in the measurement of current stocks) are added, the constant escapement rule no longer holds (see Sect. 47.3.6). A similar stochastic growth rule has been used by Weitzman (2002) to compare fishery regulation via landing fees with (the more common) harvest quota. He found that the former measure is more effective in this case. Observe that stochastic dynamics is not restricted to the population growth of some biological stock but might be relevant also to nonrenewable mineral stocks as a result of dedicated ongoing exploration efforts for new reserves with uncertain outcomes (Mangel 1985; Deshmukh and Pliska 1985).

Pindyck (1984) formulated the resource management problem under stochastic stock evolution in continuous time, employing Itô's stochastic calculus. The stock evolution follows a diffusion process which evolves according to the stochastic differential equation

$$dQ = [R(Q) - q]dt + \sigma(Q)dZ \quad (47.4)$$

where Z is a standard Wiener process and $\sigma^2(\cdot)$ is the corresponding variance. Specifying $\sigma(Q) = \sigma Q$, with σ a given constant, gives rise to a geometric Brownian motion and greatly facilitates the analysis. Taking again the expected cumulative net benefit as the objective for optimization, one can employ stochastic dynamic programming to derive the optimal extraction rule $q(Q)$ and the associated steady state distribution. The prudence implications for this type of uncertainty are again ambiguous and depend on the properties of the recharge and benefit functions (see Pindyck 1984 for examples in which the optimal exploitation rule $q(Q)$ increases, remains unchanged, or decreases as the variance parameter σ is increased).

Other examples of resource management under stochastic stock dynamics include Plourde and Yeung (1989), Knapp and Olson (1995), and Wirl (2006). The former considers pollution control when the accumulation process is stochastic due to the random absorption capacity of the ecosystem and finds that a user charge on inputs is preferable to the common "pollution standards" approach. This result is similar to that obtained by Weitzman (2002) in the discrete time setting. The second paper studies groundwater management with stochastic recharge due to uncertain precipitation, while the third studies climate policies under a stochastic global temperature process.

47.3.3 Discounting

Effects of discount rate variability are most pronounced when consequences of resource exploitation extend far into the distant future, such as in climate change or in nuclear waste disposal problems. In such cases, even slight changes in the discount rate entail exceedingly large differences in the weight assigned to the well-being of generations in the distant future and on optimal policies.

The discount rate changes with time preferences and technological shocks. Uncertain discounting due to future technological shocks has been analyzed in a number of works (see Gollier and Weitzman 2010 and references therein). Based on the discount rate distribution, an expression for the effective discount rate is derived and shown to decline gradually over time, approaching the lower end of the distribution in the long run. This feature can have large effects on optimal policies since it weighs the far future much more heavily than under the standard constant-rate discounting.

In light of the large variability observed in intragenerational time preferences, it is expected that the same holds for time preferences across generations. Thus, the time preferences of future generations are highly uncertain. These preferences depend on economic performance, technological progress, and availability of resources in the far future, and the treatment of the associated uncertainty requires integrating the canonical resource model of Sect. 47.2 within an economy-wide model. These issues are considered in Sect. 47.4.

47.3.4 Instantaneous Benefit

The flow of instantaneous benefit is also likely to be influenced by uncertain shocks, some of which are in the form of a stochastic diffusion process, while the others are substantial and abrupt. An example of the latter is a sudden drop of the demand for the resource as a result of a technological breakthrough (e.g., the effect of the development of fiber-optics communication on the demand for copper transmission lines). Such discrete shocks can be discussed in the context of uncertain time horizon T . A benefit diffusion process can be driven by a stochastic stock evolution (via the dependence of $u(\cdot)$ on the stock Q) as discussed in Sect. 47.3.2 or by benefit-specific fluctuations. An example of the latter is the stochastic demand for a nonrenewable resource introduced by Pindyck (1980).

Tsur and Graham-Tomasi (1991) studied renewable groundwater management when the demand for the resource fluctuates with rainfall. They distinguished between two information scenarios, depending on whether groundwater extraction decisions are made before or after the rainfall realization is observed. They also considered the reference case in which rainfall is stable at the mean. By comparing these three scenarios, they have been able to define the value of groundwater (the “buffer value”) due to its role in mitigating the fluctuations in water supply.

Conrad (1992) considered the control of stock pollutants when the pollution damage follows geometric Brownian motion, while Xepapadeas (1998) incorporated stochastic benefit shocks within a climate change model. The pollution stock process (atmospheric greenhouse gas concentration) is assumed to follow deterministic dynamics, but the damage it inflicts is modeled again as a diffusion process. The model considers a group of countries with deterministic private emissions and a stochastic public damage which depends on the global stock of pollution. The problem of coordinating emission abatement is analyzed via the optimal stopping methodology under cooperative and noncooperative modes of behavior on part of the participant countries.

47.3.5 Post-planning Value

The post-planning value determines the loss associated with occurrence hence the degree of effort that is optimally invested in avoiding the event or reducing its occurrence hazard. Uncertainty regarding this value is similar to that associated with the preplanning regime, such as uncertain post-planning stock dynamics or instantaneous benefit. For example, Goeschl and Perino (2009) study R&D efforts to develop a backstop substitute for a polluting resource. The exact nature of the substitute is subject to uncertainty, as it is not known in advance whether the backstop technology will also turn out eventually to be harmful to the environment (a “boomerang”) in which case yet another technology will need to be developed later on or it will solve the pollution problem for good. They show how the probability of either outcome affects the timing of adoption of the new technology.

Problems of long time horizons, such as global climate change, exacerbate the uncertainty regarding the post-planning value. Even if we knew precisely the temperature change a century ahead, it would be extremely hard to estimate the damage such a change would inflict on a future society which will surely differ greatly in its economic, technological, and demographic characteristics from what can be observed or predicted at the present time. Integrated assessment models, discussed in Sect. 47.4 below, deal with this kind of uncertainty in an ad hoc fashion.

47.3.6 Compound Uncertainties

The various uncertainty types presented above drive different responses in terms of the changes induced relative to the canonical certainty policy, with the *sign* of the change depending on the particular type under consideration. It is often of interest to study how the *magnitude* of these changes depends on uncertainty, when the latter is measured, for instance, by the variance of a related key parameter (e.g., the parameter σ^2 of Eq. (47.4)). Typically, each source of uncertainty drives the policy along a well-defined trend, and the effect responds monotonically to changing uncertainty. However, many resource management problems are subject to the combination of more than one type of uncertainty. When two (or more) types of uncertainty are combined, the policy response becomes more involved than in the case of a single type because the interaction between the types can give rise to new phenomena. Aiming to account for such situations, Clark and Kirkwood (1986) combined Reed’s (1979) discrete stochastic fish stock dynamics with measurement errors on the stock size at the beginning of each harvesting period, while Sethi et al. (2005) added a third component, namely, the inaccurate implementation of the harvest policy in each period. They showed that Reed’s (1979) constant escapement rule is no longer optimal when harvest decisions are made before realizations of the random shocks are observed, in which case the optimal policy may not admit analytic solution and the planner must resort to numerical methods.

The effect of the interactions among different types of uncertainty is evident in the work of Saphores (2003) who considered stochastic stock dynamics under the threat of extinction if the biomass hits a barrier and found a non-monotonic response to increasing the stochastic variance: The increase in variance implies more precaution when the variance is small but calls for more aggressive harvesting when the variance is large enough. More recently, Brozović and Schlenker (2011) obtained a similar outcome when the stochastic stock dynamics is combined with the risk of an abrupt shift in ecosystem dynamics. These models allow the planner to take actions at discrete points of time, and the non-monotonic behavior is attributed to changes implied by increasing the variance on the trade-off between reducing the shift probability vs. the cost of precautionary behavior.

Leizarowitz and Tsur (2012) studied optimal management of a stochastically replenished (or growing) resource under threat of a catastrophic event such as eutrophication (of shallow lakes), species extinction, or ecosystem collapse. They considered discrete time and discrete state and action spaces. The catastrophic threat renders the single-period discount factor policy dependent, and as a result the compound discount factor becomes history dependent. The authors investigated whether an optimal Markovian-deterministic stationary policy exists for this problem. They answered this question in the affirmative and verified that the optimal state process converges to a steady state distribution. They identified cases under which the steady state distribution implies that the event will eventually occur with probability one and contrasted them with cases under which the catastrophic event will never occur.

Employing a continuous-time formulation, Yin and Newman (1996) combined a stochastic output price process (as in Conrad 1992) with the catastrophic forest fires of Reed (1984) and found that the risk of fire entails different responses depending on whether the fire is a single event that prevents further exploitation or investments and fires can reoccur. In a similar framework, Balikcioglu, Fackler, and Pindyck (2011 and references therein) combined the stochastic pollution stock dynamics (analogous to Eq. (47.4)) with stochastic uncertainty regarding the damage inflicted by this stock (as in Xepapadeas 1998). The optimal response is analyzed again via stopping theory, and the complexity introduced by the dual source of uncertainty necessitates the development of a sophisticated numerical method of solution.

Zemel (2012) provides an analytic, continuous-time confirmation of the non-monotonic response by incorporating the uncertain regime shifts of de Zeeuw and Zemel (2012) into the stochastic stock model Eq. (47.4). It is verified that the simultaneous action of both types of uncertainty is indeed required to obtain this behavior. When one or the other sources of uncertainty are switched off, the other acts to promote conservation (as expected). However, when the two sources interact, increasing the stochastic variance enhances the hazard effect when the variance is small but works in the opposite direction when the variance is large. In a world of multiple sources of uncertainty, it is therefore likely that non-monotonic response is more common than the simple, single-uncertainty-type models would suggest.

Obviously, combining several uncertainty sources greatly complicates the management problem, and one usually has to resort to numerical methods to derive the optimal policy. This is the approach adopted by the integrated assessment models discussed in Sect. 47.4 below.

47.4 Integrating Natural Resources and Aggregate Growth Models

Some uncertain elements affect resource exploitation indirectly via their influence on economy-wide variables. Examples include the intra- and intergenerational variability of time preferences and technological shocks. Accounting for these uncertain elements requires incorporating the canonical resource model of Sect. 47.2 within an economy-wide (growth) framework. The approach taken in this section is in line with the views of ecological economists who have pointed out that problems of economic growth cannot be decoupled from the constraints imposed by the embedding environmental system. We briefly outline an integrated model of this kind and use it to discuss additional effects of uncertainty.

47.4.1 An Integrated Model

An important (though not the only) role of natural resources is to serve as sources of production inputs. Accordingly, suppose the extracted resource q is used as an input of production alongside capital K and human capital augmented labor AL (A is an index of human capital and L represents the labor force) to produce the output Y according to the technology $Y = F(K, q, AL)$. The wealth of an economy is measured by its stocks of natural capital Q , producible capital K , and human capital A . The former changes according to Eq. (47.1) and K changes according to

$$\dot{K} = F(K, q, AL) - C - z(Q, q) - \delta K \quad (47.5)$$

where C is aggregate consumption, δ is a depreciation parameter, and $z(\cdot)$ is the extraction cost. (In the canonical model of Sect. 47.2, $z(Q, q)$ is embedded in the instantaneous benefit $u(Q, q, t)$, which is here replaced by the consumption utility.) The evolution of human capital may be driven by exogenous labor-augmenting technical change processes or by endogenous policies. Equation (47.5), then, can be viewed as a variant of a Solow-type growth model.

Per capita consumption, $c = C/L$, generates the per capita instantaneous utility $u(c)$, and welfare is measured by the present value of the utility stream

$$\int_0^T Lu(c)e^{-\rho t} dt + e^{-\rho T} v(Q(T)) \quad (47.6)$$

where ρ is the utility discount rate which discounts future consumption solely due to the passage of time and should be distinguished from the interest rate r (the price of capital). The resource allocation problem requires to find the feasible consumption-exploitation-investment policy that maximizes the welfare Eq. (47.6) subject to the dynamic evolution of the capital stocks, given the endowment Q_0 , K_0 , and A_0 . More general variants of this model allow for multiple resources and for an explicit dependence of the utility also on some of the stocks (e.g., a clean environment or the preservation of species; see Heal and Kriström 2002 and references therein)

In equilibrium the optimal policy follows (under some conditions) Ramsey's formula $r = \rho + \eta g$, where η is the elasticity of marginal utility and g is the rate of growth of per capita consumption. This condition varies with intergenerational variations in preferences (ρ and η) and in the growth rate (g). The "correct" rate to be used is controversial (see Stern 2008; Nordhaus 2008, and references therein), and the controversy is exacerbated by the uncertain future evolution of these variables.

47.4.2 Uncertainty in the Integrated Model

The integrated model allows us to address a wider range of uncertainties as well as to study feedback effects between natural resources and the wider economy. For example, Tsur and Zemel (2009) looked at the effect of economic growth on climate policy regarding greenhouse gas (GHG) emission under threat of a catastrophic climate change whose occurrence probability depends on atmospheric GHG concentration. They found that economic growth motivates more vigorous mitigation of GHG emission such that in the long run anthropogenic GHG emission (beyond the natural rate) should be banned altogether. The reason is rather straightforward: As the economy grows richer, it stands to lose more in case the catastrophe strikes, while at the same time it can more easily afford to relinquish the resources needed to use and develop clean substitutes. What is less obvious is that, due to the global public bad nature of the threat induced by atmospheric GHG concentration, the market outcome gives rise to the opposite allocation, namely, maximal (in economic terms) use of polluting fossil fuels. Such an interaction between an economy-wide phenomenon, in the form of economic growth induced by technical change, and resource exploitation affecting the probability of triggering a damaging event can be addressed only within an integrated framework.

As integrated models (particularly those aiming at describing faithfully the real world) tend to be analytically intractable, they call for the use of numerical analysis. Examples are the so-called integrated assessment models that link together climate and aggregate growth models (see Stern 2008; Nordhaus 2008, and references therein). Uncertainty in these models is often treated by considering a distribution for each of the unknown parameters and deriving the results for a large number of "scenarios", each corresponding to a particular parameter specification. The results are then reported in terms of the most likely values as well as of some measure of their spread.

47.5 Irreversibility and Uncertainty

A ubiquitous feature of environmental management problems is the irreversibility characterizing many natural processes. This feature can come in the form of the abrupt catastrophic occurrences discussed above (examples of which are the reversal of the flow of the Gulf Stream due to global temperature rise, species extinction due to overharvesting or habitat destruction, the collapse of groundwater aquifers due to seawater intrusion, or the eutrophication of lakes as a result of the use of fertilizers along their shores). Otherwise, some of our actions (polluting emissions, forest clearing, or the extraction of exhaustible resources) cannot be undone (or can be corrected very slowly) when an unfavorable outcome is realized. These irreversible regime shifts are manifestations of non-convexities in the dynamic equations that drive the underlying natural processes. This feature implies fast transitions among competing stable equilibria and hysteresis phenomena. As stated above, the simplified description of these phenomena as irreversible transitions provides a useful approximation to derive the management policies.

The presence of irreversibility really matters only under uncertainty, because otherwise undesirable outcomes can be anticipated in advance and avoided. Heal and Kriström (2002), Pindyck (2007), and the references they cite discuss in detail the effect of irreversibility on management policies under uncertainty. Presenting the problem in terms of the theory of real options, they identify two diametrical effects. If the damage associated with occurrence will turn out in the future to be very large, then exercising the option of aggressive extraction today entails a significant social loss. This effect pushes the cost-benefit balance towards more conservation. However, abatement activities often involve sunk costs (e.g., the purchase of abatement equipment that can be used only for that purpose) which give rise to the opposite effect. If it eventually turns out that the occurrence hazard or the associated damage has been overestimated, the abatement investment cannot be undone, and failing to exercise the option to wait and learn more about the hovering threat might turn out costly.

The irreversibility-induced trade-offs are particularly pronounced in optimal stopping problems (e.g., Balıkcıoğlu et al. 2011 and the references they cite) where the problem is to determine the optimal time to enact an irreversible change in policy (e.g., reduce emissions) at a sunk cost when the pollution and damage processes follow stochastic dynamics. This regime shift problem is reminiscent of the uncertain regime shift time T discussed in Sect. 47.3.1. Here, however, the time of shift is the decision variable rather than an exogenous parameter subject to uncertainty. Optimal stopping has also been used to study the optimal time to invest in R&D efforts aimed at developing a substitute for a nonrenewable resource (Hung and Quyen 1993) or for a polluting technology (Goeschl and Perino 2009).

Wirl (2006) considered the consequences of two types of irreversibility on optimal CO₂ emission policies when the temperature follows a diffusion process. First, emissions are irreversible in the sense that active collection of the polluting gases out of the atmosphere is not allowed. Moreover, stopping is irreversible so that once the decision to stop emissions is taken, it cannot be reversed. He found that these effects work against conservation and that irreversible stopping is never optimal.

47.6 Knightian Uncertainty

The literature cited so far treats uncertainty by converting random variables into expectations based on well-specified distribution functions. Often, however, the distribution functions themselves are only partially known – a situation referred to as Knightian (or structural) uncertainty. For example, as perceived at present, future growth rates may be random with unknown mean and/or standard deviation. When realizations of an informative random variable are progressively observed, the underlying distribution can be deduced via Bayesian updating with progressive levels of accuracy.

However, if the downside of possible outcomes (e.g., the consequences of a climate change induced catastrophe) is not bounded, the expected present value may be unbounded as well for any incomplete information (finite number of observations) underlying the Bayesian updated (posterior) probabilities. This situation was illustrated by Weitzman (2009) in a two-period model in which growth is random (due to a random climate parameter) with a distribution that is known only up to a scale parameter. The analysis points to the potential limitations of combining expected utility theory and Bayesian updating in analyzing decisions under uncertainty in general and for resource management in particular. Alternative approaches, involving the precautionary principle and ambiguity-averse learners, have recently been considered for resource management problems (see Vardas and Xepapadeas 2010 and references therein).

47.7 Conclusions

The proper response to uncertainty has become a prevailing consideration in the resource management literature, and the survey in this chapter attempts to expose the diversity of approaches developed for this purpose. A necessary step in dealing with uncertainty is the recognition that uncertainty is present in nearly every aspect of a resource management problem and that different types of uncertainty call for policy responses that may differ substantially and in some cases even diametrically. For example, some types of uncertainty encourage more conservation and cautious exploitation, while other types induce the opposite response – of a more vigorous exploitation (relative to the comparable situation managed under certainty).

Although our aim was to cover the wide range of stochastic aspects relevant for environmental and natural resources management, it is recognized that a comprehensive treatment is not feasible within the limits of a single chapter and some important aspects had to be left out. For example, environmental resources are often shared by several agents, and their management is subject to strategic interactions among competing stake holders. These interactions are usually studied via the theory of dynamic games and involve again uncertainty of various types, including that due to asymmetric information among players (see Dockner et al. 2000 and the literature cited therein). The treatment of this important and complex topic is beyond the scope of this chapter.

Abstract

We cover applications of game theory in environmental and resource economics with a particular emphasis on noncooperative transboundary pollution and resource games. Both flow and stock pollutants are considered. Equilibrium concepts in static and dynamic games are reviewed. We present an application of game theoretical tools related to the formation and sustainability of cooperation in transboundary pollution games. We discuss the analytical tools relevant for the case of a stock pollutant and offer an application related to the optimal institutional arrangement to regulate a pollutant when several jurisdictions are involved.

48.1 Introduction

Static and dynamic games have offered important tools to study many strategic interactions in natural resource and environmental economics as well as regional science and management science. The main difference between static games and dynamic games is that the latter deal with situations where economic agents operate in an environment that changes over time and agents can influence the evolution of the environment.

In analyzing any problem of strategic interactions, it is usually better to begin with the simplest model. This often means that one should, as a first step, abstract from dynamic considerations. Static game theory is sufficiently rich to shed lights on many scenarios of social and economic interactions. On the other hand, many problems in economics are temporal problems by nature, and eventually the temporal dimension must be taken into account. For this reason, dynamic game models are often encountered in scientific journals in fields such as resource and environmental economics and regional and urban economics.

Some warnings are in order. The environmental economics literature with a special interest in strategic behavior between regions is large. Since this chapter seeks to be self-contained, and given the space limitation, the material presented should be seen as a sample of the application of game theoretic tools to important classes of regional environmental and resource economics problems in a multi-region context. In particular we shall omit applications of cooperative game theory and only present a selection of noncooperative game theoretic models. For recent surveys of applications of game theory in environmental economics, we refer the reader to Jorgensen et al. (2010) and Long (2011).

In Sect. 48.2, we consider within a static model the issue of environmental agreements. In Sect. 48.3, we turn to dynamic games with simultaneous moves and briefly explain various equilibrium concepts in dynamic games. In Sects. 48.4 and 48.5, we provide illustrations of these concepts applied to problems of natural resources and environmental economics with a multi-region setting.

48.2 Static Games

Static game theory is better suited for transboundary pollution problems involving emission and where a few players interact strategically. We present an application of game theoretical tools related to the formation and sustainability of cooperation in pollution games. We review emission games and abatement games and the comprehensive analytical treatment by Rubio and Ulph (2006) of the canonical model of international environmental agreements initiated by Barrett (1994).

We begin with a noncooperative game of emissions. Then we turn to the question of how cooperation can be achieved and an analysis of stable coalitions.

Note that while the models are presented in the case interaction among countries, they apply also to the case of a single country made of several regions with autonomous regulatory powers over pollution and resource use, as is the case in

many countries. The main feature of these problems is the absence of a supranational authority or the lack of constitutional power of a central authority such as a federal government.

48.2.1 The Emissions Game

Consider a world consisting of N countries $i = 1, \dots, N$. A strategy for country i is a nonpositive level of emissions $q_i \geq 0$. Country i derives a net benefit flow

$$\pi_i(q_i, Q_i) \equiv aq_i - \frac{b}{2}q_i^2 - \frac{1}{2}(q_i + Q_{-i})^2$$

where $Q_{-i} \equiv \sum_{k \neq i} q_k$ and a and b are two positive parameters. The term $aq_i - \frac{b}{2}q_i^2$ measures the gross benefit from consumption, and the term $\frac{1}{2}(q_i + Q_{-i})^2$ measures the environmental damages each country suffers from the total emissions Q . Note that since the marginal damage from emissions is normalized to one, a large value of b represents a large marginal benefit or a small marginal damage cost.

Assuming countries choose their actions simultaneously, the unique Nash equilibrium strategy is

$$q_i = q^* = \frac{a}{b + N}$$

and the equilibrium payoff is

$$\pi^* = \frac{1}{2} \frac{(-N^2 + 2N + b)}{(N + b)^2} a^2$$

Let q^c denote the level of emissions that maximizes world welfare. Then,

$$q^c = \frac{a}{b + N^2} < q^* = \frac{a}{b + N}$$

Clearly, welfare under cooperation is higher than Nash equilibrium level,

$$\pi^c = \frac{1}{2} \frac{a^2}{N^2 + b} > \pi^* = \frac{1}{2} \frac{(-N^2 + 2N + b)}{(N + b)^2} a^2$$

$$\pi^c - \pi^* = \frac{1}{2} \frac{N^2(N - 1)^2}{(N^2 + b)(N + b)^2} a^2$$

Note that the gains from cooperation is decreasing in b . The gains from cooperation are most substantial when $b \rightarrow 0$.

The above game, analyzed in Rubio and Ulph (2006), is a game of pollution emissions, which can be compared with the abatement game of Barrett (1994). (There exists a correspondence between the emissions game and an abatement game (see Appendix 1 in Rubio and Ulph (2006)).)

48.2.2 Sustaining Cooperation in a Noncooperative World

We have shown that the noncooperative outcome is inefficient. Let us consider a possible improvement by some form of cooperation. Suppose a subgroup of the players considers coordination of their strategies to improve on their noncooperative equilibrium payoff. We define an international environmental agreement (IEA) as cooperation among M countries, where $M \geq 2$. Assuming the nonexistence of a supranational authority, we require any agreement to improve on the Nash equilibrium outcome to be self-sustaining.

We formulate an IEA game as a metagame where an emissions game (Or an abatement game) is preceded by an initial stage where countries decide whether to join a coalition or not. An IEA consisting of $M \leq N$ members chooses a vector of M strategies, one for each coalition member, to maximize the sum of their payoffs. When $M = N$, the coalition is called the grand coalition.

Several criteria of stability have been proposed in the theory of coalition formation. The predominant stability criterion in the IEA literature uses the concepts of internal and external stability. This criterion is based on the assumption that when a country considers the gain from defection, it supposes that all countries in the IEA would continue to cooperate and maximize their joint welfare. (An alternative stability criterion is that of farsighted stability (for more details and references, see Benchekroun and Long (2011) Sect. 48.4.2).)

Let $\pi^s(M)$ and $\pi^{ns}(M)$ denote the equilibrium payoffs of the representative signatory and non-signatory countries. We say that a given IEA with M members is internally stable if no signatory gains by leaving the IEA, i.e., $\pi^s(M) \geq \pi^{ns}(M - 1)$. Similarly, external stability means that a non-signatory does not gain by joining the IEA, i.e., $\pi^{ns}(M) \geq \pi^s(M + 1)$. An IEA is stable if and only if it is both internally and externally stable.

Once an IEA has been formed, in stage 2 game, one may consider two scenarios: (1) IEA members and non-signatories choose their actions simultaneously or (2) IEA members are the first movers, announcing and committing to their emissions policies before non-signatories can act. Most papers in the literature prefer the second scenario, i.e., the IEA members play a leadership role in the emissions game. We report below the analysis of the second scenario, following Rubio and Ulph (2006).

48.2.2.1 Stage 2: The Emissions Game Revisited

Using backward induction, let us first determine the reaction function non-signatories. Suppose the first M countries are signatories. A non-signatory country $k > M$ seeks to

$$\max_{q_k \geq 0} \left(aq_k - \frac{b}{2}q_k^2 - \frac{1}{2}(q_k + Q_{-k})^2 \right)$$

Its reaction function is

$$q_k = \max \left\{ \frac{a - Q_{-k}}{b + 1}, 0 \right\} \quad (48.1)$$

Knowing the reaction function of the non-signatories, the collection of signatories chooses their emissions to maximize the sum of their payoffs,

$$\max_{q_1, \dots, q_M \geq 0} \sum_{i=1}^M \left(aq_i - \frac{b}{2}q_i^2 - \frac{1}{2}(q_i + Q_{-i})^2 \right)$$

subject to the reaction function of the non-signatories. Under the symmetry assumption among coalition members, the maximization problem becomes

$$\max_{q_s \geq 0} M \left(aq_s - \frac{b}{2}q_s^2 - \frac{1}{2}(Mq_s + (N - M)q_{ns})^2 \right)$$

subject to

$$q_{ns} = \max \left\{ \frac{a - Mq_s}{b + N - M}, 0 \right\}$$

where q_s and q_{ns} denote respectively the emissions of a signatory and a non-signatory country.

Following Rubio and Ulph (2006), consider three possibilities, depending on interior or corner solutions. For this purpose, define

$$g(b, M) \equiv b^2 - (N - M)(M - 2)b + (N - M)^2$$

and

$$h(b, M) \equiv b^2 + (N + M^2 - 2M)b - (N - M)M$$

The three possible cases are as follows.

- (a) Interior solutions for all countries. This occurs if and only if $g(b, M) > 0$ and $h(b, M) > 0$. The interior solutions are given by

$$q_s = \frac{ag(b, M)}{bc\omega}$$

and

$$q_{ns} = \frac{ah(b, M)}{b\omega}$$

where

$$\omega \equiv \left((b + N - M)^2 + bM^2 \right)$$

The equilibrium payoffs are given by

$$\pi^s(M) = \frac{a^2}{2b} \left(1 - \frac{bN^2}{\omega^2} \right)$$

and

$$\pi^{ns}(M) = \frac{a^2}{2b} \left(1 - \frac{(b+1)N^2(b+N-M)^2}{\omega^2} \right)$$

(b) Corner solution for signatories. This occurs when $g(b, M) \leq 0$. Then $q_s = 0$ and

$$q_{ns} = \frac{a}{b + N - M}$$

with equilibrium payoffs

$$\pi^s(M) = -\frac{a^2(N-M)^2}{2(b+N-M)^2}$$

and

$$\pi^{ns}(M) = \frac{a^2(b - (N-M)(N-M-2))^2}{2(b+N-M)^2}$$

(c) Corner solution for non-signatories. This occurs if $h(b, M) \leq 0$. Then $q_{ns} = 0$ and

$$q_s = \frac{a}{M}$$

with equilibrium payoffs

$$\pi^s(M) = -\frac{a^2(b + M(M-2))}{2M^2}$$

and

$$\pi^{ns}(M) = -\frac{a^2}{2}$$

Fig. 48.1 Contour plot of $g(b, M)$ when $N=10$

Since functions g and h cannot be both negative, the configuration $q_s = q_{ns} = 0$ is not possible in a Stackelberg equilibrium. This is because the marginal benefit at zero pollution level is equal to $a > 0$, whereas the marginal damage of pollution at zero is nil. Finally, note that when $M = 1$ or $M = N$, the solution is interior.

Which solution occurs depends on b , N , and M . The creation of a coalition or a change in the size of a coalition can result in a change from an interior to a corner solution or vice versa. Therefore, before tackling the issue of coalition formation, it is important to clarify how the signs of the functions g and h depend on the model parameters. Rubio and Ulph fix N and study the sign of g and h as a function of b and M . The analysis can be summed up in the figures below. Figure 48.1 depicts the level curve $g(b, M) = 0$. The interior of convex region depicted represents all (b, M) such that non-signatories choose zero emissions. Figure 48.2 depicts the level curve $h(b, M) = 0$. The interior of region depicted represents all (b, M) such that signatories choose zero emissions.

48.2.2.2 Stage 1: The IEA Game

We now turn to the analysis of stable coalitions within the emissions game.

Proposition:

There exists $b_1(N)$, $b_2(N)$ such that:

- (a) If $b < b_1(N - 1)$, the unique stable IEA of the Stackelberg model with nonnegative emissions is the grand coalition (Proposition 3 in Rubio and Ulph (2006)).
- (b) If $b \in [b_2(N - 2), b_2(4) = N - 4]$, there exists an upper bound given by the smallest integer no less than n_3 that belongs to a self-enforcing IEA. This upper bound decreases with b (Proposition 4 in Rubio and Ulph (2006)).

Fig. 48.2 Contour plot of $h(b, M)$

- (c) If $N > 5$ and $b > N - 4$, the maximum level of cooperation that can be achieved by a self-enforcing IEA is three (Proposition 5 in Rubio and Ulph (2006)).
- (d) If b is large enough, the equilibrium is interior and the largest size of a stable coalition is 2.

From the result above, one can conjecture that the size of the largest stable IEA is a decreasing function of b .

Thus, it is possible to get the grand coalition as a stable IEA, and this occurs when b is small enough. The possibility of a stable grand coalition is due to the leadership advantage of the IEA. Emissions are strategic substitutes (i.e., best responses are downward sloping). This in itself gives an incentive for a leader to increase its quantities relative to the case where it moves simultaneously with the non-signatories. The instability in the scenario where countries move simultaneously is due to the reaction of the outsider who increases its emissions following the creation of the IEA of $(N - 1)$ members. When the IEA is a leader, it decreases its overall level of emissions by a smaller amount than if it were not a leader (in which case, it possibly increases its emissions), and therefore, the outsider's increase in emissions is smaller than under the simultaneous-move game (where an outsider possibly decreases its emissions). This moderate reaction of the outsider is the reason why a grand coalition can be stable under a leadership model.

The externality of pollution induces the IEA (the leader) to reduce its emissions relative to the Nash equilibrium. In fact it can be shown that under the Nash equilibrium, an IEA may well end up with higher its emissions, resulting in a decrease of non-signatory emissions (possibly to a zero level). This is more likely to happen when b is small which explains the sustainability of the grand coalitions for small values of b . It is important to note that in a Nash equilibrium, the payoff of

non-signatories is always larger than that of signatories and in a Stackelberg equilibrium, this is no longer necessarily true. Interestingly, the emissions game, the range of parameters (b, M) under which an IEA is sustainable, corresponds to the range where the gains from cooperation are the largest.

48.3 Dynamic Games: Some Concepts

Natural resource and environmental problems usually involve interactions in a changing physical environment. Therefore, dynamic games are well suited for the analysis of many resources and environmental problems. (For a recent comprehensive survey of dynamic games in the economics of pollution, see Jorgensen, Martin-Herran, and Zaccour (2010). Long (2011) surveys dynamic games in natural resources.) Dynamic games are also called state-space games. In a state-space game, the environment is represented by a vector of state variables, which directly or indirectly affect the payoffs of agents. Agents influence the evolution of the state variables by using their control variables.

A dynamic game can be formulated in discrete time or in continuous time (see Long (2010, 2011) for surveys of models of both types). A dynamic game normally displays the following properties. Players receive a flow of benefits every period (or at every point of time). The overall payoff for a player is the sum (or integral) of his discounted flow of benefits over the time horizon. The benefit flow that a player receives in a period may depend on the current actions taken and on the “state of the system” in that period, as represented by the state variables. The state of the system changes over time, depending on the actions of the players. A difference equation or a differential equation describes the rate of change of each state variable.

The term “differential games” is broadly interpreted to include both dynamic games in continuous time and those in discrete time, where the evolution of each state variable is described by a difference equation.

Below is a description of a differential game in continuous time (see Dockner et al. (2000) for a more precise formulation). Time is represented by t . The game starts at time zero and ends at time T . There are n state variables, denoted by x_i where $i = 1, 2, \dots, n$. The vector of state variables is $x = (x_1, x_2, \dots, x_n) \in X \subseteq R^n$. The set $S \equiv X \times [0, T]$ is called the state-date space. An element (\mathbf{x}, t) is called a (state, date) pair. The number of player is an integer N . Player j has a vector of m control variables, denoted by u_j . Assume that $u_j(t) \in U_j \subseteq R^m$. We call U_j player j 's control space. Define $U \equiv \prod_j U_j$.

The evolution of the system is described by a system of s differential equations,

$$\dot{x}_i(t) = F_i(\mathbf{x}(t), \mathbf{u}_1(t), \mathbf{u}_2(t), \dots, \mathbf{u}_N(t), t), \quad i = 1, 2, \dots, n$$

where $x_i(0) = x_{i0}$ is given. In vector notation,

$$\dot{\mathbf{x}}(t) = \mathbf{F}(\mathbf{x}(t), \mathbf{u}_1(t), \mathbf{u}_2(t), \dots, \mathbf{u}_N(t), t)$$

Player j 's instantaneous flow of benefits at time t is

$$b_j(t) = B_j(\mathbf{x}(t), \mathbf{u}_1(t), \mathbf{u}_2(t), \dots, \mathbf{u}_N(t), t)$$

The time argument t will be suppressed when there is no risk of confusion. The overall payoff of player j is

$$\int_0^T e^{-r_j t} B_j(\mathbf{x}, \mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_N, t) dt + e^{-r_j T} S_j(\mathbf{x}_T, T)$$

where $S_j(x_T, T)$ is called the “salvage function” and $r_j \geq 0$ is the discount rate of player j .

A player can be a firm, or a government, or an individual, etc. Each player j maximizes its overall payoff. In order to do this, it must have some ideas about what other players are doing. A Nash equilibrium is a strategy profile such that each player’s strategy maximizes its own overall payoff given what is predicted for the other players. (We focus on the case of simultaneous-move games because of space limitations. Games where agents play sequentially are called Stackelberg games (see, e.g., Benckroun and Long (2011) Sect. 48.4.2 for more details on Stackelberg dynamic games in natural resource and environmental economics).) Such prediction depends on what strategy space each player is restricted to.

Consider two types of strategies: path strategies and Markovian decision-rule strategies (or feedback strategies). A path strategy (or open-loop strategy) p_j is a function that determines player j 's actions at each time t as a function of t and of the parameters of the model, including the initial stocks, but this function does not include the current value of the state variables. It is as if each player makes a commitment right at beginning of the game never to deviate from its planned time path of actions. Let P_j be the set of open-loop strategies that are available to player j . Let $P \equiv \prod_j P_j$. Once all players have chosen their open-loop strategies, the evolution of the state variables is described by

$$\dot{x}_i(t) = F_i(\mathbf{x}(t), \mathbf{p}_1(t), \mathbf{p}_2(t), \dots, \mathbf{p}_N(t), t), \quad i = 1, 2, \dots, n, x_i(0) = x_{i0}$$

or, in vector notation,

$$\dot{\mathbf{x}}(t) = \mathbf{F}(\mathbf{x}(t), \mathbf{p}(t), t), \quad \mathbf{x}(0) = \mathbf{x}_0$$

where

$$\mathbf{p}(t) \equiv (\mathbf{p}_1(t), \mathbf{p}_2(t), \dots, \mathbf{p}_N(t))$$

Assume this equation has a unique solution $x^*(t)$. The overall payoff for player j is then

$$W_j(\mathbf{x}_0, \mathbf{p}) = \int_0^T e^{-r_j t} B_j(\mathbf{x}^*(t), \mathbf{p}(t), t) dt + e^{-r_j T} S_j(\mathbf{x}_T^*, T)$$

Define an open-loop Nash equilibrium (OLNE) as a strategy profile $\widehat{\mathbf{p}} = (\widehat{\mathbf{p}}_1, \widehat{\mathbf{p}}_2, \dots, \widehat{\mathbf{p}}_N) \in P$ such that no player can make itself better off by choosing a different open-loop strategy, i.e.,

$$W_j(\mathbf{x}_0, \widehat{\mathbf{p}}) \geq W_j(\mathbf{x}_0, \mathbf{p}_j, \widehat{\mathbf{p}}_{-j}) \text{ for all } j$$

To find an open-loop Nash equilibrium, one uses the maximum principle to derive the necessary conditions of each player's optimal control problem, taking as given the time path of the vector of control variables of other players. Then one finds a fixed point $\widehat{\mathbf{p}}$ such that all the necessary conditions for all players are satisfied. Next one verifies that the sufficient conditions are satisfied at that fixed point.

One of the main advantages of the concept of open-loop Nash equilibrium is that such an equilibrium is relatively easy to find. Open-loop Nash equilibria are also attractive because they are time consistent. To see this, suppose the game is played and everyone has followed its Nash equilibrium strategy. Suppose at some time $t_1 > 0$, when the state vector takes on the value $x(t_1)$ as anticipated, player j asks itself whether it can make itself better off by switching to a different strategy. Clearly, the answer is no, because its original choice of strategy obeys Bellman's principle of optimality. (See, e.g., Leonard and Long 1992, Chap. 5 for a brief introduction to the principle of optimality.)

On the other hand, if by mistake some players have deviated from its planned course of action, so that the stock size $x(t_1)$ is different from what was anticipated at time zero, then at t_1 players will in general find that they would be better off by switching to another strategy. Therefore, open-loop Nash equilibria are not robust to "trembling hand" deviations (Selten 1975). One may say that open-loop Nash equilibria are not "subgame perfect" (even though the concept of a subgame is problematic in continuous time). For this reason, let us turn to the concept of Markov-perfect Nash equilibrium which overcomes this problem.

Define a Markovian decision-rule strategy (or simply Markovian strategy for short) as a function that determines at each (state, date) pair what action to take. Let ϕ_j be player j 's Markovian strategy, then

$$\mathbf{u}_j(t) = \phi_j(\mathbf{x}(t), t)$$

Let Q_j be the set of Markovian strategies that are available to player j . Let $Q \equiv \Pi_j Q_j$. Once all players have chosen their Markovian strategies, the evolution of the state variables is described by

$$\dot{x}_i(t) = F_i(\mathbf{x}(t), \phi_1(\mathbf{x}(t), t), \dots, \phi_N(\mathbf{x}(t), t), t), \quad i = 1, 2, \dots, n, \quad x_i(0) = x_{i0}$$

or, in vector notation,

$$\dot{\mathbf{x}}(t) = \mathbf{F}(\mathbf{x}(t), \phi(t), t), \quad \mathbf{x}(0) = \mathbf{x}_0$$

where

$$\phi(t) \equiv (\phi_1(t), \phi_2(t), \dots, \phi_N(t))$$

Assume this differential equation has a unique solution for any initial condition (x_{t_1}, t_1) . Define the performance index for player i at the (state, date) pair (x, t) by

$$J_j(\mathbf{x}, t, \phi) = \int_t^T e^{-r_j(\tau-t)} B_j(\mathbf{x}(\tau), \phi(\mathbf{x}(\tau), \tau), \tau) d\tau + e^{-r_j(T-t)} S_j(\mathbf{x}_T, T)$$

We define a Markov-perfect Nash equilibrium (also called a feedback Nash equilibrium) as a strategy profile $\hat{\phi} = (\hat{\phi}_1, \hat{\phi}_2, \dots, \hat{\phi}_N) \in Q$ such that, at any (state, date) pair $(x, t) \in X \times [0, T]$, no player can make itself better off by choosing a different strategy, i.e.,

$$J_j(\mathbf{x}, t, \hat{\phi}) \geq J_j(\mathbf{x}, t, \phi_j, \hat{\phi}_{-j}) \text{ for all } j$$

It is important to stress the requirement that this inequality be satisfied for all possible (state, date) pair $(x, t) \in X \cup [0, T]$, not just for the initial pair at time zero $(x_0, 0)$. As Reinganum and Stokey (1985) point out, a decision-rule Nash equilibrium for a given $(x_0, 0)$ is not necessarily Markov perfect. To be Markov perfect, a Nash equilibrium in decision rules must satisfy the additional property that the continuation of the given decision rules constitutes a Nash equilibrium when viewed from any future (date, state) pair. Dockner et al. (2000, example 4.2) give an example of a Nash equilibrium in decision rules that fails to be Markov perfect.

To find a Markov-perfect Nash equilibrium (MPNE), the usual method is to make use of the Hamilton-Jacobi-Bellman (HJB) equations that the value function of each player must satisfy. The HJB equation for player j is

$$rV_j(\mathbf{x}, t) - \frac{\partial V_j(\mathbf{x}, t)}{\partial t} = \max_{\mathbf{u}_j} \left\{ B_j(\mathbf{x}, \mathbf{u}_j, \hat{\phi}_{-j}(\mathbf{x}), t) + \frac{\partial V_j(\mathbf{x}, t)}{\partial \mathbf{x}} \mathbf{F}(\mathbf{x}, \mathbf{u}_j, \hat{\phi}_{-j}(\mathbf{x}), t) \right\}$$

with the terminal condition

$$V_j(\mathbf{x}, T) = S_j(\mathbf{x}, T)$$

If T is infinite, the above terminal condition is replaced by

$$\lim_{t \rightarrow \infty} e^{-rt} V_j(\mathbf{x}(t), t) = 0$$

It is worth noting that OLNE and MPNE can be thought of as based on two alternative assumptions about the ability of players to precommit. In an OLNE, players commit to a whole time path of actions. In an MPNE, players cannot precommit at all. Reinganum and Stokey (1985) argue that in some cases, players may be able to commit to actions in the near future (e.g., by forward contracts), but not to actions in the distant future. They develop a simple model where a game begins at time 0 and ends at a fixed time T , and there are k periods of equal lengths δ , where $k\delta = T$. At the beginning of each period, agents can commit to a path of action during that period. The special case where $k = 1$ corresponds to the open-loop formulation, and OLNE is then the appropriate equilibrium concept. At the other extreme, where $\delta \rightarrow 0$, the appropriate equilibrium concept is MPNE.

The choice of equilibrium concepts is to some extent dependent on tractability. The relative ease of finding an OLNE is one of its attractive features. For some examples of OLNE in the economics of natural resources, see Gaudet and Long (1994) and Benchekroun et al. (2009).

48.4 Transboundary Stock Pollutants

48.4.1 A Benchmark Model

Following Long (1992) and Ploeg and Zeeuw (1992), let us consider a world consisting of two countries. Let $Q_i(t)$ be country i 's output at date t . Assume that emissions are proportional to output, $E_i(t) = Q_i(t)$. Let $P(t)$ denote the stock of pollution. Assume

$$\dot{P}(t) = E_1(t) + E_2(t) - \delta P(t) \quad (48.2)$$

where $\delta > 0$ is the decay rate. The pollution damage suffered by country i at time t is $\frac{cP^2}{2}$. The net utility of country i is

$$U_i(t) = AE_i(t) - \frac{1}{2} (Q_i(t))^2 - \frac{c}{2} (P(t))^2$$

and its social welfare is

$$W_i = \int_0^{\infty} e^{-\rho t} U_i(t) dt$$

where $\rho > 0$ is the rate of discount.

Let us find the open-loop Nash equilibrium of this model. Since countries use path strategies in the open-loop formulation, let us suppose that country i believes that country j 's emission strategy is $E_j(t) = g_j^{OL}(t)$. Then it seeks to solve the following optimal control problem:

$$\max_{E_i(\cdot)} \int_0^\infty e^{-\rho t} \left[AE_i(t) - \frac{1}{2} (E_i(t))^2 - \frac{c}{2} (P(t))^2 \right] dt \tag{48.3}$$

subject to

$$\dot{P}(t) = E_i(t) + g_j^{OL}(t) - \delta P(t), \quad P(0) = P_0 \tag{48.4}$$

Applying the maximum principle, we obtain the necessary conditions

$$\begin{aligned} -(\dot{E}_i - \rho(E_i - A_i)) &= -c_i P - \delta(E_i - A_i) \\ \dot{P} &= E_i + g_j^{OL} - \delta P, \quad P(0) = P_0 \end{aligned}$$

and the transversality condition is

$$\lim_{t \rightarrow \infty} e^{-\rho t} (E_i(t) - A_i) P(t) = 0$$

Since the two countries are identical, we obtain the following system of two differential equations

$$\dot{E} = cP + (\rho + \delta)(E - A) \tag{48.5}$$

$$\dot{P} = 2E - \delta P, \quad P(0) = P_0 \tag{48.6}$$

with the transversality condition

$$\lim_{t \rightarrow \infty} e^{-\rho t} (E(t) - A) = 0 \tag{48.7}$$

There is a unique steady-state pair $(P_\infty^{OL}, E_\infty^{OL})$ where

$$P_\infty^{OL} = \frac{2A(\delta + \rho)}{2c + \delta(\delta + \rho)} \tag{48.8}$$

$$E_\infty^{OL} = \frac{A\delta(\delta + \rho)}{2c + \delta(\delta + \rho)} = \frac{\delta P_\infty^{OL}}{2} \tag{48.9}$$

Comparing with the case where the two countries cooperate and maximize the sum of their welfare, we see that the steady-state stock of pollution P_∞^{OL} is too high.

What happens if countries use feedback strategies? Suppose country i believes that country j employs a feedback emission strategy, $E_j(t) = g_j^{FB}(P(t))$, so that that its rate of emissions at t is conditioned on the currently observed level $P(t)$. Then country i maximizes

$$\max_{E_i(\cdot)} \int_0^\infty e^{-\rho t} \left[AE_i(t) - \frac{1}{2} (E_i(t))^2 - \frac{c}{2} (P(t))^2 \right] dt \tag{48.10}$$

subject to

$$\dot{P}(t) = E_i(t) + g_j^{FB}(S(t)) - \delta P(t), \quad P(0) = P_0 \tag{48.11}$$

Realizing that $g_j^{FB}(P)$ is a function of the pollution stock, country i knows that it can indirectly manipulate country j 's emissions at t by influencing the evolution of P . This strategic consideration was absent in the open-loop case.

To find the feedback Nash equilibria of this game, we make use of the Hamilton-Jacobi-Bellman (HJB) equations. The HJB equation for country i is

$$\rho V_i(P) = \max_{E_i} \left[AE_i - \frac{1}{2} E_i^2 - \frac{c}{2} P^2 + V_i'(P)(E_i + E_j(P) - \delta P) \right]$$

where $E_j(P)$ is country j 's feedback strategy and $V_i(P)$ is country i 's value function. The transversality condition is

$$\lim_{t \rightarrow \infty} e^{-\rho t} V_i(P(t)) = 0 \tag{48.12}$$

The first-order condition with respect to E_i is $E_i = A + V_i'(P)$. This equation gives $E_i = E_i(P)$, i.e., country i 's emissions depend only on P . Appealing to symmetry, we get the HJB equation

$$\rho V(P) = \frac{1}{2} \left[A^2 + 4AV' + 3(V')^2 \right] - \delta PV' - \frac{c}{2} P^2 \tag{48.13}$$

This equation and the transversality condition Eq. (48.12) identify the set of possible Markov-perfect Nash equilibria.

Let us conjecture that the value function is quadratic

$$V(P) = -\frac{\omega P^2}{2} - \pi P - \mu \tag{48.14}$$

Then $V'(P) = -\omega P - \pi$ and hence the feedback strategy is linear

$$E(P) = A - \pi - \omega P \tag{48.15}$$

It is plausible to expect that $\omega > 0$, i.e., a higher stock will make countries choose lower emissions, and $\pi > 0$, i.e., if $P = 0$, the marginal effect on welfare of an exogenous increase in P is negative.

Making use of Eq. (48.14) and Eq. (48.15), the HJB equation gives a quadratic equation of the form

$$\lambda_0 + \lambda_1 P + \lambda_2 P^2 = 0$$

where $\lambda_0, \lambda_1,$ and λ_2 are expressions involving the parameters δ, ρ, c and the coefficients ω, π, μ . Since this equation must hold for all P , it follows that $\lambda_i = 0$ for $i = 0, 1, 2$. Using these three conditions, we can solve for $\omega, \pi,$ and μ . We obtain

$$\omega = \frac{1}{3} \left[-\left(\delta + \frac{\rho}{2}\right) + \sqrt{\left(\delta + \frac{\rho}{2}\right)^2 + 3c} \right] \tag{48.16}$$

(To ensure convergence to a steady state, the positive root $\omega > 0$ is selected.) Next, compute π and μ as follows:

$$\pi = \frac{2A\omega}{\delta + \rho + 3\omega}$$

$$\mu = \frac{(A - \pi)}{2\rho} (3\omega - \delta - \rho) \equiv \mu_m$$

The linear feedback strategy is

$$E = \frac{A(\delta + \rho + \omega)}{\delta + \rho + 2\omega} - \omega P$$

It follows that

$$\dot{P} = \frac{2A(\delta + \rho + \omega)}{\delta + \rho + 2\omega} - (2\omega + \delta)P \tag{48.17}$$

For P to converge to a steady state, it is necessary that $2\omega + \delta > 0$. This inequality is satisfied if and only if the positive root for ω is selected. The steady-state pollution stock under the MPNE with linear feedback strategies is

$$P_\infty^{FB} = \frac{2A(\delta + \rho + \omega)}{(\delta + \rho + 2\omega)(2\omega + \delta)} \tag{48.18}$$

Clearly, the OLNE steady-state pollution stock P_∞^{OL} is lower than the MPNE steady state P_∞^{FB} . This result is dependent on the fact that we have focused on a quadratic functional form for the value function $V_i(P)$. Dockner and Long (1993) show that there are other value functions that satisfy the HJB equation. These value functions result in nonlinear emission strategies. In fact there is a continuum of nonlinear strategies, and some of them outperform the OLNE in the sense that both countries would be better off under such strategies. When there are multiple equilibria, it is not clear which one is likely to prevail.

48.4.2 Centralized Versus Regional Control of Pollution

List and Mason (2001) consider an asymmetric version of the transboundary pollution model of Dockner and Long (1993) in the case of two regions and where pollution management can be centralized, i.e., dictated by a federal authority such as the EPA for the case of the USA, or CEA in Canada, or decentralized, i.e., regulation is chosen by local states or provinces. In their model, there are two regions that have different parameter values for the regional damage function and production function:

$$U_1(t) = AE_1(t) - \frac{1}{2} (Q_1(t))^2 - \frac{c}{2} (P(t))^2$$

and

$$U_2(t) = \alpha AE_2(t) - \frac{1}{2} (Q_2(t))^2 - \beta \frac{c}{2} (P(t))^2$$

where α, β characterize differences between the two regions in vulnerability to flow and stock pollution as well as differences in abatement costs. An alternative interpretation is that differences in instantaneous utilities are the result of population differences.

They characterize the equilibrium obtained when a central authority, whose objective is to maximize the sum of the two regions discounted sum of welfare, sets the environmental policy, assuming it is constrained by the constitution to set uniform environmental policies in both regions. Given the asymmetry of the two regions, the central authority cannot achieve a first best. They show that if $\beta = 0$, i.e., one region is not affected by the stock of pollution and $\alpha = 1$, then welfare values under central control exceed those under decentralized control. However when $\beta = 0$ and α is large enough then, for small values of the stock of pollution, the present value of combined payoffs for the two regions is larger under decentralized than centralized control. The larger the asymmetry between the two regions, the larger the cost of implementing a central authority's plan under the constraint of uniform regulation. When the asymmetry is large enough, the distortion introduced by the constraint outweighs the gains from the elimination of free riding (under a central authority). This result can be extended to the case where $\beta > 0$ using a continuity argument. When $\beta = 0$, it is shown that decentralization always results in higher rates of emissions and a larger steady-state stock of pollution than under central management.

List and Mason (1999) examine whether environmental regulations should be carried out locally or centrally; i.e., by a central authority or by local regulators. Localities are assumed to have superior information or more leniency to adopt new environmental regulations. They consider the case of several pollutants. Consider two regions (states or provinces) indexed by $i = 1, 2$. In each region i production generates two flow of emissions, one local and one transboundary, denoted by F_i

and E_i . These flows of emissions accumulate and form stocks of pollutants: a local stock pollutant denoted by Z_i and a transboundary pollution stock by P . The evolution of the stocks is given by

$$\dot{Z}_i = F_i - lZ_i$$

and

$$\dot{P} = E_1 + E_2 - kP$$

where $k, l > 0$ are nature's purification rates for the transboundary and the local pollutant, respectively.

The instantaneous utility U_i of country i is given by

$$U_i = AE_i + BF_i - \frac{1}{2}E_i^2 - \frac{1}{2}E_i^2 - \frac{X}{2}Z_i^2 - \frac{S}{2}P_i^2 - \rho Z_i P$$

where X and S are positive damage parameters. The parameter ρ captures the interaction between the local and the transboundary pollutants. When the interaction reduces damages, we have $\rho < 0$, and when $\rho > 0$, the two pollutants have synergistic negative effects. It is assumed that local authorities know the value of ρ , whereas the central authority ignores the true value of ρ and uses a value of $\rho = 0$ when choosing the optimal emission policy under a centralized system.

They examine when local regulation dominates a central system in the case of carbon dioxide (the transboundary pollutant) and sulfur (local pollutants) and use parameter values based on empirical evidence. They show that there exist $\rho^+ > 0$ and $\rho^- < 0$ such that the benefits from local control can more than offset the benefits from central control if synergistic effects are such that $\rho > \rho^+$ or $\rho < \rho^-$.

48.5 Provision of Clean Air and Interregional Mobility of Capital

Regional governments may impose capital income tax to finance the provision of public goods such as clean air. However, a tax imposed on the earning of a factor of production will encourage that factor to move to another jurisdiction where the tax rate is lower. (With the exception of completely immobile factors, such as land and mineral resources.) Stigler (1965) points out that if all factors are mobile, redistributive taxation in a multi-jurisdiction world is practically infeasible. Zodrow and Mieszkowski (1986) show that if regional governments compete in source-based capital income tax rates, there will be a race to the bottom, leading to the underprovision of local public goods. The theoretical literature has identified size differences as a factor for explaining why different jurisdictions are affected asymmetrically by tax competition (Bucovetsky 1991; Wilson 1991). For generalization to two tax instruments, see Bucovetsky and Wilson (1991). Wang (1999) assumes sequential moves: the bigger region is the Stackelberg leader.

A number of two-period models have been developed to investigate the implications of simple dynamic games between the owners of partially mobile factors of production on the one hand and a local government that tries to redistribute income in favor of some group, on the other hand. Lee (1997) shows that if capital movements involve adjustment costs, there will be a wedge between the internal rate of return and the external one. Jenson and Thomas (1991) model a game between two governments that use debt policies to influence the intertemporal structure of taxation. Huizinga and Nielsen (1997) formulate a two-period model in which even though capital is perfectly mobile, foreign capitalists in effect earn rents from local immobile resources.

Wildasin (2002, 2008) presents a continuous-time, infinite-horizon model in which infinitely lived agents react to changes in taxation by moving resources across jurisdictions. Adjustment costs are explicitly taken into account. The author focuses on the case of a once-over tax change and does not deal with optimal time-varying tax rates. Instead, the analysis emphasizes the costly adjustment process and draws on the adjustment cost literature in macroeconomics (Turnovsky 2000). The main point is that capital earns quasi rent which can be taxed away, but such quasi rents erode with time. The optimal capital income tax rate depends crucially on the degree of capital mobility. Wildasin does not model a dynamic game involving the competition among jurisdictions to attract mobile resources.

A truly dynamic game model is that of Koethenbueger and Lockwood (2010). The authors consider an infinite-horizon dynamic version of the model of Zodrow and Mieszkowski (1986). There are n regions, with one firm in each region. Each region is subject to a stochastic output shock. These shocks imply that households would like to diversify their portfolios, and this dampens the tax competition among regional governments. Under logarithmic utility, they show that the Nash equilibrium path of capital income tax rate is time invariant. This constant tax rate is increasing in the preference parameter for the public good, the rate of discount, and the volatility of the output shock. There exists a critical threshold \hat{n} such that the equilibrium tax rate is increasing in n if $n < \hat{n}$ and decreasing in n if $n > \hat{n}$. As n tends to infinity, the equilibrium tax rate tends to zero, which is an inefficient outcome.

48.6 Conclusions

Both static and dynamic games have been successfully employed to shed light on many resource and environmental issues involving strategic interactions among a number of players. The insights generated by game theoretic models can potentially be used to help design mechanisms for improving economic efficiency. In particular, empirical models are useful tools for policy making. Conversely, issues in resource and environmental economics have provided opportunities for researchers to sharpen their tools and to develop new concepts and techniques for dealing with emerging issues. Because of space limitations, we have covered noncooperative games only. We have omitted empirical models of dynamic

games in resource and environmental economics that use real world data to calibrate parameters of demand and cost functions. We have also omitted games with asymmetric information. We refer the reader to the recent surveys in Long (2010, 2011) and Jorgensen et al. (2010).

Abstract

Commensurate valuation of market and nonmarket public goods allows for a more valid benefit-cost analysis. Economic methods for valuing nonmarket public goods include actual behavior-based revealed preference methods such as the hedonic property method for urban-suburban public goods and travel cost-based models for outdoor recreation. For valuing proposed public goods for which there is no current behavior or valuing the existence or passive use values of public goods, economists can rely upon stated preference methods. While there is skepticism among some economists for relying upon what people say they will pay rather than what their actual behavior suggests they will pay, there is general acceptance of stated preference methods. These stated preference methods include the well-known contingent valuation method and choice experiments (sometimes called conjoint analysis). Lastly, in situations where there is neither time nor money to conduct an original revealed or stated preference study, economists typically rely upon benefit transfers from existing revealed preference and stated preference studies to provide rough estimates of the values of public goods such as water quality, air quality, wetlands, recreation, and endangered species.

49.1 Introduction

One of the long-standing deviations from economic efficiency of even a perfectly competitive market with no subsidies to producers or consumers is that of negative externalities and provision of *public goods*. In the face of these market failures, government intervention has the potential to improve economic efficiency by imposing pollution taxes or tradeable permits to internalize the negative externalities into prices of the goods associated with pollution. Further, government has the *potential* to improve economic efficiency by supplying or financing the supply of optimal amounts of the public good.

However, the emphasis here is on the potential to improve economic efficiency through government action. For this potential to be realized, the level of the pollution taxes must be set equal to the marginal environmental cost at the socially optimum level of output. Thus, to achieve this optimum requires having an estimate of the marginal environmental cost of pollution or, alternatively, the marginal benefits of improving environmental quality (e.g., air quality, water quality). The same is true of public goods: the government has to determine the marginal benefits of these public goods to society so as to compare to the cost of producing alternative levels of the public goods to determine an optimum.

Benefit-cost analysis is a technique used by government to determine if the benefits of increased environmental quality or public goods are worth the cost. One of the greatest challenges of benefit-cost analysis is estimating nonmarket benefits of regulations imposed on industry to internalize negative externalities (e.g., installation of pollution control devices) or government supply of public goods (e.g., preservation of remote wilderness areas).

This chapter is devoted to a review of environmental valuation methods frequently used by a wide variety of economists (i.e., academic, government, consultants) to estimate the economic benefits of improving environmental quality and public goods. The conceptual foundation of all environmental valuation methods is reviewed first. This is followed by a discussion of actual behavior-based environmental valuation methods. These methods are usually referred to as revealed preference methods and include the hedonic property method and the travel cost method. This section is followed by a review of stated preferences methods including the contingent valuation method and choice experiments. The next to the last section discusses how revealed preference and stated methods can be combined to provide more robust environmental valuations. Finally, “shortcut” methods called benefit transfer are reviewed.

49.2 Benefit Measures

Value has many different meanings, and it is important for economists to be precise as to what they mean by economic value or benefits of environmental quality or public goods. The economic value or benefit received by a person for any good whether marketed or nonmarketed is the maximum amount they would pay for it. The term economists used for this is maximum *willingness to pay* (WTP). WTP is short hand for willingness and ability to pay. When estimated as the area under a consumer’s demand curve, it is usually referred to as consumer surplus. While there are many theoretical refinements to this measure, for an applied economist, consumer surplus is generally considered a reasonable approximation to these more theoretically correct concepts of consumer well-being.

It is worth noting that nothing has been said about jobs created by production of a public good as an economic efficiency benefit or jobs lost with environmental regulation as a cost. Except in times of unusually high and persistent unemployment, gains in jobs in one industrial sector are usually made up in another. Likewise, jobs lost in one geographic area are usually made up in another. Hence, jobs are considered transfers of economic activity from one industrial sector or geographic area to another. In other words, changes in jobs are not net gains or net losses to the economy as a whole and are usually excluded from an economic efficiency analysis such as benefit-cost analysis.

49.2.1 Use Values

For most market and nonmarket goods and services, the benefits are largely received by individuals who actually consume or directly use the good. The benefits of another hamburger or a new reservoir are primarily to the consumers who use it. In the reservoir example, use values would accrue to those who receive drinking water from the reservoir, receive flood protection, or water ski at the reservoir. The vast majority of benefits from a project or policy typically fall into the use category

as this is a very broad category. Use values also include the value of publicly provided recreation, scenic visibility at national parks, and commonly seen wildlife such as deer. Use values also relate to reduction in health damages from cleaning up hazardous waste sites and improving air and water quality. These use values are also measured by the users' maximum willingness to pay, so that there is consistency between valuation of market goods and nonmarket goods, i.e., the dollars are commensurate.

49.2.2 Nonuse or *Passive Use Values*

There are, however, unique natural resources such as Yellowstone National Park, rare/endangered species such as condors or panda bears from which people often receive benefits from just knowing these exist in the wild. This type of value is known as *existence value* (Krutilla 1967; Freeman 2003). Receiving this benefit does not require an on-site visit. Rather, there is an enjoyment from reflecting on the existence of the Arctic National Wildlife Refuge in Alaska undisturbed by oil and gas drilling. Likewise some people receive enjoyment and satisfaction that protection of these unique natural environments or species today will provide to future generations. This "bequest value" also does not require the current lived person to set foot in the area or personally view it.

The existence and bequest values are sometimes called nonuse values (Freeman 2003) or passive use values (US District Court of Appeals 1989; Arrow et al. 1993). These values have been the focus of natural resource damage assessment (e.g., damages from oil spills in remote areas of Alaska from the Exxon Valdez oil tanker spill – see Carson et al. 2003) and biodiversity (see Abdullah et al. (2011) for a review of these valuation studies).

Given that everyone can simultaneously enjoy the knowledge that a given unique natural environment exists, existence values have the characteristics of public goods. If valuing public goods were not difficult enough, these nonuse public goods are particularly challenging since there is little tie to a consumer's behavior. However, as discussed later in this chapter, economists have developed and implemented stated preference valuation methods that can measure the benefits of these special types of public goods. These passive use values are also measured by the maximum amount that people who benefit from these public goods would pay for them. This insures consistency between passive use values and use values and market values.

49.3 Overview of Methods and How They Relate to Values

There are two broad classes of valuation methods for nonmarket resources. Revealed preference methods refer to methods that indirectly infer WTP based on market transactions for other related goods. For example, estimating a demand curve for recreation based on the variation in visitors' travel costs. From the demand curve, visitors' WTP or consumer surplus can be calculated. The generic

label for this type of revealed preference method is *Travel Cost Model* because it relies on travel behavior and travel costs. Another revealed preference method is the *Hedonic Property Method*. This method disaggregates the price of a house purchased into the attributes of the house itself (e.g., bedrooms, bathrooms), the neighborhood (e.g., school quality), and the surrounding environment (e.g., distance to work, distance to an amenity or disamenity to be valued). Since houses with proximity to desirable environmental attributes are demanded by more households, this pushes up their prices. The price premium for a location close to an amenity such as open space or a park or good air quality can then be inferred.

In contrast, stated preference methods such as the *Contingent Valuation Method* or *Choice Experiments* rely upon what people say they would intend to pay if a certain scenario occurs. For example, how much more I would pay in trip cost for access to a recreation site with better water quality or how much more I would pay in taxes to protect an endangered species in a remote area. As will be discussed in more detail below, stated preference methods have the advantage of being quite flexible so it can measure both use and passive use values. Stated preference methods can also value a wide range of public goods including health, air quality, water quality, recreation, and endangered species. This flexibility comes at a price of potential hypothetical bias where respondents to the survey may state they will pay more for the public good than they would actually pay when they must hand over their own hard-earned money. Below we talk about what the literature finds with regard to when hypothetical bias is more likely to occur and what can be done to reduce it.

It is important to emphasize that all these estimation methods are just alternative tools for measuring WTP. They do it differently, but the measure of value is still the same. At the end of this chapter, we will also talk about how revealed preference and stated preference data can be combined to utilize the strengths of each method. But for now, we will discuss each method separately.

49.4 Hedonic Property Method

This revealed that preference technique has been applied to estimating house price differentials with natural hazards (e.g., earthquakes, floods, fires), environmental quality (air pollution, water pollution), and recreation access (e.g., open space, beaches). To understand how this versatile technique works, we will first review the theory underlying it, the data requirements, then the econometric estimation, and finally how WTP is calculated from the regression results.

49.4.1 Economic Theory Underlying the Hedonic Property Method

Competition for houses with desirable amenities pushes the prices of these houses up. Likewise, to entice home buyers to purchase homes with less desirable locations or disamenities, sellers must lower their prices. These premiums and discounts are intuitive but in order to develop valid estimates of WTP, there must be a close link

between the theoretical foundation and the empirical estimation. Further, any empirical model is based on a set of assumptions, which are often embedded in the theory. Below, we summarize the theory (see Taylor 2003 for more comprehensive discussion of the theory and empirical methods discussed below).

In the hedonic property method, the standard assumptions that consumers maximize utility and sellers maximize profits are employed. The consumer's utility function is Lancasterian in nature being specified in terms of the attributes of the house structure itself and its location. A stylized representation of the utility function is

$$U_i(X, A_s, A_n, A_e) \quad (49.1)$$

where U_i is utility of person i and X represents all other nonhousing goods and is sometimes referred to as a composite commodity. The A 's represent attributes of the housing structure itself (A_s) (e.g., bedrooms, baths), the neighborhood (A_n) (e.g., education levels), and the environment (A_e) (e.g., air quality, water quality). This utility function is maximized subject to the consumer's budget constraint (where the price of the composite commodity is normalized to 1). The consumer optimum is where

$$\partial Ph / \partial A_i = (\partial U / \partial A_i) / (\partial U / \partial X) \quad (49.2)$$

where Ph is the price of the house.

The interaction of the producers' minimum willingness to accept to supply attributes and consumers' maximum WTP for attributes results in an equilibrium price schedule for attributes A_s , A_n , and A_e . In an equilibrium between the producer and consumers, $\partial Ph / \partial A_i$ is the marginal WTP for small changes in A_i .

From the theory comes an estimable hedonic price function. In Eq. (49.3), we present an illustrative form of it:

$$Ph = \beta_0 + \beta_1(HA) + \beta_2(SQ) + \beta_3(NInc) + \beta_4(DWork) + \beta_5(EQ) \quad (49.3)$$

where Ph is the price of the house; HA is housing structure size; SQ is school quality, e.g., graduation rates; $NInc$ is neighborhood income – often proxied by census tract or zip code; $DWork$ is distance to employment centers; and EQ , e.g., air quality (parts per million of key pollutants), is distance to open space or a disamenity like a landfill.

The implicit price or marginal WTP for a small change in any attribute of the house structure, neighborhood, or environmental quality is simply the regression slope coefficient if the hedonic price function is linear. If the house price function is nonlinear, as it typically is, then the contribution of each additional unit of attribute to the house price is also related to the absolute level of house price. In this case, the formula for marginal WTP is slightly more complicated. Taylor (2003) provides formulas for the implicit price function for a variety of nonlinear functional forms.

Since the implicit price function is for a marginal change in attribute levels, it will overstate the benefits of a large increase in attributes but understate the loss of large changes in attributes. In order to accurately estimate the benefits for large gains or losses in attributes, a second-stage hedonic demand for the specific attribute must be estimated. Discussion of this is beyond the scope and space available in this chapter so the interested reader should see Taylor (2003) for more details.

49.4.2 Data Requirements

The data required for this method is of course quite detailed. The analyst needs house sale prices, characteristics of the home, characteristics of the neighborhood, and characteristics of the environment. This requires obtaining at least three different data sources. House sale prices and house characteristics are often available from county tax assessors' offices or from third-party real estate services. Characteristics of the neighborhood such as income, ethnicity, and average age are often found in block level data available from a government's population census office or sold by third-party vendors. Data on environmental quality of the neighborhood is often obtained from some form of monitoring station or field data. Location of houses relative to the amenity or the disamenity must often be calculated using Geographic Information System software. This requires that housing data be "georeferenced" in some form whether street address or coordinates. Needless to say that assembling the data can be time consuming, but no more so than the other methods we will review.

49.4.3 Econometric Modeling Including Spatial Dimensions

Since the implicit prices are essentially the regression coefficients, an econometric model must be estimated using the data assembled above. Historically, nearly all hedonic price functions were estimated using ordinary least squares regression in one form or another. Recently, there have been concerns that there may be spatial dependence of prices between houses located in close proximity to one another (e.g., same neighborhoods). This dependence may be due to real estate agents and appraisers' use of "comparable houses" when determining fair market value or appraised value for houses. It may also be due to there being some unobservable (to the analyst) characteristic of a particular neighborhood shared by houses in that neighborhood. Since this characteristic is unobservable to the analyst, it is an omitted variable in the regression equation. In the last few years, spatial econometric methods have been developed to address these problems (Anselin 1988). At present, some studies show that using these more advanced methods may result in more accurate estimates of the implicit prices, but in other cases, there is little difference (Mueller and Loomis 2008). The interested reader should see Anselin (1988) for more details.

49.5 Travel Cost Models

The revealed preference travel cost models essentially involve estimating a demand function for recreation. As such, the underlying theory is that of consumer demand theory. A visitor is assumed to maximize their utility subject to a budget constraint. Much like consumer demand theory, there are a number of admissible utility functions which result in different demand specifications. Besides the own price of visiting the recreation site of interest, these demand functions should ideally include the visitor's income and the price of visiting substitute sites. The details of how this conceptual demand model is implemented are specific to the different forms of the travel cost models which we will now be reviewing.

49.5.1 Trip Frequency Models of Recreation Demand

While many public recreation sites have no entrance fee or a minimal administratively set fee, nearly all the implicit price paid for access to the recreation site is the travel cost incurred by the visitor. Thus, travel costs act as a proxy for price in estimating the demand curve. The use of travel cost as a proxy for price hinges on a couple of key assumptions: (a) all travel costs are incurred exclusively to visit this site, and only this site on a trip from home; and (b) there are no significant benefits derived from the travel enroute to the recreation area, i.e., the sightseeing on the way to the site has little value. To meet assumption (a), visitors are queried if they are visiting multiple sites on the same trip and, if so, excluded from the estimation data in most simple trip frequency models but can be included in more complex trip frequency models (Loomis et al. 2000).

Travel cost models employ cross-sectional data that uses spatial variation in visitors' travel costs. There is variation in visitors' travel costs because visitors live at varying distances from the site. With a trip frequency model, the dependent variable is the number of trips each visitor takes over the year or the season to a particular recreation area. The price variable includes the transportation costs (e.g. gasoline), but there may be other variable costs of the trip that would be included in the travel cost variable. These might include lodging or camping fees. Other variables that are usually included as an independent variable in a travel cost model include the visitor's travel time to the site. However, sometimes this variable will be so highly correlated with travel cost that it cannot be included by itself. In that case, the monetary opportunity cost of this time is used to combine the cost of travel time with the transportation cost. Since we are estimating a demand function, other independent variables such as visitor income are usually appropriate to include. Ideally price of the nearest substitute site would be included as well, although this variable is often so correlated with travel cost to the site under study that it is difficult to include. Visitor demographics are also useful as other explanatory variables to act as proxies to control for differences in tastes and preferences.

As single-site trip frequency model is useful if the analyst is interested only in (a) what is the value of current recreation at the site and (b) what would be the loss

in consumer surplus if the site were closed due to agency budget cuts or reallocation of the land to an alternative use (e.g., mine). An example single-site demand curve specification is given in Eq. (49.4) for visitor i :

$$\text{AnTrips}_i = \beta_0 - \beta_1 \text{TC}_i + \beta_2 \text{TTime}_i + \beta_3 \text{Income}_i \quad (49.4)$$

where AnTrips_i is annual trips of visitor i to the site, TC is roundtrip travel cost of visitor i , TTime is travel time in hours of visitor i , and Income is household income of visitor i . To address the limitations of this single-site model, a multiple-site model can be estimated. We now turn to a discussion of one such type of multiple-site model.

A multiple-site trip frequency model allows answering a wider range of policy and management questions including how WTP would change for changes in environmental quality or size of the recreation area protected. In order to observe how visitation changes with size of the water body or facilities or environmental quality, there must be variation in recreation site quality or characteristics. While at one recreation site, these attributes are generally fixed, these characteristics usually vary across sites. Therefore, if the analyst pools or combines visitation data from several recreation areas which have varying levels of these attributes, then visitor response to these attributes can be estimated in the demand coefficients. This allows the analyst to estimate how the demand curve shifts with more of a desirable attribute. The area between the original demand curve and the demand curve with increased size or level of environmental quality provides an estimate of the incremental or additional WTP for the increased amount of the attribute. This feature allows the analyst and manager to answer a wide range of policy relevant questions: (a) How the recreation benefits would change with management enhancements such as additional facilities, clean up of water quality, or wildlife management. These marginal benefits can be compared to the marginal costs of carrying out the management action to determine if the added benefits justify the added costs; (b) The change in site quality with allowing an incompatible use to occur at or nearby the site, such as drawing the reservoir level down for irrigation, reducing river flows to produce hydropower, or allowing a nearby mine which would add pollution to a lake. Equation (49.5) specifies what a stylized multiple-site trip frequency demand model would look like for individual i visiting site j :

$$\text{AnTrips}_{ij} = \beta_0 - \beta_1 \text{TC}_{ij} - \beta_2 \text{TTime}_{ij} + \beta_3 \text{Income}_i + \beta_4 \text{SS}_j + \beta_5 \text{SQ}_j \quad (49.5)$$

where AnTrips_i is annual trips of visitor i to the site j , TC_{ij} is round trip travel cost of visitor i to site j , TTime_{ij} is travel time in hours of visitor i to site j , Income_i is household income of visitor i , and SS_j and SQ_j are site size of site j (e.g., number of acres) and site quality of j (e.g., water clarity, fish catch), respectively. The coefficients on the site quality variables indicate how trip changes with a one unit change in site quality. That is, how much the demand curve will shift with a one unit change in site quality? It is from this shift in the demand curve which allows calculation of the marginal benefit of the quality change. This calculation is done

by integrating the area between the current and changed (positively or negatively) demand curve and expanding that to the population of visitors at the site.

There are several econometric specifications of trip frequency models. Historically most trip frequency models were estimated with ordinary least squares regression. However, since 1990, count data regression models have been used since the number of trips taken is a nonnegative integer. Count data models include the Poisson and the Negative Binomial. Negative Binomial count data models do not require that the mean of trips to equal the variance of trips as do the Poisson model.

Since count data models are exponential models, they are equivalent to the semilog of the dependent variable functional form. As such the consumer surplus per trip is simply the reciprocal of the Travel Cost coefficient (Creel and Loomis 1990). See Parsons (2003) or Haab and McConnell (2002) for more details on the count data models.

49.5.2 Multisite Selection Models

Since the 1990s, multiple-site selection models have become popular. These models view the potential visitor as selecting a site to visit from a large choice set of possible recreation sites. These sites differ in terms of travel cost to the site and each sites quality. The individual is assumed to select the site which maximizes their utility given their budget constraint. A repeated discrete choice model has the visitor repeatedly making this site selection decision for each choice occasions (e.g., weekend) over the season and then sums up these trips over all choice occasions in a season.

The theoretical foundation of this model is known as a random utility model since not all the variables in the visitor's utility function are believed to be observable to the analyst. Thus, some of these unobservable variables are treated as random by the analyst, hence the name random utility model. Nonetheless, the site selected by the visitor reflects the one site on any given choice occasion that the visitor views as having the highest net utility. By dividing this utility by the coefficient on travel cost (which is also interpreted as the marginal utility of income), a monetary measure of WTP is calculated. The versatility of this model is that being a multisite model it can value changes in site quality or closure of one or more sites. The strong suite of this model is ability to reflect the influence of substitute sites in the choice of a site to visit. Thus, the loss of value with closing one site is just the incremental loss in utility from having to visit their second best site.

The econometric specification of multisite selection models is quite different from that of trip frequency demand models. Now the dependent variable of the site visited on a particular choice occasion takes on a value 1, and the remainder of sites in the choice set takes a value of zero on that choice occasion. A discrete choice or qualitative response model such as multinomial logit is often estimated. With this model, an increase environmental quality at one site (call it site A) is reflected by some visitors switching away from other sites to visit site A. By linking multinomial

logit site choice model to the trip frequency model discussed above, the analyst can also estimate the benefits of a change in site quality on both site selection and trip frequency. Herriges and Kling (1999) as well as Haab and McConnell (2002) and Parsons (2003) provide an in-depth discussion of these models.

49.5.3 Data Requirements for Travel Cost Models

Obtaining the individual level trip making and travel cost data for travel cost models usually requires a survey of visitors. If a single-site model is being estimated, the task is quite simple since only one site must be visited to collect the data or obtain names/addresses of visitors to send a survey to. However, with multiple-site trip frequency or site selection models, visitation data is needed on many sites. This then increases the data collection costs, especially if on-site surveys are to be used. Alternatively, it may be possible for some activities such as hunting or fishing where licenses are required to do a mail survey and ask the user about all the sites they visit in one survey. This is of course burdensome on the respondent and may reduce the overall survey response rate. However, the payoff from such a detailed survey is the ability to value changes in site quality and account for availability of substitute sites when calculating the demand function and consumer surplus.

49.6 Stated Preference Models

When the change in environmental quality is outside of the prior observed range or the desired value is one of nonuse, then the analyst cannot rely upon actual behavior as there is none. However, economists can construct or simulate a market or a voter referendum to ask people how much they would pay if quality was improved or a unique natural environment protected. The first stated preference method is called contingent valuation method.

We first discuss the contingent valuation method and then a newer stated preference method called the conjoint or choice experiment method. The two stated preference methods share many similarities in that (a) a resource scenario is described to respondents in words, often supplemented by graphs, diagrams, drawings, or pictures to clearly communicate what the resource being valued is and the quantity and quality of that resource. The scenario includes a baseline status quo with no additional cost or no tax cost, and then one or more action alternatives with an associated cost; (b) a means of payment by which the respondent pays the cost of provision of the increased quantity or quality of the natural resource or public good. The means of payment is tailored to the scenario, such that if it is nonuse some form of increased taxes (income, sales, property) or utility bill would be explained as being the mechanism in which the increment of the public good is financed; (c) the WTP question is typically a discrete choice with the respondent being asked if they personally would pay this amount (e.g., in the recreation setting) or vote to pay this amount (e.g., in a public goods setting). The magnitude of the monetary amount

varies across the sample, allowing a quasi-inverse demand curve to be estimated. Given the discrete nature of the WTP question, a logit or probit model is often estimated in order to calculate the maximum amount a respondent would pay.

49.6.1 Contingent Valuation Method

Typically, contingent valuation method is used to estimate a single WTP value for a single scenario offering just one combination of quantity and quality of a public good. For example, in the Exxon Valdez oil spill contingent valuation study (Carson et al. 2003), a one-time WTP for the single scenario of avoiding another equivalently large and damaging oil spill was elicited using in-person interviews. However, some contingent valuation surveys provide multiple scenarios along a common quantity or quality scale. Then, a series of WTP questions are asked, allowing estimation of a WTP function for that increasing quality or quantity of a public good. For example, Walsh et al. (1984) asked annual WTP for four different amounts of land protected as wilderness. Multiple regressions were then used to estimate WTP as a function of acreage protected along with demographics of the visitor.

In terms of the format of the WTP question, Carson et al. used the closed-ended approach in its in-person interviews where respondents were asked if they would pay a particular monetary amount which varied across the sample. Typically at least five, and more often ten, different levels of the monetary amount are asked so as to estimate the quasi-inverse demand curve. An example scenario and a binary closed-ended or *dichotomous choice* referendum WTP question format used by Loomis (1996) for dam removal contingent valuation survey is:

“If an increase in your federal taxes for the next 10 years cost your household \$YY each year to remove the two dams and restore both the river and fish populations would you vote in favor? YES NO”

The \$YY were 15 different bid levels ranging from \$3 to \$190, with most of the bid levels being in between \$15 to \$45.

To estimate the quasi-inverse demand curve, a binary logit model of the following stylized form might be estimated as in Eq. (49.6):

$$\log(\text{Prob Yes}/(1-\text{Prob Yes})) = \beta_0 - \beta_1(\$Bid) + \beta_2X_2 + \beta_3X_3 \quad (49.6)$$

where \$Bid are the \$YY levels asked of the particular respondent, Xs are the values of the non-bid independent variables that may represent tastes and preferences toward the resource of interest.

From this equation, median WTP are calculated following Hanemann (1984) as

$$\text{Median WTP} = (\beta_0 + \beta_2X_{2m} + \beta_3X_{3m})/|\beta_1| \quad (49.7)$$

where X_{2m} , X_{3m} , . . . , X_{nm} are the means of the non-bid Xs. Collectively β_0 plus the sum of all the products is sometimes called the grand constant.

Many early contingent valuation method studies from the late 1970s through the 1980s used an open-ended WTP question format where the individual writes into the survey the maximum amount they would pay. This can be analyzed using simple descriptive statistics or ordinary least squares regression. Another popular technique for mail surveys is the payment card, where individuals' circle one of the preprinted monetary amounts representing the maximum amount they would pay. See Boyle (2003) for a more complete description of these alternative WTP question formats and Haab and McConnell (2002) for a detail of the econometric models associated with these question formats.

If use values are obtained, these values are expanded to the user population. For example, if the WTP of asthmatics to reduce air pollution is obtained, the sample would generalize to exogenous estimates of the number of asthmatics in the population of interest. However, if nonuse values such as existence values for a pure public good like protection of the Grand Canyon or an endangered species, the relevant public could conceivably be the entire country.

For the interested reader, a recent but edited book on contingent valuation is Alberini and Kahn (2006). This book provides chapters that included updated guides for designing and implementing a contingent valuation survey, econometric methods, and applications of contingent valuation.

49.6.2 Choice Experiments

In some cases, policy makers do not have a well-defined single scenario but rather are interested in the values of individual natural resource management options that they might combine into an overall management program or project. For example, when restoring wetlands, emphasis could be placed on providing endangered species habitat, but this might require prohibition of all hunting, wildlife viewing, and camping. Alternatively, the area could be managed for waterfowl hunting in one area, wildlife viewing in another, and camping in another part of the wetland. Each of these management options has different direct monetary costs and opportunity costs in terms of other options. Policy makers and managers want to know which of the many possible combinations of management actions would yield the greatest overall net benefits. Choice experiments are designed to answer these questions by estimating the marginal values or part worths of each management option or attribute.

Thinking about this from the viewpoint of the marketing literature, where this method originated, different combinations of management options yield different "product profiles." In our example below, Restoration Option A is 200 acres, with 100 % T&E species habitat and zero hunting and viewing. Restoration Option B might be 200 acres of wetland with one-third available for waterfowl hunting, two-thirds for wildlife viewing, and zero for T&E habitat. The No Action (status quo) or Current Situation usually has a zero cost and serves as a baseline. In our example, the area may currently be a "de facto" wetland caused by excess agricultural drainage and used primarily as a "duck club" for private hunting. These product profiles are laid out in choice sets in a table such as [Table 49.1](#)

Table 49.1 Example choice set #1

Allocation of restored wetland	No action/current situation (acres and % of land)	Restoration option A (acres and % of land)	Restoration option B (acres and % of land)
T&E species	0 acres and 0 %	200 acres and 100 %	0 acres and 0 %
Hunting	160 acres and 80 %	0 acres and 0 %	66 acres and 33 %
Viewing	40 acres and 20 %	0 acres and 0 %	134 acres and 67 %
Annual cost per taxpayer	\$00.00	\$50.00	\$75.00
Choose one	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>

Table 49.1’s “Choose One” is typical of most Choice Experiments and consistent with the standard random utility formulation that underlies most choice experiments and recreation site selection models. However, this Choose One format does not obtain a great deal of valuation information from each choice, i.e., it is statistically inefficient. One solution typically used is to ask a respondent several of these choice sets. The pros and cons of this approach are briefly discussed below.

In a choice experiment, there are a large number of possible combinations of attributes. This yields a large number of possible choice sets, the exact number depending on how many levels of the four attributes. If there are eight levels of costs to get a precise estimate of the critical “price coefficient” and five levels of the other three attributes, there are dozens of possible combinations in what is called a full factorial design. A more compact design with fewer combinations is a fractional factorial design such as an orthogonal design usually focusing on just the main effects (or what will be the regression coefficient on that variable). In our example, a main effects design has 24 different product profiles, i.e., Restoration Options. The particular 24 combinations that minimize colinearity among the attribute levels are often determined using a SAS statistical software procedure (e.g., OPTEX) or other design choices discussed in Louviere et al. (2000).

The next design decision is how many of these 24 combinations to give each respondent. Generally respondent fatigue begins to set in after answering four such choice sets, and most authors argue against using more than eight (Holmes and Adamowicz 2003).

Once the survey versions are assembled and administered, analyzing the resulting data depends on the format of the choice question. Our example in Table 49.1 is typical with three options per choice set, so a multinomial logit model is usually estimated when there are three or more options in a choice set. If there are just two options, the current situation and one “action” option, then analysis of this is similar to dichotomous choice contingent valuation and uses a binary logit model.

The multinomial econometric specification for a choice example as depicted in Table 49.1 would be

$$\text{Prob}(i|3) = \frac{\exp(\beta_0 + \beta_1 A_{i1} + \beta_2 A_{i2} + \beta_3 A_{i3} + \beta_p(\$A_i))}{\sum \exp(\beta_0 + \beta_1 A_{j1} + \beta_2 A_{j2} + \beta_3 A_{j3} + \beta_p(\$A_j))} \quad (49.8)$$

j = 1, 2, 3

where in our example with just three choices the sum is of the three alternatives. Essentially the individual is comparing the value of the non-cost attributes with the cost attribute to select the bundle that maximizes the relative utility in option 1 versus options 2 and 3 in our example. See Holmes and Adamowicz (2003) for a more in-depth treatment of the econometric models for these types of choice experiment data.

Once the coefficients from this equation are estimated, the marginal values of each attribute are calculated by dividing the attribute coefficient by the coefficient on cost. With this estimated Eq., the economic values of the different management options can be calculated. Comparing all the values of the different management options allows the analyst to determine the particular combination yields the greatest value. As sometimes happens, the choice experiment survey may have to be conducted prior to managers exogenously arriving at their preferred option based on other criteria. However, once the preferred option is known, the choice experiment results could be used to value that management option for a benefit-cost analysis of that preferred option. This flexibility to value options not identical to what was asked in the survey is also an advantage in many benefit transfers (see Rolfe and Bennett (2006) for a discussion of the advantages of choice experiments for benefit transfer).

49.6.3 The Issue of Bias in Stated Preference Surveys

A commonality of all stated preference methods is the concern about hypothetical bias, i.e., that the stated WTP is not equal to their actual WTP. If hypothetical bias exists, stated WTP is not a valid indicator or “true” WTP. Economists have been concerned about and have studied hypothetical bias for decades. Nonetheless, the issue leaps to the mainstream of economics during the early 1990s when contingent valuation was being applied to estimate the reduction in passive use values from the Exxon Valdez oil spill in Alaska. With hundreds of millions of dollars at stake, the strengths and weaknesses of the contingent valuation method were debated in the *Journal of Economic Perspectives*. Those interested in the debate should see Portney (1994), Hanemann (1994), and Diamond and Hausman (1994).

While the literature on hypothetical bias is voluminous (see Loomis 2011 for a summary), a few key results are worth noting. First, with use values, the bias is not always present. Studies that compare revealed preference techniques such as the hedonic property method to contingent valuation method show no statistical difference in WTP (Brookshire et al. 1982). Comparisons of benefit estimates from travel cost models and the contingent valuation method for recreation use values show, on average, no hypothetical bias (Carson et al. 1996). However, the less familiar the person is with the good being valued the more likely hypothetical bias. Thus, public goods that are largely existence or passive use values for which people do not have firsthand knowledge or prior choice experience do show significant hypothetical bias (Champ et al. 1997).

In response to this hypothetical bias, efforts have been made in survey design to reduce it via exhortations to respondents to behave as if it is a real market where they really have to pay their own money. Ex post calibrations of WTP values

derived from the contingent valuation method have also been proposed based on respondent uncertainty (Champ et al. 1997).

Several other stated preference survey instrument design issues have been labeled as biases. One frequent concern here is payment vehicle bias. This bias occurs if WTP is influenced by how a respondent pays, e.g., via an income tax versus a utility bill. WTP elicitation format bias occurs if WTP is influenced by whether the valuation question is asked in an open-ended format or closed-ended format such as a dichotomous choice or payment card format. See Boyle (2003) for a discussion of these other biases.

49.7 Combining Stated and Revealed Preference Methods and Data

Both stated preference and revealed preference have their strength and weaknesses when estimating use values such as those that might arise from reductions in urban air pollution. Cameron (1992) was one of the first to recognize that perhaps combining revealed preference and stated preference data in environmental valuation might capitalize on their respective strengths while minimizing their weaknesses. In particular, Cameron (1992) talked about using the revealed preference data to “discipline” the stated preference data. This might help reduce the influence that any hypothetical bias might have in the WTP estimates. The marketing literature had been using this approach for more than a decade for a number of purposes including testing for hypothetical bias (see Louviere et al. 2001).

Since the early 1990s, there has been an explosion of combined revealed preference and stated preference studies, particularly in the recreation context. The most recent compendium of state-of-the art papers on combining revealed and stated valuation approaches is Whitehead et al. (2011). This book illustrates the wide variety of applications that the combined revealed preference and stated preference method has been used for. These include pesticide risk reduction, seafood, reservoir operations, as well as recreation.

Of course a reasonable question one might ask is “If you have revealed preference data, why would you want to combine it with stated preference data?” There are several reasons, all related to limitations in relying solely on revealed preference data: (a) revealed preference data may not have sufficient natural variation in amenities or environmental quality to estimate a statistically significant coefficient. This could arise because of limited data availability (e.g., only 1 year of data rather than a time series being available) or because there just isn’t much natural variation in the quality or amenity attribute; (b) the attributes are highly correlated in the data set so that it is nearly impossible to estimate a statistically significant coefficient on each of them separately (e.g., air quality and traffic congestion); (c) the policy being valued would result in changes in quality or level of the amenity that is outside the current range of quality; and (d) introduction of a private good with a new attribute (e.g., locally grown organic corn) or new public good, similar to but not identical with existing public goods.

49.8 Benefit Transfer

Oftentimes economists with state and federal agencies are asked to perform a “quick and dirty” back of the envelope benefit-cost analysis to provide a rough estimate of the benefits and costs of a particular time-sensitive policy proposal or where there is not a sufficient budget that the cost of a survey is feasible.

In this case, environmental economists have developed a set of protocols to transfer existing valuation estimates from prior revealed preference and stated preference studies to evaluate the new policy in question. There are basically four main types of benefit transfer: (a) point estimate value transfer from the most similar study, (b) an average of the values from the prior literatures’ most similar studies, (c) transferring the demand or WTP function from the prior study to the new policy study, and (d) using a *meta-analysis* regression equation estimated on the past valuation studies to calculate what the valuation per unit (e.g., visitor day, household) would be at the new policy site.

In principle, demand/WTP function transfer or meta-analysis have the advantage of being able to adapt the values from the existing literature to better match the criteria for an ideal benefit transfer than would a simple transfer of average values from the literature. Transferring a WTP function that contains demographic variables such as income and age would allow the demand function to be tailored to the sociodemographics surrounding the policy site. In principle, the WTP function approach should reduce benefit-transfer errors as compared to transferring point estimates.

Meta-analysis involves a regression with the value per unit (e.g., recreation day, acre of wetland, household) as the dependent variable and study site characteristics as the independent variables. There have been more than a dozen meta-analyses of environmental and natural resources including water (quality and quantity), electricity, value of statistical life, transportation noise and property values, and wetlands (see Nelson and Kennedy (2009) for a complete listing).

Using a meta-analysis regression equation as a benefit-transfer tool has three potential advantages over average value transfer in terms of an ideal benefit transfer: (a) ability to interpolate a value for a particular public good in a particular region that might not exist in the published literature (e.g., fish species X in region Y might not be available in the literature, only fish species Z in region Y or fish species X in region R); (b) ability to incorporate a nonlinear relationship between the value per unit and the quantity change (e.g., additional acres of wetlands may not have a constant value per acre as an average value transfer implicitly assumes); and (c) ability to account for other attributes of the good being valued (e.g., distinguishing between the value of a recreation activity on public land vs private land). Meta-analyses for benefit transfer are discussed in more detail in Bergstrom and Taylor (2006).

Interest in determining the accuracy of benefit transfer and especially comparing the accuracy of meta-analysis and average value transfers has spawned a substantial literature. This literature uses a comparison of original study values versus benefit-transfer estimates of those same values to calculate the error of benefit transfer. Rosenberger and Loomis (2003) catalog the various estimates of benefit-transfer

errors from value transfers (e.g., point estimates or average values) and function transfers (e.g., primarily meta-analyses). While most of the value transfer errors are in the range of 4–40 %, several are off by 100–200 % (and occasionally more). Benefit function transfer generally does better, but it too can be off by 200 % or more.

One of the tools for improving the accuracy of benefit transfer is for analysts to have access to comprehensive databases and benefit functions. Significant progress has been made in this area in the last two decades. A major advance came with the cooperative Australia, Canada, France, New Zealand, UK, and USA's Environmental Values Reference Inventory (EVRI see <http://www.environment.nsw.gov.au/publications/evri.htm>). This database includes air quality, water quality, wildlife, recreation, and infrastructure. General recreation value databases include Loomis (2005 at http://www.fs.fed.us/pnw/pubs/pnw_gtr658.pdf). For average value tables, databases, and meta-analyses for hunting, fishing, wildlife viewing, wetlands, salmon, endangered species, and open space, see <http://dare.colostate.edu/tools/benefittransfer.aspx> or http://www.defenders.org/programs_and_policy/science_and_economics/conservation_economics/valuation/benefits_toolkit.php.

For the most recent comprehensive discussion of benefit transfer, see the special issue of *Ecological Economics* edited by Wilson and Hoehn (2006) and Rolfe and Bennett (2006) for a discussion of using Choice Experiments for benefit transfer.

Overall, each of these benefit-transfer methods have their strengths and weaknesses, and the choice is sometimes driven by the (lack) of available data. For example, if there are no similar studies for a similar geographic region, then a meta-analysis may be the best answer if a meta-analysis has already been previously estimated by someone else. If not, then an average of past valuation studies might be the best estimate the analyst can use given the time available to conduct the benefit transfer.

However, any of these benefit-transfer approaches is likely better than omitting completely a monetary value for that health effect or recreation activity. Oftentimes the net result of such an omission from the benefit-cost analysis is an implied value of zero. Benefit transfer, while not as accurate as conducting a primary study, is typically more accurate than an estimate of zero.

49.9 Conclusions

The gist of this chapter can perhaps be summed up in a few sentences. Economic theory provides a consistent measure to value market goods and nonmarket environmental externalities and public goods. Market price is just willingness to pay for one more unit. Where price does not exist, economists can infer willingness to pay using revealed preference methods or using a “constructed or simulated market” ask respondents to state their willingness to pay. The revealed preference and stated preference methods are based on the same utility maximization process economists use to estimate demand for market goods. While the econometric details of estimating an econometric model for recreation are slightly different than estimating the demand for gasoline, often times the basic structure of the data

(e.g., cross-sectional data) and econometric issues dealt with have more in common than one might think.

What cannot be summed up in a few sentences is the wide variety of variations on these basic revealed and stated preference methods. These variations arise due to the need to tailor the valuation to the particular types of public goods. As highlighted in this chapter, the economists' toolkit has a wide variety of methods that can be applied to value nearly every type of public goods that are commonly dealt with in benefit-cost, policy, or regulatory analyses.

Environmental valuation theory and methods are evolving areas of research. While environmental valuation originated in the desire to value recreation in public water projects, it quickly saw application to value air and water quality in benefit-cost analyses of environmental regulation. Environmental valuation rose onto the popular presses radar screen with the application of valuation methods to natural resource damage assessments, including oil spills. In the last decades, as the recognition has grown that the environment provides valuable ecosystem services to people, all the valuation methods discussed above, and stated preference methods in particular, have been employed to monetize these values. Interest in developing computer packages to allow government agencies to monetize ecosystem services relies extensively upon benefit transfer. Environmental valuation techniques continue to see new policy applications and no doubt there will be many more in the future.

Abstract

Benefit-cost analysts attempt to compare two states of the world, the status quo and a state in which a policy having benefits and costs is being contemplated. For environmental policies, this comparison is greatly complicated by the difficulty in inferring the values that individuals place on an increment to environmental quality. Unlike ordinary private goods, environmental goods are not directly exchanged in markets with observable prices. In this chapter, the hedonic approach to inferring the benefits of an environmental policy is examined.

P.E. Graves

50.1 Introduction

The hedonic approach to valuing environmental benefits has its roots in agricultural economics (see, e.g., Waugh 1928; Vail 1932). Waugh related the price of asparagus, tomatoes, and hothouse cucumbers to various dimensions of perceived quality (e.g., for asparagus, color, size, and uniformity of spears). In another agricultural context, the value of agricultural land has been empirically related to soil fertility and distance from market and more recently to ecosystem services. In yet another agricultural context, this method – not yet known as the “hedonic method” – was employed to isolate “quality” changes from fertilizer price indexes as the former related to changing percentages of nitrogen N, phosphoric acid P, and potash K (see Griliches 1958 for discussion of the early history).

The method first became known as the “hedonic method” as a result of Andrew Court’s (1939) work at General Motors. Court was interested in separating quality improvements from price increases as automobiles improved rapidly during the early decades after their first introduction. One can implicitly value the horsepower, size, and various other model features with this method, and that valuation could in turn be used to increase GM profit by providing more high-value but low-cost features.

In a now-classic article, Solow used what was essentially the hedonic method in a time series context, holding constant measurable inputs to explain GDP growth – his now-famous “residual” (technological change) was seen to account for a quite large percentage of economic growth, the forerunner of modern endogenous growth models.

It is Griliches (1961), however, who is generally viewed as the “modern father” of the hedonic method. He introduced many refinements in the method in the context of separating quality improvements from price increases to allow construction of better price indices to more accurately measure GDP growth. Early studies tended to focus on either the demand side or the supply side, with Rosen (1974) being the first to present a full general equilibrium discussion; the now-classic Roback (1982) contribution brought the realization that a full general equilibrium requires joint consideration of property value and wage differentials, which we shall return to later in this chapter.

The earliest environmental application of the hedonic method was that of Ridker and Henning (1967). They established that housing prices in St. Louis were higher in cleaner areas, other things equal. There has been a proliferation of property value studies since that time. Valuing water quality is somewhat more difficult with the hedonic method for reasons beyond the scope of this chapter, and far fewer studies have been conducted for this environmental media. A relatively limited number of studies have also attempted to value noise from highways and airports as well as hazardous waste dumps. The valuation of each type of environmental amenity generally brings an amenity-specific set of problems, although the focus here will be primarily on air pollution.

50.2 Value of Statistical Life

This section discusses the first of two distinct areas in which the hedonic method is used in environmental policy, while the section to follow deals with the second. The “value of statistical life” (VSL) is useful to value mortality damages (in the “health effects” or “sum of specific damages” approach) in public policies of a wide variety, environmental policies being emphasized here. This method employs wage regressions to value the risk of on-the-job death, with more risky jobs requiring higher wages, at least in principle. In these studies, the dependent variable is wages (or \ln wages) of individual workers which is regressed upon a vector of individual personal characteristics (e.g., age, education, race, sex, experience) and job characteristics (e.g., occupation, industry, unionization). The risk of death, although quite controversially measured, is then included, with an expectation of a positive coefficient to reflect the needed compensation for job risk.

The compensation required for the higher risk can then be used to estimate the VSL for use in broader policy contexts. Suppose, for example, there is a 1/100,000th higher annual probability of dying on the job as a lumberjack than in an average job and that the typical lumberjack (of, say, 100,000 total) required \$50 more per year (2.5 cents/h, with a 2,000 h-year) to accept this risk. The expected number of excess deaths is then one, and the aggregate willingness-to-pay (the VSL) would be \$5 million, a number not far from those used in actual public policies. If a particular policy is expected to save 20 lives, with no other effects, it would have \$100 million in benefits to be compared to provision costs.

VSL has been inferred in non-labor market settings, as well, with the purchase of smoke detectors, seat belt use, various automotive safety features, etc. having been studied. These other approaches are, however, typically undertaken to corroborate the more ubiquitous labor market approach.

Focusing on the wage hedonic work that has been the dominant influence on environmental policy, there are numerous problems with the conduct and interpretation of these studies (see Dockins, et al. 2004 for an excellent, and very complete, review of existing VSL studies and their limitations):

1. Do people perceive low-probability risks at all accurately? Are actuarial risks more or less appropriate to use than perceived risks when the two differ? Are the actuarial risks themselves properly measured (e.g., a common observation is that the National Institute of Occupational Safety and Health (NIOSH) data on risks yields VSL estimates that are substantially higher than those obtained with Bureau of Labor Statistics (BLS) data, and it is likely that there is also substantial risk measurement error *within* each of these basic data sources)?
2. Is the “marginal” worker in a risky occupation more concerned about risk than the “average” worker? If so, as is likely, the VSL will be biased upward by using the marginal worker’s required compensation.
3. Does the functional specification matter (e.g., linear, \ln -linear, Box-Cox, squared terms)? There is little or no theoretical evidence on which functional form is appropriate to apply.

4. Does inclusion or exclusion of other variables affecting wages result in big apparent changes in VSL? For example, risk of non-death injury is likely to be highly correlated with risk of death; omitting the former will bias the latter upward. Black et al. (2003) find the coefficients from the wage hedonic to be highly unstable with respect to both functional form and data selection.
5. Finally, has the Environmental Protection Agency (EPA) ignored potentially important additional concerns? The EPA does not support adjustments to VSL based on how one dies in specific jobs, age, cross-sectional income, non-death risk dread (e.g., cancer), baseline health status, or voluntariness/controllability of risk – yet each of these might be relevant for an individual’s willingness-to-pay for risk reduction. Trudy Cameron (2010) offers a recent balanced view on the nature of VSL which, among other contributions, suggests that a “less incendiary” terminology than value of statistical life be substituted, perhaps “willingness-to-swap (WTS) alternative goods and services for a micro-risk reduction in the chance of sudden death.”

Progress in the estimation of VSL is ongoing, and many of the concerns raised here are being examined in an effort to improve existing VSL estimates, as seen in the Cameron paper. However, a central insight that cannot be escaped is that any policy decision that involves changes in the probability of death *inevitably* represents an implicit valuation on a statistical life. Explicitly using a specific VSL number is quite likely to lead to better decisions and to decisions that can be analyzed to determine how sensitive the benefit numbers are to alternative assumptions about the magnitude of VSL.

50.3 Hedonic Valuation of Environmental Quality

There have been many studies using either (or in rare cases both) property value hedonic equations or wage hedonic equations to value environmental quality. In either approach, the dependent variable (either wages or property value) is regressed upon as many causative independent variables as are reasonably available, to which are added variables measuring environmental quality. Numerous readily available review articles have dealt with the many theoretical and econometric issues with the hedonic method (e.g., Palmquist 2005; Taylor 2008), while Graves (2011) presents a simplified verbal and graphical exposition that is accessible to those with widely varying backgrounds. The approach taken here is to provide a “middle-ground” verbal approach to understanding the hedonic method, an approach that will be seen to clarify some interpretations that are either not widely known or which are ignored in typical studies.

As was the case with VSL studies, accurate valuations of environmental improvements in either land or labor markets require that households have “good” (perfect ideally) perceptions of both (i) where it is clean and dirty and (ii) what various levels of environmental quality mean to our health and welfare. Under such strong assumptions, one would expect people to ponder how to avoid risks of death, on the one hand, or pollution damages, on the other. The insight that

underlies the hedonic approach to environmental valuation is that as long as an individual's marginal cost of avoiding damages is less than the marginal benefits of avoiding damages, that individual would be expected to continue to avoid damages until marginal costs and benefits are equated.

Households can lower pollution damages by either moving to a cleaner town or by moving to a cleaner part of the town they currently occupy. However, since many other movers and non-movers would – other things equal – prefer to occupy cleaner locations, other things cannot remain equal. As will soon become clear, one would expect to observe falling wages and rising housing prices in the clean location until identical households are no better off in a clean location than in a dirty one.

While this central idea is straightforward, there is confusion in the details, a confusion this chapter is designed to clarify. We shall take up the labor market approach in [Sect. 50.4](#), since it follows naturally from the VSL discussion, turning to the property value approach in [Sect. 50.5](#). The only difference between our earlier discussions is that rather than focusing on wage compensation for risks of death on the job, we focus on environmental quality which varies among labor markets, hence should lead to varying levels of wage compensation among those labor markets.

50.4 Wage Compensation for Environmental Amenities

If City A, one of two otherwise equivalent cities, has higher pollution levels than City B, one would expect residents to move from A to B, reducing the labor supply (raising wages) in A and increasing labor supply (lowering wages) in B – and one would expect this movement to continue until the relatively lower wage in B exactly compensates for the utility value of B's better environment (as we shall see later, this expectation is not fully correct).

One powerful advantage of this approach is that the benefits of environmental cleanup are directly observed in dollar terms, which makes for very convenient comparison to the dollar costs of policies that would result in cleaner cities. Moreover, nonlinearities and synergistic interactions among various pollutant types can readily be explored. This can be easily seen with reference to the following estimation equation:

$$W = \alpha + \beta X + \gamma PM_{10} + \theta (PM_{10})^2 + \delta SO_2 + \lambda (SO_2)^2 + \eta (PM_{10}SO_2) + \varepsilon \quad (50.1)$$

where W is annualized (or hourly) wages, X is a complete vector of traditional wage determinants employed in earning functions in the labor economics literature (education, experience, age, occupation, region, union, etc.), and β is the vector of coefficients on the variables in X . PM_{10} is particulate matter 10 μ m in diameter or smaller, SO_2 is sulfur dioxide, and the Greek letters preceding these variables are their respective regression coefficients. The error term, ε , of the regression must

meet certain classical regression requirements (iid, no spatial autocorrelation, etc.) with failure to meet those requirements suggesting mis-specification of the regression model. Once a data set, hopefully with many observations, has been amassed and the regression in Eq. (50.1) has been properly specified and estimated, it is a simple matter to calculate marginal pollution damages:

$$\partial W / \partial PM_{10} = \gamma + 2\theta(PM_{10}) + \eta(SO_2) \quad (50.2)$$

The interpretation of Eq. (50.2) is quite simple: the first term, γ , is the marginal damage from an incremental change in PM_{10} under linearity (expected to be positive as discussed earlier); the second term indicates the degree of nonlinearity (e.g., marginal damages are increasing in pollution levels if $\theta > 0$), while the final term indicates the extent to which PM_{10} damages depend on how much SO_2 is present. All of the coefficients would be in convenient dollar form, and to the extent that the second two terms are significantly different from zero, public policy should have pollution standards for any particular pollutant (and economic incentives) that vary with both (a) levels of pollution and (b) levels of other pollutants present. At present, this possibility is completely ignored in environmental policy, and a fruitful line of research would be to delve more deeply into nonlinear and synergistic damages. Since there is very little theoretical guidance on the nature of the appropriate functional form for pollution damages, researchers (inadvertently) and advocates (deliberately) might well distort environmental values by their choices along a number of dimensions (omitting variables that are positively or negatively correlated with the environmental variables, employing a linear model when the data suggest a nonlinear form is more appropriate, etc.).

In closing discussion of the wage hedonic approach, it should be reemphasized that this method only works well when people are very aware of both where it is clean and dirty and how working in a clean or dirty location affects them. Bockstael and McConnell (2007), however, in a review of wage studies, find clear evidence that households are willing to give up wages to live in cleaner locations.

50.5 Property Value Compensation for Environmental Amenities

The property value or rent compensation method employs a virtually identical way of thinking but applies the notion that movements will equilibrate utility within an urban area through adjustments in land values. How much a house will rent or sell for is clearly related to the bundle of positive and negative traits that comprise it. The traits are many: structural (e.g., stone or wood, square footage, number of bathrooms, lot size, type of heat), neighborhood (e.g., school quality, crime rates, access to a wide variety of destinations, notably the central business district in traditional urban models), and – our interest here – environmental quality.

Environmental quality is sometimes viewed as a “public good” in the sense that whatever environment exists in an area is essentially unaffected by an individual

household's behavior and that an individual household cannot be excluded from enjoying whatever level of environmental quality exists in that area. The property value hedonic method relies on the location specificity of pollution levels – that they vary over space in an urban area – to convert environmental quality into a private good that is “bundled” with housing choice. As with the wage hedonic, assuming that perceptions are “good” (ideally perfect), the value of varying levels of pollution within a city should be captured in property values.

The process is quite similar to the wage hedonic approach and can be represented as in Eq. (50.3):

$$PV = \alpha + \beta X + \gamma PM_{10} + \theta(PM_{10})^2 + \delta SO_2 + \lambda(SO_2)^2 + \eta(PM_{10}SO_2) + \varepsilon \quad (50.3)$$

where PV, property value, is ideally actual sale price rather than listing price, with the only important difference from Eq. (50.1) being that instead of containing variables affecting wage, the X vector instead is comprised of all structural and neighborhood traits affecting housing value, with the other variables are as defined earlier. The Greek coefficients are the regression coefficients of a properly specified model resulting in an error term with appropriate properties.

To find how property values vary in a systematic, functional way with pollution levels, we again partially differentiate Eq. (50.3) with respect to a pollutant of interest, say particulates:

$$\partial PV / \partial PM_{10} = \gamma + 2\theta(PM_{10}) + \eta(SO_2) \quad (50.4)$$

The interpretation of the coefficients are exactly as before, with γ capturing the linear impact of pollution on property value, 2θ capturing the extent of any non-linearities, and η testing for synergisms ($\eta > 0$ damages are “supra-additive,” while $\eta < 0$ damages are “sub-additive”). Krumm and Graves (1982) found a significant positive η indicating synergistic increases in particulate damage, measured by hospital admissions, when more sulfur dioxide is present. As with the wage hedonic, the coefficients give us marginal damages (the benefits of cleaning up) in a very convenient dollar form enabling comparison to marginal provision costs.

As with the wage hedonic approach, there is little theoretical guidance as to the nature of the functional relationship between property values or rents and the traits that exert a causative influence, allowing advocates to intentionally publish widely varying results even from identical raw data. Krumm and Graves employed a methodology devised by Zellner and Siow (1980) that, at least in principle, eliminates biases when theoretical guidance on functional form is limited. The potential to deliberately publish biased results is of more than academic concern since there is considerable evidence that estimated property value effects of pollution are not robust to alternative specifications (see Graves et al. (1988) for more in-depth discussion).

For either of the wage or property value methods, problems related to either data limitations or assumption of perfect information exist. If, for example, some other

disamenities are positively correlated with the pollution measure and those other disamenities are omitted from the equation, the value of the pollution damages will be biased upward. For example, suppose that the more polluted parts of a city are also less desirable for other reasons (more crime, worse schools, more graffiti, street potholes, poorer lighting, fewer parks, etc.) and these other traits are omitted from the equation. By not including the other goods that are correlated with pollution, the impact of pollution will appear to be larger than it is, since the effects of the other non-included variables will be partially attributed to environmental quality (the magnitude of the bias will equal the coefficient on the omitted variable if it were included times the correlation coefficient between that variable and pollution). With constantly improving data acquisition, this problem is becoming less important over time.

Since experts argue heatedly about health and other damages and since many pollutants are odorless, colorless, and tasteless in ambient concentrations, it is plausible that households might fail to fully perceive either (a) the impact of pollution on their health and well-being, (b) how pollution levels vary over space, or (c) both. To the extent that perceptions are imperfect, one would expect that the hedonic methods would yield pollution damage coefficients that are biased downward, since households would not be expected to be willing to pay for unperceived benefits of cleaner locations.

What is the net effect of these potential biases, one suggesting overvaluation and one suggesting undervaluation? Nobody knows the answer to this question with confidence, but a great many property value studies – as was the case with the smaller number of wage differential studies – show strong positive relationship between property values and environmental quality. The property value approach might be thought to be particularly useful for valuing spatially concentrated environmental damages (e.g., toxic waste dumps), and the wage differential approach might seem more appropriate for region-wide amenities (e.g., large pollution clouds or climate). As we shall see in the following section, these beliefs are, generally, quite flawed.

50.6 Wage and Property Value Hedonics Are Not Alternatives: The Multimarket Hedonic Method

Until fairly recently (new information spreads slowly), the two approaches to valuing pollution damages were viewed as alternative approaches. It was thought that clean air, for example, could be valued either by variation in property values within an urban area or by wage variation between urban areas. Indeed, if the values happened to be similar under the two methods, greater confidence was placed in either as a measure.

It turns out that this is incorrect under plausible assumptions about people's behavior when evaluating locations. Indeed, for this view to be valid, households would have to follow a two-stage procedure when locating – first, looking only at wages, select a labor market, and at a second stage, select a location within that

labor market. This would clearly be irrational since households could make better location decisions by looking at the combination of wages, rents, and amenities available in all locations prior to selecting their best location.

To further clarify, another way to think about this is that, between two otherwise identical locations, the one that is more polluted will be less attractive – so people will move from the more-polluted to the less-polluted location until they are equally well off in both locations. But, as they move into the less-polluted location, they both increase the supply of labor (driving down wages) and increase the demand for housing (driving up property values and rents). Hence, the true value of the less-polluted locations is the sum of what must be paid for reduced pollution in both the labor and land markets.

To many, the argument of the preceding paragraph is not clear or convincing, so additional discussion is useful. Suppose, as a soon to be dropped initial assumption, that the entire world were a flat, featureless plain where all locations are identical. In this scenario, there is no variation in closeness to ocean, scenic views, and the like. Just as there would be no reason to pay more for identical automobiles, there would be no reason to pay more in either land or labor markets for one location over another. Further, as again soon to be dropped, assume that all households have the same preferences and all firms have the same cost functions (and are selling on national markets at one price, hence have the same profit functions in all locations). With these assumptions in place, there would be no variation in demand for lots of different sizes or for hours worked on the part of households nor would there be variation in the relative land/labor intensity on the part of firms.

In this simple initial scenario, wages and rents would – in equilibrium – have to be the same in all locations. If, for example, there were a location with higher rents, households would have to be compensated by higher wages or they could not be equally well off there *vis-à-vis* elsewhere. But, if they *are* compensated with higher wages, the higher wage/rent location would have to be less profitable than other locations for firms; hence, firms would leave, reducing the demand for labor and indirectly reducing land demand as household employment falls. If a location had lower rents than elsewhere, households would move in until lower equilibrium wages made them indifferent to other locations – but the lower rents and wages would stimulate firm in-migration, until wages and rents were raised to those of other locations. Hence, were the world as boring as the flat, featureless plain and homogeneous household/firm assumptions imply, rents and wages would have to be identical in all locations in equilibrium (see Graves 2011 for a full graphical presentation of this and subsequent discussion).

Now let us begin dropping these unrealistic assumptions, first by introducing variation in an amenity that households care about (e.g., a scenic view or lower humidity), but which has no impact on firm profitability. If we are at an initial equilibrium with wage and rent levels equal in all locations, any location possessing more than average amounts of the desirable amenity will be more attractive, hence will lure in-migration of households. But that in-migration will result in increased labor supply along with increased land demand. Hence, the desirable location(s) will

have lower wages and higher rents, in some combination that renders – in equilibrium – utility the same in the desirable location(s) as in the average locations.

Similarly, undesirable locations will experience household out-migration at the initial common wage and rent levels, resulting in some combination of lower rents and higher wages in undesirable locations relative to average locations. Note that the compensation paid (for desirable locations) or received (at undesirable locations) represents a measure of “quality of life.” The higher rents and lower wages do not represent a higher “cost of living” in the nice locations but rather a higher “benefit of living” there. The higher benefits of living in the desirable location – as with quality variation among ordinary goods – must be paid for in equilibrium. Hence, were all households homogeneous, there would be in equilibrium no reason to prefer one location over another, despite wide variation in amenity levels, since any gain in amenities would be fully offset by higher rents and lower wages and conversely. Locations that are unusually nice for households will have larger populations than other places.

If an amenity affects firm profitability (e.g., access to resource inputs) without having any impact on household utility that will not, in equilibrium, result in greater profits for the firm. Rather, firms will enter driving up land rents directly and indirectly via employment and driving up wages (the latter necessary to compensate households for the higher rents, which is made necessary by the fact that the location is no “nicer” for them). Note that in this case, the higher rents *do* represent a higher “cost of living” but that higher cost must be completely offset by higher wages. Locations that are unusually nice for firms will, as with household amenities, have larger populations than other places.

The preceding two cases lead to nine spatial combinations, with a rich tapestry of possible wage and rent combinations:

- a. The “average” location (average wage, W_0 , average rent, R_0 , and average size, S_0)
- b. Nice for households, neutral for firms (lower W , higher R , larger S)
- c. Bad for households, neutral for firms (higher W , lower R , smaller S)
- d. Nice for firms, neutral for households (higher W , higher R , larger S)
- e. Bad for firms, neutral for households (lower W , lower R , smaller S)
- f. Nice for both households and firms (ambiguous W , higher R , larger S)
- g. Bad for both households and firms (ambiguous W , lower R , smaller S)
- h. Bad for households, good for firms (higher W , ambiguous R , ambiguous S)
- i. Bad for firms, good for households (lower W , ambiguous R , ambiguous S)

Case 9, which we will return to in the following subsection, is of particular interest for environmental policy, since many environmental policies raise the costs of firms but provide benefits to households. Until the early 1980s, most economists believed that imposing stringent controls on firms in a location would result in them leaving that location. This led to fears of a “race to the bottom,” since firms leaving raise unemployment in the short run and firms entering less stringently regulated areas would reduce unemployment in the short run. This presumption was based on a focus on the firm impact, ignoring the impact on

households. If the cost increases associated with the environmental policy are relatively small and the household benefits relatively large, the location might well experience growth as it moves to a larger equilibrium size, S .

Ignored in, but implicit in, the hedonic discussion to this point is the impact of in-migration and out-migration on what might be called “endogenous amenities and disamenities.” That is, if a desirable location for households exists, one would expect in-migration until the lower wages and higher rents rendered that location no more desirable than other locations. But, it is also the case that in-migration might increase levels of endogenous disamenities (e.g., pollution, congestion) or might increase levels of endogenous amenities (e.g., restaurant diversity, local goods with scale economies in production). In a full general equilibrium analysis with all important amenities included, this would not matter because the “net niceness” of the location will still be captured by rents and wages.

But data limitations in actual studies are likely to lead to mismeasurement of the value of amenities. If, for example, measures of increased cultural opportunities or restaurant quality and diversity are positively correlated with the amenity but are omitted from the hedonic estimates, then the value of the amenity will be *overstated* by the wage/rent differentials observed – the coefficient on the amenity variable will be larger by the omitted variables’ effect times the correlation with the amenity. Similarly, if increased congestion is positively correlated with the amenity but was omitted from the equation, then the wage/rent variation would *understate* the value of the amenity. In the environmental context, increases in pollution and congestion are both likely consequences of movements to desirable – perhaps because of better climate – locations, but if changes in congestion are omitted from the estimating equation, the pollution variable will pick up the effect of congestion times its correlation with pollution.

A common criticism of the underlying assumptions of the hedonic method is that households and firms, especially the latter, might have very high movement costs; hence, disequilibrium might persist for very long periods. If this is the case, then observed wage and rent differentials would not be entirely compensatory. That is, high-wage places might be “high-utility” places because more of all goods could be consumed there, while high-rent places might be “low-utility” places because fewer goods could be consumed in such high-cost locations.

A couple of observations are pertinent to this issue. First, it might not take too many people or firms actually moving to yield a close approximation to a full-mobility equilibrium. This is analogous to the fact that only a few drivers need to move from “slow lanes” to “fast lanes” on a freeway at rush hour to make all lanes equally fast. Second, as an empirical matter, in recent decades, households have been moving *toward* high-rent locations and *toward* low-wage locations. With rising nationwide incomes, this trend is consistent with an equilibrium in which desirable locations are also normal or superior goods (i.e., at higher national incomes, there is even greater demand for the already desirable subnational locations).

50.7 What if Single-Market Hedonic Analyses Are Employed Rather than Multimarket Analyses?

Very few multimarket hedonic analyses have been conducted (for an early contribution, see Blomquist et al. 1988), while a very large number of hedonic analyses have been conducted in either the labor or land markets considered separately. What are the implications for environmental valuation of using a rent hedonic or a wage hedonic rather than the combined analysis implied by prior discussion? The taxonomy of household/firm amenity combinations, 1 through 9 above, has clear implications for valuation biases introduced by failure to consider both markets.

We will focus on the policy-relevant case where one is attempting to determine the value of environmental quality to households (to use that information to infer benefits to be compared to costs in environmental benefit-cost analysis). Many environmental policies tend to be applied uniformly over space, but that does not, in general, mean that their benefits and costs are uniformly distributed over space. For example, required catalytic convertors on automobiles raised costs in rough proportion to population, but the benefits of that policy would be much higher in locations (e.g., Los Angeles, Phoenix, Denver) that are sunny and warm and/or have stagnant air conditions. Hence, a uniform policy can have pronounced effects in making locations such as Los Angeles *relatively* more attractive than they would otherwise be, encouraging in-migration and resulting higher land values and lower wage rates. In cases such as this, where there are negligible impacts on local firms, it would clearly be the case that using either a property value hedonic or a wage differential hedonic in isolation would result in *underestimation* of environmental benefits relative to a multimarket approach. The extent of bias will depend on the relative capitalization rates and which of the two hedonic methods are chosen – if most of the impact of the policy goes into wages, using a property value approach will greatly underestimate benefits, and conversely.

Other more location-specific environmental policies, such as Pittsburgh introducing controls on steel polluters in the 1950s prior to nationwide control policies, will have direct impacts on both local firms (harmful) and local households (favorable). The harm to firms would lead to lower demand for labor, while the desirable impacts on households would lead to an increase in the supply of labor. Both of these effects cause wages to fall, but the net effect on property values/rents is ambiguous, depending on whether the city gets larger or smaller as a result of the policy. In such cases, a wage hedonic is much more likely to accurately value the environmental improvement than would a rent hedonic, the latter falsely implying little or no environmental benefits from the policy. As a “fluke,” it might be that the wage hedonic picks up the full value of the environmental policy, but in general, adding the information from a property value study would lead to more accurate estimates. It should be noted that the compensation shares are not limited to $[0,1]$, but rather more than 100 % of the benefits could go into wages and the rent compensation could actually be negative (e.g., if the environmental policy harmed firms very much, so that the city got smaller, with lower rents in equilibrium).

If a property value study is used in this case, it would seem like the environmental improvement had negative value!

If an environmental policy at a location is good for both households and firms, both would want to move in. Suppose, for example, that a nationwide law is passed that subsidizes firms to clean up in areas where there is non-attainment of air pollution standards, with no subsidy in areas meeting current air pollution standards. This situation would cause rents to rise in locations subject to the policy with an ambiguous impact on wages. Wages would rise if the policy benefited firms relatively more than households, while wages would fall if the policy benefited households relatively more than firms. In this case, the value of the environmental amenity would appear largely in land markets, but again only as a fluke would there be no labor market effects. In this case, the choice of a hedonic wage analysis will greatly understate the value of the cleaner air.

It has been assumed to this point that all households and all firms are homogeneous. This is of course not the case in realistic settings. Land-intensive firms would not be expected to be found in locations where land is expensive (which is why corn is not seen growing in downtown New York City). Similarly, those households who have unusually large preferences for land, perhaps those with large families or pronounced gardening desires, would not locate where land is very expensive, perhaps locating in suburbs or exurbia rather than in more central areas.

If a firm's labor demands are unusually large, it would avoid locations with unusually high wages. If a household does not supply labor (e.g., the retired as discussed in Graves and Waldman 1991), they would want to locate where amenities are mostly paid for in wages rather than rents. This would also be the case for those who have very high demand for services. Conversely, those households that supply low-skilled labor to service industries are likely to be priced out of very desirable and high-rent locations (e.g., Malibu, CA; Aspen, CO; or Key West, FL) and will have to be compensated in higher wages to locate there or commute in to work, that is, the low-skilled may actually have higher wages in desirable locations. As the preceding discussion makes clear and as even casual reference to the real world verifies, there is a very rich tapestry of locational choices when the full implications of the role of firm and household amenities are considered. This is even more the case when endogenous amenities are considered, amenities such as the amount of similar people present in a community (e.g., the ethnic neighborhoods of large cities that often make them much more attractive to particular types of people than would otherwise be the case). Summarizing, there are five reasons why hedonic methods are likely to understate the value of environmental quality improvements. The first, and most obviously damaging, is that the benefits of environmental quality must be fully perceived by households for them to be willing to pay more for cleaner locations. As mentioned earlier, even the world's foremost health experts have spirited debates about the role various pollutants play in human disease and death. It seems very implausible that ordinary people would be able to accurately perceive such things. Additionally, many pollutants are odorless, colorless, and tasteless in normal ambient concentrations; hence, ordinary people might

be unable to distinguish the clean places from others. It is unlikely then that many important environmental effects would be capitalized into property values.

Why do hedonic studies show such large environmental effects then? It is certainly the case that people will perceive localized smells, bad visibility, and other impacts of pollution that are inevitably revealed by our five senses. Yet, it is precisely such perceived damages that are ignored in the sum of specific damages approach (sometimes called the “health effects” or “averting behavior” approach) which is often used in environmental policy analysis. A good argument – the second reason why hedonic methods understate environmental values – could be made for *adding* the damages estimated via sum of specific damages (lives saved, reduced asthma attacks, etc.) to those estimated via hedonic methods. This follows from the fact that the damage categories measured by the two methods exhibit very little overlap – damages that are *perceived* would be expected to go into property values and wage differentials, while damages that are *unperceived* would be measured by the sum of specific damages approach.

The third reason – discussed at length earlier – for why hedonic methods are likely to understate environmental values is that it is still the case that separate analyses in labor or land markets are still the norm, when it has been known for several decades now that only a multimarket hedonic can accurately capture the full value of the environment. The circumstances under which a single-market analysis could accurately value an environmental amenity are extremely rare (e.g., a fixed housing stock, a retired population).

The fourth reason for expecting the hedonic method to understate true benefits is that the hedonic method, even properly conducted, only captures *use* benefits of the environmental resources of concern, since the amenities are bundled with housing and jobs. Nonuse benefits might well be of greater magnitude in particular environmental settings, and policies allocating the environmental resource should, on efficiency grounds, encourage highest value usage even if that results in nonuse of the environmental resources. Illustrating, is the California Coastal Commission properly allocating scarce ocean locations? It is clear that in the absence of this regulatory authority, virtually the entire coast of California would be lined with high-rise condos, looking much more like Miami than at present. But, the scenic Pacific Coast Highway has value to all who drive it, and to a large extent, that value has been perceived as being of greater importance than the (admittedly very large) benefits households would receive if the coast were opened to unrestricted development.

The final reason why hedonic methods might be expected to understate the benefits of environmental cleanup stems from the supplies of clean locations relative to the demands for clean locations. The hedonic method results, at least in principle, in zero spatial consumer surplus for similar households. That is, if one location is nicer than another location, households will continue to move to the nicer location, until it is no longer nicer, until identical locations have identical prices. There will be no consumer surplus over space, and indeed, this is one of the reasons the hedonic method is desirable in that the full benefits that are perceived are measured.

But the fact that people are very different means that understatement of environmental benefits (damage reduction) can occur if there are more locations with the amenity than there are people strongly desiring the amenity. Suppose, for example, that there are very few households containing really unhealthy individuals, individuals with weakened cardiopulmonary systems who would be highly damaged by pollution. Such households might be willing to pay a great deal for a very clean location, but they might only have to pay a much smaller amount, if the number of somewhat clean locations is large relative to the number of these households. They will get, in other words, consumer's surplus over space. Inferring the value of cleaning up the environment from the average person in this case would ignore the high marginal benefits received by these households. As another illustration of the potential importance of this point, a hedonic analysis of a large city might suggest that its mass transit system has low value, because those who have the greatest use value (e.g., the disabled or those who particularly dislike automobile commuting) may only have to pay a small portion of their true willingness-to-pay in land or labor markets.

When one considers the very large number of traits that can matter to a heterogeneous population with very diverse preferences, it becomes clear that a great deal of consumer surplus can remain in the hedonic equilibrium. In the case of incrementable environmental goods, the unobserved consumer surplus corresponds to a higher marginal value that might if observed justify a policy intervention to increase levels of the public good.

The hedonic method is quite popular due to its ability to provide a convenient dollar measure of marginal environmental damages (damage reduction being the benefit of environmental cleanup policies). The limitations discussed here imply that there is a great deal of room for improvement in this method and raise issues of how best to get at the *total* marginal benefits, measured in all markets that households have to pay in.

50.8 Conclusions

The goal of this chapter was to describe the hedonic method as a means of valuing environmental quality improvements. The hedonic approach requires very good, ideally perfect, perceptions of environmental benefits (or risk in the VSL case) along with good/perfect knowledge of how environmental quality varies over space (or risk over jobs in the VSL case). This assumption is highly suspect in many settings.

Moreover, it remains the case that expert legal testimony and typical regulatory practice still commonly employ either a property value study or a wage study, despite our having known for more than two decades that compensation for environmental amenities and disamenities will generally occur in both the land and labor markets. The extent to which damages appear in land versus labor markets would generally vary according to many things, but considering either market separately is likely to greatly underestimate the damages from pollution. If an environmental pollutant were highly concentrated (e.g., a hazardous waste dump),

one would expect a greater percentage of its damage to appear in property values, while the damages from more regionally ubiquitous pollutants might be expected to appear primarily in wage rates. The existence of firm amenities and disamenities complicates the ability to establish general conclusions, however, but it remains the case that using only one of the two markets in which environmental quality is valued generally results in understatement of environmental values.

Abstract

This chapter presents an overview of the mass balance principle and its applications. It is an important tool for quantifying wastes which are produced by economic processes. These wastes are equal in mass to the difference between total raw material inputs to the process and useful material outputs. Products are becoming more complex which results in an increase of input mass and wastes. It is safe to say that nowadays process wastes far exceed the mass of materials that are finally embodied in useful products.

The application of the mass balance principle can take many shapes and forms, and this chapter illustrates a few. Using mass balance and chemical engineering knowledge of processes, we found that on a yearly basis, the inorganic chemical industry has a yield of 91 % (9 % of the inputs end up in waste), and the organic chemical industry has a yield of 40 %. A second example is the rare earth metal industry, where potential recovery of these scarce metals is quantified to motivate reuse and recycling. Presently less than 1 % of rare earth metals are recovered from end-of-life products, but as the demand for these resources increases in the near future for products such as electric motors and wind power turbines, recovery will become necessary.

An introduction to thermodynamics and exergy is included, since all wastes are thermodynamically degraded as compared to raw materials. The exergy of the inputs, products, and wastes is an important factor to consider for process efficiency and environmental evaluation.

51.1 Introduction

We constantly perform material flow analysis in our daily activities without realizing it. For example, when we balance our checking account, we sum the money we are crediting to our account to the current balance and subtract our expenses. Unknowingly we are applying one of the most fundamental principles that govern our existence: the mass balance principle that states that *mass cannot be created nor destroyed*. This physical law has nontrivial consequences in economics. Economic processes require inputs, both energy and matter, and invariably generate waste. Economic products are becoming more and more complex requiring many times the materials and energy that are finally embodied in the product, resulting in many waste streams to land, air, and soil. A cellular phone 10 years ago required in the order of 20 different materials such as different plastics, copper, aluminum, and steel. Nowadays, a multifunctional mobile phone can have as many as one thousand different kinds of materials (Mueller et al. 2003). Eventually the products become waste themselves. This leads us to the idea of analyzing the *material life cycle*: a more comprehensive assessment of resource use and wastes also referred to as a “life cycle analysis” approach.

The following equation represents the mass balance principle:

$$\begin{array}{rcccl} \text{Mass} & & \text{Mass input} & & \text{Mass output} & & \text{Mass} & & \text{Mass} \\ \text{accumulation} & = & \text{through} & - & \text{through} & + & \text{generation} & - & \text{Consumption} \\ \text{within the} & & \text{system} & & \text{system} & & \text{within the} & & \text{within the} \\ \text{system} & & \text{boundaries} & & \text{boundaries} & & \text{system} & & \text{system} \end{array}$$

The mass consumption and generation terms are associated to transformation due to chemical reactions. If there are no chemical reactions taking place, then these two terms are zero. If we assume steady state conditions, there is no accumulation of mass and the equation is further simplified.

There are two basic approaches that can be used to carry out material balance. The analysis can be performed based on (a) the total mass in each stream entering and leaving the system and/or (b) the composition of each stream entering/leaving the system. Figure 51.1 represents the production of sulfuric acid (H_2SO_4) used to illustrate both approaches. In general terms, sulfuric acid production consists of a series of chemical reactions in which water, oxygen, hydrogen, and sulfur are needed and emissions such as SO_2 result as waste. Energy is needed in order to drive this process which consequently results in CO_2 emissions, useful work, and heat loss – but for simplicity we will not consider energy terms.

51.1.1 Material Balance by Total Mass

If we know the total amount (in kg) of sulfuric acid produced and the inputs required, we can easily calculate the amount of emissions that result from this process. This is illustrated by Fig. 51.1a for the production of 1 kg of H_2SO_4 and Eq. (51.1) applied to this case:

$$\begin{aligned} \text{Total input} &= \text{product} + \text{waste} \\ (190 \text{ g H}_2\text{O} + 500 \text{ g O}_2 + 330 \text{ g S}) - 1000 \text{ g H}_2\text{SO}_4 &= \text{emissions} = 20 \text{ g emissions} \end{aligned} \quad (51.1)$$

51.1.2 Material Balance by Element

If we want to know the composition of emissions, we could perform a type (b) analysis where a mass balance is performed element by element. Since the composition of the product is known, we can calculate the composition of the waste using the molecular weight (MW) of each element. This is illustrated in Fig. 51.1b: there is an input of 670 g of O which comes from the water and O_2 . We also know that the product output is 1 kg of H_2SO_4 which is equivalent to 10.2 moles of H_2SO_4 , 40.2 moles of O, or 650 g of O. Applying Eq. (51.2) by element gives the following:

$$\begin{aligned} \text{Total O input} &= \text{O in product} + \text{O in waste} \\ 670 \text{ g O} - 650 \text{ g O in product} &= \text{O in waste} = 10 \text{ g O} \end{aligned} \quad (51.2)$$

So now we know that of the 20 g of emissions calculated using approach (a), 10 g is of oxygen. This is just based on some simple calculations, but if we were to use simulation software that also takes thermodynamics into consideration, we could in theory know in what compound and in what state that oxygen ends up as in the waste stream.

To summarize, the MFA procedure follows these steps:

1. Define the process under study and the system boundaries, both spatially and temporally.
2. Label all flows, inputs, outputs, and accumulation.

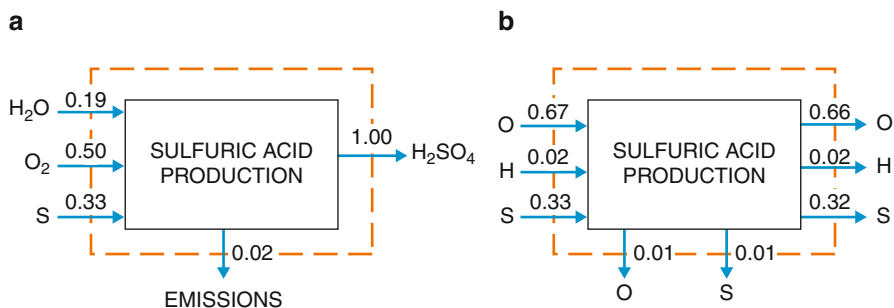

Fig. 51.1 Sulfuric acid production: (a) mass balance by chemical compound and (b) mass balance by chemical element

3. Identify all known values of composition and stream flows.
4. List all independent mass balances that are possible. Sometimes assumptions must be made when not sufficient data is available.
5. Solve the equations for unknown variables.

51.2 Applications of Material Flow Analysis

The field of industrial ecology is well known for evaluating industrial systems based on material flow analysis. The industrial system under study can be at any level: the most encompassing one being global and the simplest being a single manufacturing process such as the sulfuric acid production illustrated earlier. The basic approach is that the system to be analyzed is viewed as a transformation process that requires certain inputs such as material, energy, and “free goods” from the environment. These are converted to products, by-products, and wastes that can be airborne, liquid, or solid. In other words, the system “digests” raw materials into products and the whole process is referred to as “industrial metabolism.” Thanks to the mass balance principle, wastes can be calculated if we know the sum of the inputs and useful outputs.

There are different types of MFA depending on what system needs to be evaluated and what the objectives are. Figure 51.2 summarizes the types of material flow-related analysis that can be done. Basically, MFA is divided into two types: (a) for studying a specific environmental problem related to certain impacts per unit of flow of substances, materials, and products within certain firms, sectors, and regions and (b) for analyzing problems of environmental concern related to the throughput of firms, sectors, and regions associated with substances, materials, and products.

51.2.1 Studying Flows of Substances, Materials, and Products

The main purpose of studying flows of substances, materials, and products through a system is to clearly define the metabolism of the material or system under study.

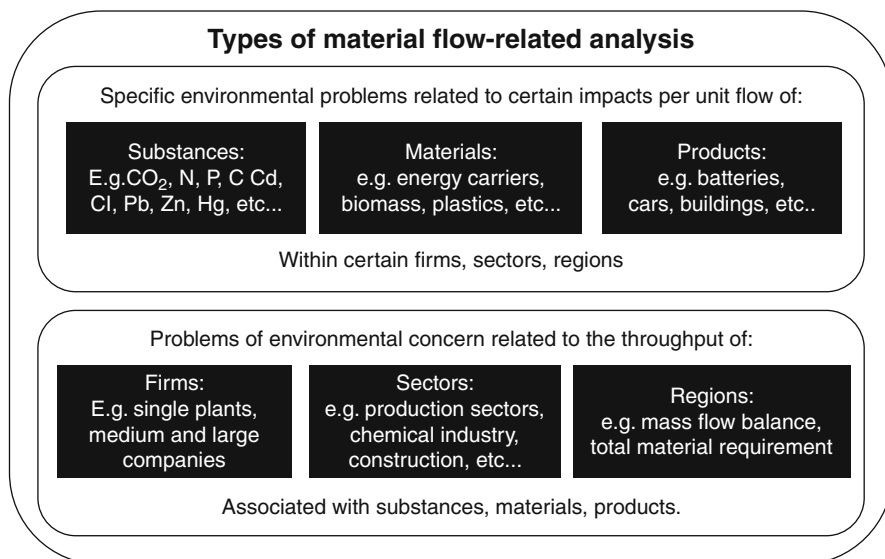

Fig. 51.2 Types of material flow-related analysis (Source: Adapted from Bringezu and Moriguchi (2002))

For example, the study of major chlorine-based chemicals defines the chlorine metabolism throughout the economy and also identifies other production processes where chlorine (Cl₂) is used to produce intermediate products such as caustic soda (NaCl) or final products such as paper (Ayres and Ayres 1998). Figure 51.3 shows the material flows in the production of major chlorine-based chemicals in the USA in the year 1993. This study quantifies all chlorine wastes and emissions during production and also identifies the most intensive chlorine-consuming sectors, in this case the organic synthetics (11.15 million t) and paper and pulp mills (4.14 million t). It was useful to quantify chlorine losses because of its toxic potential and various pollution problems, the ozone depleting effect of chlorofluorocarbons (CFCs) and the risks incurred through the incineration of materials such as polyvinylchloride (PVC). This type of MFA, also referred to as substance flow analysis (SFA), determines the main entrance routes of chlorine to industry which is useful for qualitatively assessing risks to substance-specific endpoints (Van der Voet 2002).

51.2.2 Studying Firms, Sectors, and Geographical Areas

MFAs can also be applied to firms, sectors, or geographical areas, to evaluate their environmental performance. For example, by performing an MFA to a firm producing chlorine (Cl₂), we can calculate material requirement for its production (resource depletion) and the wastes and emissions per tonne of chlorine produced. Figure 51.4 illustrates these figures for the production of 1 t of chlorine (Cl₂) by

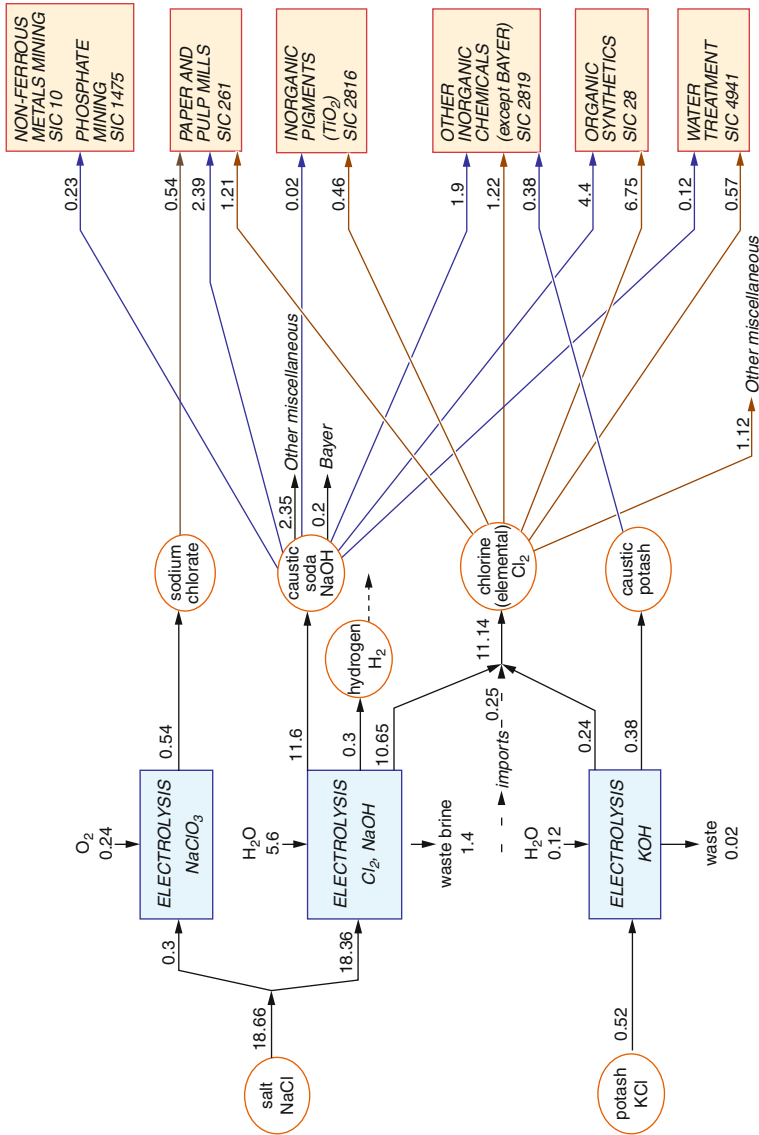

Fig. 51.3 Material flows in the production of major chlorine-based chemicals in the USA, 1993 (tonnes) (Source: Ayres and Ayres (1998))

*Wastes are pretreatment & pre-reprocessing
Cleaning & cooling water not included*

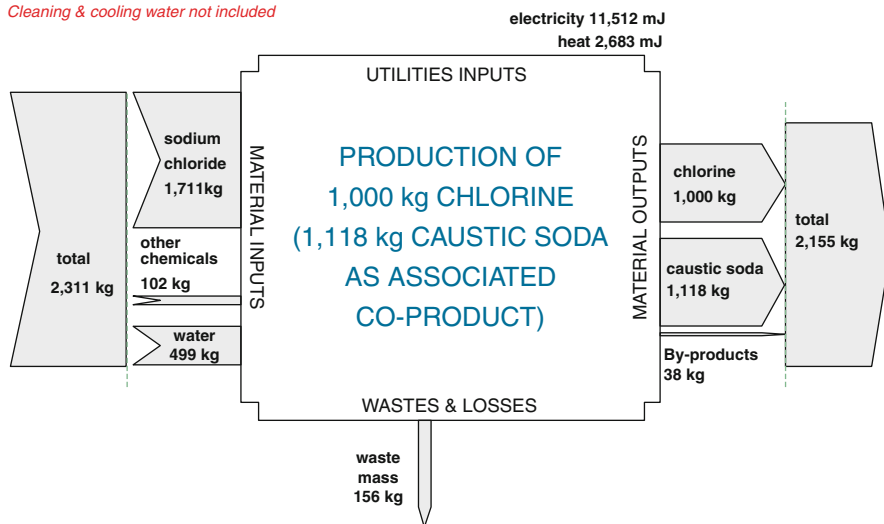

Fig. 51.4 Chlorine by electrolysis of sodium hydroxide (NaOH) in mercury cells (Source: Adapted from Ayres and Ayres (1998))

electrolysis of sodium chloride (NaCl). The inputs for this process are as follows: 1,711 kg of sodium chloride (NaCl), 499 kg of water (H₂O), and 102 kg of other chemicals which are not specified. As a result, 156 kg of waste is produced.

When applying MFA to a product or firm, a life cycle approach is normally taken and is denoted life cycle assessment (LCA). An LCA accounts the inflows and outflows of the system “from cradle to grave”; that includes all material inputs and outputs from extraction, manufacturing, consumption or use, recycling, and final disposal. The initial interest in developing LCA was to minimize the energy consumption and solve the waste management problems. The first LCA project, originally called REPA (Resource and Environmental Profile Analysis), was carried out by the Midwest Research Institute for the Coca-Cola Company in 1969. The goal was to compare several container options by quantifying emissions, material, and energy consumption of each. Presently, LCA is standardized by the International Standard Organization on the ISO14,040 series and Life Cycle Initiative program led by the United Nations Environment Programme (UNEP) and the Society for Environmental Toxicology and Chemistry (SETAC) created to develop and disseminate practical tools for evaluating the opportunities, risks, and trade-offs, associated with products and services over their whole life cycle (Mila i Canals 2003).

Section 51.3 illustrates different MFA approaches. First in Sect. 51.3.1, an analysis of the inorganic and organic chemical industry is given to quantify wastes and process conversion. Section 51.3.2 shows a material flow analysis of rare earth metals by current market demand. This is useful in order to quantify potential recovery of these critical metals in the waste streams.

51.3 Case Studies

51.3.1 Material Balance Applied to Chemical Industry

Quantitative data about industrial chemicals can be estimated with reasonable accuracy from industry production statistics. In the USA, production statistics were published annually by the US International Trade Commission (USITC) until the mid-1990s. The USITC reports included production data for virtually all industrial chemicals, including intermediates. Hence, in this example, we use production statistics from USITC for years 1991–1993. Unfortunately, these reports are no longer published.

To compare inputs and outputs for the whole sector and avoid double counting, the list can be divided into two groups: (i) basic chemicals, which are made directly from raw materials, and (ii) all others, including intermediates. For such classification, some knowledge of the industry is required. For instance, sulfuric acid is mainly made by burning sulfur but is now also produced as a by-product of copper smelting. Hydrochloric acid is no longer made from salt but as by-product of many downstream chlorination processes and thus is not considered a “basic” chemical.

Based on process information of the basic inorganic and organic chemicals, raw material inputs are quantified in mass terms, whence a material balance by elements (C, H, O, N, Cl, S, Na, Ca, etc.) can be performed. The difference between mass inputs and useful outputs is wastes and emissions. For the industry as a whole, wastes are characterized by elemental composition, but they can be estimated approximately as a mix of compounds (CO_2 , CO, H_2O , NaCl, CaSO_4 , etc.) based on knowledge of process reactions.

51.3.1.1 Inorganic Chemicals

Based on process information, the basic inorganic chemicals included are sulfuric acid, ammonia, chlorine, and caustic soda. The total production of these four chemicals represents 75 % of the total mass of inorganic chemical production (Ayres and Ayres 1999). Once the outputs are identified, we need to estimate the inputs. Mass inputs are identified based on the theoretical reaction for the production of each inorganic product.

Sulfuric Acid

Sulfuric acid can be produced from a large number of raw materials: crude oil and natural gas, copper and lead-zinc ores, organic spent acids, sulfur-containing gases, and sulfur salts. However, in practice, it is mainly produced from sulfur, oxygen, and water by single-/double-contact absorption – when sulfur has been purified and dried – and wet/combined dry-wet catalysis – when sulfur originates from the burning or the catalytic conversion of hydrogen sulfide (H_2S) gases – as illustrated in the three reactions below:

Ammonia

Ammonia is a starting material used in a wide variety of industrial chemicals and nitrogen fertilizers. The latter are responsible for 90 % of all ammonia production to obtain urea, ammonium nitrate, ammonium sulfate, and ammonium phosphates (Suresh and Fujita 2007). Most of the world's ammonia is produced from natural gas by steam reforming, except in China where ammonia is produced from synthesizing gas from coal. Steam reforming involves two main reactions: the separation of hydrogen from methane (reaction a) and its recombination with atmospheric nitrogen (reaction c):

Chlorine and Sodium Hydroxide

Chlorine and sodium hydroxide are produced as coproducts by electrolytic decomposition of sodium chloride solutions obtained from brines. The electrolysis of chlorine consists on using direct electric current to drive chemical reactions, in this case to dissociate sodium chloride in sodium cations and chlorine anions (Bommaraju et al. 2000). During the electrolysis process, chlorine anions are oxidized at the anode to produce chlorine and sodium cations with hydroxyl anions from water form sodium hydroxide at the cathode. Besides chlorine and sodium hydroxide, hydrogen is also generated (as illustrated in the reaction below):

Results

The overall mass inputs for the production of the main inorganic chemicals are hydrogen, methane, nitrogen, oxygen, sodium chloride, and sulfur. Figure 51.5 shows the elemental and component mass balance for the production of basic inorganic chemicals in the USA in 1991. Performing a mass balance by elements and components helps ensure the consistency of inputs and outputs. Mass inputs are estimated based on the production statistics of end-products and the reactions illustrated above. The mass balance shows that about 9 % of the total mass inputs are

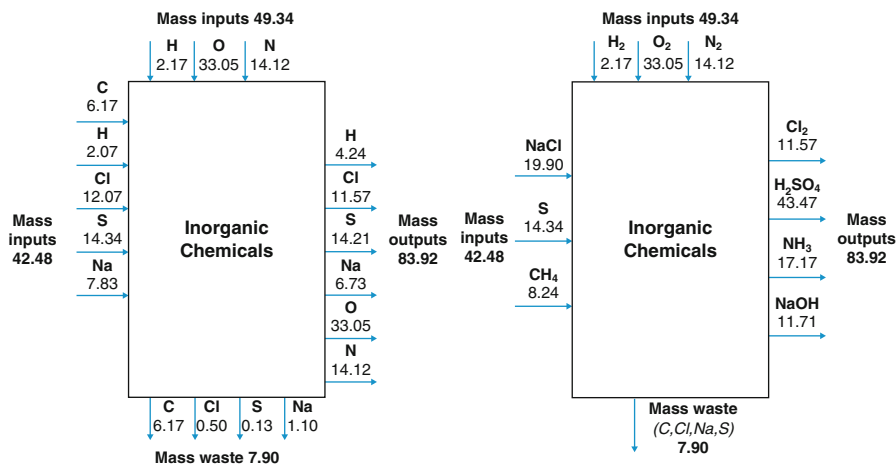

Fig. 51.5 Mass balance by elements and compounds of the production of inorganic chemicals in 1991 (MMT) (Source: Ayres et al. (2011))

wasted as compounds made of carbon, chlorine, sodium, and sulfur. The process conversion or yield can be estimated by dividing the mass output of the products by that of the inputs. For inorganic chemicals, such conversion equals 91 %.

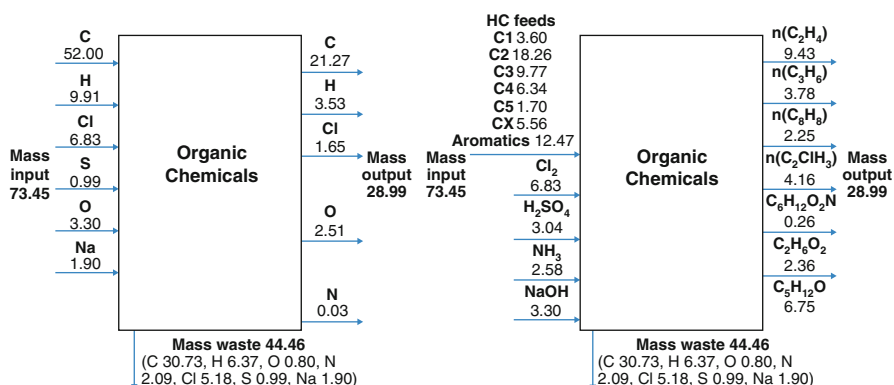

51.3.1.2 Organic Chemicals

Based on USITC statistics for 1991–1993, the major end products from organic chemicals are plastics (as polyethylene, polypropylene, polystyrene, and polyvinyl chloride), nylon 6, ethylene glycol (antifreeze), and methyl tert-butyl-ether (A fuel additive that has been largely phased out since 1991). The production of these chemicals, in mass terms, represented about 80 % of total US production of organics in 1991 (Ayres and Ayres 1998). Basic organic inputs are hydrocarbons and also inorganic raw materials as chlorine, sulfuric acid, ammonia, and caustic soda. Most organic chemicals are produced from feedstocks from natural gas or petroleum refineries, with a very small share from coal. There are three categories of feedstock: paraffin, olefins, and cyclic/aromatics. Paraffins are saturated straight- or branched-chain hydrocarbons. Examples include methane, ethane, propane, isobutene, and n-butane. Olefins are unsaturated aliphatic compounds with one or more double bonds. Examples include ethylene, propylene, butylenes, and butadiene. Cyclic aromatics are benzene, toluene, xylene, cyclopentene, cyclohexane, and naphthalene. Table 51.1 shows the organic chemicals and their primary production.

The mass input of the inorganic raw materials chlorine, sulfuric acid, ammonia, and caustic soda is estimated based on their use patterns (Ayres and Ayres 1998). Figure 51.6 illustrates material balance by elements and components for the production of the listed basic organic chemicals. The mass balance shows that about 60 % of the total mass inputs are wasted as compounds of carbon, hydrogen, oxygen, nitrogen, chlorine, sodium, and sulfur. The process conversion or yield for organic chemicals is about 40 %.

Table 51.1 US primary feedstock production in 1991 (MMT) (Source: Ayres and Ayres 1998)

Organic chemicals		Formula	Mass (MMT)
<i>Aliphatics and olefins</i>			
C ₁	Methane	CH ₄	3.60
C ₂	Acetylene	C ₂ H ₂	0.14
	Ethylene	C ₂ H ₄	18.12
C ₃	Propylene	C ₃ H ₆	9.77
C ₄	Butylene	C ₄ H ₈	1.05
	Butadiene	C ₄ H ₆	1.39
	Butene	C ₄ H ₈	0.43
	Isobutane	C ₄ H ₁₀	0.50
	Isobutylene	C ₄ H ₈	0.44
	Other C ₄	C ₄ H ₈	2.54
C ₅	Isoprene	C ₅ H ₈	0.21
	Pentene, mixed	C ₅ H ₁₀	0.19
	Other C ₅		1.29
C _x	All other aliphatics (including methane)		5.56
<i>Aromatics and naphthenes</i>			
	Benzene, all grades	C ₆ H ₆	5.21
	Toluene, all grades	C ₇ H ₈	2.86
	Xylenes, all grades	C ₈ H ₁₀	2.87
	All other aromatics and naphthenes		1.54
<i>Total inputs</i>			57.70

51.3.2 Mass Balance Applied to Rare Earth Metals

A material flow analysis (MFA) helps determine the main entrance routes of rare earth (RE) metals to the economic system. Such quantification is useful to quantify

future potential recovery of these critical metals in end products once they reach their end of life. The amount of RE metals in intermediate and end products can be estimated based on the production and market share of each metals (Kingsnorth 2009; Chegwidan and Kingsnorth 2010; Morgan 2010; Schüler et al. 2011). The main functions of RE are as dopants for semiconductors, catalysis, electricity storage, alloying elements, additive in glass and ceramic, and as abrasives. All these functions are used in intermediates and end products. For example, lanthanum is used as dopant for semiconductors in phosphors (intermediate product), and phosphors are used in liquid crystal display, plasma flat panels, and lighting, all of them end products.

51.3.2.1 Dopants for Semiconductor in Phosphors

The principal applications for RE phosphors are in display screens (cathode ray, liquid crystal, and plasma) and in low-energy fluorescent lighting tubes. Each of the different display technologies requires different types and compositions of phosphors, as do fluorescent tubes in which the phosphors reduce energy consumption and provide specific colors. Phosphors consist of a host material with an added activator or dopant. For red, the RE oxides used include yttrium, europium, and gadolinium. For green, the hosts used are lanthanum, cerium, and yttrium, while terbium and gadolinium are used as activators. For blue, europium oxide is mainly used. The combination of red, green, and blue gives white color. In 2010, 8,250 t of RE was used to produce phosphors: 6,135 t for red, 2,065 t for green, and 50 t for blue color. Phosphors are largely used for lighting (84 %), followed by LCDs (12 %) and plasma displays (4 %).

51.3.2.2 Catalysts

In 2010, 22,920 t of RE was used as catalyst. About 70 % was used in fluid catalytic cracking (FCC) and 30 % in autocatalyst converters. Cerium and neodymium are also used in non-cracking catalyst processes such as ammonia synthesis, hydrogenation, dehydrogenation, polymerization, isomerization, and oxidation and in automobile emissions control; however, the amounts used for this purposes are not published.

Fluid Catalytic Cracking (FCC)

FCC is mainly used in petroleum refining to break down long complex organic molecules as kerosene and heavy hydrocarbons into simpler and lighter molecules as gasoline and liquefied petroleum gas. The most widely used catalysts are synthetic zeolites (zeolite Y and ZMS-5 zeolites) which contain lanthanum and cerium that improves the stability at high temperature and increases catalyst activity and gasoline selectivity (Yang et al. 2003). Commercial catalysts are composed by 85 % amorphous silica-alumina cracking catalyst and 15 % of zeolites with a varying content of 0.2–3 % of RE (Estevao et al. 2005; Xiaoning et al. 2007; Schiller 2011). In 2010, the annual production of feedstock from FCC was 1,668 million l. FCC containing primarily Y zeolites account for more than 95 % of total

consumption (Davis and Inoguchi 2009). Assuming that production of RE for FCC requires 15,940 t of RE, for each liter of feedstock, an average of 9 g of RE is required, that is, 0.2 % of RE content.

Autocatalyst Converters

RE metals are also key for autocatalyst converters to reduce the emission of carbon monoxide (CO), hydrocarbons (HC), and nitrogen oxides (NO_x). They are added to the wash-coating to improve the thermostability of alumina and ensure the activation of catalyst under high temperature. In 2010, the manufacturing of 78 million units of cars required a total of 6,980 t of RE, which gives an estimate of 90 g of RE per vehicle, one-third of the amount reported in 2003 (Xiaodong and Duan 2004). The composition of RE in converters is 90 % cerium, 5 % lanthanum, 3 % neodymium, and 2 % praseodymium. Thus, in 2010, 6,280 t of cerium, 350 t of lanthanum, 210 t of neodymium, and 140 t of praseodymium were used in internal combustion vehicles.

51.3.2.3 Electrical Storage in NiMH Batteries

A nickel-metal hydride (NiMH) battery is a type of rechargeable battery composed by cathode, anode, electrolyte, and separator, all assembled in a steel case. Xu estimated the following content of metals: 50 % nickel, 33 % RE, 10 % cobalt, 2 % aluminum, and 6 % manganese (Xu and Peng 2009). RE metals are mainly contained in the anode of NiMH batteries which are described as AB₅ where A stands for lanthanide metal and B for nickel. In practice, lanthanum is substituted by lanthanum-rich mischmetal containing 50 % lanthanum, 33 % cerium, 3 % neodymium, 10 % praseodymium, and 3 % samarium (Morgan 2010). In 2010, 12,670 t of RE was used in NiMH battery alloys. For HEV which represents 65 % of the end use of NiMH batteries, the total amount of RE equals 8,060 t. According to Pillot, the remaining 4,610 t was used for retail (toys and household tools), cordless phones, and other electric and electronic devices (Pillot 2011).

51.3.2.4 Alloying Elements

Almost all the published estimation of the amount of RE metals for metallurgy agrees on giving an estimate of 32,025 t (Kingsnorth 2009; Chegwidan and Kingsnorth 2010). From this production, 75 % are used in magnets and 25 % in alloys with iron and aluminum. It is assumed that the usage of RE in magnets corresponds to the composition in neodymium-iron-boron (NIB) magnets whose average amount is 30 % RE, 69 % iron, and 1 % boron (Morgan 2010). For 2010, we estimated a total of 24,060 t used in NIB magnets. Magnets are used in wind turbines, hybrid vehicles, magnetic resonance imaging (MRI), and electric and electronic devices.

Wind Turbines

In 2010, the new wind turbine installation was 36 GW, and only about 14 % of the total new installation used NIB magnets (Schüler et al. 2011). Each MW of wind

turbine installed requires 860 kg of NIB magnets. Based on the composition given by Morgan, 910 t of neodymium, 310 t of praseodymium, 70 t of dysprosium, and 10 t of terbium were used for NIB magnets in wind turbines.

Electric Vehicles

The number of new hybrid cars registered reached 533,000 units in 2010. Assuming that each electric vehicle requires 1 electric motor per wheel and that the average amount of neodymium per electric vehicle is 6.3 kg, the total amount of RE is 4,800 t (Talens Peiró et al. 2013). The amount of each RE metal is 3,358 t of neodymium, 1,148 t of praseodymium, 264 t of dysprosium, and 34 t of terbium.

Magnetic Resonance Imaging (MRI)

In 2010, 2,500 new MRI units each of them using an average of 860 kg of NIB magnets were produced (Cosmus and Parizh 2011). The amount of RE required by them was 450 t of neodymium, 5 t of terbium, 155 t of praseodymium, and 35 t of dysprosium.

Gadolinium is a minor RE metal used in the magnet sector as an MRI contrast agent and as magnet component in research for magnetic cooling. As an MRI agent, it improves the visibility of internal body structures by altering the relaxation times of tissues and body cavities where it is present. Gadolinium is used in doses of about 0.01–0.03 g per kg of body mass (Niendorf et al. 1991). For the 80 million MRI exams performed in 2010, 90 t of gadolinium was used (Cosmus and Parizh 2011). Gadolinium is also used in magnetic cooling research as powder for creating magnetic refrigeration. In 2010, about 390 t was used for this purpose.

Minor Alloys

RE mischmetal is also used as minor alloys for controlling inclusions and improving the performance for steel and iron. For instance, cerium combined with sulfide forms particles more rounded that are less likely to generate cracking. RE mischmetal is used in zinc galvanizing applications as for zinc-aluminum alloy named Galfan (Zn-5Al-MM) which is often used as the coatings for steel, to enhance the product life for certain applications. In 2010, 7,965 t of RE was used as mischmetal in iron and aluminum alloys.

51.3.2.5 Additives

Additives are substances added to preserve the quality and appearance of coatings and for coloring. They are widely used in the glass and ceramic industry for quality and as colorants. In 2010, the total amount of REE used as additives was 17,425 t: 37 % in ceramic and 63 % in glass.

Glass Industry

Cerium and lanthanum oxides are used in glass to overcome the decolorizing to yellow green caused by iron oxide, always present as an impurity glass. Cerium is also a good UV and IR absorbent and thus used in protective glasses and in quantities of 2–4 % for glass blowing and welding goggles (Gupta and

Krishnamurthy 1992). Lanthanum is used in silica glasses to give a high index of refraction and low dispersion in lenses for autofocus single-lens reflex (SLR) cameras and video cameras. Other REE used in lower amounts are neodymium, yttrium, and praseodymium. Neodymium and praseodymium are used for coloring glasses. Neodymium colors glass bright red, praseodymium colors glass green, and their combination colors blue. Yttrium is used in the form of yttrium-aluminum garnets ($Y_3Al_5O_{12}$) to form synthetic crystals that are widely used as an active laser medium in solid-state lasers. YAG lasers use neodymium for its optimal absorption and emitting wavelength to be used in various medical applications, drilling, welding, and material processing. Other metals used as additives are erbium, ytterbium, and holmium which are used in luminescent solar concentrators and light sources for fiber optics and in laser materials.

Ceramic Industry

In 2010, 6,865 t of RE was used by the ceramic industry. The RE used were yttrium (3,495 t), lanthanum (1,190 t), cerium (980 t), neodymium (800 t), and praseodymium (400 t). Yttrium is used combined with silica for turbine blade applications. Cerium is used as phase stabilizer in zirconia-based products and in various ceramics including dental compositions. Yttrium and cerium are used in partially stabilized zirconia (PSZ) and tetragonal zirconia polycrystals (TZP), both high-performance ceramics with excellent toughness and strength properties at low and intermediate temperatures. End products of these ceramics containing yttrium are components for adiabatic diesel engines, cutting tools, wire drawing dies, and furnace elements for use up to 2,000 °C in oxidizing atmosphere. Lanthanum is used in lead-zirconate-titanate (PLZT), a transparent ferroelectric ceramic material. Neodymium is used in ceramic glazes to produce blue to lavender colors. Praseodymium incorporated in zirconium silicate lattice is used for the production of high temperature resistance lemon yellow pigments for the ceramic industry.

51.3.2.6 Abrasive

RE oxides are excellent abrasives for glass polishing in the manufacture of LCD, optical glass, mirrors, photomasks, plate glass, lenses, and cut glass. RE oxide powders provide a high mechanical abrasion react with the surface of glasses plus a high-quality finishing (Xu and Peng 2009). There are various grades of RE oxide polishing powder. They can be fully composed by cerium oxide, or with a content of 45–75 % cerium with the remaining of other RE oxides. The average composition of polishing powders is 32 % lanthanum, 65 % cerium, and 4 % of praseodymium (Morgan 2010). In 2010, 13,750 t of REE was used as polishing powder in the glass industry, about 40 % of which was consumed in LCD industry.

51.3.2.7 Results of MFA of Rare Earths

With each of rare earth metals identified and quantified in intermediate products, we can also estimate their content in end products. This quantification helps do some estimation about their recovery. Not all of these metals can be recovered in practice; however, if we know what the intermediate and end products are used for,

a theoretical potential recovery can be calculated for non-dissipative uses. For example, let us trace the 24,060 t of RE in magnets in 2010, which lie under the function “alloying elements” in Fig. 51.7. Magnets are used in wind turbines, electric vehicle batteries, magnetic resonance imaging (MRI), electronic products, and magnetic cooling applications. If we know the amount of each metal present in each of these end products, we could calculate what could, in theory, be recovered at the end of life. Following our example, based on several references and estimations, we calculated that 1,300 t of RE was embodied in magnets of wind turbines, of which 910 t was of neodymium. Using the same approach, we found that 3,358 t of neodymium was used in magnets in electric vehicles, 450 t in MRI, and 11,980 t in electric and electronic devices, totaling 16,700 t of neodymium that could in theory be recovered at some point in the future. This is a substantial amount if we compare with neodymium production for that year which was 21,615 t. According to Graedel, the actual end-of-life recycling rate for neodymium is less than 1 % (Graedel 2011).

If we look at phosphor applications, in 2010 a total of 8,250 t of REM was consumed. These ended up in lighting applications, liquid crystal display screens (LCD), and plasma panels. If we trace europium which is the only metal known that can emit blue light, 24 t was used in lighting, 20 in LCD, and 6 in plasma panels, adding to a total of 50 t of europium used for blue phosphors. Graedel estimates that less than 1 % of europium is recycled at the end of life of these products.

As the demand of rare earth metals increases in the future, it will become necessary to increase the recovery of these metals at the end of life of the products that contain them and improve present production from base metals. MFA helps identify potential sources.

51.4 The Laws of Thermodynamics

Material flow analysis is useful in quantifying resource consumption, wastes, and process losses. However, it becomes even more useful when we combine it with the first and second laws of thermodynamics. Energy, just like matter, cannot be created nor destroyed; energy is conserved in every action or transaction. That is the first law of thermodynamics, perhaps the most fundamental of all physical laws. But energy can be degraded and be transformed to “less useful” types of energy such as low-grade heat. This fact is a consequence of the second law of thermodynamics, sometimes known as the entropy law that states that global entropy increases in every irreversible process.

Exergy is measure of the potential work that can be performed by a system (Szargut et al. 1988). In other words, as a system degrades, its entropy increases and its exergy, or potential to do work, decreases. Exergy is not conserved: the exergy component is “used up” as it does work.

Exergy is also a thermodynamic quantity that reflects the “distance” from thermodynamic equilibrium of a “target” material, or subsystem. It is therefore

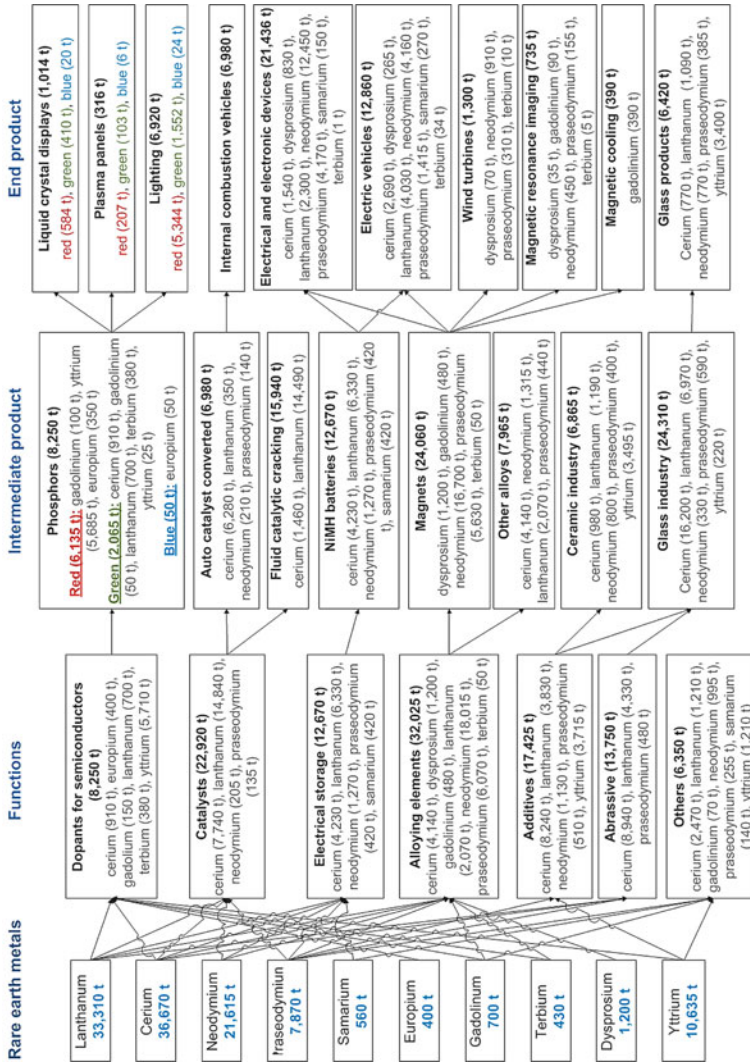

Fig. 51.7 Rare earth metals contained in intermediate and end products (Source: Talens Peiró et al. 2012)

only definable in terms of a reference state, such as the atmosphere, the ocean, or the average earth's crust, depending on which of them the subsystem will eventually rejoin and become indistinguishable from. Since the quantity of exergy contained in a subsystem is a measure of potential work, it is measurable in the same units as energy and work (joules, kWh, Btu, etc.). In the case of fuels, the exergy content is almost exactly the same as the enthalpy or heat content. For foods, the exergy content is essentially the same as the calorie content. For metals, the exergy content is the amount of heat that would be generated if the metal were to be completely oxidized. Exergy has been calculated and tabulated in reference books such as Szargut et al. (1988).

Calculating all flows in exergetic terms allows us to include both material and energy in our balance model. This is especially useful in order to calculate process efficiency and resource productivity. For more literature on exergy and material flow analysis, see Chapter "Material Balance Models in Research Tools in Natural Resources" in Ayres and Villalba Méndez (2011).

51.5 Conclusions

Material balance is based on the mass conservation principle which states that the sum of the weight of all inputs must be exactly equal to the sum of all outputs. Such simple postulate provides significant information when used for evaluating systems. First, when inputs and outputs are known, amount of wastes can be calculated, and the composition can be identified when chemical reactions. Second, it helps estimate the conversion or yield of processes which serves as a measure of the efficiency of the process in mass terms. There are many possible applications depending on one objective. For example, material balances across a geographical level aid to monitor the physical flows of materials across regional boundaries. At global level, MFA can be used to identify the end uses of materials which serve to estimate potential recovery.

Decision makers, engineers, and researchers need appropriate information tools to evaluate resource intensity, processing technologies, and resource efficiency. Using material flow analysis to evaluate economic processes helps identify opportunitiest strategies. For reducing waste and increasing recovery, and recycling. The combination of material balance and exergy analysis is the next logical step to accounting wastes and emissions since exergy gives a quantitative and qualitative measure of material potential usefulness.

complex models of spatial processes. This chapter presents knowledge developed in several areas of research in spatial environmental and natural resource economics. First, it discusses the role played by spatial heterogeneity in designing optimal land conservation policies and efficient incentive policies to control pollution. Second, it describes the role space plays in nonmarket valuation techniques, especially the hedonic and travel cost approaches which inherently use space as a means to identify values of nonmarket goods. Third, it explains a set of quasi- or natural-experimental empirical methods which use spatial shocks to estimate the effects of pollution or environmental policy on a wide range of outcomes such as human health, employment, firm location decisions, and deforestation. Finally, it describes spatial models of human behavior including locational sorting and the interaction of multiple agents in a land use/conservation setting. The chapter ends with a discussion of some promising future areas for further evolution of the modeling of space in environmental economics.

52.1 Introduction

Space is a key dimension of the physical, ecological, and human processes that affect environmental quality and the health of natural resource stocks. Therefore, environmental and natural resource economics has long wrestled with spatial elements of human behavior, biophysical systems, and policy design. The treatment of space by academic environmental economists has evolved in important ways over time, moving from simple distance measures to more complex models of spatial processes.

Researchers have long recognized that the environment is connected to space. Whether because of the distribution of resource quality across space, differential pollution loads, or site-specific policies, space and location matter in environmental and resource economics. Further, there are spillover effects across space; emissions from one place can affect environmental quality in neighboring locations, and fragmentation can degrade the habitat benefits of a given area of conserved land.

Spatial work in environmental and natural resource economics has evolved over time. To take space into account, theoretical work by environmental economists began by including simple spatial resource heterogeneity and contiguity in research on optimal policy design. Initially, heterogeneity was defined as a simple uniform distribution over space, and a single contiguous area was assumed to generate higher ecosystem or habitat benefits than fractured parcels regardless of proximity or the intensity of intervening land uses.

Much of the early empirical work that used space came in the form of hedonic regressions to value location-specific environmental amenities. As a first step, as with the theoretical work, space was usually defined in terms of distance from environmental features or location in certain polygons of the landscape. Spatial empirical work advanced with the introduction of spatial econometrics.

Many empirical papers in environmental economics began to take space into account, initially treating it as a nuisance parameter that generated spatially correlated error terms (Anselin 2002) instead of as an informational component of the data generating process.

Later innovation in environmental economics adopted more nuanced and detailed treatments of spatial processes. For example, research began to differentiate between neighbors on the basis of the direction of pollution flows. Detailed modeling of the spatial nature of ecosystem services, such as habitat provision, is also becoming more common in the literature. Thus, instead of simply controlling for spatial interactions based on a predetermined definition of “neighbors,” authors are now justifying why and how space might affect their model or empirical results, drawing from relevant literatures on natural processes or human interactions.

The most recent step in the evolution of spatial environmental and natural resource economics is the identification and estimation of strategic behavior over space. The idea that location affects land use has been around since von Thunen. Recent work allows for human migration in response to transportation costs or differential preferences. For example, we have seen large growth in research on locational sorting. Another literature has begun to explore spatial strategic behavior in the subfield studying land use. Some work addresses how actors respond to land use changes or policies and incorporates those reactions into models that target land for conservation. Recent papers have also begun to take the existence of multiple policy makers, private agents, and possible strategic responses into account to better reflect the multitude of principals and agents that collectively affect land use decisions.

In this chapter, we present knowledge developed in several areas of research in spatial environmental and natural resource economics, emphasizing areas that have been and continue to be foci of active research in recent years. We begin with models of simple spatial heterogeneity, starting with a discussion of optimal land conservation policies and moving to analyze how spatial heterogeneity affects efficient pollution trading. We next discuss the use of space in nonmarket valuation techniques, especially the hedonic and travel cost approaches which inherently use space as a means to identify values of nonmarket goods. The third section of the chapter explains a set of quasi- or natural-experimental empirical methods which use spatial shocks to estimate the effects of pollution or environmental policy on a wide range of outcomes such as human health, employment, firm location decisions, and deforestation. Originally common in labor economics, these methods have been increasingly adopted in environmental economics as an alternative, or at times a complement, to the hedonic approach. Finally, we describe spatial models of human behavior including locational sorting and the interaction of multiple agents in a land use/conservation setting. We conclude with a discussion of some promising areas for evolution of the modeling of space in environmental economics. While this chapter is by no means comprehensive, it is intended to give the reader a sense of how space is treated in modern environmental and natural resource economics.

52.2 Spatial Heterogeneity and Optimal Policy

52.2.1 Spatial Heterogeneity in Land Conservation

Early work in environmental and resource economics determined how to choose conservation and reserve sites optimally when costs and environmental benefits are heterogeneous across space. Simple computational optimization routines can be used to choose sites or spatially target conservation funds to generate the maximum environmental benefits possible, often taking account of complementarities between multiple parcels in the landscape. With fixed parameters of the problem – budget size, benefits, and costs of conserving the parcels – optimal site selection routines will select sets of parcels that have high benefit-cost ratios where benefits consider both the quality of ecological resources on a parcel and the likelihood that the parcel would be degraded in the absence of conservation (Polasky 2005).

Analysis of protected-area network design can, however, also account for the role of space in complex ecological processes when such processes have important effects on optimal design. Production of ecosystem services from reserves often depends on the configuration as well as the total area of lands that are protected. Thus, the integer programming models used for optimal reserve-site selection have been enriched to favor patterns of land that display certain levels of agglomeration.

Sophisticated versions of this work use programming models to choose cost-effective terrestrial reserves in light of detailed spatial idiosyncrasies of the conservation target at hand. Such a model can include details about the population dynamics of the species which is the focus of conservation activity, and models of how the species population depends on proximity to certain features of the landscape and the quality of the unprotected land that lies between reserves. Such models should also incorporate information about spatial heterogeneity in economic use and value. The outcome of such an analysis is identification of the network of lands that maximizes economic surplus in the area while satisfying ecological requirements related to species survival (Albers et al. 2010). Research in marine environments can also use spatial patch population dynamics, specifically knowledge of species source/sink features of different areas in a marine landscape to help policy makers design fishing regulations (including marine reserves) that serve to protect overharvested species and improve social surplus in commercial fisheries (Grafton et al. 2005). In both terrestrial and marine analyses, the best policy is not to place spatially homogenous restrictions on human behavior (protect all wetlands, reduce total fishing effort). Instead, heavy protection of core habitat (or population source sites) can be cost-effective approaches to increasing species populations (and possibly sustainable economic harvest rates), though attention must be paid to patterns of species dispersal through space when designing such policies.

Spatial environmental and natural resource economics has also developed tools for optimal non-reserve policy design that account for important spatial phenomena. For example, economic theory helps us understand how to make spatially

explicit conservation payments. Given that the marginal benefits of conservation on one parcel often depend on the spatial configuration of conservation (or lack thereof) on neighboring parcels, voluntary conservation programs can yield patterns of conservation that are suboptimally fragmented. Effective policies can offer payments for conservation activities which depend on the status of nearby lands. Policy makers can offer agglomeration bonuses – extra payments to landowners for conservation if neighboring parcels are also conserved. Such payments provide incentives that can yield less fragmented patterns of conservation in a landscape (Albers et al. 2010); they may also, however, yield uncompetitive behavior in the bidding process. Auction mechanisms have been developed to provide incentives for agglomerated voluntary conservation while encouraging competitive bidding to minimize rent transfer from the conservation agency to the land owners (Reeson et al. 2011).

In addition, policies are sometimes needed to protect natural resources from threats. Economists have studied how to design such policies efficiently when spatial features of the threats are important. For example, developing countries establish parks and protected areas within which extraction of natural resources is illegal, but it can be difficult to design a cost-effective policy to prevent illegal extraction on the part of nearby villagers. Because extraction activities are carried out by people on foot, there is a strong spatial component to the costs and benefits of extraction in different places within a park. Optimal enforcement may be concentrated in a ring excluding the center and the perimeter of the park; for most cases, the commonly used spatially homogeneous enforcement strategy is highly inefficient (Albers et al. 2010). Policies to control threats to natural resources from invasive species should be spatially explicit as well, using information about spatial heterogeneity in the expected costs and benefits of invasive species control to focus on invasive-species detection and control activities cost-effectively (Kaiser and Burnett 2010).

Finally, spatial environmental economics makes clear that we need to be careful about spatial features of some policies designed to reduce pollution. For example, we would expect development of renewable energy sources such as solar and wind farms to reduce air pollution from electricity generation and thus might put policies in place to encourage such investments. However, spatial idiosyncrasies of the national power transmission grid are such that renewable investments in some locations could actually increase total emissions from that sector by changing the intensity by which some existing fossil fuel-powered plants are utilized. Because the marginal benefits to society of renewable energy installations are spatially heterogeneous, incentives for renewable investments should be as well (Blumsack and Xu 2011).

52.2.2 Effect of Space on Market-Based Solutions

A standard result in environmental economics is that when pollution generates negative externalities – costs not borne by the polluter – then inefficiently large amounts of pollution will be produced by an unregulated market. In the simplest of

cases, the problem of negative externalities from pollution can be solved by imposing a tax on pollution equal to the marginal external cost of the pollution evaluated at its efficient level (Cropper and Oates 1992).

However, pollution and resource use often have spatially heterogeneous negative externalities. For example, air pollution is more harmful if it blows directly into populations of people, and water pollution is more harmful if emitted directly upstream from a sensitive receptor like a lake. Under these circumstances, the optimal policy response is not homogenous across space. Optimal pollution taxation in the spatial context, for example, might not only affect the quantity of emissions, but also shift the location of those emissions. Suppose the harm done by pollution increases with proximity of the emitter to an urban area. If emissions closer to the city have a higher marginal damage, they should be taxed at a higher rate. The difference in taxes would effectively flatten the slope of the transportation costs to the urban center, altering the standard von Thunen rings of economic activity around the center (Geoghegan and Gray 2005). However, this approach takes the location of the urban center as given. Tax policy could also alter the location of people who are affected by pollution; in some cases, it is more efficient for affected persons to relocate than for the sources of pollution to be moved.

Market-based solutions to externalities such as creating tradable pollution permits are an alternative to taxation. Like the design of optimal taxation, market-based approaches to environmental regulation are complicated by heterogeneous spatial effects of pollution. While a simple trading regime would allow one polluter to buy a permit for 1 unit of emissions from another firm who reduces emissions by 1 unit, if these firms are in separate locations and the effect of emissions is not homogenous across space, this simple trading regime will not result in the optimal distribution of pollution among sources. For example, it is clearly not optimal to trade off 1 unit of emissions in a low-impact area against 1 unit of emissions in a region where pollution causes more harm. Thus, efficient trading can be complicated for pollutants that have specific regional impacts. One policy solution is to divide an area into subregions and only allow trading between sources that are in the same region, but this approach has the potential cost of creating thin markets. Another approach is to insist that pairs of sources trade permits at ratios that accurately reflect heterogeneity of marginal damages caused by pollution from different sources, but this solution creates administrative complexity. Spatial heterogeneity presents policy-makers with trade-offs: charging firms their true marginal damage yields efficiency gains, while increasing the costs of complexity (including the need for increased monitoring), and raising concerns about distributional features of spatially heterogeneous policies (Olmstead 2010).

52.3 Spatial Elements of Nonmarket Valuation

Even before spatial analysis gained prominence in economics, some nonmarket valuation techniques (such as hedonic analysis and the travel-cost method) were intrinsically spatial. Environmental economists have enhanced the use of space in those methods over time, and spatial concerns have been incorporated into other

nonmarket valuation tools as well (Bateman et al. 2006). This effort has been facilitated by the development of a wide range of tools for applied spatial data analysis and econometric regression (Fischer and Getis 2010).

52.3.1 Hedonic Valuation

Hedonic housing price analysis is grounded in the economic intuition that the price of a house will be a function of all its features including the environmental quality and access to natural amenities that are associated with its specific location in space. Sellers choose features to supply to maximize profit; buyers choose which house to buy (for a given price) to maximize utility. The market equilibrium yields a hedonic price function (price as a function of attributes) that can be estimated econometrically using spatially explicit data on houses, their sales prices, their conventional attributes (e.g., number of rooms, square footage), and their environmental attributes. One can interpret the marginal effect on price of an environmental feature as the marginal willingness to pay of people in this market for that feature. These marginal willingness-to-pay measures inform us about the welfare effects of highly localized changes in the environmental quality. However, it is notoriously difficult to use hedonic analysis to estimate the welfare effects of a widespread change in environmental conditions (e.g., cleaner air in all of Southern California) because the market equilibrium would change and create an entirely new hedonic price function which can be difficult to predict from current conditions (Cropper and Oates 1992; Palmquist 2005).

Observations in hedonic analyses can display spatial autocorrelation because of two processes. A spatial lag process arises when the outcome observed in one location is a function of the outcome of neighboring locations. For example, the price of one house may directly affect the price of the neighboring houses, perhaps by updating seller information about current market values. A spatial lag can also arise through the common use of a resource, such as neighbors competing with each other in the use of irrigation water (Anselin 2002). In contrast, a spatial error process refers to spatial correlation in the residuals. In the hedonic analysis literature, several studies have used econometric approaches that take into account possible spatial autocorrelation from both sources. Failure to account for autocorrelation can yield inconsistent estimates of the coefficients on environmental quality, while failure to capture spatial lag lead to bias, meaning that the estimates of the marginal effects of changing environmental quality in one location are missing spillovers into neighboring properties (Anselin 2002).

Estimating how much pollution affects a specific house is nontrivial, since most pollution is usually only measured at a few locations in space. Thus, pollution measures are often spatially interpolated from these point data using kriging to generate an estimate of pollution at any specific latitude and longitude. Another approach to dealing with limited pollution data is to analyze housing prices within a larger spatial unit that either conform more closely to the point data or use geographic averages of the point measures.

One concern is that, like all interpolated variables, these environmental variables are measured with error, and this error may well be correlated with other unobservables that are also correlated with housing prices. For example, houses on a certain ridge could be subject to cooling ocean breezes that also result in a highly localized drop in pollution. The potential heteroscedasticity induced by using estimates for pollution can be addressed by correcting for both spatial and heteroscedastic error terms. However, the more fundamental concern about omitted variable bias remains. Such bias may be present even without interpolated environmental variables, for there may always be important location-specific unobserved variables that are correlated across space with both the housing price and the environmental characteristic. The problem of omitted variables can be addressed by using repeated sales of the same house over time, or by including other regional fixed effects.

Traditional hedonic analysis has employed fairly simple notions of location, space, and neighbors. For example, it has usually used measures of environmental quality onsite (e.g., air pollution levels) or simple distance to an environmental amenity or disamenity (e.g., open space, hazardous waste site). However, such simple definitions may fail to capture important effects. For example, the walking or driving time to a park might affect the price of a house more than the Euclidian distance, and having an amenity across a major road might increase the perceived distance of that amenity more than having it across a minor street. While the value of water quality improvements in a lake is diminishing with the distance of a house from a lake, there may be a discontinuous jump in value at the waterfront; there is often a complex story to be told about the actual ecosystem services that are being valued through the proxy of pollution measures (recreation, visual aesthetics, ecological health) and the role that space plays in mediating people's experiences of those services. Furthermore, when estimating how house prices might affect each other, such as when estimating a spatial lag, houses on the same block might affect each other's values more than houses one block over even if they are the same distance apart.

Such concerns can be addressed by taking a broader spatial view of the ways in which environmental quality might affect the relative desirability of homes in a housing market, and by taking care to define variables in hedonic models to reflect spatial realities and processes on the ground. The effects of pollution may not be simple – neither uniform, nor merely a matter of being in a polygon that is contiguous with a source, nor a linear function of distance from a source. In such cases, one can use detailed information on the dispersion of the effects of pollution to inform a hedonic analysis that estimates people's willingness to pay to reduce it.

The hedonic spatial model can also be enriched by enhancing the interaction between space and time, extending the standard hedonic model to allow households to be forward looking and to face transaction costs of moving (Bishop and Murphy 2011). Under such plausible circumstances, households weigh the cost of an environmental amenity (captured by the price premium associated with houses in locations with good environmental values) against the present discounted value of

the stream of future utility they will obtain from the amenity. Incorporating forward-looking behavior yields much bigger estimates of consumer marginal willingness to pay for a spatially heterogeneous environmental amenity.

52.3.2 Travel-Cost Analysis

The other nonmarket valuation that is most intrinsically spatial is the travel cost approach to estimating the values people place on the quality of natural resources. This method estimates demand for recreational sites such as beaches, lakes, and forests as a function of features of those natural sites; the results yield estimates of the values of the features (e.g., water quality, species populations) included in the analysis. The travel-cost approach uses data on how often people visit the sites of interest and how much those visits cost each individual in the data set, where travel cost depends in part on how close someone lives to a site. Single-site models use econometric analysis to estimate how quantity of visits to a site depend on environmental quality; multiple-site models use a random-utility model (RUM) econometric approach to estimate how the choice of which of several sites to visit depends on the attributes of all the sites and how much travel to them costs (Cropper and Oates 1992).

Travel-cost valuation methodology has evolved to include new features of space. The cost of travel was always measured as a function of how far a person lives from a site, but if people engage in locational sorting, distance from a site (and hence measured travel cost) will be correlated with unobservable preference heterogeneity, creating biased coefficient estimates. Latent class models can be used to control for this endogeneity (Barenklau 2010). Other problems can arise if multiple sites between which people choose for recreation (e.g., patches of a forest for hunting, lakes in a chain for fishing) are connected physically and ecologically across space. If, for example, a change in water quality at one lake causes fish populations to change and redistribute through an entire chain of lakes, then conventional travel-cost analysis can yield misleading information about the welfare effects of that change. A structural model of recreation site choice and harvest intensity must be coupled with a spatial model of population dynamics to understand the welfare effects of making improvements to features of one or more sites in such a system (Albers et al. 2010).

52.3.3 Stated Preference Valuation Techniques

Stated preference valuation methodologies (contingent valuation and choice experiment studies) use information from hypothetical survey questions to estimate consumers' willingness to pay for environmental goods and services even if the values they gain are not based in any way on direct use (Cropper and Oates 1992). Nonuse values may not be affected by distance to environmental amenities. However, distance may play a factor in the values people place on the environment if

people have a localized “sense of place” or if use values comprise a large fraction of the total value people place on environmental public goods.

Thus, space is recognized now to be an important part of even stated-preference valuation approaches. Data on how far people are from the amenities to be valued can be included directly in the specifications of such studies to measure how distance affects environmental goods and ascertain how that effect varies with income. Including distance explicitly in individual willingness-to-pay functions helps cost-benefit analysts avoid making arbitrary choices about the spatial extent of the population of people that are affected by a project (Bateman et al. 2006). The value people place on an environmental improvement may also depend on spatial variation in the current quality they experience for the amenity in question.

52.4 Spatial Empirical Identification Strategies

As noted in Sect. 52.3.1 on hedonic analysis, space or location has long been used as a source of information to identify and estimate the effects of variation in environmental quality. As an alternative to the more structural hedonic model, the last decade has produced substantial growth in the application of quasi or natural experiments to estimate the effects of pollution and environmental policy. Spatial variation can be used to identify the effect of a treatment such as a policy shift or change in environmental conditions (Smith 2007). If policies or shocks are specific to a location, it is possible to compare outcomes in these areas to outcomes in other untreated locations to measure the effect of the treatment. If the outcomes are observable before and after the treatment, one can control for time-invariant observables which can often confound estimates obtained from other approaches. Standard policy evaluation procedures (such as difference-in-difference, matching, or regression discontinuity methods) can then be applied to estimate the effect of the treatment.

Matching is a technique that compares treated with control observations on the basis of their observable characteristics. This technique addresses potential bias that might arise due to systematic differences in covariates between the treated and control observations. It does not, however, address the concern that treatment might be related to some unobservable characteristic that in turn affects the outcome of interest. A difference-in-difference approach compares treatment and control observations before and after the introduction of the treatment. This approach controls for time-invariant differences between the treated and control observations. Regression discontinuity design makes use of a fixed threshold that determines whether an observation is “treated” or not. For example, if the treatment occurs when an individual turns 65, one can use the outcomes of 64½-year-olds as controls. For a discussion of these and other program evaluation techniques, see Khandker et al. (2010).

The shocks used for identification in spatial environmental and natural resource economics have ranged from a decrease in pollution (e.g., from a recession or a localized plant closure), to natural disasters, and to the introduction of protected

areas. Along with measuring the effect of policies on intended outcomes, the use of this quasi-experimental technique has been applied to estimate nonmarket valuation of environmental amenities and health outcomes. By definition, one requirement of the quasi-experimental approach is that when using variation across space as a source of variation, one needs a spatially varied shock. For example, spatially heterogeneous policies, such as air-pollution emission standards that vary non-attainment status of a country, have become popular sources of identification to estimate willingness to pay for pollution or the influence of pollution on health or economic activity.

While it has some advantages, the quasi-experimental methodology has limitations as well. One challenge is in choosing the appropriate spatial scale for analysis. Often researchers cannot observe responses at the individual level and use regional values instead. At least two problems arise from this. First, patterns of correlation among variables across space are not always robust to the spatial units over which the data are aggregated. This problem of ecological fallacy (Anselin 2002) is most pronounced if individual variation within a region is large compared to the variation among regions. Second, non-parcel level data may not be fine enough to observe the effects of some environmental shocks (Smith 2007). Quasi-experimental studies may also yield biased results if they assume treatment effects that are constant with distance when, in fact, both the treatment itself and the impact of a treatment on housing prices are idiosyncratic across space (Auffhammer et al. 2009; Smith 2007).

Last, one crucial assumption required for the use of quasi-experimental methods is that the treatment is not assigned based on unobservables that also affect the outcome. While some random shocks, such as weather variation, may well fall into this category, other shocks (such as a regional policy, the shut-down of a plant, or spatially delimited critical habitat for endangered species) are potentially more problematic. If those unobservables are time-invariant, the use of fixed effects may mediate the problem. Fixed effects, however, do not solve the problem of unobserved variation generating a differential effect of observed characteristics on the outcome. For example, if unobserved political influence affects the location of a new environmental policy and political influence also determines how that policy affects economic outcomes, one could still estimate a biased coefficient for the effect of the policy on economic outcomes even with fixed effects.

52.4.1 Environment and Health

Arguably the largest growth area in the use of these natural or quasi-experiments in environmental economics has been on measuring the effect of pollution on health. As with the willingness-to-pay literature, this is a topic that has previously seen the broad application of hedonic analysis. There is a substantial literature that measures the costs of environmental health risks and disease that use epidemiological methods to estimate a dose-response function of, say, exposure to a chemical and health outcomes, and then use wage hedonics to estimate the perceived costs of

those work-related risks (Viscusi and Gayer 2005). Other papers have estimated the cost of health effects using variation in housing prices.

Various authors have used natural experiments arising from a temporary plant closure or changes in traffic patterns to estimate the effect of emissions on health outcomes. Other authors have used economic downturns as an instrument for changes in county-level pollution to estimate the effect of pollution on health. As with the other quasi-experimental studies, one concern is finding the appropriate scale of analysis. More recent papers make use of smaller scale variation in pollution levels, using within-zip-code or school district variation to be better able to control for other neighborhood fixed effects (for example, see Currie et al. 2009).

Another approach is to use natural and environmental disasters as a source of variation to estimate the effect of these disasters on health outcomes. A continuing challenge is how exactly to model the spatial and temporal exposure to these shocks and to address human responses to either the threat or incidence of exposure (such as migration). In using this methodology, researchers also need to be careful to rule out potential spillovers resulting from the treatment into neighboring control regions; such spillovers could render the control group uncontrolled, and therefore bias the estimate of treatment effect.

52.4.2 Evaluations of Protected Areas and Payment for Environmental Services Programs

Spatial analysis has been and can be used to estimate the effectiveness of conservation measures in preventing environmental degradation such as deforestation. The methodology has been developed to study programs that establish protected area policies that offer payments to landowners for activities that preserve or increase flows of environmental services – “payment for environmental services” (or PES) programs. Location-specific attributes and the spatial process of land use play important roles in estimating the effects of these programs.

Early evaluations of conservation efforts compared outcomes (such as deforestation rates) in areas subject to a conservation measure, such as legal protection, to outcomes in plots outside the boundaries of this protection. The problem with this approach is that protected and unprotected areas frequently differ in ways that systematically bias the comparisons (Andam et al. 2008). For example, countries may naturally place their protected areas in regions that face lower deforestation pressure (Joppa and Pfaff 2010). In these circumstances, estimates from a simple comparison of outcomes inside and outside of the protected area boundaries would overstate the impact of conservation policies. To overcome these biases and develop more accurate comparisons, conservation research must consider realistic counterfactual scenarios (Ferraro 2009). Thus, researchers must adopt evaluation techniques that permit comparison of observed outcomes with what would have happened in the absence of a conservation effort. The difficulty lies in that counterfactuals cannot be observed directly and instead should be carefully estimated.

Recent research has attempted to estimate a counterfactual in evaluations of conservation programs. Costa Rica's payment for environmental services program has been assessed using linear regression models and two types of matching estimators to compare the deforestation rates of communities that participate in the program and communities that do not, controlling for observable features of the landscape such as slope, distance to cities, and ecological zones; the results indicate the program had little effect on deforestation (Andam et al. 2008). It is also possible to take an explicitly spatial approach to the analysis of conservation program effectiveness. One technique is to control for possibility of spatially autocorrelated errors in the regressions that analyze the impact of conservation policy on landscape degradation (Alix-Garcia 2007). A second approach is to control for spatial spillovers from one observation to the next, by explicitly estimating the spatial lag associated with land use change. Failure to control for such spillovers has been found to have large effects on the estimates of treatment effects (Honey-Roses et al. 2011). A third spatial strategy is to estimate the effect of the program on nearby areas, or explicitly estimate the leakage caused by the policy. If there is a spatial lag process associated with deforestation, land use in observations on the boundary of the treatment area might well be affected by the treatment of the neighboring area, implying that they are not appropriate control observations.

52.5 Models of Behavior in Space

Until now, this chapter has largely focused on models where spatial effects arise from features of nature. Such models assume that resource locations are given and that the heterogeneous effects of pollution are determined by factors exogenous to humans, like wind or hydrology. However, spatial heterogeneity may arise from human behavior and the resulting economic forces. Research in environmental and natural resource economics has developed understanding of various spatial dimensions of human behavior.

From the simplest von Thunen model of land use being driven by variation in transport costs to market to the rise of New Economic Geography in the 1990s, we now have models that predict the growth of cities. The New Economic Geography approach models population centers as arising from tension between agglomeration economies (driven by monopolistic competitive firms) and congestion costs. These models still assume at their base a featureless plain, where migration is driven by differences in real wages. Once one introduces an influential spatial feature, people with a strong preference for that amenity may migrate for other reasons. This innovation has led to the concept of spatial sorting.

Economics predicts that people respond to incentives. Incentives may themselves arise from features of the landscape other than just proximity to the nearest urban center. For example, zoning and other land-use rules may place restrictions on the use of some land, pushing these land uses elsewhere (an effect also known as leakage). As some land is removed from potential development, the price of

development rights may increase in other regions. These and other behavioral responses are incorporated into modern models of land use and land conservation research.

Regulation of environment and natural resource use is complicated by the existence of multiple regulators and multiple regulated actors, giving rise to the potential for strategic behavior and collective action problems. These problems gain an extra dimension of complexity when the cooperation or competition occurs over space. Spatial environmental and natural resource economics now incorporates some of these multiagent behaviors in space.

52.5.1 Spatial Sorting Models

One recent thread of research in the field of environmental and natural resource economics has rapidly become an established and influential feature of the literature: spatial sorting models (Palmquist 2005). This body of work evolved from early work by Tiebout (Banzhaf and Walsh 2008) on how people “vote with their feet” and move to places that have bundles of attributes – including environmental quality and cost – they prefer. Modern spatial sorting models are theoretically and computationally complex, and are used for a wide range of functions.

One category of research on sorting models is positive – just seeking to describe whether (and if so, how) people sort across space in the face of spatial heterogeneity of attributes. This research can help us to understand the forces that drive demographic patterns within urban areas, and shed important light on questions of environmental justice. These models can also be used to explore how proposed changes in environmental quality will affect the distribution of people in the landscape and their subsequent well-being.

Early theoretical models of spatial sorting equilibria assumed that households have heterogeneous incomes and preferences over housing and public good characteristics of a location. Communities vary in how expensive they are and in the level of the public good they provide. Individuals choose where to live to maximize their utilities subject to their budget constraints; housing prices in communities adjust until equilibrium is reached such that no household would prefer to live somewhere other than where they are living. Even in the simplest models, assumptions must be made about the structure of indirect utility functions in order to ensure that equilibrium exists. The models also assume (implicitly or explicitly) that all households have perfect information about community characteristics and the preferences of other households, all households are able to purchase as much housing as they want in their preferred locations, and moving is costless. The resulting equilibria have communities that are stratified by income if preferences are homogeneous, and households sorted differentially according to the features they care most about if preferences vary (Palmquist 2005).

Later models (e.g., Bayer and Timmins 2005) allow for spillovers between individuals that choose a given location; spillovers can either be positive

(as in the case of agglomeration economies) or negative (if there is congestion). Under these circumstances, multiple equilibria are often possible, particularly if there is a strong agglomeration effect. One can still use data to estimate the features of models that have multiple equilibria, but multiplicity makes it more difficult to draw conclusions about what the re-sorting effects will be of major changes in a region such as cleaning up a hazardous waste site.

Empirical work has sought to identify whether sorting behavior in response to spatial environmental heterogeneity is an important factor in residential markets. Econometric approaches to this problem include statistical analysis of changes over time in socio-demographic and housing characteristics of locations near sites that experience changes in environmental quality (Banzhaf and Walsh 2008). There is evidence that people locate at least partly in response to environmental features of neighborhoods, and that such dynamics can exacerbate income segregation in urban areas.

Because of their utility-theoretic underpinnings, sorting models have been used as the foundation for a new approach to estimating the values people place on elements of environmental quality that do not have market values. Researchers can use neighborhood-level land value data to obtain structural estimates of the parameters underpinning residential sorting models and thus estimate values of spatially differentiated environmental amenities such as air quality and open space (Klaiber and Phaneuf 2010). In addition to generating value estimates that can be used in cost-benefit analyses, this research reveals several insights about environmental policy and research. First, the benefits of an environmental improvement policy depend on how it is distributed in space. Second, benefit estimates based on traditional nonmarket-valuation techniques may be incorrect if the environmental changes to be valued are large enough to induce significant re-sorting. An example can illustrate. Suppose air quality in the neighborhood of Gryffind is originally much lower than in Slyther; people would sort such that the people who value clean air most intensely would pay a premium and live (disproportionately) in Slyther. If we improve air quality in Gryffind, there is initially just a small welfare increase because the people who live there care relatively little about air pollution. With resorting, there are two effects: (1) The people who value air quality more highly move to Gryffind, and thus the benefit to residents there is higher. (2) Housing prices fall in Slyther and rise in Gryffind, causing indirect price effects on welfare that depend in size and spatial distribution on details of the situation.

The structural sorting-equilibrium approach does have the great advantage of taking dynamic factors into consideration. However, it requires analysts to impose much structure on the underlying model and to make arbitrary choices about the boundaries over which communities (which are the unit of observation) are defined. This latter activity may be extremely problematic given that results of spatial statistical analysis have long been known to be sensitive to the manner in which data are aggregated across space (Anselin 2002). Future work on this methodology may seek to resolve these issues.

52.5.2 Behavior in Land Use and Conservation

Land use is an area that straddles several disciplines in economics (urban economics, environmental economics, and economic geography) and has long recognized the importance of human interaction with space. Early models of land use often ignored the behavioral component and were largely meant to fit, as opposed to explain, the data.

More recently, models of optimal conservation planning have been developed that incorporate spatial heterogeneity of environmental costs and benefits with spatial economic models of the probability of land use change. Instead of merely conserving land based on selecting parcels with the highest environmental benefit per dollar, it improves economic efficiency to target those parcels with the highest environmental benefit per dollar that are also under the highest threat of development.

Other models of land-use change have begun to take into account behavioral responses to development or development policy changes. In general, restrictions on land use in one part of space (such as zoning) can intensify the limited activity in other areas that are not controlled by the restrictions; this is the generalized phenomenon of leakage. Some land-use restrictions, such as urban policies mandating embedded open space, can increase the value of development in neighboring areas so much that they accelerate leapfrog urban sprawl (Irwin et al. 2009).

Finally, some research incorporates the fact that multiple actors are involved in conservation, and that these actors likely interact, and often interact strategically. Spatial strategic behavior is best known in models of how local governments set their levels of public goods, taxes, and/or regulatory stringency. If firm location choice is endogenous, nearby jurisdictions may compete on the level of taxation and public goods. This competition is further complicated by economic activity induced by firm location having spillovers to neighboring locations. Strategic private responses can thwart governments in many of the actions they try to take to improve environmental quality, creating hold-up problems when an agent is trying to establish an agglomerated protected area that requires buy-in from multiple land owners, sometimes shifting private conservation into parts of a landscape that are spatially disparate from the locations of public conservation activities (Albers et al. 2010).

The most recent generation of research on conservation reserve design uses economic theory to inform the strategic choice of lands for reserves taking into account the spatial responses of multiple human agents to those choices. Empirical research has identified many ways in which human behavior in space responds to changes in the environment; for example, the establishment of government-protected lands can increase the price of land and the threat of development (or likelihood of conservation) in the area (Irwin et al. 2009). Thus, optimal reserve choices by one agent should be strategic, taking into account the likely responses of other agents (Albers et al. 2008) and likely changes in the land market which affect the risk to other parcels of conversion and the cost to the decision maker of future conservation (Armsworth et al. 2006). Such strategic decision making can yield improved conservation outcomes, but can entail making seemingly counterintuitive choices such as avoiding putting protected areas in some locations with high

ecological value. Similarly, econometric work has documented how harvesting activity varies across space with changes in factors such as target (e.g., fish) populations and the presence of regulations such as spatial closures (Grafton et al. 2005; Albers et al. 2010). Endogenous harvesting behavior affects the outcomes of spatially explicit harvesting regulations – if one area is closed, harvesters work more intensively in another area, and if regulations increase target populations, harvesting effort will increase. Socially optimal spatial resource use regulations can be designed in ways that take such endogenous behavior into account (Grafton et al. 2005).

52.6 Conclusions

Some areas for future work in spatial environmental and natural resource economics seem to be particularly important and promising. In the area of spatial policy evaluation, one area where future work is needed is to more formally incorporate spatial data-generating processes into the quasi-experimental setting. For example, the use of propensity-score matching (PSM) is potentially biased in the presence of spatially correlated error terms. Just as a probit estimation generates potentially biased estimates in the presence of heteroscedasticity, the initial probit regression used to generate the propensity of treatment may be inherently biased by the presence of spatial correlation. More fundamentally, in the presence of a spatial lag, estimates will likely be biased, and further, control observations neighboring treated regions may themselves be affected by the treatment (Honey-Roses et al. 2011). The bias in this instance could go either way depending on the nature of the lag process. While this spatial effect may complicate difference-in-difference analyses, it is even more potentially problematic for regression discontinuity design where the regression discontinuity is spatial in nature. Note that since the amount of spillover is not constant over time, and may be directly affected by the treatment, using observation-level fixed effects does not solve the bias.

A related area of concern is that a treatment itself may actually change the scale and scope of important spatial processes related to that treatment. For example, a fuel tax may affect the degree of spatial spillover from economic activity in one area to economic activity in neighboring areas by changing patterns of commuting behavior. These effects on spillovers may be substantial and have large effects on policy outcomes which have not systematically been studied.

In the area of spatial policy design, truly optimal policies need to take spatial strategic reactions into account rather than treating other actors as merely reactive. Papers that apply game theory to spatial policy decisions are rare (Albers et al. 2008); more work needs to be done in this area. For example, private actors are known anecdotally to buy land for speculation if they anticipate conservation agents wanting to buy it for protected areas. This phenomenon is different from that of markets responding to conservation with increased prices nearby and should be worked into spatial-dynamic models of optimal reserve-site selection.

Future work in spatial environmental and natural resource economics may even move to redefine what we mean by “space.” Extant research and knowledge in this field conceptualizes space in traditional geographic terms. However, other dimensions of space exist that may affect natural processes and human behavior. Economic interactions may facilitate technological adoption more than mere geographic proximity. Social distance and social networks can affect attitudes and behavior through facilitating both information flow and influence. As an example, information and influence can affect individual’s valuation of a disamenity such as hazardous waste. Further, social influence can be used to improve monitoring, enforcement, and, therefore, management of a local common pool resource, such as a community pasture. Current research in spatial econometrics is moving forward to allow researchers to estimate spatial weights or spatial spillover patterns, as opposed to merely estimating the degree of spillover given an assumed structure of the extent to which different spatial units function as neighbors. These advances in spatial econometrics will facilitate future research that quantifies the effects of spillovers in environmental and natural resource economics.

Knowledge in spatial environmental and natural resource economics already includes theoretical and empirical models that inform spatial environmental policy design, evaluate policy effectiveness, help us predict human behavior in a landscape, and help place values on environmental goods that are spatially heterogeneous and convey benefits in ways that vary with spatial processes. However, work in this field of research is still very much ongoing and the field is still evolving; much more needs to be done.

Abstract

The expected global impacts of climate change can be attributed to a set of common stressors. The magnitude of specific impacts, however, depends on the extent to which regional resources – from ecosystems to human-made

infrastructures – are at risk and the abilities of regions to mitigate that risk. This chapter begins with an overview of some of the impacts expected from climate change, stratified by the density of populations and economic activities. Then we review differences in risk and mitigation capacities across major regions. The inherent interconnection of environmental, economic, and social dimensions of climate impacts underscores the need to assess climate change impacts in ways that address these dimensions.

53.1 Introduction

The arguments made by researchers, policymakers, and activists on the need to curb greenhouse gas emissions often revolve around an implicit or explicit understanding of the expected costs and benefits of probable impacts. The result of any structured comparison between costs and benefits, in turn, depends on the impacts that are considered, how these impacts are defined and distributed across the economy, society, and its environment, how they are measured and weighted, and how they are aggregated to generate a *net* cost or benefit that then guides action. On the one hand, many of the expected impacts from climate change can be usefully discussed together – temperature increases, changes in precipitation, and an increase in the number of more severe weather events that threaten to disrupt **urban** and **suburban** centers; **infrastructure networks** like roads, energy transmission lines, and shipping routes; and evolved **ecosystem** relationships important to agriculture and natural landscapes in many densely populated regions. On the other hand, the situational variables, where an impact occurs and whom it affects and to what extent, determine the magnitude of the damages and must be understood in the local context of the capacity to prepare for an event or deal with its aftermath.

Regional variability cannot be subtracted out from global assessments of climate change impacts, and it introduces enormous complexities into the global decision-making process of designing and agreeing on a united response. Each region has its own economic and trade portfolios at risk and its own historical and political value systems to deal with that risk. This chapter presents an overview of some of the impacts expected from climate change that are common across the world based on the level of urbanization – from densely populated urban areas to less-populated regions. Then we review differences in risk and **mitigation capacities** across major regions, how economic and political interconnectivity links regions closer, and the differences in the means that are necessary to mitigate or adapt to the risk and to deal with the impact itself. Much of our analysis relies on existing geophysical models and their estimates.

Many such climate models exist that relate hundreds of complex global parameters together to chart out the circulation patterns between the Earth's atmosphere and its oceanic system and to derive potential responses to the current emission trends. Uncertainty is an inherent part of the modeling process. Because of the differences in how the models treat the various parameters and their relationships, to actually estimate impacts of climate change, **the Intergovernmental Panel on**

Climate Change (IPCC) uses a number of models' projections to arrive at its results. Their details are described by the IPCC itself (Intergovernmental Panel on Climate Change 2007). Beyond the geophysical models, integrated assessment models (like the RICE and the DICE models developed at Yale University, the Stanford-based MERGE model, the FUND model developed by the Dutch economist Richard Tol, or the PAGE2002 model used in the influential Stern review) provide the framework to picture how climatic changes may overlap with societal dimensions (for detailed overviews of such models, see Stanton et al. 2009 and Ortiz and Markandya 2009). Often the models are used to calculate the net or the average impact of climate change – or to perform a benefit-cost analysis, arriving at conclusions that mask regional vulnerabilities.

Among the poignant critiques of such benefit-cost analyses are that the models in the background tend to ignore the existence of low probability but catastrophic outcomes and that the models estimate future damage probability functions relying on normal distribution rather than the so-called fat-tail Pareto distribution that may more accurately represent the uncertainty involved given that the current concentrations of greenhouse gases exceeds any past experience. Simply substituting the type of probability function used alters the estimates for probabilities of temperature changes experienced under different scenarios. For instance, at a concentration of greenhouse gas emissions double the 2011 levels, under the assumption of a normal probability distribution, the probability that global average temperatures will stabilize at 10 °C higher than the 2011 temperature is more than seven times lower than when using a “fat-tail” distribution (Weitzman 2011). Clearly, the size of the temperature increase determines the severity of damages. Other problems with using the models persist, such as finding the proper rate of discounting to estimate long-range impacts. In other words, seemingly small decisions about which parameters to include or exclude in the models can have a large impact on the outcomes presented – and on the policy debate.

Rather than present a range of outcomes derived from such models, we construct a baseline look at what is at stake. Our goal is to disaggregate the potential regional impacts and to discuss them in two interrelated ways – one that uses the theoretical and empirical underpinnings to gauge potential impacts based on the level of urbanization and another that connects the IPCC estimates to regional socioeconomic data to describe the range and location of potential impacts.

53.2 Expected Impacts Based on Level of Urbanization

53.2.1 Density-Dependant Impacts

Regional differences in population densities bring with them differences in the diversity and extent of economic activities, differences in the need for infrastructure systems and services, and differences in stresses on the local environment. The latter range from the need to convert land to make room for people and their economic activities; to changes in water availability, air quality, and species

diversity; and to changes in the local and regional climate. Global economic and environmental variables have become essential drivers behind these local and regional changes, often exacerbating already existing stressors on social, economic, and environmental conditions.

With most of the world's largest cities located close to oceans, lakes, or rivers, flooding has been and will continue to be a major concern to urban populations. While the average rate of sea level rise from 1961 to 2003 was approximately 1.8 mm per year, that rate has accelerated during the last decade of that period to 3.1 mm (Intergovernmental Panel on Climate Change 2007). As a result, low-lying areas become more readily inundated during high-tide events, storm surges are magnified, coastal ecosystems and their abilities to protect inland areas are rapidly lost, and aquifers and agricultural soils near coasts lose productivity because of salt water intrusion. Recent estimates suggest that by the year 2080 sea level rise and its associated impacts will affect five times more people than it did in 1990 (Nicholls et al. 1999) because both climate change and coastal population sizes will accelerate. Some settlements, particularly many small island communities in the South Pacific, are likely to be completely submerged.

Increases in the frequency of heavy **precipitation events** – most notably rainstorms but also snowfall – have been observed globally throughout the twentieth century, and these trends are expected to continue throughout the twenty-first century. As a result, in some cases, the lakes and rivers on which cities are located will flood; local storm water and flood control systems will be overwhelmed; residential, commercial, and public infrastructures will be inundated and in some cases destroyed (United Nations Human Settlements Programme 2011); ecosystems will be impacted by increased loading of wastes – from untreated sewage to debris to runoff of fertilizers, pesticides, and other potentially harmful substances – and thus experience a loss of their water absorption capacities; water quality will be impaired; land will erode, leaving uphill populations with a need to cope with destruction of their living space and downhill populations with the challenges of dealing with the influx of materials – from soils to debris and other wastes; human physical and mental health will be compromised and lives will be lost; and economic productivity will be undermined, and with it the ability will be reduced to prepare for future flooding impacts because of the need to divert funds for emergency measures and rebuilding efforts and because the loss of economic activity may bring with it a loss of regional, national, and international competitiveness. In some instances, heavy precipitation and rising sea levels, particularly during tropical cyclones, will combine to affect millions of urban dwellers.

Extreme heat events are also predicted to become more frequent and intense. Impacts of heat on urban populations will vary considerably, depending on their acclimatization (Ruth et al. 2006) and their ability to invest in cooling – requiring access to air and space conditioning but also changes in building materials and designs, as well as development of green spaces in cities. Some of these investments, especially where they will require increased energy demand, are bound to contribute to urban **heat island effects** (Akbari 2005), which in turn may set off a spiral of higher energy consumption, further increases in urban temperatures,

changes in regional precipitation patterns, and declines in urban air quality, leading to further cooling needs. Particularly when heat waves coincide with droughts, exacerbation of urban heat island effects and stresses on water and energy supply and distribution ensue. And because not all sectors and households in the urban environment have equal need for or access to cooling, water, energy, disaster relief, and health services, climate impacts in urban areas will likely be not uniform and often exacerbate already existing economic and social inequalities.

Urban areas, of course, are intricately linked to their hinterlands through exchange of water, energy, agricultural, and manufactured goods, services, and people – commuting or migrating, sending and receiving money, or setting trends and expectations. As a consequence, impacts of climate change on urban areas are likely to ripple through to affect larger regions and potentially the global flow of people, goods, and services, and vice versa, and impacts on rural areas will make their mark on the economic, social, and **environmental performance** of cities. About half of the world's population lives within 200 km of a coastline (Small and Cohen 2004).

One notable example of urban–rural interconnections concerns the provision and use of ecosystem services – from flood control to provision of building materials to supply of food and beyond. Such services are essential to revenue generation and quality of life in cities. However, already approximately 60 % of ecosystem services evaluated in the Millennium Ecosystem Assessment are considered degraded or used unsustainably (Millennium Ecosystem Assessment 2008). Increasing urbanization and climate change are likely to continue undermining the provision of ecosystem services with far-reaching consequences for local, regional, and global sustainability.

53.2.2 Agriculture and Forests Impact

Opportunities to study and understand potential climate impacts on agriculture and forests are provided both through natural experiments – such as the El Niño/Southern oscillation and North Atlantic oscillation phenomena – and deliberate manipulations through the so-called **FACE experiments** (free-air CO₂ enrichment experiments). The latter allow for inferences from temperature variations, while the former test impacts of enriched carbon environment on growth of plants and forests. One of the main findings is the difference in responsiveness between two types of respiration systems found in plants. Most herbaceous plants have a C3 metabolic pathway, including wheat, barley, oats, rice, and soybeans. Higher carbon dioxide levels enhance the growth of these plants. Corn, sugar cane, sorghum, millet, and tropical grasses are C4 plants. For these, higher temperatures (to a certain threshold) are beneficial, but they do not appear to respond to increased atmospheric CO₂. Another physical response mechanism involves a long-ago developed adaptation technique in plants. In times of decreased water availability, the stomata on leaf close, reducing **evapotranspiration** and, therefore, the plant's water demand. In fact, although some studies indicate that the overall irrigation requirements will greatly increase in the USA in the upcoming decades, stomatal closures reduce the impact by around 35 %. FACE experiments with forests indicated that young trees

respond very well to increased CO₂, although mature forests have a much lower (and in some cases, negligible) response (Backlund 2009). Clearly the distribution of plants with differing metabolic systems within and across continents is one component in identifying regional differences in risks.

An aspect of plant-level processes that adds variability to impacts of climate change on agricultural production comes from the different responses that plants show to changing ecosystem attributes, such as shifts in conditions favorable to insect populations, weeds, and disease agents. For instance, although soybean yields are projected to respond positively to higher temperatures, one experiment showed that damage from a harmful insect increased by 57 % when fed on soybeans grown under higher CO₂ concentrations. The main unknown effect is the result of the competition between C3 and C4 plants. Many weeds are C3 plants, so their ranges will likely spread in the upcoming decades. On the other hand, the most popular herbicide, glyphosate, has been shown to lose efficacy for plants grown with more CO₂. Another costly (but unaccounted effect) is the projected higher demand for nutrient inputs.

Although water will be the **limiting factor** in some regions in the following two to three decades, productivity of forests and many crops (wheat, corn, soybean, less so for cotton) is expected to increase for other regions. In fact, timber productivity may increase from 20 % to 60 % in the next three decades. Beyond a certain temperature threshold, however, many crops will be unable to survive. If greenhouse gas emissions continue unabated, we will likely reach this point around 2050–2060. The concept of these thresholds is a bit misleading, however, since most productive and marketable yields are produced under much lower-temperature conditions. For instance, even though the official temperature threshold for corn is around 35 °C, optimal yields are achieved between 18 °C and 22 °C (Backlund 2009).

53.2.3 Natural Landscapes

Grasslands, inlands, and coastal wetlands, shrub ecosystems, and other hotspots for ecological biodiversity will likely experience declines in area and probable changes in their functionality. The more fertile ecosystems with quick reproduction and decomposition rates may initially benefit from warmer temperatures and increased CO₂ concentrations. Yet more severe storm events will likely counteract these benefits as greater **runoff** rates contribute more nutrients to the local waterways stressing aquatic ecosystems and water resources. A comprehensive review of 866 studies on movements of ecological patterns found that several worrisome changes can be attributed to warming. Particularly at risk are range-restricted species and mountaintop species that will see drastic contracts of their ranges, tropical coral reefs and amphibians are also affected, and many disruptions to coevolutionary forces between predators and their prey as well insects and plants have been observed. Impacts on migratory and songbirds, butterflies and dragonflies, flowers like lilac and honeysuckle, and aquatic and tropical species are already apparent (Parmesan 2006).

In most cases, **ecosystem resilience** is being tested not just from the changes in climatic factors but also by other challenges associated with expansion of human activity, such as fragmentation of suitable habitats when forests and grasslands are converted to agricultural or urban uses, chronic overuse of fertilizers, discharge of pollutants, interference with water ways, and deliberate or incidental introduction of alien species.

Beyond plant and animal **biological responses** to changes in levels of greenhouse gases or temperatures or surrounding moisture in the atmosphere, land areas with agricultural production and forest lands are also affected by damages from more frequent severe weather like massive flooding and extreme heat and drought. Recent examples of incidents that illustrate severe weather impacts include a series of heat waves in Europe in 2003, 2007, and 2010, immense landslides in South America and Asia in 2010 and 2011, the sweeping fires raging across vast swaths of Russia and Australia in 2010, and the powerful and devastating floods in Pakistan the same year. The impacts to urban infrastructure, agricultural fields, rural landscapes, and people's livelihoods are clearly immense.

53.3 Regional Differences in Risk and Mitigation Capacity

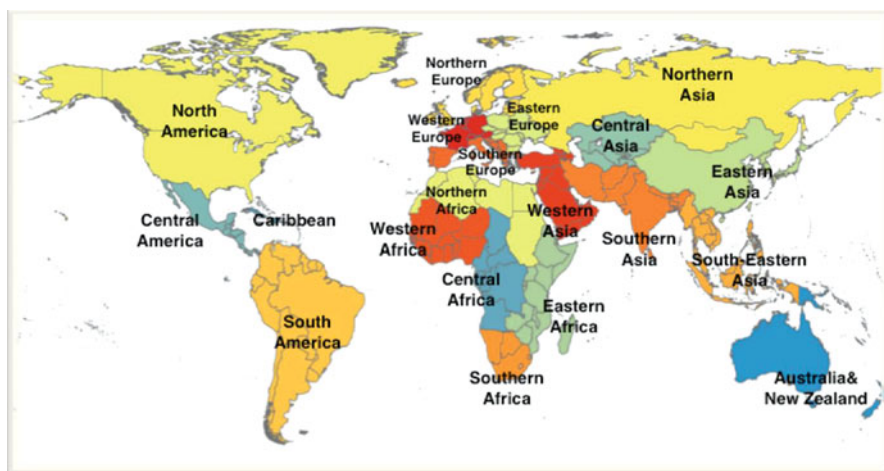

Some impacts from climate change will likely be similar across economic sectors in many countries around the globe. One useful way to understand such impacts is by differentiating them according to regional levels of urbanization. The severity of climatic effects further depends on a region's **physical geography** as well as regional and local economic and sociopolitical arrangements. For example, diversity in economic sectors, levels of investment in assets at risk from climate change impacts, and dependence on **vulnerable infrastructure** define economic threat. The built-in capacity of institutions to plan, respond, adjust, remain flexible, innovate, and cooperate across government offices and across international borders is inherently local and underlies the duration and magnitude of the impacts.

The stressors on systems are similar across the globe: increases in temperature, changing precipitation patterns, rising sea levels, and more frequent intense storm events. The resultant effects determine shifts in species diversity and distribution, functional changes in natural and managed ecosystems, changes in water availability and pathogen transport, and disruptions to human-made infrastructure. The affected sectors are likewise similar. Agriculture, forestry, tourism, hunting and fishing, coastal real estate, insurance, as well as physical property like buildings, bridges, roads, railroads, and airports may see damages or disruptions as climate change intensifies. Estimating impacts requires measuring many types of activities at their location – settlement and infrastructure sensitivity, food security and agriculture, ecosystem sensitivity to disturbances, human health sensitivity, and water resource sensitivity. The extent of these losses depends, first of all, on exposure, that is, the distribution of assets prone to risk. On that front, stark regional differences emerge.

The Intergovernmental Panel on Climate Change (IPCC) provides the most comprehensive review of regional impacts (Intergovernmental Panel on

Climate Change 2007). For the purposes of the 2007 review, the IPCC uses its own regional designations to describe patterns of impacts estimated through several different global climate models. We match those designations with data from the World Bank and the Food and Agricultural Organization of the United Nations to sketch out the factors that form the baseline for regional differences in terms of impacts and in terms of capacity to respond. The snapshot we provide is from the decade after the international community started negotiating a united policy framework to deal with contributing factors to climate change in 1990s. We use the latest data available for the 2000 to 2010 period (details are described in the [Appendix](#) at the end of this chapter) and connect it to the climatic impacts the IPCC projects for the same regions. This aggregation serves to connect the socioeconomic layer to climatic projections. Yet it conceals many of the country-specific and within-country differences, as well as the ever-evolving status of socioeconomic indicators. Still, the aggregation allows for a regionally comparable look at the **baseline conditions** that already underlie the vastly different response capacities – both to mitigate and to adapt to the projected changes. Understanding the starting point onto which such future changes are projected is essential to understanding the entire scope of potential impacts. [All monetary figures used are in US dollars].

The map below shows the regional designations used here.

53.3.1 North America

The continent of North America as a whole is projected to see more weather-related storms of all types and increases in associated damages. But in contrast to the western, southeastern, and northeastern regions, which already have incurred costs related to the changing climate, the northern portions of the continent may initially experience benefits as milder winters bring longer growing seasons. A study of potential economic impacts from climate change in the United States based on eight

regions revealed the depth of those differences (Ruth et al. 2007). Looking at the snapshot of the socioeconomic situation in 2000s shows that around a third of the US population resided along all the coasts. But the population was not distributed evenly. A third of the country's private property was located on the northeastern coast, for example, which is also home to four of the largest cities in the United States. The eastern side of the continent is especially prone to impacts from rising sea level because a natural process of **subsidence** is already pulling the continental board downward. The northeast portion of the country has already seen an increase in severe weather, with the largest increase in very severe events, complemented by a warming of 2.2 °C. An insurance company's analysis found around US\$4 trillion in assets vulnerable to hurricanes in that area alone. What are expected to become more common, category 4 hurricanes touching down in heavily populated metropolitan regions could cost upward of \$50 billion (Ruth et al. 2007).

Major American cities have points below sea level, such as New Orleans, Miami, Jacksonville, Houston, Boston, New York, Washington DC, and Seattle. Five of the ten cities most exposed to a 1 in a **100-year flood event** are here (Nicholls et al. 2008). The estimate of a flood occurring of that magnitude is based on historical data, and projections indicate that such events will become more and more frequent. All together, around US\$19 trillion of insured property are potentially on the path of North Atlantic hurricanes. Since sea-surface temperature plays a major role in hurricane formation, scientists are exploring the possibility that climate change may indeed intensify storms. While it is still a matter of some debate, a recent study found a dramatic shift in the average annual number of tropical storms and hurricanes between 1995 and 2005. The previously steady rate of 9.4 storms jumped by over 50 % to reach an average of 14.8 storms per year (Pearce 2005; Hecht 2007). States on the southern border of the continent – Texas, Alabama, Georgia, Florida, and North Carolina – have each seen over 20 natural disasters causing damages over \$1 billion in the 25-year period between 1980 and 2005 (Lott and Ross 2006). In the United States in 2000s, hurricanes have caused an average damages of \$5 billion per year (National Oceanic and Atmospheric Administration 2010). Nearly 90 % of the population of the continent lives in urban areas, implying that impacts that affect urban infrastructure may be more immediately relevant. The continent enjoys a vast transportation network with around 730 million kilometers of railroad and nearly 8 million kilometers of roads, most of them in the United States.

The southeastern, southern, and western regions of the continent will see severe challenges related to water availability. In addition to a complex political system that guides current water distribution in much of the western portions of the United States, climate change will bring a much drier climate there. Not only water resources for human consumption will be stressed but also water needed to sustain the natural ecosystems and fauna.

The center of the continent relies much more on agriculture. Many millions hectares of agricultural crops that are used not only domestically but are exported throughout the world are grown in the United States. But this means that changes in weather patterns, especially more frequent extreme weather events, cause much

damage. Flooding in the Midwest – which has become more frequent – causes billions of dollars at a time. For example, floods in the summer of 2008 caused \$15 billion damages in the region. Crop damages totaled over \$2 billion that year. On average, floods in the USA caused \$5 billion annually in 2000s. Over the last 10 years, 15 % of flood damages were to crops, one of the most important agricultural commodities. The United States Global Climate Change Impacts team projects continued increases in precipitation and flooding in the center of the continent. Agriculture will see changes across the country. Overall, heat stress will likely alter the relative composition of pests to plants to nutrients used. Increased insect outbreaks are possible in the northwest reaches of the continent to the southwest (Karl et al. 2009). Temporarily, climate change may extend growing season and be beneficial toward the industry, such as in the Pacific Northwest. But other concerns may undermine this trend. For instance, many invasive species benefit from warmer climates, and they cost \$120 billion a year to control in 2000s (Pimentel et al. 2005).

Although not many people work in **agriculture**, the sector is very important economically and geographically. Across the entire continent, agriculture added over \$50 billion to the economy annually in 2000s. In the United States, agricultural uses take up around half of the country's land area. Recently, studies show adverse impacts from climate change on specific agricultural industries across the nation – for example, the dairy cows suffering lower productivity as temperatures rise or grape quality diminishing as springtime advances. Milk production and wineries are small but growing profitable agricultural activities, especially in the United States. As research continues and focuses on more specific industries and locations, more impacts are revealed.

53.3.2 Europe

The European continent will see varying changes. For example, every scenario run through the models used for the latest IPCC report indicate that the northern areas of Europe will see greater warming during the winter months, while southern regions will need to prepare for hotter summers. Maximum temperatures experienced over an average year are projected to rise more steeply in central and southern European countries. The socioeconomic context in the 2000s provides the baseline conditions on which the impending changes will occur. A quarter of Europe's 600 million people resided in one of the southern European countries and the Mediterranean region – Italy, Portugal, Slovenia, Serbia, Albania, Greece, or others. Another quarter lived in eastern Europe. On average, projections show increases in precipitation in the north, but decreases in the south – albeit intensity of the events will continue to strengthen across the entire continent. Incidence of **heat waves** and duration of droughts will increase in central and southern European countries. Countries in western Europe and alpine regions will also see more dry periods and hot days. Melting of **permafrost**, less snowfall, and loss of glaciers in mountainous regions are expected, as well as increased flooding along the coastlines. In general, changes in precipitation will affect water resources, with consequences for

both the non-managed and managed landscapes. Since less wintertime precipitation will end up as snowpack, flows in major European rivers during winters will increase, while decreasing in summer months. Eastern and southern Europe may see especially dramatic declines. Because of regional climatic trends, sea level rise along the European coasts may be 50 % more than the expected global average. In 2009, the European Commission's Directorate General for Maritime Affairs conducted a survey of 22 coastal European countries, finding that around US \$700 billion to 1.4 trillion of assets were located within half a kilometer of a coast. Over a third of the GDP of these countries is created within 50 km of the coastline (Directorate-General for Maritime Affairs and Fisheries 2009).

Infrastructure impacts reverberate through many sectors. For instance, transportation reliability may suffer. In 2000s, railroad systems in eastern and Western European countries transported 95 billion and nearly 220 billion passenger kilometers on an annual basis, respectively. The total network of roads was over 2 million kilometers in western Europe and around 1.5 million kilometers in the other regions. But again, distribution matters. On average per country, road density in Western European countries was nearly eight times that of Eastern European countries and four times of southern European countries. The exposure portfolios are starkly different. To every 1.16 cars that a person in western Europe owns (or 1.5 in North America), an Eastern European had a third of a vehicle. This means practical differences in the level of development of infrastructure and, therefore, its exposure to impacts. It also means that personal mobility of families may be compromised in an emergency.

Because many of the trends in climate changes are ongoing, researchers have observed impacts on those systems already. The capacity to deal with the impacts relates to how exposed countries' portfolios are to particular risks. For instance, managed landscapes like **croplands** and **fisheries** will be at risk from a combination of factors, but the resultant damage may be less severe as affected parties adapt to changing conditions. The associated socioeconomic impact of that response comes down to several factors. To a large degree the impact will depend on the amount of water available to cope with increasingly drier conditions. In southern European countries, about 10 % of agricultural lands were irrigated – in contrast to less than 5 % in northern Europe. On average, southern and Eastern European countries were economically more dependent on agriculture than the other regions. Employment was more concentrated in agriculture too – with about a sixth of the population working in agriculture in southern and eastern Europe in 2000s. Changes in the climate threaten agricultural stability, potentially threatening economic livelihood of many people. On the other hand, on average, agricultural employment stood at 3 % in Western European countries and at less than 5 % in northern Europe. The southern and eastern regions appear to be more vulnerable. For example, although mild warming will have little effect on agriculture, increases of over 5 °C can lead to 10 % reductions in crops overall, but around 25 % reductions in southern Europe (Agrawala 2007).

Water availability and flow affect capacity to produce **hydroelectrical** power. In 2000s, countries in northern Europe derived about a third of their total electricity production from such sources. Over a quarter of electricity production in southern European countries came from hydropower. Eastern European countries annually

utilized over half of their internal freshwater resources, in contrast to Western European countries using a third and southern European countries about a quarter on average. This is in comparison to less than 10 % used by countries in North America, signaling some strain on the resource already across the entire continent.

53.3.3 Asia

The Asian region spans across Russia to the Middle East through Southern Asia to China to the Pacific coast and its many islands in the IPCC report. In 2000s, around two-thirds of the world's population lived here. While the number of rainfalls in the region has declined, the severity of storms has gone up. Severe storm events are now more frequent and more intense, resulting in increased floods and landslides. This trend is expected to continue as average precipitation is expected to increase across this sweeping region, especially across boreal forests in Asia. But parts of the continent that are currently arid or **semiarid** – most notably regions in Pakistan, India, and Indonesia – will continue to experience decreases in rainfall and see an increase in the number of **droughts**. In a similar manner, the number of tropical cyclones in the Pacific has dropped, but the intensity and the resultant damages of cyclones that form have gone up. The duration of **heat waves** has prolonged and will likely continue to prolong across Asia. Annual warming of 3 °C by the 2050s and of 5 °C by the 2080s is projected on average. Highest warming rates have been observed in North Asia, including Russia. Once again, risk to species and entire ecosystems is intensifying, altering functional relationships and pushing their physiological boundaries.

In 2009, the region was home to 4.2 billion people, with about 40 % living in southern Asian countries like India, Bangladesh, Pakistan, Iran, and Afghanistan. Nearly as many people lived in eastern Asia – in China, Japan, South Korea, or North Korea. Another fifth of the population resides in southeastern Asia, in Indonesia, Thailand, Vietnam, Fiji, or the Philippines. Many of these countries are **small island nations**. These are especially vulnerable to sea level rise. Six out of ten coastal cities with the highest populations vulnerable to a very major flooding event are spread across Asia (Nicholls et al. 2008). One study on three megacities in Asia – Manila, Ho Chi Minh City, and Bangkok – found that by 2050 damages associated with **floods** will be more and more substantial – 2 % to 6 % of the region's GDP. Much of the damage was attributable to the expected land subsidence (The World Bank 2010).

Intensified **water stress** can reduce crop yields of essential diet staples like rice, corn, and wheat. Yields for rice crops decline 10 % for every degree Celsius increase. Area of land suitable to agriculture is projected to decline in east Asia, which now has 16 % of its land classified as arable. Russia and countries in central Asia will likely see expanded agricultural production, yet it is uncertain how different crop portfolios will react to projected changes. For instance, China grew more than 30 million hectares of corn and nearly as many of rice. Russia and Pakistan had 25 million hectares of land under cultivation for wheat production each. In 2000s, agricultural production took up large swaths of the land.

For instance, around 44 % of land in northern Asia agriculture and 60 % of land in central Asia were under agricultural cultivation. Western Asian countries like Saudi Arabia, Iraq, Turkey, Israel, United Arab Emirates, Georgia, Armenia, Lebanon, and others had over a third of their land in agricultural production, on average. The agricultural sector was much more important to the region's GDP and the population's employment than in Europe or in North America. For example, in 2000s, the agricultural sector contributed nearly a fifth of value-added activities to the GDP in central and southern Asia, where around 40 % of people were employed in agriculture. Clearly, many people will be exposed to climate change impacts to agriculture.

Plus, the same impacts threaten natural ecosystems. Asia is home to some of the most biologically rich spots, like the ones in China, Japan, Russia, India, Indonesia, and Papua New Guinea. To a large extent, such biodiversity continued to prosper because considerable portions of the continent were left undeveloped. For example, the infrastructure of the region in the 2000s decade was less extensive than in Europe or in North America. Around 40 % of the roads were paved in southeastern and northern Asia, each with about a million kilometers of total roads. Southern Asia had about 5 million kilometers of roads, many of them unpaved. The Asian continent – both with its megacities and sizeable rural populations scattered across the landscape – may be more vulnerable to certain climate change impacts because of its socioeconomic portfolio more so than the regions discussed thus far.

53.3.4 Latin America

The Latin American region, as delineated by the IPPC, stretches from the Caribbean and Central America in the north to the very southern tips of Chile and Argentina containing around a tenth of the world's population (about the same percent as Europe) in 2009. The IPCC reports that most of the central belt of the South American continent has seen an increase in precipitation, although southern Chile and regions up along the western coast – southwest Argentina and southern Peru – have observed lower levels of rainfall. **The Amazon** has seen a 10 % increase in flood frequency, and rivers in the center of the continent have had a 50 % increase in their **streamflows**. Little data exist about the middle of the continent, making it difficult to discern any trends. But much is known about the glaciers, which are receding at an accelerating pace as temperature and humidity conditions change and precipitation cannot compensate for the rate of melting. The **glaciers** spanning the continent are projected to disappear by the mid-2020s. Not only is this a loss of an important ecological constituent, the disappearance of the beautiful skiing slopes threatens an important industry and limits recreational opportunities.

Models predict warming for Latin America on average with increases in temperatures from 1 °C to 7.5 °C by the end of the century. The occurrence of significant storms and periods without precipitation will likely increase. Frequency and intensity of hurricanes around the Caribbean islands will also likely increase – the 2001 and

2005 seasons were two of the worst on record. The United Nation Environment Programme estimates that over 11 million individuals in Latin America were affected by natural disasters in 2001 and in 2005. Around 530 million people lived within 100 km of the coast in 2005 (United Nations Environmental Programme 2008).

In the central portion of South America, agricultural production has seen a benefit from greater precipitation – soybean yields increased up to 38 % and corn to 18 %. But natural land cover is retreating as tropic **deforestation** continues, fueled by the booming prices of agricultural crops like soybeans and corn (although notably by 2012, the rate of deforestation fell). In 2000s, agriculture took up nearly a third of land area in the Caribbean and South American countries. It also contributed to roughly 10 % of the GDP of those regions. Large-scale crop production was not widespread in the Caribbean, where only Cuba, Haiti, and the Dominican Republic had sizable plots of rice and corn. Expansive countries like Brazil and Argentina had around 20 million hectares of soybeans each. Climatic changes affect agricultural production and agricultural prices. Future planting decisions may need to take into account the agricultural commodity's resistance to a host of climatic variables. On the other hand, as mentioned, many areas of the continent have seen positive effects from the climatic changes. Plus, much of the region has plentiful water resources, sparing it the impacts associated with water availability.

In contrast to some other regions, in 2000s, South American and Central American countries used their internal water resources sparingly, withdrawing 2.4 % and 4.4 % of their freshwater annually. Still, other areas faced a different situation. Caribbean nations withdraw more than 20 % on average, making them more vulnerable to upcoming changes in water availability. Plus, hydroelectric sources constitute the main source of electricity for many Latin American nations.

In 2000s, a large portion of the populations live in rural areas – 40 % in Caribbean and Central American countries and 25 % in South American countries. The difference in infrastructure development has the same implications as discussed before. Less concentration of people makes the region less vulnerable to some of the impacts. Yet there are still incredibly dense areas like in the Caribbean nations where 60 % of the population lived in the largest city. That region is also the one more likely to suffer from increased frequency in extreme weather events. There, much infrastructure is at stake since road density in the Caribbean nations is than 12 times the road density as the open South American continent. Nonetheless, generally speaking and as a whole, the continent seems to be fairly resistant to the most serious impacts, at least in the short- to medium-term timeframe.

53.3.5 Africa

The African continent is home to one-seventh of the world's population. The IPCC warns that it will likely be hit the hardest by a combination of changing climatic factors and existing development challenges. The continent is projected to see a 3–4 °C increase in mean annual temperature, but the northern and southern

parts will likely see disproportionate warming with up to 9 °C increase in the north during the summer and up to 7 °C increase in the south during the spring (September to November) by the end of this century. Northern African countries are some of the driest in the world – they received less than 200 mm of rainfall per year in average precipitation, in contrast to the arid Middle Eastern countries that receive 330 mm of rainfall per year on average. Projections for changes in precipitation in Africa are less clear, especially across the **Sahel desert**. Generally, however, precipitation will likely decrease in the northern African countries up to 20 %. It will follow a similar pattern in the south but will increase in the east. It is uncertain which precipitation trends will emerge across the expansive Sahel region. Still, the number of extreme dry and wet years is projected to rise – an expectation consistent across the globe.

Although in 2000s a tremendous shift from rural to urban lifestyles was and has been ongoing across the continent, a large proportion of the population lived in rural areas. It was the largest in eastern African nations with 68 % and the lowest in northern African nations with 41 %. Agriculture was a significant portion of the region's GDP – reaching 32 % in western African nations and 25 % in Eastern Africa. Employment in agriculture is also high with nearly 50 % of the population working in the sector in western and central African regions. Whereas about half of agricultural cropland in the North American nations is dedicated to just three crops – corn, soybeans, and wheat – much of Africa's agriculture is done on a smaller scale translating into more diversified cropping patterns. Yet as climate changes progressed, agricultural production will change as well. One study indicated that wheat may disappear from the continent altogether. Some positive effects on agricultural crop production are possible in the eastern areas, but northern, central, western, and southern Africa showed negative trends.

Libya, Sudan, Egypt, and other northern African countries are facing severe water shortages. The three countries withdraw much more freshwater resources than is available already. For the 250 million people in the northern and southern African regions whose water resources are already stretched and for whom climate change will likely mean a decrease in precipitation, the situation will worsen. Western and eastern African nations, however, may see some relief. In 2000s, the regions annually withdrew 12 % and 34 % of their **internal freshwater resources**, respectively. This could mean that enough water may be available to continue the central and eastern African regions' reliance on hydroelectric sources to provide electricity to its populations with nearly 80 % and 63 % of the total production generated by these sources. In contrast, northern and southern African nations got 8 % and 23 % of the electricity from these sources.

The road network was not as extensive in Africa as it is elsewhere. This indicates that movement may be difficult in an emergency. In comparison to road density in North America and Australia of about 40 km of road per 100 km of land, road density ranges from around 8 km of road per 100 km of land in central Africa to 28 km in the eastern countries. Many of those kilometers are not paved, however. About 15 % of the roads were paved in central Africa, 20 % in western Africa, and 66 % in northern Africa. Vehicle use there was the lowest out of all the world

regions. This cursory overview does little justice to the extent of the social, developmental, and political challenges many regions on the continent face. Impacts from climate change, unfortunately, appear to be another challenge for many areas. The damages from the impacts may be magnified because of inadequate capacity – structural and political – to reform and to adapt.

53.3.6 Australia and New Zealand

Australia, New Zealand, Tasmania, Fiji, and Samoa are projected to experience significant warming by the end of this century. Temperatures in the central portions may increase up to 8 °C with smaller increases closer to the coast – up to 5.4 °C within 400 km of the coast. Near the coast precipitation is expected to drop by up to 80 %. Southern and subtropical Australia will also see decreases, but northern and central territories may see some increases. Just like on the North American continent, southwestern regions of Australia will see many more droughts – up by 80 % by 2070 as simulated by one study. New Zealand will likely also experience more frequent severe droughts. Precipitation will increase in the west and decrease in the east.

In 2000s, out of the population of 27 million people (or 4 % of the world's population) in the region, 85 % of Australians live within 50 km of the coastline, nearly 100 % of Tasmanians and all residents of the small islands. Everyone in New Zealand lives within 100 km of the coast. This region of the world is especially vulnerable to the impacts from climate change related to encroachment of seawater and more frequent storms and hurricanes.

Australia, New Zealand, and **small island nations** are projected to experience particularly harsh impacts from climate change – some of these like changes to natural ecosystems and stress on available water are already underway. Economic damages from consequences of more frequent natural disasters, such as floods, droughts, storms, or landslides, are rising. The 2002 drought cost Australia \$7.6 billion. New Zealand alone suffered losses to its agricultural sector of \$800 million in the multiyear droughts in the late 1990s. Floods cause an annual \$85 million in damages there.

The populations of these nations were concentrated fairly tightly with nearly half of them living in the largest city. Australia and New Zealand's rural population was about 10 % of the population, while Fiji's was closer to 50 % in 2009. The road density in Australia was close to that in South America or central Asian countries like Kazakhstan or Uzbekistan. The stretch of the road network was six times smaller in Australia and New Zealand than in the United States. This means that less infrastructure is on the path of destruction, yet mobility may be more limited. The fairly sizable rural populations also mean that agriculture is an important source of income for many – and more comparable to the numbers for Europe and North America.

On average, 8 % of the continent's GDP was attributable to the agricultural sector, which employed around 5 % of the population in 2000s. Agricultural productivity may be compromised as a result of temperature increases and changes

in precipitation. In 2000s, Australia received about 530 millimeters of precipitation each year – less than three times what New Zealand got. This is comparable to the average on the southern tip of Africa. Future projections for lower precipitation across much of the continent puts in question continued expansion of agriculture (which grew nearly 7 % in Australia, but contracted 12 % in Fiji according to the latest available numbers). Lower water supplies may also alter how much electricity is derived from hydroelectric sources. While Australia derives just over 5 % from hydro, New Zealand draws more than 55 % from the source. Overall, the continent has strong baseline conditions to deal with many projected impacts in the short-term future, but its capacity may be strained as impacts intensify.

53.4 Interconnectivity and Reach of Impacts

The economies of the regions described above are highly interconnected globally. This **interconnectivity** can propagate environmental impacts in one region to affect many others – one poignant example of such was the quick shrinkage of sales of Japanese automobiles across the globe when production halted following a disastrous tsunami in the spring of 2011. The magnitude of such **ripple effects** depends on the extent to which a country's economy is tied to global markets. International tourism is a particular case in point. This service industry is the economic backbone of many beach destinations, skiing and winter sport spots, and wildlife-touring locations. In 2000s, tourism attracted over 70 million people from around the world to the North American continent annually, generating over \$100 billion in receipts. And travel services account for over a quarter of the countries' average commercial services exports. Uncomfortably high temperatures, lack of snow, and degradations of ecological landscapes can diminish the sector's contribution to national economies.

Several European countries share the fears of declining tourism because of climate change, especially to the well-off snow sports industry hugging the Alps, whose annual profit is on the order of \$70 billion. Only a third of the current number of resorts will remain if warming reaches 4 °C, and those able to remain open may need to supplement snow through artificial means, raising their operating costs and reducing their competitiveness. In 2000s, southern economies were also dependent on international tourism, which accounted on average for 20 % of the total export bill. All together Western European countries hosted 150 million tourists annually, while southern European countries welcomed 140 million. Interconnectivity is strong not only through travel but also through **trade**. This is especially true for the Western European countries where two-thirds of their GDP came from exports. A third of southern European countries' GDP related to exports.

Asian countries' economies are also closely tied to trade relationships with other nations. In 2000s, exports were growing at very high rates in many Middle Eastern countries – like Qatar, Oman, Turkey, Saudi Arabia, Afghanistan – and countries previously tied to the Soviet Union: Turkmenistan, Tajikistan, Georgia, Armenia, and Azerbaijan. For eastern Asia, exports accounted on average for three-quarters

of the countries' GDP. International tourism was booming. All of Asia welcomed around 330 million tourists in 2000s – or nearly 30 % of the total world traffic – and brought in over \$265 billion. Eastern Asian countries, especially Hong Kong, China, and Korea, are particularly active in the global stock market, trading annually in stocks three times the value of their GDP, on average.

Latin American countries also leaned heavily on exports to support their economies, realizing also that international tourism was a profitable business. It brought in around \$60 billion for the Latin American region with over 6 million annual visits in 2000s. Australia and New Zealand economies rely less on trade but have a lucrative international tourism industry. Although the region attracted less than 1 % of world's international tourists with around 8 million visitors, it drew 3.2 % of the tourist receipts.

The situation in Africa in terms of exports is much different than in the rest of the world. Although trade constitutes a large portion of most African nations' GDP, **export and import volumes** for the continent were relatively low during the same time frame. For instance, the value of the Africa's imports and exports was a tenth of Asia's. African exports were growing in the eastern and western regions but stagnated in central and northern Africa, even though those areas were net exporters of energy. Africa drew in 60 million tourists a year – about the same number as Latin America or North America. North American countries, however, received twice as much revenue from their guests than their counterparts in Africa.

The variable – and ever-changing – interconnectivity of the world is a difficult dimension to account for when estimating potential impacts of climate change. Each region has a unique suite of economic, social, and historical relations with other nations and experiences a different mix of climate impacts. The baseline conditions in 2000s described above give some perspective on where the different regions were in their economic vulnerabilities. The capacity to deal with the consequences is another dimension that complicates the issue of climate change.

53.5 Global Social Justice

While every continent will see impacts from climate change, some regions are much better prepared to deal with the consequences. Countries on the North American continent for instance have a very high average per capita GDP of nearly \$50,000, affording them the financial means to address some of the consequences. Virtually the entire population enjoys modern **sanitation** facilities and has access to clean water and sufficient food. In 2000s, population growth was less than 1 % per year across North American countries. Resources and time are on the regions' side. Still, challenges remain. Aging infrastructure across the United States is a growing pain. In 2009, the American Society of Civil Engineers split the country's infrastructure resources into 15 categories, giving only four categories the grade of C or C+, while the rest received D or D-. Maintaining **drinking water** requires an additional \$11 billion in annual funds. At least \$100 billion is needed to update the

nation's levee system. The government spent less than 40 % of the \$190 billion needed to preserve the many kilometers of road.

Many European countries likewise enjoy solid baseline conditions to deal with climate change impacts. But sharper differences emerge region to region. GDP per capita ranges from a low of \$9,000 in current US dollars on average in Eastern European countries to a high of \$78,000 in Western European countries. Economies are diversified and the populations are well educated for the most part. This gives some economic stability and capacity. Challenges abound, however. Southern European countries have an average unemployment of over 16 %, for instance, and their workers attained lower educational levels than their counterparts in other parts of Europe. Families with low incomes have fewer resources to deal with the effects of storms or increased temperatures. The cost of cooling equipment and energy can be prohibitive. **Migration** is also high into western and northern European countries, where nearly 3 million people migrate annually. Even more, 3.5 million people, moved to southern European countries, particularly to Spain and Italy. An increase in people stretches institutional resources, perhaps leaving less for adaptation or mitigation purposes. Migration is a hot-button issue in Europe, and one concern there is of an increase in migration as people move to avoid the worst impacted areas.

Countries in the Asian region span a full spectrum of economic and political developmental stages. As a result, government capacity to respond to costly emergencies varies. Health infrastructure, **food security**, and capacity of physical systems to handle growing populations and growing demand for a higher standard of living also vary. In 2000s, GDP per capita ranged from very low ranges (an average of less than \$2,000 current US dollars in southern Asian countries and around \$2,800 in central Asian countries to the average) to medium levels (\$5,100 on average in northern Asian countries and \$6,500 in south-eastern Asian countries) to relatively high incomes of \$18,000 in western Asia and \$26,000 in eastern Asia. Clean sanitation facilities were available to 60 % of the people residing in southern Asian countries, 67 % in southeastern and northern Asia, and 80 % in eastern Asia. Clean water was available to over 83 % of the population in every country, on average. Such present-day challenges undermine the regions' capacity to respond to impacts from climate change. Sanitation and availability of clean water are crucial tools in preventing the spread of **disease vectors**, many of which may benefit from warmer temperatures.

Latin American countries have varying availability of infrastructure. While they still have many unpaved roads, over 90 % of the population has access to good water sources and around 80 % to clean sanitation. The GDP per capita there is comparable to medium-range incomes in Asian countries. Individuals in the Caribbean Basin have around \$10,000 in current US dollars, while those in Central America have less than \$4,500. Individual capacity to respond to disaster depends in part on the availability of resources.

Many of the African nations were impoverished in 2000s. The western African region has the lowest GDP per capita in the world with \$836. Eastern African nations average a GDP per capita of about \$1,500, nearly \$400 less than southern

region in Asia, which has the lowest GDP per capita there. The northern African region has the highest GDP per capita of the continent with around \$4,000 – less than half of what it is in Eastern European nations and nearly 20 times less than what it is in Western European nations. This discrepancy points not only to the different level of economic development but also to the potential individual capacity to deal with a crisis. Adequate health and environmental resources are also necessary to expand individual capacity. About a third of the population lacked access to clean water in central, eastern, and Western African regions. Three-quarters lacked access to clean sanitation facilities in western Africa, and two-thirds lacked access to sanitation facilities in central and western African nations. Northern and southern regions were better off – 80 % of people in the north had access to both clean water and sanitation. Half of the people have access to sanitation facilities, and 86 % have access to clean water in the south. So although actual impacts from climate change will affect northern and southern African regions disproportionately, some capacity exists to adjust.

Australia and New Zealand have capable and stable governmental, economic, and physical structures. The GDP per capita is nearly \$20,000 on average between New Zealand and Australia, but the GDP per capita in Samoa and Fiji are about a tenth of that. Almost the entire population has access to clean water and clean sanitation facilities. There is virtually no **malnutrition** prevalence, whereas rates were at around a quarter of children under 5 or more in all of the regions in Asia (in southern Asia the rate is 41 %, as measured by the height for age ratio) and around the same in Africa – with 45 % of the children malnourished in eastern African countries. Inability to deal with existing problems highlights the level of institutional capacity. More disruptive weather events promise to test it further.

53.6 Conclusion

This chapter presented an overview of the range and magnitude of resources at risk from climate change and highlighted the overlapping climatic, ecological, and socioeconomic dimensions. No particular impacts are certain in their magnitude or timing. Trends, however, are clearly emerging. Still, uncertainty is part of all projections, especially complex ones like those linking global climate change with regional economic and social dynamics. The scientific portion of connecting natural processes to observed and anticipated impacts is on solid footing. The sociopolitical portion is much less certain, not least because we have few ways to communicate impacts beyond economic terms. At a minimum, economic measures provide a convenient common ground for comparing fairly simple concepts across regions, such as damage to physical coastal property, rising insurance costs, foregone prices of ruined agricultural crops, declining receipts in the tourism sector, or repair bills associated with infrastructure damage. More nuanced concepts like the fairness of associated regional distributions of those impacts, the social costs of human suffering related to increased incidence of disease and disaster, the environmental stress inflicted on the natural systems, the widely differing adaptive capacities, or

the fairness questions that divide the developing and developed nations do not easily fit into standard models of climate impacts and responses. They can hardly be reduced to numbers, let alone to dollars. Yet such nuanced and multidimensional assessments will be needed to better understand regional impacts and guide responses.

Appendix

All economic data used in this report came as country-level indicators from the World Bank's World Development Indicators and Global Development Finance database and the Food and Agricultural Organization of the United Nations. We use the latest available statistic from 2000 to 2010 for individual countries for the World Bank data and the latest available from 2000 to 2009 for the FAO data (World Bank 2011; FAO 2009). The countries are assigned regions according to the regions in the IPCC report and subregions using the UN Geoscheme categories because the IPCC report did not provide a country-by-country breakdown of the regions. We made the following modifications. Russia and Mongolia were placed in the Northern Asia region in line with the IPCC report. This is not a region within the UN Geoscheme. Several small island nations were not listed in the UN Geoscheme and were placed to the closest IPCC region. We also grouped Melanesia, Micronesia, and Oceania islands with the Australia and New Zealand region – although because of dearth of socioeconomic data for these nations, many of them were not included in the analysis. We renamed the Middle Africa region as the central African region for more consistency. All data listed is specified as either the average per country or the total data point for countries with available data for the region. All monetary figures are in current US dollars.

Abstract

Sustainability has become a key concept in the quest to define a normative framework for urban and regional development. This chapter presents an overview of what is meant by sustainability first from the regional and then from the city level. Both scales have a long history in the planning domain, but the notion of a *sustainable city* is key to both realms and is the main focus of this chapter. While there is widespread agreement on broad parameters and principles about urban and regional sustainability, there are entrenched debates over implementation. On one level, there are debates over implementation methods, especially the degree to which partial success in implementation is better or worse than doing nothing. More fundamental debates about sustainability involve the distinction between process vs. form and the integration of city versus nature.

54.1 Introduction

On the subject of urban and regional sustainability, the debate is no longer *whether* cities and regions should be less environmentally harmful and more human scaled but what the specific policy and design responses should be – whether government subsidies and funding priorities, market incentives, new kinds of codes, transportation systems, or urban design schemes are achieving what is needed. Our views of the *sustainable city* and region have evolved from “what is it?” to “how do we get there?” in much the same way that many environmentalists decided several years ago that the debate over *global warming* had been settled, despite the continuing pushback from the other side.

Most urban planners would now argue that, in principle and in broad terms, we know what the *sustainable city* and region is supposed to be and what the economic, social, health, and environmental benefits of it could potentially be. The Wikipedia definition adequately sums up the main objective: “A *sustainable city* can feed and power itself with minimal reliance on the surrounding countryside, and creates the smallest possible ecological footprint for its residents.” Sustainable development at the regional level is often more abstractly defined, broadly attempting to balance equity, economic, and ecological concerns. Berke and Conroy define sustainable development as “a dynamic process in which communities anticipate and accommodate the needs of current and future generations in ways that reproduce and balance local social, economic and ecological systems, and link local actions to global concerns” (Berke and Manta-Conroy 2000, p. 23). With these broad principles in mind, the focus, in the Western world and in the USA especially, is squarely on implementation.

This chapter first reviews the generalized principles of sustainable cities and regions, moving from a broader review toward a more specific definition. It begins with the basic principles and then spells out what those principles might mean for the physical form and pattern of cities. It will become clear that as we move from broad principles to specific design strategies, the degree to which planners agree becomes increasingly strained. The second part of the chapter focuses on the key debates within the literature on *sustainable cities*. Although planners largely agree about what a *sustainable city* should be on a certain level, there continue to be entrenched disagreements about the best approach to getting there.

54.2 Principles

We can start with the meta-principle – the notion of “*sustainability*” from the often-quoted *Brundtland Report* is as follows: “Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs” (World Commission on Environment and Development the Brundtland Commission 1987, p. 43). Sustainability involves adopting a lifestyle “within the planet’s ecological means” to ensure that development does not compromise the needs of future generations and to ensure that

population growth is “in harmony with the changing productive potential of the ecosystem.” Urban and regional planners have translated this to mean that cities must endure environmentally, economically, and socially, balancing what have come to be known as the three “E”s: environment, economy, and equity (Berke 2002, p. 30; see also Campbell 1996). Basically, this means that planners should help cities develop in ways that last.

Often sustainability is cast as a continuation of environmental planning. While planners seem to agree that *sustainability* requires a holistic view “that includes equal concern for environmental, economic, and social sustainability” (Daniels 2009, p. 185), the environmental perspective dominates. Thus, urban *transport* is to be energy efficient, solar power is to be promoted where possible, and water is to be used efficiently – in short, cities are to be redefined as “eco-technical systems.” Cities are going “green,” and thus Routledge’s comprehensive four volumes entitled “Sustainable Urban Development” are principally devoted to environmental assessment. Out of this larger environmental focus, many subtopics have evolved that are of particular relevance to urban planners, like the relationship between sustainability and technology, sustainability and architecture, and even “sustainable Olympic games.”

Sustainable development can engage a complex array of political views that range from “free-market” *environmentalism* to ecofeminism, animal rights, and bioregionalism. The three-way conflict between *environmentalism*, economic development, and social justice – green cities, growing cities, and just cities, as Campbell (1996) refers to them – is present in all of these approaches, and each manifests a human vs. nature duality to varying degrees (this duality is discussed in more detail at the end of this chapter). Proposals include “greening the market,” liberal *environmentalism* in the tradition of John Rawls, ecosocialist theory, or the biological rooting of culture through “reinhabitation.” In many of these applications, there remains a fundamental, lingering duality that conceptualizes an environmental crisis in human vs. nature terms.

While these concepts have found their way into the rhetoric of metropolitan development reform, there is a significant question about the degree to which rhetoric is being translated into actual practice. Sustainability is a concept endorsed by both economic development proponents and radical ecologists, and as Campbell (1996) points out, “any concept fully endorsed by all parties must surely be bypassing the heart of the conflict.” Cultural theorists who study the social construction of nature have argued that sustainability is simply another version of the “recovered garden” consisting of biodegradable industries, preservation of pristine wilderness, and social justice that finally achieves the “end drama,” a “postpatriarchal, socially just ecotopia for the postmillennial world of the twenty-first century” (Merchant 1996).

Sustainable cities require that economic, environmental, and social needs be balanced and interconnected. *Sustainability* is based on the idea that it is necessary to find the proper balance between human-made and natural environments, the “warp and woof that make up the fabric of our lives” (Van der Ryn and Cowan 1995). This constitutes a new brand of environmental thinking. Under what is

sometimes branded “the new urban ecology” (Collins et al. 2000), cities are no longer viewed as necessarily detrimental but are in fact part of the solution to environmental problems.

To make these kinds of ideals relevant, planners have translated urban impacts using concepts like “carrying capacity” to promote the idea that metropolitan development should not consume resources faster than they can be renewed or more than natural systems can process. Similarly, the “*ecological footprint*” is used to measure sustainability by calculating the amount of resources consumed, postulating that sustainable development requires reduction of ecological footprints by reducing levels of human consumption that do not exceed the ability of ecosystems to provide them. This method has lately been criticized for failing to fully account for the trade-offs and benefits of compact urban form, among other things. The ecological footprint may foster human vs. nature duality because of its emphasis on establishing a causal link between cities and accelerated global ecological decline.

54.3 Sustainable Cities and Regions

The *sustainable region* and the *sustainable city* are intertwined for one obvious reason: the *sustainable city* is almost always discussed in terms of its regional context. In a planning sense, regionalism is about the pattern of human settlement (villages, towns, and cities) set in protected open space. Anyone advocating the development of self-contained units of human settlement knows that these units must be positioned geographically but also that it is necessary to think of them in terms of an integrative framework. On this point, there is little disagreement, and the idea has been operative since the regionalist perspective applied to city planning came into fruition more than 100 years ago.

Looking at the world from a regional perspective began even earlier and can be traced back as far as the eighteenth century when the natural and cultural geography of Europe was particularly suited to regional differentiation. A number of definitions evolved, ranging from a focus on human economy and cultural distribution to the identification of natural boundaries. Peter Hall (2002) points out that the idea of towns of limited population surrounded by agricultural green belts is a recurrent theme, found in the writings of Ledoux, Owen, Pemberton, Buckingham, and Kropotkin, and More, Saint-Simon, and Fourier had cities arranged within a regional complex.

Sustainability at the regional level revolves around a related idea that issues like housing, *transportation* and the environment, and the political governance of each must be treated as an interconnected, multijurisdictional whole. There is a need to balance human activity and nature by keeping settlement at the proper scale and level of self-sufficiency. The *Regional City* envisaged by contemporary regionalists (Calthorpe and Fulton 2001) conceptualizes the “emerging region” as a revitalized central city coexisting with strengthened suburbs and preserved natural areas.

In the USA, sustainable cities are a more common conception than sustainable regions, although in Europe, this is not the case. In all regions, planners seem

especially in agreement about what an *unsustainable* city looks like. There is no disputing that malls surrounded by parking lots, disconnected apartment complexes, and vast expanses of low-density detached housing – that is, sprawl – have a higher carbon footprint than attached buildings in a walkable context. The recent book *Green Metropolis* by David Owen (2009) presented the most thorough documentation of this fact to date: compact neighborhoods bring with them the intrinsic environmental, social, and economic benefits of living smaller, driving less, lowering energy costs, strengthening social connection, and fostering networks of economic interdependence. The book *Sustainable Urbanism* by Doug Farr (2008, p. 10) provided an even more explicit vision: “Sustainable urbanism is an integration of walkable and transit-served urbanism with high-performance buildings and high performance infrastructure.” Planners largely agree that the *sustainable city* is more than just green buildings and pervious pavement; it involves the design of walkable communities along with the connection to transit, food, and amenity they require.

How does urban planning support sustainable ideals more specifically? Of course, the concept of a “*sustainable city*” includes more than the physical and infrastructure qualities of built form. In particular, institutional strategies like recycling programs, local governance, and civic participation are considered important for promoting sustainable cities. And always, green building and infrastructure technologies – efficiencies in structural design, energy use, and materials, as well as green infrastructure – are an important part of the task of city building.

We can summarize the key principles that promote the *sustainable city* from an environmental point of view. Cities must (a) lower vehicle miles traveled (VMTs), limiting carbon emissions by looking for ways to reduce reliance on fossil fuels (cars) and increase reliance on clean *transportation* (e.g., bus rapid transit, light rail); (b) lower energy costs by lowering infrastructure, like highways, and utility lines, which in turn results in lower transmission loss; and (c) limit damage to natural environments by lowering impervious surfaces and runoff, compacting development, and lowering disruption of *biodiversity* and natural habitat. Sustainable industrial and energy systems, food production, and mitigation of heat-island effects are also essential. Sustainable cities also promote “green streets” that handle stormwater within their right-of-way; contain visible, green infrastructure; and maximize street trees to improve air quality, reduce temperature, and absorb stormwater. Sustainable cities support passive solar design, sustainable stormwater practices, organic architecture, the harnessing of waste heat, and the protection of *biodiversity* corridors. Local jurisdictions in the USA have been attempting to incorporate sustainability in their activities, regulations, and development approval processes, promoting eco-industrial park development, bicycle ridership programs, point systems for green architecture, or the use of sustainability indicators.

That is just the environmental side. To endure economically, the *sustainable city* needs to foster diverse economic networks of interconnected relations, a view that Jane Jacobs famously advocated in *The Death and Life of Great American Cities* (1961). The basic idea is this: “the combinations of mixtures of activities, not separate uses, are the key to successful urban places” (Montgomery 1998, p. 98).

Allan Jacobs and Donald Appleyard wrote a widely cited manifesto in which they argued that *diversity* and the integration of activities were necessary parts of “an urban fabric for an urban life.” The maximizing of “exchange possibilities,” both economic and social, is viewed as the key factor of urban quality of life (Greenberg 1995) and, now, *sustainability*. What counted for Jane Jacobs was the “everyday, ordinary performance in mixing people,” forming complex “pools of use” that would be capable of producing something greater than the sum of their parts (Jacobs 1961, pp. 164–165).

Thus, sustainable cities are tied to, or ultimately derived from, social and economic *diversity*. The book *Building Sustainable Urban Settlements* (Romaya and Rakodi 2002), for example, lists “mixed land uses” first under its set of principles for building sustainable settlements. Reduction of travel costs, and therefore energy consumption, is usually a primary motivation. The “land use–transport connection” is put forth as a counterresponse to the problem of non-diversity, that is, functional isolation (Newman and Kenworthy 1996). A mixture of land uses has been shown empirically to encourage non-automobile-based modes of travel such as walking and bicycling, which in turn are seen as having a positive impact on public health.

An economically *sustainable city* is one that fosters opportunity. In Jacobs’ words, cities, if they are diverse, “offer fertile ground for the plans of thousands of people” (Jacobs 1961, p. 14). Non-diversity offers little hope for future expansion, either in the form of personal growth or economic development. Nor are non-diverse places able to support the full range of employment required to sustain a multifunctional human settlement. *Diversity* of income and education levels means that the people crucial for service employment, including local government workers (police, fire, schoolteachers) and those employed in the stores and restaurants that cater to a local clientele, should not have to travel from outside the community to be employed there.

This brings us to the third dimension – that of social *sustainability*. As with economic sustainability, *diversity* is seen as a key variable. A socially diverse city – one that avoids differentiation of social groups into segregated housing enclaves – ensures better access to resources for all social groups, providing what is known as the “geography of opportunity” (Briggs 2005). *Diversity* builds social capital of the bridging kind by widening networks of social interaction. Where there is less social *diversity* and more segregation, there is likely to be less opportunity for the creation of these wider social networks. This could be a significant disadvantage for segregated neighborhoods and could even have the effect of prolonging unemployment.

While socially diverse neighborhoods continue to be seen as essential for broader community well-being and social equity goals, the connection to *sustainability* is also made – mixing incomes, races, and ethnicities are believed to form the basis of “authentic,” sustainable communities (Talen 2008). In addition to mixed housing type, land uses that complement each other to promote the active use of neighborhood space at different times of the day will create “complex pools of use” (Jacobs 1961), a component of natural surveillance and social

sustainability. Supporting this are findings that a mix of neighborhood public facilities plays a role in reducing crime. Studies of socially mixed neighborhoods consistently identify *urban form* as a key factor in sustaining *diversity*.

It is possible to focus more specifically on the human-built dimensions of *urban form* – streets, lots, blocks, land uses, buildings, and the patterns they create. A kind of meta-principle for sustainable *urban form* is compactness. All of the environmental principles of *sustainability* suggest or even require it. Some of this is obvious. Compactness means that there will be fewer highways, greater transit feasibility, greater opportunities for combined heat and power, and lower pumping requirements for water and sewer. Conversely, low-density development has been linked to higher infrastructure costs, increased automobile dependence, and air pollution. Density has been seen as an essential factor in maintaining walkable, pedestrian-based access to needed services and neighborhood-based facilities, as well as a vibrant and diverse quality of life (Newman and Kenworthy 2006).

Walkable access to services is an essential part of the *sustainability* equation because people living in well-served locations will tend to have lower carbon emissions (Ewing et al. 2008). The higher the access to opportunities like jobs and services, the lower the *transport* costs. Related to this, sustainable *urban form* is defined by the degree to which it supports the needs of pedestrians and bicyclists over car drivers. This has been motivated by a concern over the effect of the built environment on physical activity and human health. Streets that are pedestrian-oriented are believed to have an effect not only on quality of place but on the degree to which people are willing to walk. Researchers have argued that activity levels can be increased by implementing small-scale interventions in local neighborhood environments, and a whole catalog of design strategies are now used to make streets more pedestrian-oriented.

Finally, sustainable *urban form* is associated with what could be termed poly-centric or multinucleated urbanism – the idea that urban development should be organized around nodes of varying sizes (see Frey 1999). Whereas sprawl tends to be spread across the landscape uniformly, sustainable *urban form* has a discernible hierarchy to it – from regional growth nodes to neighborhood centers or even block-level public spaces. At the largest scale, centers may be conceived as regionally interconnected “urban cores,” with higher intensity growth converging at *transportation* corridors. At the neighborhood level, nodes support sustainable *urban form* by providing public space around which buildings are organized.

54.4 Implementing Sustainability Goals

While there is wide agreement among urban planners on the principles outlined above, it is during implementation of these ideals that tensions about sustainability are exposed. In fact, there is plenty to debate, and those debates frame some of the most interesting aspects of *sustainability* in planning.

Debates about *sustainability* in planning are often a matter of degrees. Studies of the connection between, say, *urban form* and travel behavior, or between *urban*

form and health, may admonish planners for failing to see the full complexities involved in linking particular forms to *sustainability* outcomes, but they are unlikely to call for the wholesale reversal of the basic idea that compact, diverse, walkable urbanism supports *sustainability*. Between business-as-usual sprawl development of the “nineteen real estate product types” that define suburbia (Leinberger 2008) and urban planners seeking compact urbanism, there is a significant divide. Debates on the planning side center on how much compactness, walkability, and *diversity* of land use, not whether compactness and *diversity* are important goals. While it is entirely possible to discuss the level of social *sustainability* – in terms of equity, justice, and social capital – that might be impacted by alternative *urban forms*, these too are a matter of degrees (Ancell and Thompson-Fawcett 2008).

One source of debate is over the degree to which partial success in implementation is better or worse than doing nothing. Ancell and Thompson-Fawcett raise a legitimate question about whether intensifying parts of a city makes a city more sustainable: “if this results in diminished opportunities for lower-income groups to live in the central city, is such intensification necessary or sufficient as a basis for social *sustainability* with respect to planning for housing?” (2005, p. 427). One response is that this might be more a matter of failed implementation than of failed principle.

But what might be more elusive and interesting is not the degrees to which different sustainable *urban forms* achieve their desired purpose and not whether implementation is actually occurring – although both of these questions are critical and continue to engage researchers – but whether there are debates that are even more fundamental. There are two debates in particular: process vs. form and city vs. nature.

The first concerns the tension between flexibility and open-ended process vs. preconceived forms and concrete visions expressed as ideal models of *urban form*. In the book *The Original Green* by Steven Mouzon (2009), the argument is made that cities, to be sustainable, must embody a number of specific design principles, from walkable streets to preservation of the embodied energy of historic buildings, to design that encourages the use of public space and the civic interaction that results. But for some, the specific design qualities needed to enhance *sustainability* at this level should be more open ended and flexible – not normative.

In lieu of the normative approach of new urbanists, some argue that *sustainability* in planning amounts to managing “the continuous processes of change” (Brown 2006, p. 100). Brown notes that this was the perspective of the revered urban planner Kevin Lynch, who wrote in the book *Good City Form* (1981): “The good city is one in which the continuity of this complex ecology is maintained while progressive change is permitted. The fundamental good is the continuous development of the individual or the small group and their culture: a process of becoming more complex, more richly connected, more competent, acquiring and realizing new powers – intellectual, emotional, social, and physical” (Lynch 1981, p. 116). Planners and designers who agree with this view are against “a steady state with respect to human–environment relations” and instead devote their energies to promoting the best possible process.

Process and form are not necessarily in opposition. New urbanists would contend that both are needed, relying on the charrette process to implement their model of sustainable *urban form*. But many planners, while they would agree with the basic outlines of what a *sustainable city* looks like, are more interested in ensuring a sustainable process for getting there. Phil Berke summed up what the authors in a special issue on green communities in the *Journal of the American Planning Association* called for: “collaborative planning processes aimed at strengthening and mobilizing social networks to support green community initiatives, requirements and incentives that stimulate greener community and household behaviors, and new assessment tools for green building rating, and greenhouse gas inventory and analysis” (Berke 2008, p. 393). In other words, the focus is on process, procedure, and assessment rather than specific design ideals. Largely this entails prioritizing resident views: “it is important to avoid undertaking research with pre-conceived notions as to whether impacts of urban compaction such as smaller houses are negative or positive, and instead to let the residents speak for themselves” (Ansell & Thompson-Fawcett, 2008, p. 440). Others have argued that the *sustainable city* is being thwarted by “unresponsive bureaucratic procedures” that are ill prepared to deal with the reality that “sustainable development is political rather than analytical” and that overly pragmatic policy solutions (i.e., urban design ideals) might forever frustrate the value-laden complexity of *sustainability* (Batty 2006, p. 38).

In the architecture field, models of sustainable *urban form* that appear to be universalist (such as those of the new urbanists) are rejected. Architects are especially “skeptical of the assumption that a single approach, model, or list of best practices can be universally applied,” arguing instead for a “much needed transdisciplinary conversation to emphasize the long-term consequences of our actions, not their ideological or disciplinary purity” (Pragmatic Sustainability: Theoretical and Practical Tools (<http://www.rouledge.com/books/search.asp>)). Reviewing why one city is better able to develop sustainably than another rests on “particular dispositions toward politics, nature, and technology,” not “a single abstract model” (Moore 2007).

An even more fundamental debate concerns the relationship between cities and nature, which can be described as the “human vs. nature duality.” There is a long history to this in urban planning, and the focus on *sustainability* has not escaped it. It comes from the regionalism of early-twentieth-century botanist Patrick Geddes, who viewed metropolitan development as dependent upon knowledge of the large-scale, regional complexities of the landscape and the human response to that landscape. However, early regionalists believed no synthesis between *existing* metropolitan development and nature was possible. This imbalance, which was explicitly outlined by MacKaye (1928) in *The New Exploration*, came to epitomize the view that large metropolitan areas were the antithesis of environmental conservation.

Historian William Cronon explored the phenomenon of separating human and natural worlds in the book *Uncommon Ground: Rethinking the Human Place in Nature* (1996). He argued that wilderness, the “ideological underpinning” of the environmentalist movement, is a highly problematic concept because it is viewed

as something wholly separate from ourselves. Even the opening line of the Union of Concerned Scientists' *Warning to Humanity* (1992) included the premise of separation; it begins: "Human beings and the natural world are on a collision course."

What may be the most lucid example of human/nature duality in planning is the way in which the "greening" of human places is interpreted as something unilaterally positive for the environment, regardless of broader impacts. There may be a failure to recognize that metropolitan development patterns that appear "natural" in the suburban landscape actually disrupt natural systems. In fact, maintaining green spaces may be harmful both in direct ways (through soil compaction, irrigation, and the need for chemical treatment) and in indirect ways – increasing atmospheric pollution through increased automobile use caused by spreading out the urban pattern. In short, interweaving green spaces through human settlement may sometimes be more harmful than not when viewed at a larger scale. Somewhat ironically, the most environmentally sound pattern of human settlement – in some cases – may be the one with lower rather than higher levels of green space.

This tension between cities and nature has been identified by Godschalk and others as the "green cities conflict." It is essentially a conflict over the degree to which natural vs. human connectivity is to be prioritized. New Urbanism has been criticized for failing to accommodate more environmental sensitivity (Berke 2002), and this often boils down to their focus on maintaining urban connectivity. But new urbanists counter that environmental regulations may inadvertently thwart compact urban development, including suburban retrofits. They point to a potential problem with Low-Impact Development, which is attempting to replace the old stormwater system approach of "pave, pipe, and dump engineering" with something more eco-friendly. The old system resulted in high runoff rate, volume, and pollutant loads and needed to be changed. But new stormwater regulations, currently being advocated by the US Environmental Protection Agency (EPA), might actually incentivize sprawl and reduce retrofits by making each site "emulate the natural hydrologic conditions of the site." Since this becomes much easier in greenfield sites but is onerous on redeveloped sites, the urbanization of existing places may ultimately be avoided.

An alternative to the Low-Impact Development approach has been proposed in the *Light Imprint Handbook: Integrating Sustainability and Community Design* (<http://www.lightimprint.org>). The book lays out environmentally friendly stormwater management and includes 60 techniques for "paving streets and walkways, channeling and storing water, and filtering surface runoff before release into the aquifer." It is described as "an intrinsically green design strategy" that not only sustains compact urban places but also "respects site terrain." The approach is based on the idea of an urban-to-rural transect as a way of maintaining the proper interconnections among urban elements – a balanced mix of landscape, building type, and streetscape, for example.

How should compact urban development integrate with green infrastructure practice? Projects that are greenfield rather than infill, disconnected from existing

infrastructure, and not particularly concerned with stormwater runoff and the restoration of wetlands are problematic (Berke et al. 2003). But it is also true that environmental “Best Management Practices” and “Low-Impact Development” can result in a lack of urban connectivity, undermining the ability to develop walkable, diverse, compact places – sustainable *urban form*.

54.5 Conclusions

There is an interesting overlap between the two debates discussed above: the need to balance process vs. form and the need to integrate city vs. nature may ultimately converge in our approach to sustainable urban planning. For example, it could be argued that creating visually explicit models of future development *and* providing an inclusive process are both needed to help resolve the human vs. nature duality problem. Perhaps development that is represented tangibly (as compact urban neighborhoods) can help overcome human/nature duality by helping people visualize how development that meets human needs can also protect natural areas. Recognizing that urban development is not a zero-sum game with trade-offs between social and environmental goods, normative visions of development could be used to help illustrate the possibilities. And an inclusive process that allows flexibility and the exploration of alternative proposals is needed not only to ensure that development actually addresses human/nature integration but that it does so in a way that makes sense to people.

The definition of the *sustainable city* and region is, in principle, resolved. The question is how to get there: via a reliance on the right process that guides city building toward a more sustainable outcome, or via a stronger articulation of what the *sustainable city* and region is supposed to be, or via an urban development approach that prioritizes natural systems or one that allows natural systems to be trumped in some cases in order to promote urban connectivity and compactness? City and regional planners need to find a balance between visualized ideals and inclusive process and between the unequivocal protection of nature and the corresponding human claim to land development. In both cases, there is a need to bring the language of integration into sharper focus. In sustainability, actions are supposed to balance natural, economic, and social concerns. *Sustainability* challenges us to make every decision supportive, and integrative, of each realm.

Abstract

The impact of human population growth on the environment represents the major challenge of our time. This chapter reviews demographic change over the last century, set in historical context, and different perspectives on population-environment interactions. Differences in population growth rates and demographic change across space are explored, followed by perspectives on the population-environment nexus at multiple scales with a particular focus on those contexts where impacts are likely to be the very greatest on humankind. The alignment of individual and higher-level actions resulting in environmental impacts and the negative force of the impacts of actions are important, to signal the need to change behaviors. Interrelationships are shown to be highly complex. It is argued that multidisciplinary efforts to tackle complexity and to focus on resilience at multiple scales are critically needed, with the importance of multidisciplinary regional science thought being underscored. The question is raised, however, whether

these efforts will be coordinated well enough across multiple scales and with multiple disciplines and publics to avoid what could be catastrophic impacts. These are most likely to occur at local and regional scales where population growth rates are high, natural environments already vulnerable, and resilience limited.

55.1 Introduction

Vitousek et al. (1997), among many other scholars, convincingly argue that the impact of human population growth on the environment represents the major challenge of our time. Increasingly, humans dominate the landscape, driven by population growth, its distribution and affluence. Population growth rates over the last century are unprecedented, stemming from multiple factors including higher survival rates of the young and old, albeit coupled with a recently falling birth rate (UNFPA 2011). World population now exceeds seven billion. Population Reference Bureau (PRB 2010) projections to 2050 indicate a doubling of the world's population from 2010 levels in the least-developed countries (i.e., 2.0 times more), 1.6 times more in the less-developed countries excluding China, 1.4 times more in the less-developed countries with China included, and 1.1 times more in more-developed countries. Simultaneously, economic growth and development has been attained in many regions of the world previously considered – even 50 years ago – as almost endlessly trapped in poverty.

The physical environment, which historically kept human population growth in check, has been altered to the point that many question whether and what individual and collective human actions are needed to exert the impact that the environment previously – and harshly – did. The tables are turned; human population growth, expected to continue over the next century, threatens the natural environment even as overall rates of population growth are projected to decline. Caveats are in order. The long-term perspective is important, as documented by historian J. R. McNeill (2006). And the epidemiological and agricultural transitions that contributed to higher survival rates are known to be reversible. However, Campbell (2007) challenges us when she observes that recent literature across multiple disciplines remains amazingly silent on the population growth issue. In part this is a result of conflict over the role of family planning. What is clear is that the complexity of the population-environment nexus and underlying mechanisms are major challenges for scientists across a wide spectrum of disciplines.

Ehrlich and Holdren (1971) summarized the complexity of the population-environment nexus in the famous $I = PAT$ equation. Here, the aggregate environmental impact (I) is the product of the size of the population (P), per capita consumption (A for affluence level), and the environmental impact of a unit of consumption determined by level of technology T. The basic assumption is that environmental impacts, whether level of pollution or depletion of the natural resource base, are functions of the total demand for goods and services in the economy. Technological improvement implies discovery of ways to substitute natural resources among one another and to substitute ideas and manufactured

capital for natural resources. This enables higher levels of production and consumption even without making higher demands on the natural resource base. IPAT is evidently too simplistic: it does not account for the interactions among the variables. For instance, technology can be more efficient as the level of affluence increases. Another serious shortcoming is that it specifies impact as a linear relationship ignoring the very important threshold effects. But despite these simplifications, IPAT points out the ruthless logic of the well-known Malthusian framework: the ever-growing population and level of affluence will continue to have a greater toll on the earth's natural resource base and ecosystem. To what extent technological progress can stretch the eventual limit of the earth's carrying capacity is a source of continuing debate, but the simple IPAT equation underscores the apparent problem of assuming an infinitely elastic limit.

Viewed thus from a Malthusian perspective, IPAT points to an impending "population problem." Scientists from different disciplines have different ideas on why the problem exists. For example, for economists, one challenge is to find out why the problem at the aggregate level cannot be solved at the level of individual rational actors. Given the constraint on the natural resource base, rational actors should adjust their reproductive and consumption behaviors so that the optimum levels of population and consumption can be perpetually maintained. Of course, this does not happen in reality in part because the private and social benefits and costs of reproduction are not the same. Reproduction generates crowding externalities for others, which the reproducing individuals acting on their own are not expected to take into account. One likely source of these crowding externalities is the obvious finiteness of space. Thus, crowding externalities provide population-environment interaction a spatial perspective, making it of paramount interest to every regional scientist.

The overall population growth trend is coupled with an apparent unevenness in population growth rates across regions: in Japan and the EU, growth rates are negative, while numbers across the developing world continue to climb. The totals projected in the literature for some countries are really astounding. As documented by Campbell (2007), by 2050, Nigeria expects to grow from 27 to 131 million, Niger from 14 to 50 million, and India "by a net million every three weeks, nearly all of this growth in the lowest income regions of the country" (Campbell 2007, pp. 237–238). This unevenness has already led to human suffering in place. It has led to forces pushing internal migration to find food and water. Transnational and transregional migration is common. While the pull of better opportunities elsewhere is a major incentive, higher than average population growth rates in already resource-poor regions of the world set in motion forces that also push population out of homelands, putting additional pressure on regions where resources are more abundant and/or native populations are declining. The developed countries are not off the hook in terms of the impacts of their *own* behaviors on the natural environment. Over the past half century at least, the trend toward higher levels of consumption is an important driver of environmental degradation. *The ability to have more* puts stress on the natural environment not only in the developed world but also in developing countries and regions, often important suppliers of specific natural resources. Further, imitation within developing countries can be an important driver of innovation.

Recent demographic trends raise a host of challenges to scientists and to the world's public: how to efficiently and equitably feed the human population concentrated in urban centers or the elderly who are becoming a larger proportion of the rural population; how to maintain human health and well-being in these places in the long run; how to sustain the natural resource base in populated spaces; and how to design appropriate policies to balance social, economic, and environmental goals. Addressing these challenges requires understanding the complexity of the human system and larger ecosystem, which underlie the population-induced transition process. A study of recent debates in the literature on the interrelationships among human population growth, economic growth and development, and environmental impacts will convince most that the underlying system is complex, requiring the cooperative problem-solving that some believe humans may be genetically programmed to do best.

This chapter reviews selected works from multiple literatures contributing to disciplinary, multidisciplinary, interdisciplinary, and transdisciplinary efforts to understand and solve the complex challenges posed by the population-environment problem. After reviewing the historical context and documenting population growth and distribution trends, literature at different scales – micro, meso, and macro – is reviewed. The underlying question to be answered by future researchers is the following: Can a balance between humans and the environment be struck to attain a sustainable state? And, importantly, how can regional scientists contribute to the process of solving the population-environment challenge?

55.2 Century of Dramatic Population Growth and Population-Environment Theories

The “Malthusian trap” has fortunately not (yet) been realized. In *An Essay on the Principle of Population as It Affects the Future Improvement of Society*, Malthus (1798) argued that the rate of growth of population would outstrip growth in food production, the latter being constrained by increasingly scarce land resources. He believed that human fertility could not be curtailed, that is, humans would reproduce without restraint, although Malthus later softened his stance. Birdsall (1988) observes that while population growth happened in the eighteenth and nineteenth centuries, growth was slow, “seldom exceeding one percent a year” (Birdsall 1988, p. 478). From 1750 to the twentieth century, the overall population growth rate averaged 0.5 % per year, with rates higher in what are now the more-developed countries. While couples likely controlled their own fertility to a greater extent than we perceive, “environmental conditions” (notably disease) limited growth – to be young puts you at peril, and relatively fewer lived to be “elderly” as we know it today.

It is important to emphasize at this juncture that the Malthusian emphasis on the “direct race” between population growth and food growth fails to uncover the underlying forces behind the mechanism at work. Production after all depends on the level of employment, not the level of population. But there is not a one-to-one mapping either between population growth and employment growth or between employment growth and food production growth. Over the last two and a half

centuries, changes in fertility and life expectancy obviously have changed the labor force participation rate or the employment level.

Technological change also has boosted agricultural productivity, yielding higher levels of food production for the same level of employment. Higher aggregate income may not result in proportionate food growth. Further, growth in the food sector crucially depends on the distribution of income. Technological change is again instrumental in the determination of factor rewards and income distribution. Thus, the determining factor behind the Malthusian thesis is the extent to which the forces of technological change affect the key relationship between population and food growth.

Extended Life Spans, the Epidemiological Transition and Voices of Concern.

Economic growth and development and technology, in particular, extended life spans in the years following World War II. The “epidemiological transition” was built on advances in public health through disease prevention (e.g., immunization, improved sanitation) and effective forms of disease control (e.g., antibiotics). Technological advances in agriculture contributed to higher yields and greater food security in many of the world’s regions and to arguably better nutritional status. Significantly lower mortality rates emerged, which when coupled with continued high fertility rates, resulted in population growth rates of 2.4 % per year in the 1960s (Birdsall 1988). High population growth rates were especially concentrated in the less-developed countries; Europe had less than a 1 % rate of growth and North America exceeded “1.5 % only briefly” (Birdsall 1988, p. 479). Japan’s rates also were low. However, the higher than replacement rates documented in almost every country of the world raised significant concern. As early as 1953, the United Nations published *The Determinants and Consequences of Population Trends*, and Coale and Hoover (1958) followed with *Population Growth and Economic Development in Low-Income Countries*. Human population growth coupled with economic growth and development over this time period began to raise questions about the ability of the earth’s natural resources – the so-called Malthusian “flower pot” – to sustain the unprecedented growth.

The voice of concern became even louder in the 1960s and early 1970s, when academics from multiple disciplines focused energy and public debate on two alarming trends – emergence of signs of environmental degradation at multiple scales worldwide tied to ever more population coupled with greater affluence in some regions. *The Population Bomb* (1968) credited to Paul Erlich (and Anne Erlich); *The Limits to Growth* commissioned by the Club of Rome and authored by Donella Meadows, Dennis Meadows, Jorgen Randers, and William Behrens III; and Rachel Carson’s earlier (1962) *Silent Spring*, among other published works, raised public awareness and alarm. Publication of the National Academy of Sciences’ *The Growth of World Population* in 1963 further contributed to understanding by the public and academic community. *The Limits to Growth* and *World Dynamics* by Jay Forrester are exercises in system dynamics and cutting-edge computer simulation that gave those works an aura of scientific precision and increased respectability.

The simultaneous growth in population and affluence triggered the Neo-Malthusian alarm. The essential logic rests on the imperfect substitutability

between natural and man-made resources. Given imperfect substitutability, if land and natural resources remain fixed, growth in labor and physical capital cannot sustain output growth forever; it is only time before diminishing marginal returns to labor set in and per capita production and consumption begin declining. *The Limits to Growth* emphasizes this point by asserting that limits to arable land will soon be reached and per capita consumption will decline, leading to famine. Even if a food crisis is avoided, the demand for industrial output will exhaust the earth's mineral resources; the growing pollution resulting from industrial output will generate pollution levels beyond the earth's exhaustive capacity, eventually leading to catastrophic collapse.

Neoclassical and Cornucopian Thought. In a devastating but pointed criticism, Nordhaus (1973) dismissed the models in *World Dynamics* and *The Limits to Growth* as devoid of empirical content. The predictions of these models are highly sensitive to specifications. He objected that the models that had been constructed were based (merely) on subjective assumptions and were not reconciled to the real world. Thus, if the assumptions did not hold, the results indicated by the models would not hold either.

The dire Neo-Malthusian predictions stem from simplifying assumptions that can indeed be challenged. Natural resources may not be fixed: new natural resources are being discovered through relentless exploration, although even here limits to growth could eventually become binding. But within a well-functioning market system, the prices of scarcer resources will rise, providing incentives to substitute for them. The work of Ester Boserup demonstrated that the post-industrial revolution in agricultural production occurred side by side with population growth as a result of the greater substitution of capital and labor for natural resources. The Boserup hypothesis is thus the widely known claim that population growth triggers production increases through intensification – greater use of capital and labor instead of land. From this perspective, the key barriers to reaching an optimal production level are either market failures (such as insecure property rights, pervasive externalities) or policy distortions or both.

The discovery of ways to substitute abundant resources for scarcer ones is itself an important form of technological improvement. Technological innovation responds to incentives in the market. For example, Popp (2002) provides systematic evidence using patent data from 1970 to 1994, documenting the impact of energy prices on patents for energy-saving innovations. The propensity of technological innovation to respond to incentives had been emphasized by Julian Simon in *The Ultimate Resource* (1981) and *Theory of Population and Economic Growth* (1986), as well as other works. Simon argues that since human ingenuity to discover new ideas is the ultimate resource, population growth is the greatest boon. More people mean more ideas, that is, a greater number ways to substitute and circumvent resource constraints. Larger population also means a greater size of the market, greater specialization, and greater per capita productivity. Thus, as opposed to the future of the Malthusians, Simon's ideas prognosticate a rosy future of material abundance – hence the name cornucopian theory.

The relatively recent development of Paul Romer's New Growth Theories provides impetus to the cornucopian school. Investment in research and development

yields increasing returns to scale because the benefits of ideas do not diminish through sharing. Yet the logical corollary to cornucopian thought is the claim that infinite growth in output makes no more than a finite demand on the natural resource base. This claim is famously refuted by stating that no degree of production intensification in a flower pot can potentially grow enough to feed the entire world.

Quelling some concern, population growth rates in almost all developed countries declined to replacement rates in the 1970s, although rates in the developing world remained high. While in part in response to growing public discourse on *The Population Bomb*, *The Limits to Growth*, and *Silent Spring* (among others), more importantly (and pragmatically) this decline was in response to the advent of widespread availability of more effective fertility control and the return of women to paid jobs. This occurred regardless of the income level of the country; Birdsall (1988) makes the compelling case that while countries with higher incomes tend to have lower rates of fertility and mortality, many countries with individual and household low incomes have achieved lower fertility and mortality rates too. Lower rates were achieved through advances in women's status and greater access to modern fertility control, education, and health services.

Two forces diffusing the concern at this stage are the following: (i) the second demographic transition, the gradual decline of fertility approaching replacement level, and (ii) the environmental Kuznets curve (EKC), the empirical observation that environmental quality *appears to* initially deteriorate with economic growth but then improves as income growth continues. These two phenomena working together mitigated some of the alarm of impending catastrophe and modified public and academic discourse on the population-environment problem.

Second Demographic Transition and the EKC. For most of human history, the rise of per capita income had a positive effect on population growth. Population growth in turn caused diminishing marginal labor productivity to set in, and the Malthusian check eventually reduced per capita income to near subsistence levels. Low mortality with continued high fertility, a phenomenon called the first demographic transition, similarly could have a diluting effect on income per capita. *However, this dilution of per capita income was counteracted by the acceleration in technological progress and capital accumulation.*

An important recent development has been the crucial role of human capital. Galor (2005) argues that further acceleration in the rate of technological progress increased the demand for human capital in the second phase of the industrial revolution, inducing parents to invest in their children's human capital. The rise in life expectancy also increased the rate of return to investment in human capital. While human capital investment increased productivity and the opportunity cost of time, advances in household production technology, the introduction of (more) fertility control technologies, and changes in gender norms and the institution of marriage gave women greater control over reproduction. The net effect has been Gary Becker's quantity-quality trade-off in fertility choice. Thus, the second demographic transition of the post-Malthusian epoch began where sustained economic growth coincided with the simultaneous decline in fertility rates.

Further, it was observed that since the 1990s, the relationship between environmental degradation and per capita income has exhibited an inverted-U shape (Grossman and Krueger 1995). Analogous to the Kuznets curve between per capita income and income inequality, this relationship is aptly named the environmental Kuznets curve (EKC). The primary reason behind the EKC is perhaps structural change. Early stages of economic growth are driven by industrialization – the growth in manufacturing giving rise to increases in the rate of pollution. Further, economic growth increases the share of the service sector, which is less harmful to the environment. Also, the income effect on demand for environmental quality is nonlinear – as per capita income crosses a certain threshold – consumers demand environmental quality at a much higher rate. This creates the incentive for even the manufacturing sector to employ cleaner technology. Empirically, the EKC relationship has been estimated, for example, with GEMS' (Global Environmental Monitoring Systems) emissions data as measures of environmental degradation. Recently, the EKC relationship has been questioned by Carson (2010) who provides empirical evidence to the contrary.

Recent Challenges. Many have challenged the cornucopian school's optimism and again raise significant concern over lasting and irreversible environmental damage and societal and ecosystem collapse (see contributions of Jared Diamond). The academic and public dialogue is heated but healthy. Unevenness of where population growth is taking place is creating very substantial gaps among the world's major regions; serious gaps in food security, access to water, and access to energy resources are well documented. At the same time, Nobelist Elinor Ostrom's well-known research shows that local systems can adapt positively to change, even for shared (common) resources; that is, *adaptation to preserve the local environment is possible even in light of population growth*. Whether institutions of governance at higher levels can reduce transboundary externalities (e.g., the "borderless" problems stemming from SO₂ emissions) or can be designed to do so remain critical concerns. These issues are certainly receiving much attention.

Meanwhile, global population has continued to expand and expand rapidly, although the rate of growth is finally declining. Projections to 2100 by IIASA (International Institute for Applied Systems Analysis) indicate that maximum global population will be attained in this century. As argued convincingly by Scherbov et al. (2011), uncertainty, in part stemming from "unreliable statistical information" from many areas of the world but also the inherent uncertainty of future fertility, mortality, and migration rates, casts doubt on when overall and region-specific maximums will be attained. However, they conclude that "there is little uncertainty that world population will peak and start to decline before the end of the century" (Scherbov et al. 2011, p. 575).

55.3 Regional Differentials

All countries in the world are undergoing the demographic transition (Hugo 2011). Very significant regional differentials in population growth rates exist, creating

regional variations in human and environmental conditions and also in knowledge/perceptions of the extent and character of environmental degradation. Affluence varies widely by region and within regions. The well-known contributions of Paul Krugman and others have contributed key insights into why differentials exist and persist.

Almost all population growth over the next 20 years is projected to take place in Asia and Africa and to a lesser extent in Latin America. Asia's population is estimated to be 4.2 billion, expected to peak at a projected 5.2 billion around mid-century (2052) and decline thereafter (NIC 2008; PRB 2010). Africa, having had relatively modest population growth so far, is projected to experience strong population growth until at least 2,100. This will result in a much larger population living on the African continent. In Europe, North America, Oceania, Latin America, and the Caribbean, population densities are lower and projected to be maintained at lower levels. Roughly, 1.7 billion of the world's population now lives in these regions.

Lower growth rates in the West will create larger differentials between the West and both Asia and Africa. In 1980, 24 % of the world's population lived in the West. By 2009, 18 % did; projections to 2025 indicate that this percentage will decline further to 16 % (NIC 2008). Europe and East Asia face declines in their total and working-age populations, as a result of continuous below-replacement-level rates (Hugo 2011). Western countries with relatively high in-migration rates (e.g., USA, Canada, Australia) are expected to experience population growth through immigration (NIC 2008).

UNFPA (2011) statistics indicate that 43 % of the world's population is now under 25 years of age. Regional differences in population growth rates are due, at least partially, to the large percentage of the world's population in the childbearing years and living in low-income countries. At the other end of the age spectrum, in 2011 there were 893 million people – or nearly 1 billion people – over the age of 60 years; by 2050, this figure is expected to be 2.4 billion (UNFPA 2011). Population composition could differentially influence environmental outcomes (positive or negative), due to variations in propensities for different age cohorts. For example, young adults have a higher propensity to migrate than older ones (Hunter 2000).

Worldwide, convergence in the average length of life is documented (see Edwards 2011), although country exceptions exist. The challenge of HIV/AIDS clearly has had an impact on life spans. Edwards (2011) reports that overall life expectancy in the developing world has grown by an *additional* 0.24 years annually as compared to the wealthier countries, more than doubling the rate in the developed world (Edwards 2011, p. 499). Research on within-country variation in life expectancy at birth and other survival measures underscores the underlying variability over time. Interestingly, convergence in expected length of life at birth is in contrast to divergence in income per capita (see studies referenced in Edwards 2011).

According to NIC (2008), “The ‘oldest’ countries – those in which people under age 30 form less than one-third of the population – will mark a band across the northern edge of the world map. . . . the ‘youngest’ countries, where the under-30 group represent 60 % of the population or more, will nearly all be located in Sub-Saharan Africa” (NIC 2008, p. 19). Population cohorts “in the middle” are challenged to provide for this young and rapidly growing population. Both young and

old population segments pose challenges to social and economic systems and to the working-age population challenged to provide for them. However, the impact on the environment is under debate; Dietz et al. (2007) report that while they find that population levels and affluence are drivers of environmental degradation, population age structure appears to have little effect.

Finally, structures and preferences of household units have changed, in some instances putting pressure on ecosystems. For example, University of Michigan researcher Jianguo “Jack” Liu showed that in rural China, the traditional extended household structure – with multiple families living together in the same house – is now a less-preferred lifestyle. Thus, more houses are built to accommodate the greater number of families preferring to live on their own. The research shows that this demographic change pressures Panda habitat. This represents just one of many possible examples.

Correlations Among Multiple Indicators. Overlaying maps of regional indicators of population density, population growth rates, levels of economic development, and conditions of the physical environment raises as many questions as this exercise answers. Population density and level of income fail to show a clear relationship across the earth’s regions: some regions are characterized by high population densities and are poor, whereas others are dense and wealthy. Some sparsely populated regions are rich and others poor. However, studies show that the highest population growth rates tend to occur where economic growth has been least likely (Gallup et al. 1999).

Resources in the less- or least-developed regions will be under intensified pressure as these regions cope with a larger share of the world’s population. That current population growth rates are particularly high in tropical regions is a not surprising result given recent advances in disease control and rapid adoption and diffusion of immunization, antibiotics, and other health-related technologies across the tropics. Historically, higher disease burdens, and especially a broad range of infectious diseases, have been typical. Also in the tropics, food security and agricultural productivity have been lower, given old soils (such as the soils of East Africa), human-degraded soils, higher insect pest burdens in agriculture, and high rainfall variability, among other factors.

Gallup et al. (1999) observe the following when comparing worldwide population densities, population growth rates, economic development, and underlying geography:

1. Tropical zones are “not conducive to [economic] growth,” due to presence of malaria and other diseases (Gallup et al. 1999, p. 204). But prevalence of malaria is positively correlated with population density (Gallup et al. 1999, p. 209).
2. High population density appears to be positive to (economic) growth in coastal regions but “inimical to growth in the hinterland” (Gallup et al. 1999, p. 204).
3. Geography and policy “matter,” but good policy will not be enough to counter geographical disadvantage (Gallup et al. 1999, p. 204).

In short, some of what are considered the most vulnerable places on earth are inhabited by populations with high population growth rates and lower chances of developing economically for reasons largely stemming from their natural

environment and geography. McNeill's (2006) assessment of challenges related to land use, water use, and air pollution clearly points to the pervasive issue of the distribution of resources, regional shortages, and implications for the physical environment. The upward pressure of strong population growth against an already weak natural resource base encourages a variety of responses, including the potential for multiple responses: scavenging and other survival behaviors, out-migration (Zelinsky 1971), evolution toward greater agricultural intensification, urbanization, reductions in fertility (see work of Graeme Hugo), and an array of other adaptive behaviors. Human mobility or migration in response to population change is recognized as a complex phenomenon, not easily explained. But differentials between more-developed and less-developed regions likely contribute to both "push" and "pull" incentives for internal and international migration flows.

The following section concentrates on understanding theory, and adjustments and impacts at the micro level (individuals, households, communities) and macro/regional (meso) levels. The micro perspective is covered first because population-related decisions are typically made at this level and can have local repercussions. The micro is then linked to the macro/regional (meso) perspective since environmental impacts importantly play out at these higher scales; a few examples include impacts of international and rural-urban migration, exurban land use, and the associated problem of sprawl and problems stemming from transboundary pollution. The focus of Sect. 55.4 is on less- and least-developed places because these places are among the most likely to be widely impacted by population-environment interactions. Such places also face the greatest challenges, solving the environment problem through technological change.

55.4 Micro Perspective on Population Decisions and Community Resilience and High-Level Effects

Micro Perspective. A new micro perspective has emerged in population-environment research, especially related to less- and least-developed countries. Three aspects deserve emphasis. First, a primary feature of this perspective is the focus on household-level population dynamics and relationships to environmental change. A second feature is the mediating variables approach: analysis and identification of variables (e.g., poverty, government policies, cultural norms, market or nonmarket institutions) through which population dynamics affect environmental change (Hunter 2000). Mediating variables often reinforce or even reverse the role of population dynamics in environmental degradation or enhancement. Finally, it is recognized that there is more to population dynamics than population size and growth. New micro research has gone beyond attribution of environmental degradation to increases in population, to seeking to understand how other population variables – for example, household size, age, sex composition, and migration – affect and in turn are affected by environmental change.

At its core, the micro perspective is guided by the belief that observed patterns and trends of population dynamics and associated environmental change can be

mapped to the individual household unit which makes the actual decisions about production, consumption, and reproduction. Since the pioneering work of Gary Becker, researchers have sought to identify the determinants of fertility by focusing on the reproductive decisions of individual households. Demographic research in the following half a century has uncovered that apart from the techniques available emphasized by the works of Richard Easterlin, household demand for children strongly influences fertility behavior. Demand for children in turn depends on determinants: income level, parental education, rules of inheritance, and other institutional factors, along with a host of other mediating variables.

However, a major difficulty with the focus on household as a decision-making unit is that households in reality are not monolithic. Questioning the so-called “unitary” view of the household making choices to maximize its welfare Dasgupta (2003), among many others, points to ample evidence of gender inequities within poor households; these affect allocation of education, food, healthcare, and other household resources. The unitary household model effectively ignores an important fact: if all benefits and costs are not borne by the decision maker, decisions may not be optimal. Women bear the disproportionate share of the cost of having children including the cost of pregnancy, breastfeeding, daily care, and risk of maternal mortality. Yet, in many traditional societies, men are primary decision makers as to the desired number of children. *Thus, the problem of externalities – the situation when the decision maker does not bear all the costs and benefits of the decision – prevents the optimal allocation even inside the household.*

Outside the household, mediating factors may create population-environment externalities by driving a wedge between the benefits and costs borne by the decision maker. At times, these variables can create a feedback loop that contributes to a downward spiral of resource depletion, poverty, and high fertility. The self-reinforcing patterns of sustained high fertility in the face of declining environmental resources create “vicious cycles.” The key to understanding vicious cycle in the population-poverty interaction is the nonlinear response to the change in decision variables. Poor households depend on their own unskilled household labor, low-productive agricultural land held as private property, and also surrounding environmental resources available as common property. There are thresholds in the use of each of these endowments – the point where the response to the decision variable changes nonlinearly.

Vicious Cycles, from Nutritional Status to Common Property Resources. Partha Dasgupta outlined a pioneering vicious cycle model (see Dasgupta (2003) and references therein) where nutritional status has a critical threshold in terms of capacity to work. Below that nutritional status, labor is not productive enough to grow enough food to achieve better nutrition. Thus, the poor nutrition-low productivity state is self-sustaining. Above that threshold, a good nutrition-high productivity state is similarly self-reinforcing. For household private property, there can be a critical threshold of a productive asset (e.g., agricultural land), below which similar poverty traps may exist.

The critical threshold in the extraction of common property resources is even more interesting. Since household decisions on the extraction of the common

property resource are likely to be affected by expectations of other households' decisions, the strategic response and peer effects may create vicious cycles and multiple equilibria, as explored in the recent exploding literature across many disciplines on social interactions. Further, the interplay of population dynamics with these critical thresholds can change an existing vicious cycle. For example, fertility can modify Dasgupta's model on nutritional status and capacity to work. Poor nutritional status leading to higher infant mortality causes high fertility due to the "insurance of birth." With diminishing returns to labor, high fertility lowers labor productivity, contributing to lower nutritional status and higher mortality rates, *further increasing the motivation for higher fertility*. On the other hand, with abundant land, if production is within the range of increasing returns (e.g., nineteenth-century US Western frontier), high fertility can reverse the initial vicious cycle model of nutritional status and labor productivity. In a capital-scarce environment, greater labor intensification increases fertility through raising the demand for farm labor. High fertility, in turn, creates further demand for food. Further intensification contributes to land degradation, causing a declining resource base and further poverty. De Serbinin et al. (2008) describe the literature on the relationship between fertility and the resource base – farm size, cattle and land, water, etc. Consistent with the vicious cycle hypothesis, they find the relationship to be negative. In contrast, some other authors have found the relationship to be positive. The postulated hypothesis is that households with larger land size have a greater demand for children to retain use rights of the land.

Common property resources provide another example of vicious cycles. In South Asia and sub-Saharan Africa, rural households lack access to tap water or energy sources. They derive a considerable portion of their livelihood resources (firewood, timber, non-timber forest products, fish, bush meat, water, etc.) from common property natural resources. Households make decisions on childbearing as well as labor allocation and marketing. Apart from the intrinsic benefits, the material benefits of children in household goods production are compared against costs of birthing and child maintenance. When a substantial portion of livelihood comes from common property resources, a household's share of the common property depends on the number of hands it can employ to convert common property to private property. Empirical studies from Nepal, Pakistan, and South Africa find evidence supporting the positive relationship between fertility and resource dependency. While having a large number of children exploiting the commons is marginally optimal from an individual household's point of view, it is not optimal for the community. Greater entry into common access resources may lower labor productivity, which households try to offset by adding more hands. This creates incentives for greater household size and higher fertility. But since everyone is doing the same – without consideration to the effect of each household adding more hands on the average productivity and sustainability of resources – degradation accelerates. Environmental resources often have a critical threshold point at which the ecological system loses regenerative capacity, a phenomenon which the ecologists call "loss of resilience". The concept of the resilience has been used in two senses in the environmental science literature. The first one called

“engineering resilience” is defined by the time it takes to return to an equilibrium or steady state after the shock. We here refer to “ecological or Hollings resilience” which presumes the existence of multiple regimes or equilibria. The “loss of resilience” in the latter sense means that the ecological system moves to another equilibrium and no longer retains its former function, structure, identity, and feedbacks. Caught in the fertility-environmental degradation feedback loop, when competition becomes intense to extract resources before others do, the ecological system would gravitate into the catastrophic equilibrium point of “loss of resilience”.

The mediating variables approach is built on recognition that in many regions of the world, the range of choices and trade-offs available to low-income households is affected by the quality and state of the surrounding environment on which their livelihood depends. Thus, informal institutions such as kinship, social norms, and culture and formal institutions (e.g., well-functioning markets for land, labor capital, insurance) are important mediating variables in the population-environment nexus. In sub-Saharan Africa, fosterage within the kinship group has long been viewed as a determinant of high fertility because the costs of responsibility of children diffuse among kinship. On the positive side, Elinor Ostrom shows that traditional communities often protect their local commons from overexploitation by relying on social norms that put restraint on individual community members. Here, social norms may resolve the “coordination problem.”

Formal institutions are often thought to have subverted the traditional informal institutions of common resource management. The emergence of modern governments is often believed to have taken away the authority of villages to impose sanctions against those who violate locally instituted norms of use. As social norms degrade, parents pass off some of the cost of raising children to the community by overexploiting the commons. Baland and Platteau (1996) document the cases of several Sahel states, exerting detrimental impacts on traditional resource management practices. Access to formal markets can affect resource degradation both ways. On the one hand, access can increase resource-depleting productive activities due to higher prices for goods. On the other hand, increases in real wages may increase the harvesting cost of common property.

Relationship Between Migration and the Local Environment. Current research focuses on the relationship between the local environmental condition and household-level decisions to migrate (de Sherbinin et al. 2008), with a focus on growing resource scarcity and ability to access new resources elsewhere. Although more studies are needed to understand the impact of resource scarcity on a household’s decision to migrate, historical examples suggest that scarcity of land resources leads to waves of out-migration to new land. Besides European history, there are more recent instances of core-periphery movement in the developing countries. Examples of core-periphery movement include movement from regions of Brazil and the Ecuadorian Andes to the Amazon. Migration to rural frontiers can give rise to new rural frontiers, utilizing valuable resources in the process; households settled in the first wave of frontier migration use up resources and then send younger members to settle in more distant areas, with the potential for the same pattern repeating itself in the next generation.

Empirical research on the relationships between migration and the environment shows mixed results. Henry et al. (2004) show that in Burkina Faso, the risk of migration is higher in villages with unfavorable agroclimatic conditions. They also find that villages with increased water conservation technologies have a higher likelihood of out-migration. These effects are supposed to be more pronounced for short-term migration as a strategy to diversify income sources in risky environments. Land scarcity has also been shown to be a key driver of migration in Uganda and Nepal. Too unfavorable environmental conditions can also hinder migration; the cost of migration is deemed as an investment, and severe resource constraints may limit the ability to make the investment.

Remittances may have beneficial impact on local environment if the purchased goods are substituted for the goods extracted from local environment. They may also be invested in resource conservation. Farming system is one mediating variable that influences the impact of migration on environmental outcome. Impacts may be less significant in cattle-raising systems where labor demands are small. If there is no functioning credit and insurance market, migration may be adopted as a strategy to mitigate risk. On the other hand, Van Wey (2005) finds that both a lack of land and a large amount of land can motivate migration in Thailand and Mexico. Van Wey (2005) suggests that individuals from households with large landholdings migrate to access capital for investments in technology and other agricultural inputs.

As countries complete the demographic transition with lower fertility and mortality, migration becomes an increasingly dominant force in demographic change. The traditional focus has been at higher levels (aggregate or macro/meso levels) and only on the impact on the destination environment. But more recent work has focused on the “push” created by environmental degradation at the origin and impacts on the origin itself.

Mobility and Population Pressure at the Macro and Meso Levels. The well-cited work of Wilbur Zelinsky builds on the underlying theory of human migration described by Ravenstein, Thomas, Stouffer, and Lee (see Zelinsky 1971 and references therein). Zelinsky (1971) explores the temporal and spatial dimensions of transition in human mobility hypothesized to happen with modernization at macro/meso levels. Zelinsky’s mobility transition model hypothesizes five stages in the transition. Hugo (2011) provides a useful review, criticizing models like Zelinsky’s for failure to consider the two-way migration that is often observed, by focusing on net migration.

Spatial differentials across regions likely contribute to what Hugo (2011) recently described as the “increase in the scale and complexity of both internal and international movement over time” (Hugo 2011, p. S23). He observes that the middle stages of the demographic transition tend to correlate with international migration and with rural-to-urban migration. Further, in these stages – characteristic of many of the world’s developing regions today – young adults tend to be found in higher concentrations in the population and typically have a higher likelihood of migrating compared to older age cohorts (see Hugo 2011 for discussion of other demographic effects).

From an environmental perspective, out-migration to more resource-rich locations with lower population densities may reduce population pressure (and environmental stress) at the origin. However, the regional disruptions that can occur as a result of out-migration may mean disruption of local social norms which keep in check bad environmental behaviors. On the other hand, out-migration accompanied by return migration can bring in new ideas and stimulate innovation, including new environmentally sustainable technologies. The higher degree of temporary mobility that is documented – for example, “international shuttling” behaviors between Mexico and the USA and also the growing density of commuting networks in many regions (Goetz et al. 2010) – may work as a diffusion of innovation generator. Also, the interaction between new (e.g., mobile phone) technologies that generate product demand (to be “like the Jones” in the more-developed world) and the truly massive flow of international migration remittances to the origin may stimulate consumption at the origin. What is clear from a review of the literature is that population growth, environment, and migration are likely interrelated but deserve much more attention.

Rural-Urban Adjustments. Finally, no review of the population-environment nexus would be complete without mention of the growing prominence of urban places across the globe. Urban places have become particularly attractive population magnets; the global urban population has now surpassed the global population defined as rural. This reflects domestic and international migration fueled by GDP concentrations in city centers. The trend appears to be worldwide; even in South and Southeast Asia, Africa, and Latin America, humans are rapidly concentrating into urban centers (PRB 2010). Long-term trends show that the US population but also per capita GDP have become even more concentrated in metro areas, an international trend shared by the OECD countries and most countries worldwide.

Rapid urbanization “hinders the development of adequate infrastructure and regulatory mechanisms for coping with pollution and other byproducts of growth, often resulting in high levels of air and water pollution and other environmental ills” (Hunter 2000, p. xiii). Urbanization can also alter “local climate patterns” (Hunter 2000), with concentrations of artificial surfaces creating heat islands (Hunter 2000). Another common result is sprawl. Unless checked by geography or policy, population eventually spreads over the surrounding landscape. In some cases, consumption drives the transition. Greater mobility of the human population also contributes to the spillover onto nearby landscapes, for consumption of natural resource amenities, for perceived healthier lifestyles and safety, but also for lower costs of living. Environmental amenities in the countryside are recognized as strong attractants (see Cherry and Rickman 2011).

Population growth and greater mobility, higher consumption levels in some places, and the age distribution of the population are expected to influence patterns of rural-exurban-urban transformation and rates of transition of the landscape and ecosystem services. Important related issues include the following: food production for growing urban populations, provision of specific ecosystem services, and use of natural resources including land proximate to population centers. Food availability and regional and local food production capacity represent major concerns, with access to food and water in the less- and least-developed regions being paramount.

Finally, while countries are at different stages in this process, the process itself appears to be essentially the same (Findeis et al. 2009). That is, the population-driven changes taking place across exurban or peri-urban landscapes are in some respects very similar worldwide.

55.5 Conclusions

The total population living on earth continues to grow rapidly, putting significant pressure on the earth's ecosystem. While the rate of growth has recently declined, absolute numbers of people sharing the earth's space continue to grow. Technological change (e.g., sustainable agricultural technologies), input substitution (e.g., substitution of biopower for fossil fuels), and the emergence of new institutions will contribute to reduce the environment problem in the developed countries, although impacts on the environment stemming from affluence and high levels of consumption will remain issues. Further, transboundary externalities – the shifting of the costs of economic development from the “haves” to the “have nots” but also among the “haves” – will continue to take center stage in environmental discourse. Well-known issues include climate change, loss of biodiversity, and water quality and quantity, among other well-publicized environmental issues.

The less- and least-developed regions of the world will face particularly stiff challenges. Population growth rates are projected to be highest in these regions. As argued in this chapter, some of what are considered the most vulnerable places on earth are inhabited by populations with high population growth rates and lower chances of developing economically for reasons largely stemming from their environment and geography. The major challenge will be to be resilient in the face of the dual challenges of own growth and the force of transboundary externalities created by others. Innovation should help to reduce impacts, but whether innovation will be targeted to sustainable solutions adaptable to these regions is a critical question.

For regional science, the challenge will be greater focus on three issues: (i) the interface between the earth's more-developed and less-/least-developed regions, and how to reduce environmental impacts stemming from the developed world; (ii) development within the less-/least-developed regions of the globe to reduce environmental impact as growth occurs; and (iii) the three-way interaction between population, environment, and migration. Population change was identified recently by the Social, Behavioral and Economic Sciences Directorate of the National Science Foundation as one of four major topic areas for future research (NSF 2011). “Sources of disparities” is the second of the four areas identified for major emphasis. Regional scientists can provide insight into both major challenges but especially deepen our understanding of how to effectively reduce differentials between affluent and poor regions of the world in this century, a challenge of paramount importance.

As shown in this chapter, the incentives, thresholds, and nonlinear relationships surrounding population change and sources of disparities are highly complex.

In many respects, we are only in the early stages of understanding the complex underlying mechanisms and relationships behind a full understanding of the population–environment nexus. Evolution of the interrelationships among regions, a purview of regional science, is known for its complexity. Also complex is how to balance – *over a very short period of time* – population growth and food, water, and other resource requirements by humans in different regions of the world. Hunter (2000) argues that we need a more “precise scientific understanding of the complex interactions between demographic processes and the environment” (Hunter 2000, p. xx in report’s foreword). Scientists, including regional scientists, will need to collect robust data and develop new models that link natural and social-economic-behavioral processes and build a compelling library of credible evidence from across the globe to inform decision-making and governance at multiple scales. A major challenge will be coordinating this work across the multiple scales and with multiple disciplines and publics to avoid what could be catastrophic impacts. However, there is really no choice.

Abstract

This chapter begins with definitions of geographic information science (GIScience), of geocomputation, and of spatial analysis. We then discuss how these research areas have been influenced by recent developments in computing and data-intensive analysis, before setting out their core organizing principles from a practical perspective. The following section reflects on the key characteristics of geographic information, the problems posed by large data volumes, the relevance of

geographic scale, the remit of geographic simulation, and the key achievements of GIScience and geocomputation to date. Our subsequent review of changing scientific practices and the changing problems facing scientists addresses developments in high-performance computing, heightened awareness of the social context of GIS, and the importance of neogeography in providing new data sources and in driving the need for new techniques.

56.1 Introduction

Geographic information science (GIScience) addresses fundamental issues associated with geographic information and the use of geographic information systems to perform spatial analysis, using a scientific approach (for detailed discussions of the nature of geographic information science, see Duckham et al. 2003). The issues may be practical, as in the question of how to address uncertainty in geographic information; they may be empirical, as in the observation generally known as Tobler's First Law of Geography ("All things are related, but nearby things are more related than distant things.") (Tobler 1970); or they may be theoretical, as in the fundamental contribution known as the 9-intersection of topology (Briefly, the set of topologically distinct relationships that can exist between two areas in the plane) (Egenhofer and Franzosa 1991). To some, the term implies the use of geographic information systems (GIS) as a scientific tool in research and decision-making, and as such it has been widely applied to the solution of virtually any problem that is embedded in geographic space, from global warming to crime and water pollution. Much progress has been made in GIScience in the two decades since the term was coined (Goodchild 1992), through the efforts of a growing scientific community. It is also important to note that other terms convey similar meaning, including geomatics, geoinformatics, and spatial information science, and that GIScience plays an important role in the practice of regional science, both as a technology that can support research and as an approach to problem-solving.

Geocomputation is also fundamentally concerned with geographic information, in other words information about features and phenomena and their locations on or near the Earth's surface. Coined a little later by Openshaw and Abraham (1996), the term is often used in cross-sectional analysis to describe the repeated analysis and simulation of spatial distributions, in order to explore spatial distributions and to draw inferences about them. More specifically, the term is often taken to imply simulation of processes operating in the geographic domain and thus with geographic information that is primarily dynamic. The major issues in geocomputation often center on the computational problems that arise in simulating complex systems with massive numbers of features, data items, or agents. In this sense geocomputation develops an application-led focus upon the way the world *works*, founded upon rich digital representations of the way that the world *looks*, and makes prediction a central goal. The main contribution of geocomputation may thus lie in the development of better tools for dealing with complex, dynamic systems.

From these definitions it is clear that GIScience and geocomputation have much in common, that their interests overlap substantially, and that it may even be helpful to think of geocomputation as a computationally intensive, application-led component of GIScience. Accordingly, the focus of this chapter is on the common ground between them, using the terms somewhat interchangeably. The term GIScience is used wherever the context seems to demand it and similarly with the term geocomputation. Both terms are fundamentally concerned with spatial analysis, defined as the set of methods whose results change in response to changes in the locations of the objects being analyzed, and we sometimes use this umbrella term. The remainder of this section elaborates on the basic definition of GIScience and the research conducted under its banner. This is followed by a discussion of the basic principles of GIScience; in a nod to geocomputation, the discussion emphasizes those areas where GIScience has been successful at solving computationally intensive problems. Major methods of analysis are reviewed. The third section of the chapter addresses changing practices in GIScience, focusing on the increasing importance of collaboration, on novel data sources, and on the problems of dealing with uncertainty. Science generally is changing in response to the need to study complex systems and the use of simulation, and this trend is certainly affecting GIScience. The concept of data-intensive science, the so-called *Fourth Paradigm* (Hey et al. 2009), has a natural fit to geographic problems and their massive volumes of data, while the meta-issues of documentation and provenance are beginning to loom large in a science that is no longer dominated by the individual investigator. Finally, the fourth major section speculates on the future and discusses the coevolution of GIScience and geocomputation. Future developments are likely to be driven, as in the past, by trends in data, in computation, and in the society that forms the context for both fields.

While debates about the nature and meaning of *science* have raged for centuries and will probably never end, the core ideas are clear. First, science seeks laws and principles that can be shown to be valid in the observable world and are generalizable in the sense that they apply everywhere and at all times. Both of the examples cited earlier – Tobler’s First Law and the 9-intersection – are clearly of this nature, and as a theoretical conclusion, the 9-intersection not only applies everywhere at all times but also applies in any imaginable space. Second, science is founded on definitions of terms that are rigorously stated and understood by all scientists. Third, scientific experiments and their results are replicable, being stated in sufficient detail that someone else could expect to obtain them by carrying out an identical experiment. In this context the term *black box* is pejorative since procedures that are hidden inside a box cannot be described and therefore cannot be replicated. Well-understood principles also apply to the details of reporting, as in the rule that any measurement or numerical result be stated to a precision (number of significant digits) that reflects the accuracy of the measuring device or model. Principles such as these help define GIScience and geocomputation and distinguish them from less rigorous applications of GIS and related technologies.

A distinction is often drawn between *pure* science, or science for the sake of curiosity and the quest for general discoveries, and *applied* science, or science that aims to solve problems in the observable world using scientific methods.

The geo- prefix reminds us that the Earth provides a unique laboratory for scientific investigation, and the uniqueness of the places on it often limits the scope for the kinds of controlled experiments that characterize scientific activity in other disciplines. Geographic space is the space of human activity, and most of the problems human society is facing are embedded in it, from poverty and hunger to health. Indeed, it is hard sometimes to avoid application in GIScience because the field is inevitably close to the real world, a fact that perhaps accounts for at least some of the passion displayed by its practitioners. Moreover, curiosity has often provided the motivation to explore, characterize, and map the geographic world, though the results of such exploration are rarely generalizable in the sense that Newton's laws of motion or the Mendeleev periodic table are generalizable.

This pure/applied distinction explains how progress in spatial analysis is measured. On the one hand, the refereed journals in which much successful GIScience research is published and the presentations at conferences such as the biennial International Symposia on Geographic Information Science emphasize the purer forms of science, while other conferences, such as the biennial International Conferences on Geocomputation, emphasize how the core organizing principles and concepts of GIScience can be brought to bear on solving practical problems. A large industry, valued according to some estimates as \$20 billion annually (Longley et al. 2011), has sprung up around the data acquisitions and tools needed in such practical problem-solving. Clearly the metrics of success here are much more diverse than in pure science.

56.2 Principles of GIScience

In this section we describe some of the major achievements of GIScience in its first two decades. The selection includes advances that closely resemble geocomputation in the sense of being concerned with large, complex systems and with large volumes of data. We begin with a discussion of the characteristics that distinguish geographic information and geographic problem-solving from data-driven science in other domains. We then discuss the strategies that have been adopted in GIScience for avoiding or successfully dealing with the problems of large data volumes, including aggregation, divide and conquer, and compression. We discuss some of the unintended consequences of such strategies, in the form of uncertainty, the ecological fallacy, and the modifiable areal unit problem. We elaborate on the nature of simulation in geographic space, on some of the more successful research conducted in this area, and on some of the issues it raises. Finally, we present a brief summary of progress in GIScience in the past 20 years.

56.2.1 The Characteristics of Geographic Information

One of the first attempts to identify the special characteristics of geographic information, or *what is special about spatial?*, was made by Anselin (1989).

He argued that two characteristics were universal: spatial dependence and spatial heterogeneity. Reference has already been made to the first, in the form of Tobler's First Law of Geography: "All things are similar, but nearby things are more similar than distant things." While we can argue about whether the statement meets the criteria for a law as that term is normally understood by philosophers of science and whether exceptions should be allowed, it is clear that the vast majority of phenomena distributed over the Earth's surface and near surface adheres to it while differing in precisely how similarity decays with distance. Moreover, there is no doubt of the law's efficacy in GIS.

The principle is essentially one of context, since it requires a phenomenon at one point to be consistent with the same phenomenon at nearby points. It appears to apply well in three-dimensional space and also to apply in four-dimensional space-time. Perhaps the easiest way to demonstrate its validity is by a thought experiment in which it is not true, where a minute displacement on the Earth's surface produces a completely independent environment – clearly this does not happen and cannot happen except in rare circumstances.

As a cornerstone of GIScience, the principle has two major implications. First, similarity over short distances allows the Earth's surface to be divided into regions within which phenomena are approximately homogeneous, achieving great economies in data volume by expressing attributes as properties of entire areas rather than of individual points. In short, the principle enables the assumed-homogeneous polygons that dominate many representations in GIS. Similarly, it allows reasonable guesses to be made of the properties of places that have not been visited or measured, in a process known as spatial interpolation. The principle thus justifies the techniques that are used, for example, to create weather maps from scattered point observations.

Unfortunately the principle of spatial dependence also provides a major headache for researchers working with geographic information, since it runs counter to the assumption made in many statistical tests that the data were acquired through a process of random and independent sampling from a parent population. An analysis of the 58 counties of California, for example, cannot make that assumption since the principle implies that conditions in neighboring counties will be similar. Moreover, there is no larger universe of which the set of all counties of California constitute a random sample.

Anselin's second principle addresses spatial heterogeneity, or the tendency for parts of the Earth's surface to be distinct from one another. This also has profound implications. Consider, for example, a local agency seeking to define a taxonomy of local land use. The result will inevitably be different depending on the agency's location and the local conditions in its jurisdiction, and every jurisdiction will argue that its scheme is better than any global or national standard. In early geodesy, the figure of the Earth (the mathematical function used to approximate the Earth's shape and thus define latitude and longitude) was unique to each jurisdiction or region, and it was not until the 1960s that pressure for a single standard prevailed, driven by the growing importance of air travel and the targeting of intercontinental ballistic missiles. Unfortunately any universal standard will inevitably be

suboptimal for any local jurisdiction, whether it be over land-use classification or the shape of the Earth, so there will always be tension between the desire to be locally optimal and the desire to be globally universal.

56.2.2 Dealing with Large Data Volumes

The previous section was concerned with principles that can be demonstrated to be empirically true. We now move to a discussion of some of the principles that guide the design of GIS technology and allow GIS to deal with problems that might otherwise be overwhelmingly voluminous, a key issue in geocomputation given its goal of addressing large problems. The Earth's surface has approximately 500 million square kilometers, and a description of it at a resolution of 1 m² would therefore create 500 trillion data elements if no strategy were adopted to reduce the volume. Even allocating a single byte to each data element would create half a petabyte of data.

In the previous section we discussed Tobler's First Law, the basis for aggregating data elements into statements about entire polygons. California's land area amounts to 403,800 km², and describing each sq m with a two-byte designation CA would produce roughly 0.8 terabytes of data. But capturing the coordinates of its boundary and adding a single attribute CA to the polygon could clearly compress this to only a few kilobytes, even with precise coordinates, and by recording only a single attribute would avoid the potential for error in the vast number of identical attributes that would have to be recorded in the raster approach. Alternatively, a variety of compression techniques can also be used to replace a raster of individual data elements with a series of <run-length, value> pairs. Many other methods of compression, generalization, and abstraction have been devised to deal with the volume problem, some of them *lossy* in the sense that the result is only approximately identical and the original data cannot be recovered from the compressed version and some of them *loss-less*.

In a *divide-and-conquer* strategy, a geographic area is partitioned, and analysis or modeling proceeds one partition at a time. The term *tile* is often used for partition, especially where the partitions are rectangular. Instead of solving a problem for the whole of California, for example, one might solve it separately for each of its counties. Interactions exist between counties in almost every application: in analyzing water pollution, for example, the actions of a county will influence the water quality in any downstream county, and air pollution will travel to any counties downwind. Thus, a successful divide-and-conquer strategy must also consider the degree to which counties interact and include this in the model, often by iterating between modeling within-county effects and modeling between-county effects. Nevertheless, the overall computational efficiency of the modeling will probably be improved by adopting this strategy. Many GIS algorithms make explicit use of divide and conquer, as an approach to handling the vast amounts of data provided by satellite-based remote sensing, and implicit divide and conquer has been an intrinsic part of human problem-solving from time immemorial.

56.2.3 Scale-Related Issues

The term *scale* is often used in GIScience in the sense of spatial resolution, to distinguish between fine-scale or detailed data and coarse-scale or generalized data. Some of the techniques described in the previous section essentially sacrifice scale in the interests of reducing data volume. To a cartographer, reducing a map's *representative fraction*, the ratio of distance on the map to distance on the Earth, is similarly a sacrifice of scale, often in the interests of visual clarity. To a compiler of social statistics, reporting counts of people based on large, aggregated reporting zones may also be a means of reducing data volume.

All of these techniques have consequences that are well recognized in GIScience. The *modifiable areal unit problem* refers to the effects that changes in reporting zone boundaries will have on the results of any geographic analysis. The term was first formally characterized by Openshaw (1983), who demonstrated that changing reporting-zone boundaries could produce dramatic swings in results, even when holding scale constant. His solution, which became a fundamental tenet of geocomputation, was to recommend exploring the aggregation effect in any specific case, by repeated analysis using different zones. Unfortunately in most cases, this can only be done by aggregating predefined zones, producing different results but at a still coarser level of aggregation, since data compiled for different zonal arrangements at the same level of aggregation will usually not be available. Many studies have documented the problem, while others have argued that it results not from a failure of analytic method but from a failure on the part of the investigator to be explicit about the scale at which the hypothesized effects occur. For example, in Openshaw's original example, the 99 counties of Iowa were used to explore the relationship between percent of the population over 65 and percent registered Republican voters. Aggregating the counties in various ways did indeed produce different results but at coarser scale. What is missing in this case is a well-defined hypothesis as to why this correlation should appear and at what scale. Perhaps the process works at the individual level, and older people are more likely to vote Republican, in which case the hypothesis is best tested at the individual level. Or perhaps the process is ecological: a neighborhood with a large percent of people over 65 also attracts a large percent of Republican voters, whether or not they are over 65. In the latter case, the appropriate scale of analysis is that of the neighborhood, requiring a formal definition of that concept and an aggregation of fine-scale data, such as block-group data, to the neighborhood level. The general point is relevant to the definition of spatial analysis in Sect. 56.1 — that we should not be looking for statistics that are invariant to the phenomenon that we wish to study. As such, the MAUP is not an empirical problem but rather is a theoretical requirement to hone statistics to the geographic context in which they are applied.

A closely related problem, also well recognized in GIScience, is the ecological fallacy, the fallacy of reasoning from the aggregate to the individual. The fallacy already appeared in the previous paragraph, since it would be wrong to infer from a county-level correlation that individuals over 65 tend to vote Republican – in fact, in the extreme, Openshaw's correlations could exist in Iowa at the county level even

though no person over 65 was a registered Republican. King (1997) reviews the problem in greater detail and suggests ways of addressing it. Other approaches to downscaling, or replacement of coarse-scale data by fine-scale data, can be found, such as the work of Boucher and Kyriakidis (2006) in the context of remote sensing.

56.2.4 Simulation in GIScience

Many processes that operate on the Earth's surface can be abstracted in the form of simple rules. One might hypothesize, for example, that consumers always purchase groceries from the store that can be reached in minimum time from their homes. Exactly how such hypotheses play out in the real world can be difficult to predict, however, because of the basic heterogeneity and complexity of the Earth's surface. Christaller was able to show that such simple assumptions about behavior led to simple patterns of settlements in areas dominated by agriculture, but only by assuming a perfectly uniform plane. Similarly, Davis was able to theorize about the development of topography through the process of erosion, but only by assuming a starting condition of a flat, uplifted block. Research in both areas has clearly demonstrated that the perfect theoretical patterns predicted never arise in practice.

One strategy for addressing such issues is to assume that in the infinite complexity of the real world, all patterns are equally likely to emerge, and that the properties we will observe will be those that are most likely. This strategy enabled Wilson (1970) to show that the most likely form of distance decay in human interaction was the negative exponential, and Shreve (1966) was able to show that the effect of random development of stream networks would be the laws previously observed by Horton. Similar approaches have been applied to the statistical distribution of city size or the patterning of urban form (Batty and Longley 1994).

Nevertheless, while they yield results that are often strikingly in agreement with reality, such approaches lack the practical value that real-world decision-making demands. Instead, GIScience and geocomputation are increasingly being used to simulate the effects of simple hypotheses about behavior on the complex landscapes presented by the geographic world. The generality of such approaches lies in the hypotheses they make about behavior; the landscapes they address, and the patterns they produce, are essentially unique.

Such approaches fall into two major categories, depending on how the hypotheses about behavior are expressed. The approach of *cellular automata* begins with a representation of the landscape as a raster and implements a set of rules about the conditions in any cell of the raster. The approach was originally popularized by Conway in his Game of Life, in which he was able to show that distinct patterns emerged through the playing out of simple rules on a uniform landscape. Such patterns are known as *emergent properties*, since they would be virtually impossible to predict through mathematical analysis. The cellular-automata approach has been used by Clarke (e.g., Clarke and Gaydos 1998) and others to simulate urban growth, based on simple rules that govern whether or not a cell will

change state from undeveloped to developed. Such approaches allow for the testing of policy options, expressed in the form of modifications to the rules or to the landscape, and have been widely adopted by urban planners.

The alternative approach centers on the concept of *agent*, an entity that is able to move across the geographic landscape and behave according to specified rules. This *agent-based* approach is thus somewhat distinct from the cell-based approach of cellular automata. Agent-based models have been widely implemented in GIScience and geocomputation. For example, Torrens, Li, and Griffin (2011) have studied the behavior of crowds using simple rules of individual behavior, with applications in the management of large crowds with their potential for panic and mass injury. Evans and Kelley (2004) have studied the behavior of decision-makers in their role in the evolution of rural landscapes and examined policies that may lead to less fragmentation of land cover and thus greater sustainability of wildlife. Maguire, Batty, and Goodchild (2005) discuss several other examples of cellular automata and agent-based models in GIScience and geocomputation.

Both approaches raise a number of issues (for a general discussion of these issues, see, e.g., Parker et al. 2003). From an epistemological perspective, several authors have explored the role of such modeling efforts in advancing scientific knowledge. On the one hand, a model is only as good as the rules and hypotheses about behavior on which it is based. It is unlikely that the results of simulation will lead directly to a modification of the rules and more likely that rules will be improved through controlled experiments outside the context of the modeling. If patterns emerge that were unexpected, one might argue that scientific knowledge has advanced, but on the other hand, such patterns may be due to the specific details of the modeling and may not replicate anything that actually happens in the real world.

Validation and verification of simulation models are always problematic, since the results purport to represent a future that is still to come. *Hindcasting* is a useful technique, in which the model is used to predict what is already part of the historic record, usually by working forward from some time in the past. But the predictions of the model will never replicate reality perfectly, forcing the investigator to ask what level of error in prediction is acceptable and what is unacceptable. Moreover, it is possible and indeed likely that rules and hypotheses about social behavior that drive the model will change in the future. In that regard, models of physical processes may be more reliable than models of social processes.

56.2.5 Achievements of GIScience

As we noted earlier, the term *GIScience* was coined in a 1992 paper (Goodchild 1992). In some ways the paper was a reaction to comments being made in the literature about the significance of GIS that it was little more than a tool and did not therefore deserve a place in the academy. The funding of the US National Center for Geographic Information and Analysis (NCGIA) in 1988 by the National Science Foundation seemed to indicate a willingness in some quarters to see more in GIS

than technique. Nevertheless the tool/science debate continued for some time and is summarized by Wright, Goodchild, and Proctor (1997).

Two decades later, several efforts were made to look back and assess progress. A meeting for that purpose was convened in Santa Barbara in December 2008 (<http://ncgia.ucsb.edu/projects/isgis/>), and a paper summarizing its results and offering a personal perspective has been published by Goodchild (2010). It draws on the assessments of several individuals and on a bibliographic analysis performed by Skupin. While any level of consensus is inevitably difficult to achieve, the following might be argued to be the major achievements of two decades of GIScience:

- Clarification and specification of the basic data model, including recognition of the fundamental significance of discrete-object and continuous-field conceptualizations, the emergence of object-oriented data modeling, and the specification of spatial relations
- The development of place-based techniques of spatial analysis, including local indicators of spatial association (Anselin 1995; Ord and Getis 1995), spatial regression models (LeSage and Pace 2009), and geographically weighted regression (Fotheringham et al. 2002)
- The specification of standards for simple features, metadata, real-time interaction across the Internet, and many other aspects of GIS practice, led by the Open Geospatial Consortium and the US Federal Geographic Data Committee
- The development of digital globes such as Google Earth that allow real-time interaction with three-dimensional models of the Earth
- Recognition of the importance of ontology, as the key to interoperability across communities, languages, and cultures
- Search and retrieval based on geographic location, through mechanisms such as the geoportal (Maguire and Longley 2005)
- Advances in geovisualization, going far beyond the capabilities of conventional cartography to include animation, the third spatial dimension, reduction of high-dimensional data sets, and many other topics
- Achievement of a new level of understanding of uncertainty in geographic information, its handling, and its effects, together with a fundamental shift of focus from accuracy to uncertainty

Perhaps more important are the institutional achievements, which can be seen as the indirect result of such advances. GIScience is now widely recognized in the titles of journals and the names of departments and programs. In recent years several GIScientists have been elected to prestigious institutions such as the US National Academy of Sciences and the UK's Royal Society. GIScience conferences have proliferated, and the GIScience bookshelf now contains an impressive array of titles.

56.3 Changing Practice and Changing Problems

In this section we examine the changing nature of GIScience and speculate on its future. GIS has always been driven by competing factors. On the one hand, it has been at the mercy of trends and changes within the larger computing industry,

including new technologies that may or may not offer significant benefits for GIS. For example, the relational database management systems of the 1970s led to a major breakthrough in data modeling in GIS. GIS has also been driven by the need to solve problems of importance to society, from the resource management that provided the initial applications of GIS in the 1980s to the military applications that have always been important but half hidden, and new applications in public health that are as yet only partially developed. GIS as a tool for science is subject to the winds of change that are currently blowing through the scientific community, pushing it toward a more collaborative, multidisciplinary paradigm. Finally, GIS exists in a social context of concerns about privacy and about the role that an expensive technology can play in empowering the already empowered, and is beginning to recognize the importance of the average citizen as both a consumer and producer of geographic information.

This section is structured as follows. We begin with a discussion of high-performance computing and its importance for the kinds of massive simulation models discussed previously. We then move to a discussion of the social context of GIS and the social critique that emerged in the 1990s and now drives the research of many GIScientists. Finally, we examine the phenomenon of *neogeography* and the importance it may hold in providing new data sources and in driving the need for new techniques.

56.3.1 CyberGIS and Parallel Processing

A major report of the US National Science Foundation (NSF 2003) proposed the term *cyberinfrastructure* to describe the kinds of computing infrastructure that would be needed to support science in the future. Instead of the lone investigator and the desktop system, the report envisioned a distributed infrastructure that would support widespread collaboration across a range of disciplines, following the notion that science in the future would address complex problems with complementary teams of scientists of varied expertise. The solution of complex, large-scale problems would also require a heavy level of investment in high-performance computing (HPC) with its massively parallel architectures. Parallel architectures have an inherently good fit to the nature of geographic space and its somewhat independent individual and community agents, all of which can be seen as semi-independent decision-makers acting in parallel rather than serially.

A number of authors have argued that geographic research and problem-solving require a specific form of cyberinfrastructure that addresses several key issues and have coined the term *cyberGIS*. How exactly should the geographic world be partitioned across processors? How should one measure computational intensity as a geographic variable? How should the user interface of an integrated cyberGIS be designed? What types of problems, models, and analyses best justify these new approaches? What incentives will persuade the average GIScientist to engage with cyberGIS, given the initial impression of complexity and inaccessibility and a high level of personal investment in conventional GIS?

Efforts to parallelize GIS data from the 1990s but were not successful for several reasons. First, parallel computing was expensive at the time, and it was difficult for investigators to justify the cost. Second, parallel computing was rendered inaccessible by the need to reprogram in specialized languages. Third, while it was easy to find examples of geographic problems that involved massive volumes of data, it was harder to find ones that involved massive computation. Finally, collaborative technologies had not yet advanced to the point where it was possible for widely distributed research teams to work together productively.

Many of these arguments are now moot, however. HPC is widely available, and Cloud and Grid technologies are making the transition from conventional computing almost transparent. The need for collaboration is much stronger, and the kinds of problems that used to be solved by individual investigators are now hard to find. Finally, geocomputation has opened the doors to the kinds of massive computation that HPC is designed to address. Indeed, the most compelling examples of the need for HPC lie in the kinds of agent-based and cellular simulations reviewed in the previous section.

In recent years it has also become possible to parallelize processing on the desktop, following the addition of graphical processing units (GPUs) to graphics boards in order to improve the quality and speed of image rendering. Although an innovation of the computer games market, GPU chips were subsequently adapted to more general-purpose computing: today, Nvidia (which, along with AMD, is the world's largest graphics-card manufacturer) produces chips designed specifically for non-graphics applications and provides a specialized programming-language architecture for use with them. GPUs outperform traditional computation on a central processing unit (CPU) because a GPU has a higher density of cores and uses a process called streaming to handle a number of operations simultaneously. The result is increased processing speed of computationally intensive algorithms. General-purpose computing on graphics processing units (GPGPU) describes the exploitation of the resources of the GPU for various tasks which might previously have been conducted on a CPU. It has particular advantages for real-time systems where the speed of return of results is fundamental to usability and interaction.

Adnan, Longley, and Singleton ([in press](#)) describe an application in geocomputational geodemographics, in which k -means (a frequently used algorithm in the creation of geodemographic classifications) is enhanced to run in parallel over a GPU. This work exploits the parallel-computing computer unified device architecture (CUDA), which allows code written in standard C or C++ to be used in GPU processing.

56.3.2 The Social Context of GIS

Although the GIS technology that underpins GIScience and geocomputation is an established part of the IT mainstream, there is enduring unease in some academic quarters about the social implications of this technology. Early statements were contained in Pickles' (1995) edited volume *Ground Truth: The Social Implications of Geographic Information Systems*, which remains an enduring statement of

concerns built around four principal issues. First, there is the view that GIS technology is used to portray homogeneity rather than representing the needs and views of minorities and that this arises in part because systems are created and maintained by vested interests in society. The roots to this critique can be traced to a wider debate as to whether the umbrella term GIS is best conceived as a tool or as a science and is something that can be addressed through clarifying the ontologies and epistemologies of GIScience and geocomputation. Second, there is the view that use of a technological tool such as GIS can never be inherently neutral and that GIS is used for ethically questionable purposes, such as surveillance and the gathering of military and industrial intelligence. Web 2.0, discussed below, has begun to address this criticism, since it has gone some way to level the playing field in terms of data access and enabled participation of a wider cross section of society in the use of this technology of problem-solving. Moreover, it is difficult to construe the views of the Earth promulgated through services such as Google and Bing as intrinsically privileged, not least if they are open to all with access to an Internet browser. Third, there has been a dearth of applications of GIS in *critical* research and a preoccupation with the quest for analytical solutions rather than establishing the impacts of human agency and social structures upon unique places. The rise of mixed-method approaches to GIS (Cope and Elwood 2009) has gone some way toward addressing these concerns. Finally, there is still a view in some quarters that GI systems and science are inextricably bound to the philosophy and assumptions of the approach to science known as *logical positivism*. This implies that GIScience in particular, and science in general, can never be more than a positivist tool and a normative instrument and cannot enrich other more critical perspectives in geography. Although still featured in many introductory courses on social science methodologies, this critique is something of a caricature of the positivist methods that pervade scientific investigation more generally.

56.3.3 Neogeography, Wikification, and Open Data

Recent years have seen the reuse of the term *neogeography* to describe the developments in Web mapping technology and spatial data infrastructures that have greatly enhanced our abilities to assemble, share, and interact with geographic information online. Allied to this is the increased crowd sourcing by online communities of *volunteered geographic information* (VGI: Goodchild, 2007) and *user-generated content* (UGC). As such, neogeography is founded upon the two-way, many-to-many interactions between users and websites that have emerged under Web 2.0, as embodied in projects such as Wikimapia (www.wikimapia.org) and OpenStreetMap (www.openstreetmap.org). Today, Wikimapia contains user-generated entries for more places than are available in any official list of place names, and the term *vernacular region* is used to describe regions which emerge from geocomputational analysis of feeds from social networking sites. OpenStreetMap is well on the way to creating a free-to-use global map database through assimilation of digitized satellite photographs with GPS tracks supplied by volunteers.

This has converted many new users to the benefits of creating, sharing, and using geographic information, often through ad hoc collectives and interest groups. Such sites go some way to alleviating concerns about the social implications of GIS, insofar as participation in the creation and use of GIS databases is not restricted, and the contested nature of place names and other characteristics can be tagged in publicly editable databases. As such, Web 2.0 simultaneously facilitates crowd sourcing of VGI while making basic GIS functions increasingly accessible to an ever-broader community of users. This creation, maintenance, and distribution of databases has been described as a *wikification of GIS* (Sui 2008).

Official data are also becoming available through renewed pressures for government accountability, and the broader realization that wide availability of data collected by government and pertaining to citizens can lubricate economic growth. The result has been a plethora of open-data initiatives in many developed countries, leading to Web-based dissemination of data relating to many areas of public concern, such as personal health, transport, property prices, and even the weather. Conventional official sources such as censuses of population today account for a very much smaller proportion of the data that are collected about citizens, and there is a sense in which open-data initiatives are playing catch-up – providing researchers and analysts with some facility with which to understand the increasingly diverse and complex social, economic, and demographic milieu that characterizes advanced societies. Despite the hubris that has been generated around open-data initiatives, however, most of the data sources that have been released present extremely partial and disconnected representations of the world. For reasons set out in the discussion of modifiable areal unit effects above, the much more holistic concerns with issues of choice and service delivery, or the localism agenda in general, require linked characteristics at the level of the individual citizen or at the very least small neighborhood units.

This will require clear thinking of issues of spatial resolution (level of detail) and disclosure control that are central to the wider spatial literacy agenda (Janelle and Goodchild 2011). One consideration that is likely to reignite aspects of the social critique of GIS is that it is unlikely that privacy strictures can ever be absolute. Open-data initiatives are creating the need for a broader policy framework for data that responds to concerns of citizen privacy and confidentiality while remaining cognizant of the benefits that can accrue through opening up, integrating, and using the contents of government data silos. What level of data degradation is an informed public likely to be happy with, if it can be shown to bring benefits in terms of efficient and effective provision of public and private goods?

A related challenge is that empowerment of the many to perform basic (and even advanced) GIS operations brings new challenges to ensure that tools are used efficiently, effectively, and safely. Whether using official statistics or VGI, Web 2.0 can never be more than a partial and technological substitute for understanding of the core organizing principles and concepts of GIScience. These highlight the need to know and specify the basis of inference from the partial representations that are used in GIS to the world at large, yet such information is conspicuous by its absence from many VGI sources.

56.4 Conclusion

In undertaking a wide-ranging review of the achievements of GIScience and geocomputation, this chapter has also set out the principal issues and challenges that face these fields today. Improved computation and the facility to create, concatenate, and conflate large data sets will undoubtedly guide the future trajectories of the fields in the short to medium term. Ultimately, though, our focus in this chapter has been upon changes in scientific practice that may appear mundane but are nonetheless profound and far reaching. Good science is relative to what we have now, and improved understanding of data and their provenance is a necessary precursor to better analysis of spatial distributions in today's data- and computation-rich world.

Ultimately, GIScience and geocomputation are applied sciences of the real world and in large part will be judged upon the success of their applications. Improved methods and techniques can certainly help, as can ever-greater processing power. Yet the experience of the last 20 years suggests that there are rather few purely technical solutions to substantial real-world problems. The broader challenge is to address the ontologies that govern our conception of real-world phenomena and to undertake robust appraisal of the provenance of data that are used to represent the world using GIS.

This argues that the practice of GIScience and geocomputation poses fundamental empirical questions that require place or context to be understood as much more than location. Scientific approaches to representing places will undoubtedly benefit from the availability of new data sources and novel applications of existing ones, as well as citizen participation in their creation and maintenance. Yet a further quest for GIScience is to develop explicitly geographical representations of the accumulated effects of historical and cultural processes upon unique places.

Abstract

This chapter provides an introduction to geocomputation and geocomputational methods. As such it considers the scope of the term geocomputation, the principal techniques that are applied, and some of the key underlying principles and issues. Chapters elsewhere in this major reference work examine many of these ideas and methods in greater detail. In this connection it is reasonable to ask whether all of modern spatial analysis is inherently geocomputational; the answer is without doubt “no,” but its growing importance in the development of new forms of spatial analysis, in exploration of the behavior and dynamics of complex systems, in the analysis of large datasets, in optimization problems, and in model validation remains indisputable.

57.1 Introduction

For many researchers the term *geocomputation* refers to “the art and science of solving complex spatial problems with computers.” This definition, which is the tag line of the academic conference series run under the banner “geocomputation.org,” captures the essence of the term geocomputation. As such it embraces all manner of concepts, tools, and techniques that form part of mainstream geographical information systems (GIS) and science (GIScience: Goodchild and Longley, this volume*) and the methods employed in spatial analysis. For example, the 2011 Geocomputation conference included, among other topics, sessions entitled Geodemographics, Genetic Algorithms and Cellular Automata Modeling, Agent-Based Modeling (ABM), Geostatistics, Space-Time Modeling and Analysis, Network Complexity, Machine Learning, GeoVisual and Terrain Analysis, and Geographically Weighted Regression. Thus, parts of the academic world currently use the term geocomputation to apply to a very wide range of spatial analysis and modeling procedures, particularly those for which computational resources are central to the techniques employed. Readers will have noticed that each of the above topics, with the exception of machine learning, is represented by one or more chapters in this major reference work.

As Fischer and Leung (2001), Prologue have noted, geocomputation may also be viewed as a *research paradigm* that has changed the view of research practice in geospatial science over the past two decades. The driving forces behind the paradigm are fourfold: first, the increasing complexity of our spatiotemporal systems (nonlinearity, uncertainty, discontinuity, self-organization and continual adaptation); second, the need to develop new ways of utilizing and handling the increasingly large amounts of spatial information from the GIS and remote-sensing revolutions; third, the availability of attractive computational (intelligence) technologies which provide the modeling tools; and finally, the advent of high-performance computers.

As individual analytical methods that are considered geocomputational become accepted as providing effective solutions to specific spatial analysis problems, so they start to appear in more generic software with widespread usage. This is particularly apparent in some areas of remote-sensing data analysis, visualization tools, and agent-based modeling and in association with a number of statistical and spatial optimization problems. Thus, we are led to the conclusion that geocomputation is often used as an umbrella term for approaches to the analysis of problems that have a specifically geographical or environmental data focus, use modern computational techniques, and leverage high-performance computing hardware. This remains consistent with Openshaw’s original vision for the discipline (Openshaw and Abrahart 2000, p. x). As such, therefore, geocomputation is not a fixed set of techniques and models but an evolving, shifting collection of ideas, computational tools, and techniques with a particular emphasis upon the spatial domain, at scales from the architectural to the global. Modern geocomputational research remains true to the objectives Openshaw laid out more than a decade ago as being “. . .all about the use of relatively massive computation to tackle grand challenge (viz. almost impossible to solve) [geo]problems of immense complexity” (Openshaw and Abrahart 2000, p. 9).

In recent years many fields of scientific research have become dependent upon computational rather than so-called analytical methods. This is particularly apparent in mathematics, in areas such as combinatorial analysis, network analysis, and much of modern statistics. Likewise, developments in GIS software and remote sensing have relied very heavily on advances in computer memory, disks, processor speed, processing architectures, and visual display technology in order to provide the tools that are regarded as essential for digital mapping and related tasks. The challenge for geocomputational techniques is to provide real added value by providing practical tools that help solve complex problems, extract essential information from large datasets, and enhance the understanding of spatial processes and outcomes. Such techniques and modeling exercises may not be simple or parsimonious, but frequently they have the merit of providing more meaningful outcomes that match real-world experiences more closely than traditional analytical models. The real world (physical and social) is intrinsically complex, dynamic, and often unpredictable, and thus, computational spatial modeling tools that embrace this complexity can make a powerful contribution to our understanding of how the world works.

57.2 Geocomputation and Spatial Analysis

In our introductory section, we noted that geocomputation is a term that is applied to computationally demanding methods of spatial analysis. By definition problems that are addressed by geocomputational methods push the boundaries of computing technology. Since this is a rapidly changing field, with continuous improvements in processing power, memory availability and speed, networking, and storage capacity, yesterday's geocomputational problem may well become today's standard procedure. Problems that had previously to be run on limited size datasets, or with severe limitations to the spatial and temporal resolutions employed, can in due course be run with much finer resolution datasets, with more realistic assumptions, and with many repetitions if so required.

Specialized computing architectures can be leveraged very effectively for many spatial problems – for an excellent recent discussion of this field, see Huang et al. (2011). For example, it is becoming straightforward to use multiple processors on single computers or across multiple computers (e.g., using grid networks or cloud computing: Adnan et al. this volume*) to run many simulations in parallel that are identical other than with respect to their initial and boundary conditions. Likewise, classification techniques, such as k-means clustering, can be readily implemented using parallel systems processing since the procedure involves a series of similar runs for $k = 2 \dots$ to 20 say, iterated for a set of (randomly) chosen initial seed locations. In other instances the software application itself requires substantial redesign in order to operate effectively across multiple processors and memory regions. This is particularly true for data-intensive applications, where the dimensionality of the problem may be limited but the volumes extremely large (e.g., very high-resolution satellite imagery and LiDAR (Light Detection And Ranging) point

clouds, determination of optimal parameters for fine-resolution spatial interaction models). In such cases splitting the problem into smaller units (e.g., decomposition of the data into tiles or cells), processing the separate units in parallel, and then merging the results may be the only practical approach that can be adopted.

With the rise of increasingly large spatial datasets, almost all aspects of spatial data processing become a challenge, but with geocomputation the focus is upon problems that resist classical forms of analysis. One of the clearest examples of this arises in the field of spatial simulation (often now referred to as geosimulation – see the work of Paul Torrens at <http://geosimulation.org/>). Although there are a variety of approaches to such simulation – for example, cellular automata, agent-based modeling, and randomized network-based modeling – the results obtained at the macroscale from microscale (or bottom-up) modeling are often unexpected and unpredictable. Macroscale structures and behaviors “emerge” from simple microscale processes, in a similar manner to the emergence of macroscale features in biological systems – such as the appearance of segmented body structures and articulated limbs in a wide range of insects and higher life forms and the appearance of “swarms” or flocking behavior among birds, fish, and many other animals. In geospatial analysis, examples include modeling the behavior of pedestrians during evacuation emergencies, examining the way in which disease spreads among communities, and modeling and predicting urban land use and transport changes over time.

Microscale or “bottom-up” simulation is only one of a number of major application areas for geocomputational methods. Other examples include computational spatial statistics – procedures that seek to provide statistically valid insights into complex spatial datasets; optimization problems, ranging from optimal location and routing problems to the determination of optimal model parameters for highly parameterized models; procedures that seek to augment data at a given scale and point in time with related datasets at different levels of aggregation and/or extending over a number of time periods; and a wide range of advanced visualization techniques. In many instances these issues are not separate, independent concerns but apply simultaneously to the iterative process of model building, thereby demanding considerable skill in model construction, software engineering, data management, and validation. The results of such work are often surprising and impressive but may also be difficult to follow in detail and hard to justify. Is understanding always advanced when such methods are employed or do such models match the past and present so well because they are highly parameterized and intensively fitted?

In the sections that follow, we commence in [Sect. 57.3](#) by examining a number of geocomputational methods that have been inspired by analogy with biological processes. These include cellular automata and agent-based models, computational neural networks, and evolutionary algorithms. In [Sect. 57.4](#) we then discuss a number of geocomputational techniques that have been applied to network-related problems rather than point- or areal-based spatial problems. In [Sect. 57.5](#) we look at the rising importance of computational methods in statistical science and the impact of this development to the field of spatial statistics. We conclude in [Sect. 57.6](#) by commenting upon issues of spatial and temporal resolutions and questions of model complexity.

57.3 Geocomputational Models Inspired by Biological Analogies

The analogy with biological processes runs far deeper in the field of geocomputation than might be expected. Three major classes of methods commonly applied in geocomputation have been inspired by biological analogies (see, further, de Smith et al. 2009, Chap. 8). The first of these embraces a number of simulation techniques, many of which owe their origins to a simple cellular automaton (CA) simulation known as “the Game of Life.” This extremely simple model, which operates within the framework of a 2D matrix of square cells, was introduced by the mathematician John Conway in the 1970s and has a surprisingly extensive and complex range of outcomes. The rules of the Game can be summarized as follows:

The Game of Life has only two *states* for each cell (alive or dead, or 1 or 0) and three simple *state transition rules*: (i) *survival*: if a cell is ‘alive’ (i.e., its *state* is ‘true’ or ‘1’, for instance) and it has two or three alive neighbors it remains alive; (ii) *reproduction*: if a cell is ‘dead’, but has three alive cells within its *neighborhood* its *state* becomes alive, and (iii) *loneliness* (less than two neighbors) or *overcrowding* (more than three neighbors): the cell dies. Despite these simple rules, the Game of Life can produce a range of complex behaviors from different initial conditions.

This archetypal spatial model demonstrates an important characteristic of many geocomputational methods – the emergence of broad classes of pattern that could not have been predicted prior to simulation. It also highlights a number of other common features of such procedures: the outcomes of geosimulation exercises have an element of framework dependency (structures and boundaries) and, in some instances, path dependency (i.e., the future path is heavily determined by past steps and initial conditions and may lead to stable or unstable/widely divergent results). Hence, key structural attributes of each type of simulation model have a direct bearing on the kinds of outcome seen. These attributes (for problems of the cellular automata type) include state variables (the possible states the system supports and the set of initial states that are examined); the spatial framework used for modeling (e.g., use of a 2D rectangular grid, a 3D lattice, a toroidal space, etc.); the form of neighborhood effects permitted (e.g., single or multiple steps, distance bands, different forms of adjacency); the state transition rules applied (i.e., how the states may change over time); and finally, how the time dimension is treated – discrete or continuous, serial or parallel.

Wolfram (1983) studied the Game of Life in detail and demonstrated that the outcomes for all simulations of this general type fall into four classes. For the Game of Life, these are (i) static patterns, (ii) oscillators (or periodic patterns), (iii) spaceships (patterns that repeat themselves but translated in space), and (iv) patterns that increase in population size (a range of different patterns and behaviors). A useful summary with examples and references is available on the Wikipedia page “Conway’s Game of Life.” The unexpected complexity of the resulting behavior from the rules Wolfram identified led him to believe that complexity in nature may be due to similar behavior.

Batty (2000) provides an excellent review of CA models and their application to urban systems modeling, including commentary on their strengths and weaknesses, and identifies areas for future research in this field. Central among these are questions of improved representation of the real world, moving from the fixed framework of square cells to incorporate irregular zones, streets, and other linear forms, and new definitions of how such elements interact. To an extent, these issues have been tackled in recent years using an alternative geosimulation framework, known as agent-based models (ABMs).

Commencing with this simple cellular-based simulation framework, computer scientists have developed a large and expanding family of techniques and tools based on microscale or bottom-up simulation. Among these are a range of approaches that liberate the simulation from the spatial constraints of a lattice-based framework and permit-free movement in 2D or 3D space (agent-based models). One example is the so-called ant colony optimization (or ACO) approach, in which the space of interest is explored by synthetic ants (the agents in this case) – those that reach a desirable objective (e.g., a target location/food source) by any route then return to the ant colony by a relatively direct route laying a synthetic pheromone trail. Subsequent ants are attracted to the pheromone trail reinforcing its usage. But because the pheromone evaporates over time, only the route or routes that are most used tend to be retained, and since shorter routes lead to and from the food source more quickly, these tend to be reinforced at the expense of longer (i.e., less desirable) routes. ACOs are a form of agent-based model (where the ants are the agents), and because of the way such systems are implemented, with large populations of independent agents acting in a collective manner, ACOs and similar procedures fit within the broad area known as “swarm intelligence.” Other microsimulation procedures within this broader paradigm have been applied with considerable success to crowd behavior modeling, for example, helping to manage large-scale street events such as carnivals and protest marches, football stadiums, and emergency evacuation of complex buildings. Note that in these more advanced geocomputational models, a clear distinction exists between the population (agents in this case) and the environment. This is not the case with cellular automata. There is also the inherent assumption that while the population responds to the environment, the reverse is generally not the case – for some applications (e.g., those involving anthropogenic change), such assumptions are not realistic.

Recently a number of urban geosimulation models have sought to reflect real-world spatial structures and their attributes within the model framework. In these models the spatial framework for the model utilizes fine-scale digital maps of the study area combined with synthetically generated population data. A synthetic population is a computer-generated randomized set of individuals, households, or other entities of interest that match predefined aggregate attributes (or classifications) for zones within a study region. Such populations are often used as the building blocks for microsimulation projects of the kind described above, where the necessary individual-level data does not exist and a match to “ground truth” information is required (e.g., in land use planning, a traffic simulation model, a medical study, or even a model of burglary events that incorporates the potential

victims of crime). Typically the finest level of available zonal data (such as small area census zones) is used to specify the attributes of the synthetic population. The aggregated characteristics of this computer-generated population are chosen to ensure that they closely approximate the zonal figures. A recent comparison of procedures for achieving such approximations is provided by Heppenstall et al. (2011), whose tests identify the use of simulated annealing (SA) as the most effective (if relatively slow) procedure for minimizing classification error. The synthetic individuals are then allocated to particular locations within the study area zones. This might be a process of random allocation to known buildings or by reference to land use maps. In many instances the most practical option is to rasterize the zones and to allocate the synthetic population to cells based on a probabilistic assignment derived from land use. The result is a representative population of individuals, allocated to meaningful point or cell locations (thereby minimizing spatial aggregation bias) that may be used within a microsimulation model. This lends such models credibility and a level of realism derived from the knowledge that their aggregate characteristics match those that are known, even though they do not strictly represent the actual set of individuals within the study area. Thus, a form of “study error” remains, but the approach goes some way to resolving the ever present issues of statistical and spatial aggregation associated with many datasets.

The second main area of biologically derived geocomputational methods is the field known as computational neural networks (CNNs). These methods take their inspiration from highly simplified models of neurological processes, originally drawing on models of how neurons in the retina operate. In practice the analogy has proved useful in guiding the general structure of computational models rather than any direct appeal to biological process similarity. CNN methods have been successfully applied to a limited number of geospatial problems – most notably the modeling of trip distribution data (see, e.g., Fischer 2006) – and for multispectral image analysis. Typically three layer models have been applied, with an input layer, single middle layer, and an output layer. CNNs are models whose behavior is determined in part by the model structure itself and in part by the data used to “train” the model parameters. Once the structure has been specified by the research scientist (which may be an iterative process in itself) and training data selected, applied, and evaluated, the result is a modeling system that can be used on more general “unseen” datasets. As with the previous discussion of systems inspired by artificial life, the outcomes achieved are strongly dependent on a number of well-defined attributes of the model: the number of layers used in the neural model, the number of nodes used in each layer, the form of the forward and backward propagation algorithms, and the connectivity of the network. This dependency on the structure of the model is then accentuated by an element of data dependency since the selection of the training dataset and control (evaluation) dataset defines the parameters that are then used on unseen data. CNNs have found their most widespread geospatial application in the field of remote sensing, where they have been found to be a very effective tool for inferring land use and land use change. However, the nature of such models suggest that they operate primarily as a form of pattern recognition engine, a relatively highly

parameterized black box, that like higher animals can be very good at recognizing familiar shapes and textures but by itself contributes little to understanding and thus can be quite specific to the datasets any specific model can be applied to. In the longer term a combination of high speed automated CNNs with “intelligent systems” may produce much more generic and flexible tools that offer a real step forward in efficient processing of large spatial datasets.

The third biological analogy we discuss here is “survival of the fittest.” Here the objective is to solve a range of difficult combinatorial optimization problems using analogies from genetics. There is a wide range of important optimization problems for which it is believed no solution algorithm exists that can be run in polynomial time – that is, such problems are intrinsically nonpolynomial (or NP). What this means in practice is that for problems that involve any realistic quantities of data (i.e., n objects, where n is not small), it is impossible to find a provably globally optimal solution in a finite amount of time. As n increases so the problem becomes increasingly intractable. The archetypal example of such a problem is the simple traveling salesman problem (TSP). The TSP involves finding the optimal route through a set of points (e.g., towns) that ensures each is visited just once and the total length of the tour is minimized. The best algorithms for solving the simple TSP can now provide provably optimal solutions for n in the 1,000 s, which is very impressive. Genetic algorithms (GAs) can be used to “solve” the TSP but are far less efficient than many other approaches – that is, GAs typically produce poorer results (suboptimal solutions) and take longer to achieve these (many 1,000 s of iterations or “generations”). One reason for this is that GAs are a generic rather than specific approach to problem solving – they can often provide a reasonably good answer rather than the best answer. And this raises another interesting question – is the optimal solution the best solution? Initially we would immediately respond “of course,” but in many instances this perspective must be qualified by recognizing that it applies to the problem as specified, which is typically very tightly specified and generally static. If the kinds of problem to be tackled are less well specified and dynamic or involve more complex choice models, it is possible that apparently suboptimal computational methods might well fare far better than fixed algorithms.

GAs are a particular subset of a broader class of algorithms known as evolutionary algorithms (EAs). EAs have been applied to a variety of dynamic optimization problems with some success. This raises the question of what is meant by “dynamic.” Clearly all problems exist in a temporal context but are only considered dynamic if some aspect of the problem changes over time. Key issues are therefore the frequency and scale of any such changes, their behavior (e.g., predictable or random, trending or cyclical, or some combination of these), and the nature of the changes taking place – are the relevant dynamic elements changes in the environment the objective function or perhaps constraints that affect the system behavior? In a static optimization problem, a traditional genetic algorithm attempts to converge toward a global optimum by a process of genetic selection – retaining genetic strings that are fitter (provide solutions closer to the optimum, as measured by some fitness function) and modifying genes by various forms of mutation and crossover. Since these strategies are designed to migrate the solution toward a static optimum, they are

too restrictive for problems that include dynamics. Dynamic optimization problems require modification of such survival strategies by taking into account the nature of the changes that may occur. In some instances such changes are so dramatic and unpredictable that attempts at developing solution procedures will never succeed, but in many instances changes are smoother or have a more predictable effect (e.g., reducing the severity of some constraints), and in these cases dynamic EA procedures can be used. Example approaches that have been found to be effective include the concept of introducing random immigrants into the population, helping to maintain genetic diversity, and so-called forking of populations, in which an entire subset (e.g., a selection of children) are separated off and explore their own evolutionary path transposed from the parent population (a form of emigration).

57.4 Networks, Tracks, and Distance Computation

Many of the techniques described above apply to point and areal datasets (zonal or lattice-based), although some relate to networks. Until recently attention on linear forms has tended to concentrate on a range of network optimization problems, such as determining shortest paths, least cost routes, multivehicle (capacity constrained) route allocation, optimal on-network facility location, and optimal arc routing (e.g., street cleaning) – see de Smith et al. (2009), [Chap. 7](#) for a detailed review of this area. In many cases very fast algorithms have been obtained to solve such problems, and in some cases these solutions are known to be optimal. In other cases achieving a provably optimal result may be impossible and/or require unlimited computed resources for large problems (i.e., problems with many links and nodes). As a result a wide range of suboptimal but effective procedures have been developed, which provide very acceptable if not optimal solutions. Among these are highly problem-specific algorithms (e.g., the A* algorithm for determination of the shortest path in a network), various forms of linear programming and dynamic programming, and much more generic procedures, such as genetic algorithms (GAs), cellular neural networks (CNNs), simulated annealing (SAs) algorithms, ant colony optimization (ACO) methods and many more.

In most cases these models and methods seek optimal or near optimal solutions to complex routing problems in static network environments. However, it is increasingly apparent that solution procedures need to reflect the dynamics of real-world networks, where road traffic or telecommunication traffic intensity and connectivity may vary rapidly in time and space (see Cheng, this volume*). Thus, geocomputational systems need to be able to respond in near real time to events as they occur, particularly when applied in command and control situations.

The emergence of new forms of data flows, most notably from individuals (people, animals) or vehicles on the move and from satellite tracking and sensing, has led to a substantial new body of spatial data that demands our attention. In some instances these data need to be fed directly into the processing systems in order to identify problems and direct changes to the way these systems manage and forecast near-term events (e.g., traffic routing, crowd control, evacuation management), while in other

cases the data can be seen as a complex series of tracks, marking out the routes chosen by numerous individuals or other entities over time. This tracking information, often generated by communications devices that incorporate Global Positioning System (GPS) or similar technologies, provides an entirely new body of complex spatial data that demands new forms of analysis to interpret and leverage results. Research into the use of such data is at an early stage, with initial applications in fields such as attempting to predict animal behavior (e.g., migration routes, preferred habitat selection), modeling the behavior of would-be burglars, and analyzing the tracks of hurricanes.

Accurate computation of distance is a fundamental requirement of almost every form of geocomputation, but in many instances approximations are used that may result in systematic errors. The main issues are the use of Euclidean measure when network-based measures are more appropriate and the use of local Euclidean distances when undertaking operations across raster files (see further below). These issues become more complex when constraints are added, for example, when restricted areas are included, barriers and turn restrictions are accounted for, and where the underlying space is no longer treated as being homogeneous.

In the first case, Euclidean measure may substantially underestimate interpoint distances. Computation of network distances across dense street networks can be time consuming, with the result that some GIS operations such as calculating the extent of drive-time polygons, or computing optimal facility locations, may be very slow. Where distance computations are not based on networks and are computed using Euclidean, spherical, or geodesic measure, they can be calculated extremely quickly. In some instances such measures may be used as a surrogate for network distance or as a means of generating good “candidate lists” of solutions which can then be used as initializations for network-based optimization.

In the second case, distance computations on raster files, many applications use operations on the immediate eight neighbors of each cell in the raster (i.e., work on a 3x3 array of cells). Where these involve distance calculations, for example, when the lengths of paths are computed across a cellular model or hydrological flows analyzed in a digital terrain model, the distance computations are often incorrect. Local Euclidean distances (1 for N, S, E, W movements and 1.414... for diagonal compass movements) result in errors of almost 8 % in overall distances and result in errors in optimal path selection. The solution in such cases is to use optimal 3x3 or 5x5 values (real or integer approximations) or to use exact Euclidean distance transforms (DTs) that correct the propagated errors (see, further, de Smith et al. 2009, Sect. 4.4.2.2). Furthermore, DTs may be used as a geocomputational procedure that can solve a variety of spatial optimization problems, notably optimal route finding in nonuniform free space (nonnetwork) environments where gradient, curvature, and other constraints apply.

57.5 Computational Spatial Statistics

Our earlier section on biologically inspired models embraces a large part of the subject we have been referring to as geocomputation. To some extent in parallel,

a separate and rather different area of geocomputation has been developed. This involves the application of computationally intensive methods to a range of problems arising in spatial statistics. Openshaw's (1987) groundbreaking work in this field involved attempting to apply raw computing power to identify potentially significant clusters of point-referenced data such as the incidence of rare diseases (e.g., cases of childhood leukemia).

More recently geocomputational methods have been developed that provide similar functionality within a more statistically robust framework. Principal among those now widely used are spatial scan statistics, originally developed by Kulldorf (1997) at the National Cancer Institute in the USA. Kulldorf's scan procedures have been developed and extended over the years and many of these developments have been implemented in the software package SaTScan (for a recent example application, see Greene et al. 2010).

As the SaTScan authors' state, the software is designed to:

- Perform geographical surveillance of disease, to detect spatial or space-time disease clusters, and to see if they are statistically significant
- Test whether a disease is randomly distributed over space, over time, or over space and time
- Evaluate the statistical significance of disease cluster alarms
- Perform repeated time-periodic disease surveillance for early detection of disease outbreaks

This description of how SaTScan operates, as a computationally intensive approach to spatial statistical analysis, is typical of many forms of modern spatial analysis. It utilizes computational power to search for and examine patterns within large volumes of data. In this case the procedures applied involve a scanning process, similar in concept to scanning algorithms applied in remote sensing and image processing (e.g., as used in the computation of distance transforms, noted above) – it is fast, simple, and exhaustive. In many other instances the search space is more complex, often multidimensional, and the search procedures cannot be exhaustive but must rely on heuristics, including those biologically inspired procedures described earlier.

Another feature common to geocomputational statistics is the production of pseudoprobability distributions by large-scale simulations or random permutations. These procedures recognize the limitations of traditional analytical methods and seek to use observations and/or aspects of observed spatial structure to generate a large set of possible outcomes under conditions of randomization. Using these simulations one or more statistics of interest are computed and the observed value in a given dataset is then regarded as a particular realization within the simulated population. If the observed statistic appears exceptional (e.g., the mean distance to nearest neighbor in a bounded point set is measured and found to be very small or very large when compared to a large number of random simulations using the same number of points within the same spatial extent), then it can be regarded as “significant.” Care must be taken when carrying out such procedures to avoid generating pseudoprobability distributions that involve resampling the same data (or regions) multiple times and to take into consideration questions of the independence of samples.

Likewise, for data relating to planar lattices (e.g., all census tracts within a state), statistics may be computed and compared with a large number of permutations of the observed data values across the lattice. This procedure, which is widely used to generate pseudoprobability distributions and evaluate the “significance” of observed patterns, is less satisfactory from a statistical perspective. It assumes that the data values for the M zones are effectively fixed and could have been allocated at random to any of the M zones in the study area. In practice this is not the case – it is more reasonable to assume that the total count (e.g., of cases of a specific illness) could have been randomly divided into M partitions (based on a uniform or observed frequency distribution) and each then assigned at random to one of the zones. The assigned values may then be used to calculate the statistics of interest, with repetition of this process yielding a pseudoprobability distribution that can then be used for comparative purposes. However, this procedure also has limitations since the partitioning and allocation among zones is purely random and may not reflect important variations between these zones, for example, in terms of the size of the population at risk. Furthermore, establishing an appropriate null hypothesis in such cases may be difficult or impossible since zonal boundaries are often arbitrary and some level of spatial autocorrelation is always present.

Procedures such as geographically weighted regression and spatial regression models (see, further, *Spatial Econometrics*, this major reference work*), spatial analysis on networks (SANET), and geostatistical modeling can also be considered as geocomputational methods. They rely on computational power to produce insights into the statistical significance of patterns and to facilitate model building where the parameter space is large and the observed datasets increasingly large and complex. Other computationally intensive statistical procedures, such as Markov Chain Monte Carlo (MCMC) techniques widely used in Bayesian model building (e.g., the GeoBUGS project), bootstrapping, and cross validation, all may be considered as having close links with the field of geocomputation.

57.6 Conclusions

A feature of many spatial datasets is their increasing complexity and size – many datasets are now available at a variety of levels of aggregation, not always relating to the same data. Techniques for maximizing the use of such data – for example, combining point and areal measures – are becoming more common. Likewise there is a growing availability of spatial datasets for different time periods, varying from relatively long period time slices (e.g., annual), to monthly, daily, or even shorter-time windows. This has led to researchers seeking to revise some traditional models, such as those relating to spatial interaction and trip distribution, to incorporate diurnal variations in population (e.g., home-based and work-based shopping trips, evaluating the optimal location of ambulances or police patrols). In such cases the objective is to improve the quality of models in order to provide improved understanding of the processes at work and the outcomes that can reasonably be predicted.

However, in a wide ranging discussion of computational model building, Batty (2011), p. 28 argues that “as the level of detail in terms of sectors, spatial-locational resolution, and temporal resolution increases, data demands generally increase and models become increasingly difficult to validate in terms of being able to match all the model hypotheses . . . to observed data. As temporal processes are added, this can become exceptionally difficult. . .and we face a severe problem of validation.... This tends to force modeling back to the traditional canons of scientific inquiry where parsimonious and simple models are the main goal of scientific explanation.” Thus, there is much to be gained from advances in model construction using computationally intensive procedures, but the results can be very difficult to validate, comprehend in detail, or justify to stakeholders, leading to considerable tension among the research community. Advances in visualization, ranging from improved 2D and 3D graphics to new metaphors for data exploration (e.g., Google Earth, dynamic fly throughs, immersive systems) and video display of the progress of geosimulations, all help to overcome some of the issues raised by Batty. And despite the difficulties, as the program for the 2011 Geocomputation conference identifies, this field is one attracting intense interest, is of great practical significance, and is set to become one of the defining scientific paradigms of the twenty-first century.

58.1 Introduction

The current ubiquity of data collection is providing unprecedented opportunities for knowledge discovery and extraction. Data sources can be large, complex, heterogeneous, structured, and unstructured. In order to explore such data and exploit opportunities within the data deluge, tools and techniques are being developed to help data users generate hypotheses, explore data trends and ultimately develop insights and formulate narratives with their data. These tools often rely on visual representations of the data coupled with interactive computer interfaces to aid the

exploration and analysis process. Such representations fall under the purview of visualization, in which scientists have worked on systematically exploiting the human visual system as a key part of data analysis. Research in this area has been inspired by a number of historical sources, examples include physicist James Maxwell's sculpture of a thermodynamic surface in 1874, Leonardo da Vinci's hand-drawn illustration of water from his studies to determine the processes underlying water flow, or the flow map of Napoleon's March on Moscow produced by Charles Minard in 1869. Each of these examples attempts to explain data in a visual manner, and, as visualization has progressed, principles and practices have been adopted to standardize representations, and, more importantly, better exploit properties of the human visual system.

In this chapter, we will focus on how visualization research has effectively utilized one of the most ubiquitous visual representations, the cartographic map. Cartography is the study and practice of making maps and is situated as perhaps the most well-studied visualization technique available to scientists. For centuries, cartographers have looked at combining science, aesthetics, and analysis into the mapmaking process on the premise that such tools will be able to effectively communicate information and aid in knowledge generation. One of the most famous examples of such knowledge generation is John Snow's mapping of the location of cholera deaths in Soho, England, in 1854. By plotting cholera deaths and the locations of water pumps, Snow was able to develop a hypothesis about the water-borne nature of the disease. Snow was able to use his visual explorations of the cholera outbreak patterns to persuade the local town council to disable the water pump central to the disease center.

This sort of data analysis utilizing cartographic principles as a means of representing spatiotemporal data and exploring patterns within this data is often referred to as *geographic visualization* or *geovisualization*. Geovisualization focuses on visually representing spatiotemporal data, exploiting known cartographic techniques as part of the interactive graphical representation of the data, and incorporating dynamic interactions for querying and exploring data. A rigorous definition of geovisualization can be found in MacEachren (1994): "Geographic visualization (can be defined) as the use of concrete visual representations - whether on paper or through computer displays or other media - to make spatial contexts and problems visible, so as to engage the most powerful human information-processing abilities, those associated with vision."

Note that the above definition discusses the use of visual representations (plural) of the data. Representations can range from complex glyphs, shaded areas, lines, and diagrams, and given the amount of data and differences in ways to represent data, it is important to consider what sort of questions will be asked of the data. Thus, rather than trying to make one "best" map or data representation which depicts only a subset of the available information, geovisualization systems often incorporate a variety of data views in an attempt to generate more insight for analysts. Often, the views generated involve the computation of basic statistics and summaries of the data as a means of providing the user with an overview of their data prior to, or as part of, the exploration process.

58.2 Statistical Graphics

As perhaps a precursor or overlapping field with data visualization, much of the groundwork in describing and exploring data sets comes from the *statistical graphics* community. Statistical graphics are tools used to reveal details about data sets, such as outliers and trends within the data. By revealing such features, one can speculate on how data can be further processed, transformed, explored, and analyzed. Hypothesis generation would begin in this stage, and such hypothesis generation would lead to the use of certain methods for hypothesis testing and data modeling. Finally, proper statistical methods could then be chosen for a further refined analysis of the data.

What is of key importance in data visualization is that when a statistical graphic is made, the information from the data set being explored is encoded by the chosen display method. An analyst will look at the visual representation, and then a decoding process will occur. During this decoding process, visual perception becomes the vital link. No matter how impressive the encoding is, if the visual decoding cannot be done by the analyst, then the data analysis will fail. This encoding and decoding of graphical elements is explored in *The Elements of Graphing Data* (Cleveland 1985), and detailed perceptual studies that discuss how well humans are able to perceive encodings (relative angles, line lengths, etc.) are described. Much use has been made of these studies in further developing visualizations, and a variety of methods are discussed in *Visualizing Data* (Cleveland 1993). Three of the most common exploratory data analysis graphics used for exploring the distribution of data include the box plot, the histogram, and the scatterplot (Fig. 58.1).

58.2.1 Histograms

One of the first things explored when analyzing data is the distribution of the given data measurements. According to Wilkinson (2005), the histogram (Fig. 58.1, left) is one of the most widely used visual representation and first-look analysis tool. Introduced by Pearson (1895), the histogram provides a visual summary of a univariate sample within a data set. The visual summary consists of rectangles drawn over discrete intervals (called *classes* or *bins*) where the height of each rectangle corresponds to the number of data samples that would fall into a given bin.

The main concern in creating a histogram lies within the choice of the number of bins and the width of the bins. Different numbers of bins and different bin widths can each reveal different insights into the data. Thus, the initial choice of the bin number and size can have a dramatic impact on the knowledge that can be derived when using a histogram visualization. Most statistical graphics programs default to one of two options when creating a histogram: the *square root choice* or *Sturges' choice* (Sturges 1926). The square root choice is defined such that given a data set with n samples, the number of bins k will be calculated as follows:

$$k = \lceil \sqrt{n} \rceil. \quad (58.1)$$

Fig. 58.1 Common statistical graphics. (Left) Histogram. (Center) Box plot. (Right) Scatterplot

Once the number of bins are known, it is assumed that each bin will be of equal width. Thus, the bin width h is defined as follows:

$$h = \left\lceil \frac{\max(x) - \min(x)}{k} \right\rceil \quad (58.2)$$

where x is the univariate data set under analysis. For comparison, Sturges' choice (Sturges 1926) is defined as follows:

$$k = \lceil \log_2(n) + 1 \rceil \quad (58.3)$$

Both the square root choice and Sturges' choice have an implicit assumption of a normally distributed data set. However, in the construction of the approximation, Sturges considered an idealized frequency in which the distribution will approach the shape of a normal distribution. Thus, if the data is not normal, the number of bins chosen will need to be revised. However, for moderately sized n (approximately $n < 200$), Sturges' rule will produce reasonable histograms. For further details on other histogram bin choices, please refer to (Wilkinson 2005).

While a vast amount of research has been done on bin selection, the key factor to take away is that there are strengths and weaknesses behind bin choices. If small values of h are used (with respect to the data in question), the histogram will model fine details within the data; however, noise in the data set can obstruct the information being presented and may obfuscate the analysis. Conversely, with large values of h , the density becomes too smoothed and one can oversimplify the description of the data.

58.2.2 Box Plots

While a histogram allows us to explore the distribution of a univariate measurement within our data set, an analyst often wants to quickly determine the mean values of the data distribution and compare this distribution to others. One measure that is key to visualizing data distributions is the *quantile*. The f quantile, $q(f)$, is defined as the value along the data measurement scale where approximately a fraction f of the data are less than or equal to $q(f)$. In the case of quantiles, this would be where

approximately one fourth of the data is less than $q(f)$ for the *lower quartile*, half for the second quartile (or the *median*), and three fourth for the *upper quartile*. The benefit of such measures is that the f-values provide a standard for comparisons across distributions.

One graphical way of using quantiles to compare distributions is the *Box plot*. Box plots, Fig. 58.1 (middle), consist of several distinct graphical elements, namely, the *box* and the *whiskers*. The box itself represents the range from the lower quartile to the upper quartile of the data, with the bottom edge of the box being the lower quartile and the top edge of the box being the upper quartile. The dot in the middle of the box represents the sample median. Note that if the dot is not directly in the center of the box, then it is an indication of data skewness.

The whiskers are the dashed lines that extend above and below the box. These lines represent the extent of the remaining data samples, and, assuming no outliers, the maximum value of the distribution is represented by the top line attached to the whisker, and the minimum value of the distribution is represented by the bottom line. If outliers exist, a small circle at the top or bottom of the plot will be used to represent this fact. A data sample is considered to be an outlier if its value is more than 1.5 times the interquartile range away from the top or bottom of the box.

While a box plot may seem simpler (or even less intuitive) than a histogram, its main advantage is its limited screen space requirements. A larger number of box plots can be plotted on the screen at once for comparison than would be possible for entire histograms. Furthermore, the visual representation of a histogram is highly influenced by the choice of bin width; there is no such limitation on the box plot.

58.2.3 Scatterplots

While the box plot allows users to compare and summarize distributions of like groups, analysts often wish to search for correlations between variables within their data set. One common means of visually representing the relationship between two variables within a data set is the *scatterplot*. Scatterplots visualize multi-dimensional data sets by assigning two of the data dimensions to a graphical axis, Fig. 58.1 (right). Points of the data set are then rendered in the Cartesian space defined by the axis. These plots are typically employed as a means of analyzing bivariate relationship within a planar projection of the data and are used to help researchers understand the potential underlying correlations between variables (Tufte 1983).

These visualizations provide a quick means of assessing data distributions, clusters, outliers, and correlations. Given a scatterplot, an analyst will visually assess the relationship between the variables being plotted by looking for trends in the plot. If the points tend to approximate a line running from the lower left to the upper right, this is often indicative of a positive correlation between variables. Likewise, if the points tend to approximate a line running from the upper left to the lower right, this can be indicative of a negative correlation. Such plots can also be enhanced by fitting a line to the data to help visualize such linear correlations.

However, (Cleveland 1993) notes though that putting a smooth curve through the data in the mind's eye is not a good method for assessing nonlinearity and can bias the analyst.

While scatterplots are good at assessing linear correlations, they can also be effective at implying higher-order correlations as well. Points in the plot may visually approximate other shapes, such as exponential or logarithmic curves. These early insights into the data can provide an excellent starting point for analysts and further generate new hypotheses about the relationships between variables within their data.

While scatterplots allow one to assess the bivariate relationship of data, data sources being analyzed today are typically multivariate. Common extensions to the scatterplot include encoding another variable to color the points on the plot or encoding a variable to the size of the points. However, even more commonly, a matrix of all possible variable combinations may be drawn such that each column of the matrix contains the same x-axis and each row contains the same y-axis for a given scatterplot. Such a matrix is called a *scatterplot matrix* and is useful for visualizing how a data set is distributed through multiple variables.

58.2.4 Parallel Coordinate Plots

While scatterplots can provide an overview of relationships between multivariate data dimensions, they are limited in terms of screen space and the fact that they only present two variable relationships at a time. Even by extending scatterplots to scatterplot matrices, the amount of screen space needed to represent the variables can still be inadequate for showing all possible relationships within a data set. In order to overcome such limitations for multidimensional data explorations, the *parallel coordinate plot* was introduced by (Inselberg 1985).

Parallel coordinate plots are comprised of a series of univariate data axes, with each axis representing some measurement within a data set. These axes are drawn parallel to each other as shown in Fig. 58.2. Each element of the data set is then represented as a line running through its corresponding axis value. As more variable attributes are added, more axes are added and more connections are made. In interpreting the parallel coordinate plots, the idea is that the user will recognize correlation values simply by the shape the plots make. If lines between two axes are close to parallel, they would have a correlation coefficient approximately equal to 1. If lines between two axes intersect one another in the middle of the graph, they tend to have a high negative correlation. If lines cross each other at different angles between two axes, the correlation coefficient between these two variables is approximately zero.

It is crucial to note that the ordering of the coordinate axes will play a major role in the analysis phase. In fact, effective dimensional ordering is a key component of many visualization techniques (e.g., star glyphs, pixel-oriented techniques), and a good ordering of the data can enhance the overall analysis process (Ankerst et al. 1998). Furthermore, the scaling of each axis and spacing also plays a major role in the analyst's ability to extract information from a parallel coordinate plot.

Fig. 58.2 A parallel coordinate plot representing six data attributes

Thus, while parallel coordinate plots are capable of representing more variables than a traditional scatterplot, more consideration needs to be taken when creating the visual representation.

58.3 Choropleth Maps

As discussed in the introduction, visualization is the process of creating interactive visual representations of data in order to generate knowledge about a particular process or phenomena found within the data. While any pictorial representation of the data may have the potential to generate knowledge, the question being asked of the data can directly influence what type of visualization could be most effective. In the previous sections, common statistical graphics were explored, each providing an overview of data distributions. However, in the previously explored visualizations, spatial relationships inherent within the data were ignored.

In geovisualization, often the first question being asked of the data is “compare location x to location y .” Such a question can easily be answered by plotting data elements on the map, and the user can visually explore such data for patterns. Data is often in the form of geographically reference latitude/longitude pairs, or aggregated into geographical areas on a map. [Figure 58.3](#) illustrates various potential geographical visualizations of spatial data on a map. In [Fig. 58.3a](#), locations of criminal offenses are plotted with respect to a centralized location denoted by the pin glyph and the semitransparent circle. In [Fig. 58.3b](#), an aggregation of a pandemic influenza simulation is visualized, where each county is colored by the number of simulated ill patients. In [Fig. 58.3c](#), the estimated probability

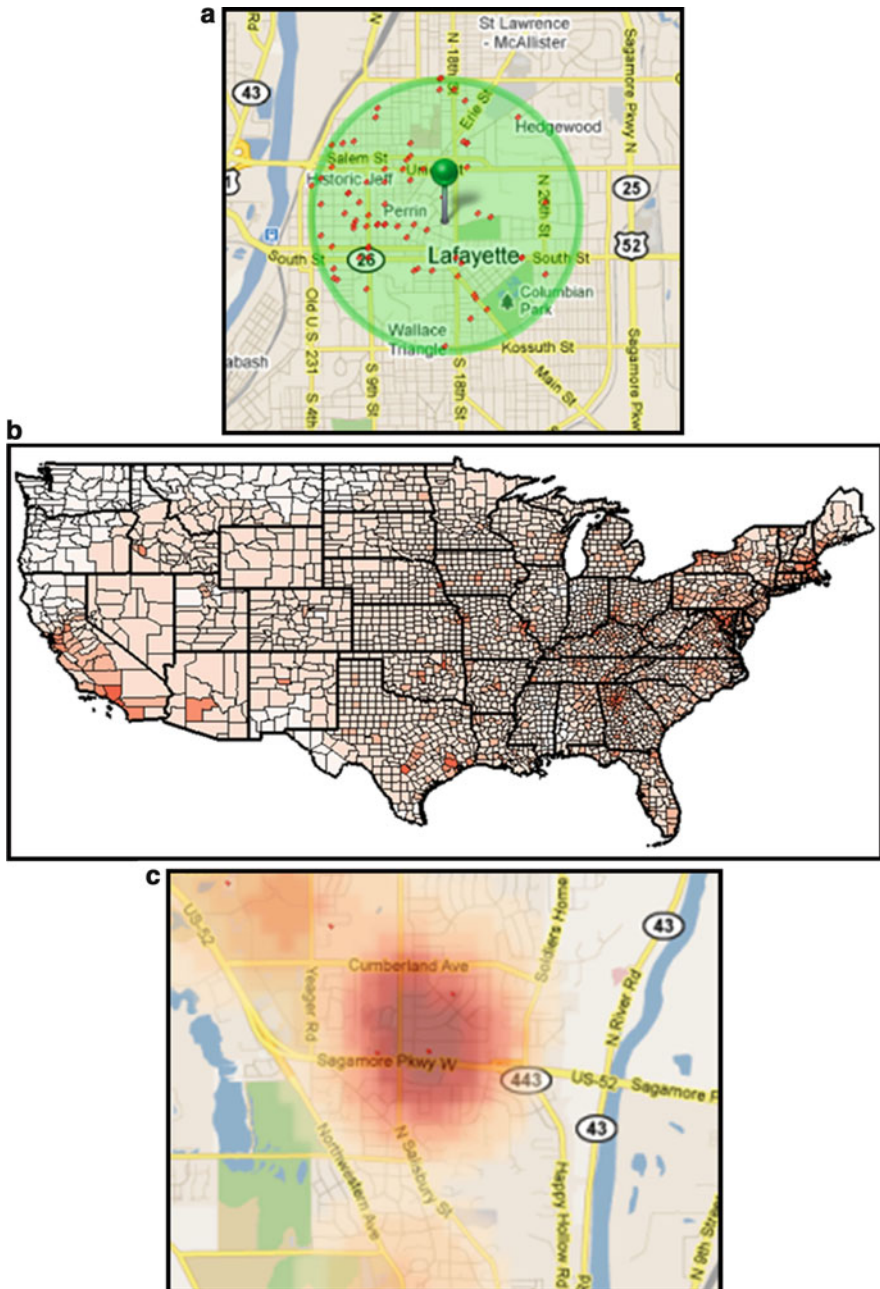

Fig. 58.3 Sample geographical data visualizations. (a) Plotting data as symbols/glyphs. (b) aggregating data by county in a choropleth map. (c) Abstracting and estimating data through density estimation

distribution of a criminal offense occurring is plotted, where the darker color represents a higher probability. Each of these representations is able to answer different questions about the data, and the underlying choice of an appropriate representation is crucial in constructing an effective geographic visualization.

In order to construct an effective geographic visualization, designers must be aware that choices of glyph shape, size, and color can have a direct impact on how the information presented is perceived. Such choices are important not only in geographical representations, but in all visual representations of the data. In *The Semiology of Graphics* (Bertin 1967) and *The Grammar of Graphics* (Wilkinson 2005), the mapping of quantitative attributes (e.g., counts, rates, and other measures) to aesthetics (e.g., color, size, shape) is described in great detail. Of key importance, though, is how these mappings are perceived and interpreted by those using the visualization. The motivation behind this is that the graphics being displayed on the screen are the precise elements of which we are questioning. Thus, when choosing what visual aesthetic will be used, the designer first needs to consider what sort of data is going to be mapped to the aesthetic and how this may interact with other items being rendered. With regard to geovisualization, this interplay between cognition and perception for understanding how maps work is succinctly presented in *How Maps Work* (MacEachren 1995). In this work, MacEachren describes the ways in which the representational choices inherent in mapping interact with our information processing and knowledge construction to form insights into the data.

As such, proper design choices based on data attributes is of critical importance in creating a successful geovisualization. In order to illustrate the importance of such design choices, one can consider perhaps the most common type of thematic map, the choropleth map (see Fig. 58.3b). A choropleth map is a map in which areas are shaded or textured/patterned based on the measurement of a statistical variable in that region (e.g., income, population density). Such maps are based on data aggregated over previously defined regions (e.g., counties, states, countries) and are often used as a first-pass tool for exploring spatial statistics, for example, in exploring the data in Fig. 58.3b one may ask “where are the highest rates of illness?” However, questions such as that can be gleaned simply from a table of numbers, with the choropleth map, a user may now begin comparing rates spatially across regions. In order to effectively compare rates, the colors chosen to render the map need to be interpreted, and much research in both the cartographic and visualization domain has been done on what constitutes an effective color mapping for data values.

58.3.1 Color

The choice of the color scale is a complicated design choice that depends primarily on the data type, domain problem, and chosen visual representation. Typically, one will choose to constrain the color mapping to a univariate scale. While data is becoming increasingly multivariate, for example, the data set may have many

Fig. 58.4 Examples of univariate color maps for data visualization

different statistical measures within a county, many users often have difficulty interpreting bivariate or higher-dimensional color schemes. For a univariate color map, we can constrain ourselves to three types of color schemes (Harrower and Brewer 2003): sequential, divergent, and qualitative (Fig. 58.4).

Each color scheme has its own strengths in regard to what type of data it can best represent. For data containing some sequential order (e.g., rates going from low to high), as the name suggests, a sequential color scheme is the most appropriate. In a sequential scheme, the color is mapped and ordered such that light colors (typically) represent lower values, and dark colors represent higher values. The divisions between each color band are chosen to be perceptually differentiable (Harrower and Brewer 2003) and to also give the impression of increasing and decreasing values to the user.

The divergent color scheme functions in much the same way as the sequential color scheme. The key difference is the use of a comparison point or a zero point from which the data is being explored. In divergent scales, a key value of interest is mapped to the middle region of white, and values above and below this value are mapped along sequential color scales. Careful choices must be taken when choosing the high- and low-end representations for the scale. Often this is done with the concept of “cool” colors and “warm” colors as defined by Hardin and Maffi (1997), where red and yellow colors are considered warm and blues are considered cool.

The qualitative color scheme is unique in that the bands of this scheme are not perceptually ordered. Instead, the bands of color are chosen to be perceptually different and unorderable. This mapping would be used to map distinct data classes to a color, for example, counties that skew towards one political party would be one quantitative band, and those that skew to a different party could be another.

58.3.2 Class Intervals

While the choice of color scheme is critical in creating an appropriate rendering, the way the map is colored is based on a classification of the distribution of the variable being visualized. This classification is analogous to the previous discussion of creating histograms. Here, the number of colors being used is analogous to choosing the number of bins. First, the data over the entire geographical space can be analyzed, providing an overview of the data distribution. This distribution is then transformed into a histogram, where each bin of the resultant histogram will map to a particular color. Unfortunately, choosing the number of bins to represent the data is even more critical of a task when generating a choropleth map. If too many bins are chosen, analysts will be unable to distinguish the different color values mapped to different regions and may be distracted from seeing trends within their data. If too few bins are chosen, the overall trends will be over-smoothed, and patterns

can become hidden within this smoothing. Common methods for classification include quantile, equal interval, and standard deviation classifications; details and comparisons of methods can be found in (Monmonier 1972).

Once the number of colors is chosen (a good description of color maps and classifications is presented in Harrower and Brewer (2003)), then each geographical unit is colored based on its given statistical value. Along with the complexity of choosing categories for choropleth map colors, it is important to understand that size plays a dominant role in our perception. Geographic areas (e.g., counties, zip codes) vary in their shape and area (compare Alaska to Delaware), and a choropleth map is designed such that the map colors provide an equal representation to all areas within the map. Unfortunately, the different sizes of geographical areas can play perceptual tricks on the analyst, hiding changes in the data, or draw attention to unimportant areas of the map. Furthermore, when aggregating data, small areas (like major cities) may overwhelm the data of larger regions (like states). Such aggregation problems give rise to ecological fallacies as choropleth maps provide analysts with ample opportunity to make inferences on their data based on the aggregate region.

58.4 Exploratory Data Analysis

Until this point, the discussion has centered around generating statistical graphics and relatively simple choropleth maps. Each of these techniques has strengths and weaknesses; however, one can think of these techniques as individually being powerful tools for exploring data. The idea of using these tools as a means of investigating data was termed *exploratory data analysis* by Tukey (1977). Tukey compared the exploration of data to that of detective work in which a detective investigating a crime would need the tools necessary to analyze the crime scene (e.g., a finger printing kit) as well as an understanding of how crime works. He noted that data analysts need ways to look at their data, and whether these techniques are graphical, arithmetic, or in-between, the simpler they are made, the better they will be at conveying information to the user. Thus, we can think of the previously discussed visualization methods as a set of tools that can be used in creating geographical visualization systems.

Rather than trying to make the best map that can show all of our variables, it is perhaps best to expand from the notion of a single view. Instead, we should realize that data can be represented in a variety of ways, and given the highly multivariate nature of data being collected, a single map or statistical graphic may not be enough. Rather than trying to make one best view of the data, interactive graphics systems can provide multiple representations of the data. Furthermore, these representations can be programmatically *linked* or *coordinated*.

Figure 58.5 illustrates the concept of coordinating views. In this figure, an analyst is exploring criminal incident report data through a variety of displays. These coordinated multiple views (North and Shneiderman 2000) allow an analyst to create several displays of the data, typically involving statistical graphics and/or

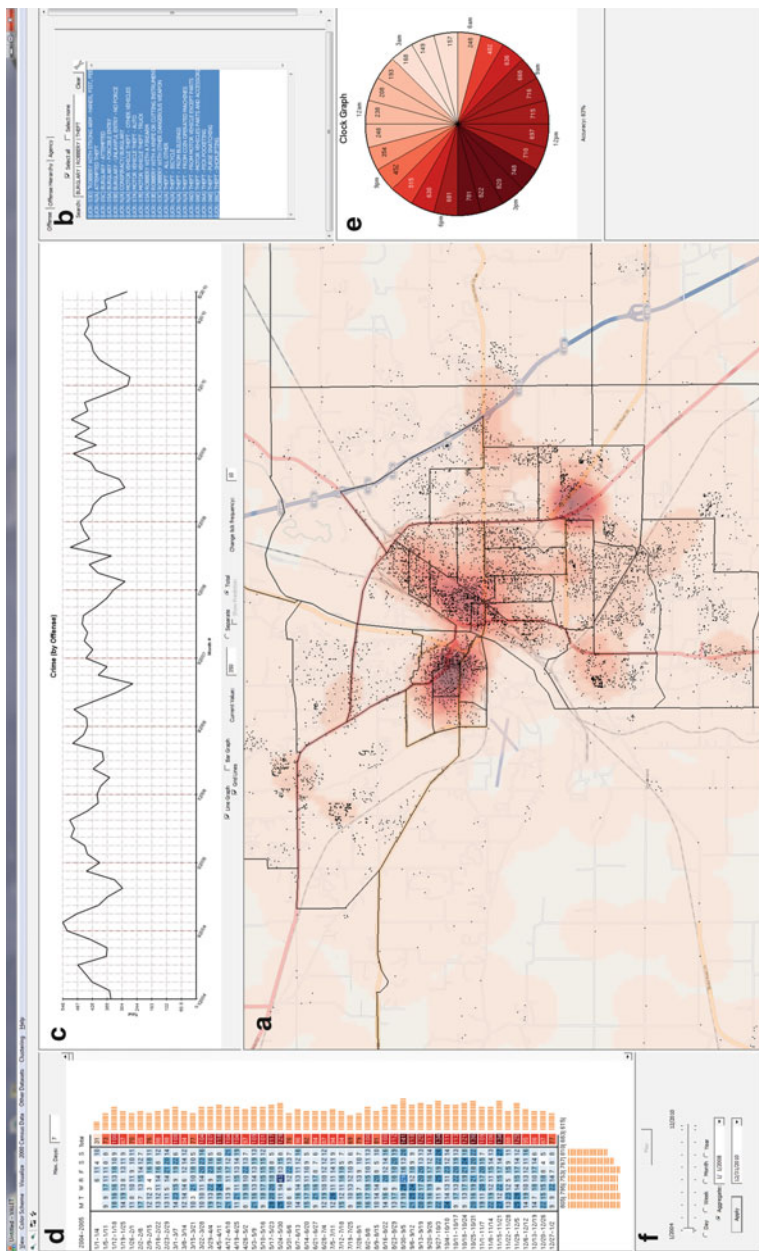

Fig. 58.5 The visual analytics law enforcement technology toolkit. Here, the user is exploring criminal incident reports using coordinated multiple views. The *top-right* window (b) shows an interactive menu that allows users to filter through multiple offenses/offense hierarchy/agencies. The *top* window (c) shows the time series and the *left* window (d) shows the calendar views of the selected incident report data. The *right* window (e) shows a clock view that provides an hourly temporal view of the data. The *bottom-left* window (f) shows the time slider with radio buttons that allow different temporal aggregation levels

geographical maps. Each display provides details on data entities, or aggregations of the data, and is linked through a variety of brushing and selection methods. It is through these interactions with the data that analysts are able to derive even more insight into their data. First, initial data views are typically constructed as a means of describing the data to the analyst, thus providing an overview of the data. An analyst then explores the data, generating and investigating hypotheses in a process that is often referred to as the *Visual Information Seeking Mantra* coined by Shneiderman (1996): “Overview first, zoom and filter, then details on demand.”

Perhaps the most basic interaction techniques are those of *scrolling and panning*. Given a large data set, it is possible that some data will be rendered outside of the screen space. In order to explore this data, the user will need to move the display by scrolling or panning in order to bring other data elements into view. These basic interaction techniques spatially separate the current focus from the larger information space by providing a sliding virtual window. However, scrolling/panning interactions introduce a cognitive burden upon the user where the analyst must now keep track of the context of their data.

Similarly, *zooming* techniques temporally separate focus regions from the information context, inducing a virtual hierarchical ordering at various zoom levels. Zooming also places a significant cognitive burden on the user to assimilate focus into the overall information space as the various zoom levels may not provide any explicit contextual cues. This causes problems such as “desert fog” (Jul and Furnas 1998) in which a view of the data information provides no details on which to base further navigations within the data set.

In order to reduce the cognitive load, *overview + detail* and *focus + context* techniques were introduced. Overview + detail techniques attempt to reduce the cognitive burden associated with exploratory navigation (i.e., panning and zooming) by providing simultaneous synchronized views of overview and detail of the information space. An example would be the thumbnail views provided in Adobe Reader and Microsoft Powerpoint. Focus + context techniques embed the focus region within the larger information space using a transition function in order to overcome issues with cognitive reorientation between overview and detail. Fisheye lenses (Furnas 1986), implemented using a distortion-based transition function, are a commonly used design choice for focus + context techniques. Evaluations of focus + context techniques, however, suggest that they are not always beneficial (Gutwin and Skopik 2003). Object targeting becomes difficult due to “hunting effects” of the fisheye that occurs as a result of magnification. Fisheye distortions have also been found to interfere with a user’s spatial comprehension as well as with other tasks involving location recall and visual scanning.

While such interactions are useful for exploring details within the data, perhaps the most critical interaction is that of *brushing*. Given a statistical graphic, the user can interactively select (brush) data elements, for example, histogram bars, points on a scatterplot, and lines on a parallel coordinate plot. If several different views are linked to the same data source, this brushing will highlight these elements across all views. (Monmonier 1989) further expanded this notion of integrating brushing (particularly scatterplot brushing) with maps, calling this a geographic brush.

By selecting areas of the map, points in the scatterplot would be highlighted, and vice versa. Examples of brushing in coordinated multiple views are shown in Fig. 58.6.

By employing interaction techniques such as brushing, linking, and drill-down operations, users can now explore areas on the graphic and retrieve the exact data values. Furthermore the use of interactive techniques for exploring data graphics has several advantages over traditional static graphics. The first is that such interactivity will allow for greater precision. For example, when analyzing a static map, colors represent a range of value; the addition of interactivity allows one to query the exact value of a region. Second, this interaction not only adds precision but also provides users with a quicker means of data retrieval. Attention is no longer split between looking at the graphic and looking at the legend or scale; instead, users can click regions to retrieve data values. Such techniques all fall under the umbrella of exploratory data analysis, and statisticians within geography have further expanded on these ideas, terming them *exploratory spatial data analysis*. A review of exploratory spatial data analysis can be found in Anselin (1998) and Andrienko and Andrienko (2006).

Exploratory spatial data analysis utilizes the same tools and interaction techniques listed above; however, the focus is primarily on spatial or spatiotemporal data. As such, exploratory spatial data analysis systems link tools such as scatterplots, histograms, and others to interactive maps. The links between these statistical graphics are through brushing and highlighting, where users can interactively select a portion of the data in one view and see these elements highlighted in other views. In this way, users can begin developing and exploring hypotheses about their data. Such tools are then linked to analytic algorithms that can provide deeper insight into data correlations and statistics. These methods focus explicitly on the spatial aspects of the data (spatial dependence, association, and heterogeneity). The goal is to discover spatial patterns and relationships within the data by combining a variety of exploratory data analysis techniques with spatial analysis algorithms and geographic information system tools. Currently, a variety of exploratory spatial data analysis tools are available online, and details of these systems can be found in *Handbook of Applied Spatial Analysis* (Fischer and Getis 2010).

58.5 Exploring Time

The discussion up to this point has focused on visualizations for summarizing data and exploring spatial components of the data. However, we do not want to constrain geovisualization to only spatial data, as often data being collected geographically contains information about rates, movements, and changes over space and time. Instead, we want to create systems and visualizations that are able to answer questions not only about where but also when, and by combining representations that can answer these sorts of questions, we can begin generating insight into how or why something is occurring. In fact, many questions asked about temporal data have to do with the change throughout time. These patterns are formed by the combination of four characteristics (Few 2009): the magnitude of the change, the

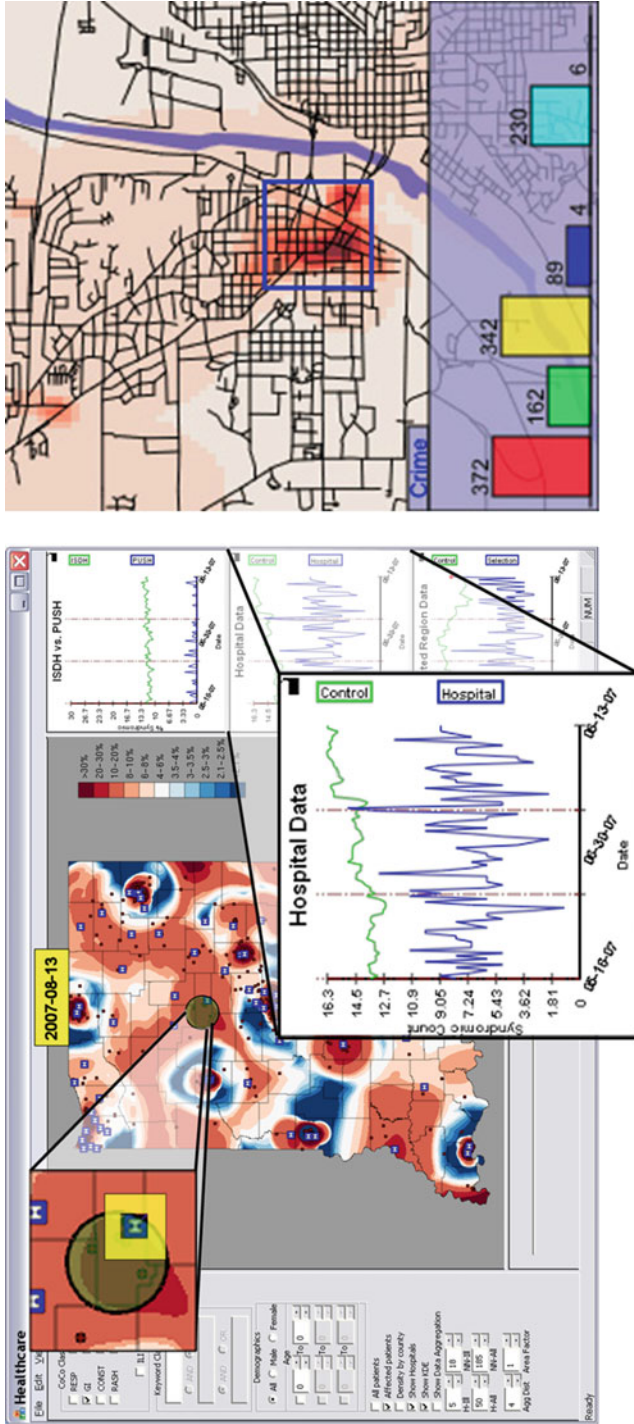

Fig. 58.6 Brushing in coordinated multiple views. (Left) exploring hospital patient records using linked time series plots. (Right) exploring criminal incident reports using histograms

Fig. 58.7 An example space-time cube. Disease rates are mapped over space and time to explore how spread vectors may occur and what clusters are potentially of interest

shape of the change, the velocity of the change, and the direction of the change. A recent review of temporal visualization methods can be found in Aigner et al. (2008); however, this section will focus on two techniques primarily used for spatiotemporal data (as opposed to strictly temporal data).

58.5.1 Animation

One of the most common ways of displaying spatiotemporal data is through the use of animation. Since time moves in a linear fashion, one can animate graphics to show the movement of trends over time. Unfortunately, the animation of choropleth maps brings with it a series of new challenges. In previous sections, a discussion on class interval selection was provided, and the choice of class interval looks at data for only one given time interval (or aggregate thereof). However, when the statistics are allowed to change temporally, the choice of class intervals becomes increasingly challenging. Now, the class choice must work not only across one map, but across multiple maps, and the choice of class interval can potentially emphasize relatively small fluctuations due to temporally global choices in class selection. While such issues complicate the creation of an animated choropleth map, many systems allow for either looped playback animation or user-controlled exploration through an interactive time slider.

58.5.2 Space-Time Cube

While animation provides an obvious way to display spatiotemporal data, it also introduces cognitive burdens onto the user similar as the user now must retain

information of the last state of the data visualization and compare it to the current state. One way of removing such a burden would be to display both space and time concurrently in a visualization. At the end of the 1960s, Hågerstrand (1970) introduced a geographical technique called the *space-time cube*. This technique utilized a three-dimensional diagram (or space-time cube) to visualize spatiotemporal data. The space-time cube consists of a two-dimensional geographical space and a third dimension of time. In this way, spatiotemporal data can be visualized showing movement patterns and trends in a single graphical representation. Figure 58.7 is a space-time cube visualization of disease rates, showing clusters over space and time. Like animation, space-time cubes introduce their own cognitive burdens. When rendering in three dimensions, data occlusion can occur, and rotation, panning, and zooming becomes necessary, thus creating a larger cognitive load.

58.6 Conclusion

Currently, data is being generated and collected at unprecedented rates, particularly georeferenced data. Cell phone locations, georeferenced tweets, street cameras, and others all provide analysts with new streams of data containing locations about incidents that may or may not be of interest. Furthermore, with the development and growing popularity of *geobrowsers*, more and more individuals can now readily map their own georeferenced data. For example, Google Maps provides an API (application programming interface) in which users can quickly plot and browse their georeferenced data in a sophisticated and intuitive user interface. Such tools provide opportunities to explore data from bike traffic routes to crime patterns to individualized restaurant preferences.

In exploring current research in data visualization, it becomes clear that geographical visualization is playing a larger and larger role as a central piece in data analysis and exploration. Geovisualization is not purely about creating maps of data. It is about generating tools and techniques for visually representing spatial and spatiotemporal data and facilitating the exploration of this data for hypothesis generation and exploration. The next step in geovisualization is to expand from hypothesis generation and exploration and begin incorporating tools for data modeling and hypothesis testing. Currently analysis tools (e.g., Anselin et al. 2006) are incorporating both interactive graphics and advanced statistical analysis algorithms for data exploration and analysis.

Given the ability of the human visual system to recognize patterns within data sets, it is imperative to allow analysts to explore and interact with their data. In the problems given here, data analysis was presented as more of a searching and hypothesis generation problem; however, it is often the case that data sets have been generated with specific domain questions in mind. By tailoring our analysis, visualizations, and interactions to these domains, it is possible for an analyst to gain more insight into their data than would have been possible with static graphics or traditional tools. Furthermore, this chapter has discussed only the most basic components of visual analysis. Hypothesis testing algorithms and data mining tools exist that allow

analysts to readily sift through their data; these techniques are being coupled with novel graphical displays in an attempt to generate large amounts of insight into data. The details presented here form only the beginnings of geographical visualization.

Current research explores geometrical modeling of cartographic techniques such as flow maps. Notations, streamlines, and other visual cues have been added to space-time cube visualizations as a means of enhancing information. Three-dimensional density maps can be easily generated and explored using interactive techniques, and combinations of various textures, glyphs, symbols, and colors are being explored as a way to represent larger amounts of data to a user in a single display. These visuals are used not only in the analysis and exploration process but also as a means of explaining data trends and narratives to others. With geographical visualization, the general populace understands a map, and by linking their data to these sorts of displays, they become invested in the analysis. However, care must be taken when choosing our graphical representations. It is easy to lie with statistics, and as shown here, statistics is one of the foundations of data visualization. As such, we should strive for creating reliable and correct representations of data, while providing analysts with interactive means of exploring and ultimately analyzing their data.

Abstract

The modifiable areal unit problem (MAUP) is a serious analytical issue for analysts using spatial data. The MAUP manifests itself through the instability of a wide range of statistical results derived from analysis on spatially organized data. When spatial data are aggregated, the results are conditional on the spatial scale at which they are conducted, and the configuration of the areal units that are employed to represent the data. Such uncertainty means that the results of spatial data where the MAUP has not been considered explicitly should be treated with caution. Although solutions have been proposed, none have been applicable in more than a couple of specific cases. As such, it is likely that the MAUP will never be truly solved. This chapter charts the two related aspects of the MAUP, the scale and zonation effects, and details the role of spatial autocorrelation in understanding the processes in the data that lead to the

e-mail: d.manley@bristol.ac.uk

statistical nonstationarity. The role of zone design as a tool to enhance analysis is explored and reference made to analyses that have adopted explicit spatial frameworks.

59.1 Introduction

A serious problem for analysts of spatial data is that while the phenomena they are investigating may be continuous, the data available frequently are not, and the areal units used to present the continuous data are arbitrary compromises designed to suit a wide range of uses rather than spatial equivalents of the day, month, or year. As a consequence, statistical analysis of individual data that has been aggregated into areal units is susceptible to nonstationarity across a wide range of measures. This problem is known as the modifiable areal unit problem (MAUP), and it has vexed users of aggregate data for many decades. Countless investigations have demonstrated that it is unlikely that an analytical solution to the MAUP will be identified, and those solutions that have been proposed frequently suffer from substantial flaws. Indeed, as yet, we have neither a full and detailed understanding of the problem nor the underlying causes. It is unlikely that an analytical solution to the MAUP will ever be realized due to the wide range of possibilities that arise when the partitioning of continuous space is implemented as well as the wide range of analytical tasks that aggregated data are required to perform (for comprehensive overviews of the MAUP, see Openshaw 1984; Wong 2009). Instead, the MAUP needs to be accounted for clearly in the research hypothesis that precedes analysis. In the twenty-first century, spatial data are an increasingly important factor in everyday life. Almost all nations in the developed world collect and publish data using administrative boundary systems – areal units. In the United Kingdom, the decennial population census is published using small, low-level areal units. Small area geographies, for a comprehensive range of area characteristics such as are available for the British Census, are valuable as the hidden aspects of the problem are less likely to occur, other things being equal, at fine levels of granularity than coarse ones. It is also worth noting that the small areal units of the British Census were designed explicitly drawing on the principles of the MAUP, promoting, amongst other things, internal homogeneity across a range of important indicators such as housing tenure. The problem of the MAUP is magnified by the temporary nature of the areal units and the frequent revisions that are made to the coverages to reflect changes in population data.

Despite the prevalence of the MAUP in spatial data, it is an issue that is all too frequently ignored or neglected in geographical analysis. A search in Google Scholar on the term “modifiable areal unit problem” reveals only 4,160 publications, a low number when you consider the number of papers that deal with aggregated data in their analysis (around 400,000). The lack of attention paid to the MAUP has, perhaps, two underlying causes. Firstly, the readily available nature of many areal unit systems means that the majority of research using aggregate data adopts areal boundaries that are generated a priori and an engagement with the creation of areal units is not required. Secondly, the results of many quantitative studies that employ aggregate data of one

sort or another rely on the implicit assumption that the MAUP isn't a significant problem in order to present valid results. To acknowledge the MAUP, even informally, would be to question the validity of the analysis conducted and conclusions reached. Openshaw's conclusion from almost three decades ago remains as pertinent today as it was when he wrote it: "this is hardly a satisfactory basis for the application and further development of spatial analysis techniques in geography" (1984, p. 5).

This chapter explores the problem of the MAUP in the context of spatial data analysis, outlining the two major aspects of the problem, the scale effect and the zonation effect. Definitions are provided for both these aspects, and examples are drawn from the literature to illustrate the problems. Following these two sections, an overview of the evidence relating to the MAUP is provided.

59.2 MAUP Definitions

There are two aspects to the MAUP known as the scale effect and the zonation effect (also called the aggregation effect in some literature (for instance Openshaw 1977), but since the process of aggregation is involved in both scale and zonation decisions, an important distinction is made here, and the term zonation effect employed). This section outlines the two aspects with reference to relevant examples and provides the context for a discussion around empirical results in the following sections.

59.2.1 The Scale Effect

The scale effect arises because of the nested hierarchies within which human society is arranged and is expressed through the task of choosing the most appropriate scale for analysis (Arbia 1989) (Fig. 59.1). It is rarely that clear at which spatial scale an analysis should proceed, and frequently, there are multiple spatial scales at which an analysis could theoretically be conducted. Drawing on the United Kingdom Census as an example, output areas (OAs, typically 140 individuals) form the basic spatial units and can be aggregated into higher-level spatial units, such as wards (usually a couple of 1,000 individuals) and districts (many 100,000s of individuals).

The "classic" example of the scale effect was published by Gehlke and Biehl (1934) and used three different datasets including random coin tosses, census data, and experimental groups of rural counties drawn from the United States (see also Yule and Kendal 1949). They demonstrated that coefficients from correlation analyses between, for instance, census data reporting juvenile delinquency and monthly house rentals tended to increase as the number of areal units representing the data decreased. Table 59.1 reproduces the results of their correlation analysis. While the census data may be susceptible to structures within the data that cannot be observed, which in turn cause the instability of the statistical results, the coin toss data demonstrated that correlation coefficients changed even when the underlying data were generated randomly, and each data unit was independent of all others. From their analysis, Gehlke and Biehl concluded by questioning whether or not

Fig. 59.1 The scale problem: The three different scales could represent (a) output areas, (b) wards, and (c) districts

Table 59.1 Correlation coefficients under aggregation using juvenile delinquency and monthly rentals (from Gehlke and Biehl 1934, p. 169)

Number of areal units	Correlation coefficient (r)
252	-0.502
200	-0.569
175	-0.580
150	-0.606
125	-0.662
100	-0.667
50	-0.685
25	-0.763

“a geographical area is an entity possessing traits, or merely one characteristic of a trait itself” (p. 170). In essence, they urge caution in the treatment of data from areal units and “that variations in the size of the correlation coefficient seemed conditioned on the changes in the size of the unit used” (op.cit.).

Exploring the scale effect, Kirby and Taylor (1976) use data on referendum voting patterns to illustrate the potential pitfalls and identify pockets of the population who vote differently to the overall outcome for an area. The implication of this finding being that if analysis is conducted at difference scales it is possible to produce different area results from a single pattern of individuals voting. Kirby and Taylor also discuss the dilemma of choice of scale: at a scale that is too small, then it is not possible to compare data sources from different (modifiable) unit systems. However, with the scale too large, then much of the more local-level detail within an analysis is lost through the aggregation process. The scale effect has, therefore, a number of different elements, including the enhancing or smoothing of spatial processes, akin to the statistical smoothing of data to remove noise. The nontrivial nature of the scale effect was emphasized by Openshaw (1984), noting that even a relatively small set of zones can produce a sizable range of combinations: for instance, combining 1,000 zones into a new system of just 20 groups produces 10^{1260} unique combinations!

59.2.2 The Zonation Effect

Once the scale of the zonal system has been determined, then we can consider how the space is to be divided up—the zonation effect. The zonation effect occurs where there are

Fig. 59.2 The zonation problem. Each of these diagrams demonstrates a division of a sample space into five distinct areal units, yet each could potentially yield different results

Table 59.2 Correlation coefficients from Openshaw and Taylor (1979, p. 129) showing zonation effect (adapted)

Number of areal units	Correlation coefficient (r)
Six republican-proposed	0.482
Six democratic-proposed	0.627
Six congressional districts	0.265
Six urban/rural regional types	0.862
Six functional regions	0.713

“any variations in results due to alternative units of analysis where . . . the number of units, is constant” (Openshaw and Taylor 1979). There are potentially an infinite number of different ways in which a continuous space can be subdivided into discrete areal units. A diagrammatic interpretation of the zonation problem is presented in Fig. 59.2.

For Openshaw (1984) the zonation effect was by far the greater of the two aspects of the MAUP, as there is considerably more freedom choosing the delineation of boundaries than in choosing the number of zones required. The consequence of this is that “the process of zonation becomes susceptible to the whims of those involved in the overall aggregation process” (Openshaw and Taylor 1981, p. 61). While this position may be extreme, it makes the point that there are serious problems with the arbitrary nature of the many areal units.

Openshaw and Taylor (1979, 1981) conducted one of the largest investigations into the MAUP. Replicating the earlier work of Gehlke and Biehl, they used correlation analysis to assess the instability of statistical analysis as a consequence of the MAUP. In the first instance, they correlated the proportion of republican voters against the percentage of the population above 65, using the 1970 US Census. To assess the impact of the zonation effect, Openshaw and Taylor produced correlation coefficients for multiple arrangements of counties in the state of Iowa. They set the scale constant each time aggregating the base units into six counties. Table 59.2 reports the results of their analysis.

Openshaw and Taylor (1979) demonstrated that it was possible to obtain highly changeable correlation coefficients for a single set of data. They went further than this in the article by attempting to describe the universe of correlation coefficients that were possible to achieve using the different scales of zonation. For many of the scales, they claim that the theoretical range of coefficient was from -0.999 to 0.999 . However, this was rarely the case for many of the zonation systems that they devised.

For instance, using 72 zones the minimum found was -0.579 , and the maximum was 0.927 . This demonstrates the impact of the zonation effect as differing boundary choices change the correlation coefficient values.

59.3 Approaches to Understanding

There is a vast body of research that has sought to gain greater understanding about the MAUP and how it can impact the results of statistical analysis. This section reviews work that has sought to unpick how the MAUP can lead to different results in statistical analysis. Starting with the simple examples of uni- and bivariate analysis, evidence is provided that shows the potential severity of the MAUP. This is built on by introducing research that has examined the impact of the MAUP in models that are more explicitly spatial in configuration. Attention is then paid to the role of spatial autocorrelation and spatial cross-correlation, two of the fundamental processes that lie behind incidence of the MAUP. Finally, attention is paid to the process of zonation, or zone design, and the research that has been undertaken to explore the MAUP from the perspective of the aggregation process.

59.3.1 From Univariate Statistics to Spatial Models

There are many examples of investigations into univariate and bivariate parameter instability as a consequence of the MAUP. In a recent article that clearly demonstrates the importance of preserving the availability of small area estimates for understanding societal processes, Flowerdew (2011) took 2001 Census data for England and presented an investigation on the severity of the MAUP. While there are many studies that demonstrate that it is possible to obtain different statistical results for different spatial scales and configurations, there are fewer studies that then provide statistical evidence that these differences are significant. Developing this theme and 18 common variables, Flowerdew demonstrates that even just using the three standard spatial scales that the data are released at leads to results with significant statistical differences. Flowerdew uses the Fisher transformation to standardize the correlation coefficients and concludes that after standardization the MAUP effect leads to different results in around 60 % of the cases. In general, under increasing scale aggregation, the increase in correlation coefficient is a consequence of the data smoothing properties associated with the aggregation process. As such, the variation between variables tends to decrease as aggregation increases – the heterogeneity *between* units will fall as greater number of the population are combined into single entities and the heterogeneity *within* units increases.

There are fewer examples of investigations into the MAUP in multivariate analysis. However, Fotheringham and Wong (1991) did tackle this problem using American Census data and demonstrated the problem with a regression model that related mean family income for multiple unit configurations at various spatial scales.

As with the work presented above, Fotheringham and Wong demonstrate that different spatial scales lead to systematic variability in the outcome of the regression analysis so that for some parameters (percentage elderly and percentage blue collar workers) the relationship to mean household income becomes more negative. Conversely, other parameters (percentage of home owners and the percentage of black residents) become systematically less negative as aggregation increases. Again, the importance of the MAUP is demonstrated by investigating whether the differences in the parameters obtained at the different scales and zonal configurations are statistically significant. Fotheringham and Wong use distribution of the parameter estimates and judge significance using a standard difference means test with 1.5 standard deviations (the 95% confidence level) as the key cutoff point. As they conclude, there are “many places[...] where the parameter estimates are significantly different” (1991, p. 1035).

Although the models above consider the MAUP, none of them explicitly incorporate the spatial structure of the data. Moving beyond these aspatial models requires a more complex modeling strategy and the explicit adoption of a spatial framework. An example of a spatial investigation into the MAUP has been conducted by Baumann and colleagues (1983). In their work, they investigate what they term as the scale hypothesis and the aggregation hypothesis (the scale effect and the zonation effect in other words) with respect to the supply of labor in multiregional labor markets. Adopting a standard MAUP approach, they suggest that the way in which the model of labor supply is measured through participation rates and commuting flows may be affected by the scale at which an analysis is conducted and the regions through which the multiple labor markets are realized. In their findings, Baumann and colleagues present a number of interesting outcomes: firstly, in terms of determining labor participation (the number of males and females in employment), the effects of scale are relatively small. Thus, there is little variation in the result as the spatial scale of the analysis is altered. However, in a model representing commuting patterns, the scale effects are much larger, a finding which intuitively makes sense as commuting is only realized in the framework when zone boundaries are crossed. Increasing the scale will, all other things being equal, reduce the number of boundaries and so the level of commuting. In surmising their findings, Baumann and colleagues highlight that the spatial framework that is adopted for an analysis is crucial, and it is “by no means admissible to ignore possible effects of the choice of a spatial framework in spatial model building” (p. 67). Finally, they suggest that when seeking out the most appropriate spatial framework, a range of criteria including model R^2 , t-values, and a priori signs should be considered. This might lead the analyst to conclude, therefore, that the most appropriate spatial framework would be one that leads to the greatest level of explanation in the final model the best model performance overall. Within an econometric framework, this is an entirely reasonable assertion.

A major area of interest where the spatial organization of individual units within and between areas is segregation (see also Poulsen et al. 2011). It is a highly spatial phenomenon, and there are many examples within the literature where spatial statistics have been used to attempt to understand the role that the definition of

the areal units and the scale of analysis can have on the resulting measures. Wong's investigation into segregation indices and the MAUP demonstrated that, in general, as the spatial resolution (scale) increases, the greater the degree of segregation identified (Wong 2003). As discussed above, the scale process is akin to data smoothing, so that sharp inconsistencies between smaller units are removed. Thus, as the areal units become smaller, the potential level of homogeneity within the areal unit will increase because there are fewer individual data points represented within each unit (up until the level of the single individual atomistic unit beyond which it is no longer realistic to decompose and represent a perfectly homogenous social unit). Using multiple scales of aggregation, Wong demonstrates that different scales produce different results for the dissimilarity index, D (see Duncan and Duncan 1955). To understand the impact of the MAUP scale effect, Wong proposes that the index can be decomposed into regional and local effects and that the local-level measure demonstrates the deviation of each unit from the global regional D value. The range of values achieved can give insight into how much each local unit influences the overall segregation pattern. High values record areas that deviate substantially from the global regional value, while lower values demonstrate congruence. Of course, one influence that Wong does not attempt to cover is the effect of zonation differences. It is clear however that with a small extension it would be possible to use Wong's methodology to effectively assess the impact of altering the boundaries on the resulting segregation outcomes. A second example using the diversity index, H , is used to highlight that with modification, it is possible extend the decomposition process to other segregation measures.

Two further examples of the MAUP impacting on the results of spatial statistical analysis are provided by the health literature, where research into the MAUP has been particularly active. The first study investigated the effects of the Dounreay Nuclear Power Plant in relation to instances of childhood leukemia as part of a public inquiry into an application to introduce reprocessing facilities (Heasman et al. 1984). In close proximity to the Dounreay plant were apparently high incidences of childhood leukemia. To investigate whether or not these represented significant clusters of leukemia in children, the Scottish Health Service analyzed data recording all incidences of cancer between 1968 and 1986. The initial results of the analysis reported that there was a significant excess of cases in the Dounreay area. However, at the subsequent public inquiry, a number of methodological weaknesses were identified, amongst which was the issue of boundary definition, the MAUP. Wilkie (1986) provided details of the methodological problems which included the potential gerrymandering (manipulation) of the time period studied and radial distances used to detect the cancer clusters. Creating tight boundaries around cancer points would have the effect of forcing the mortality rates upward, creating artificially high results because of the smaller population bases. Similarly, looking at a different time period, either by cutting the time series data into different lengths or curtailing the investigation at an earlier time point, would have the effect of altering the outcomes observed. Further problems arise from the presence of edge effects (cases appearing near the edge of the study space) and irregularly

shaped areal units used for the aggregation. Finally, the use of areal units as a means to imprecisely locate individual incidence data introduced small errors which cumulatively could result in the erroneous generation of clusters where there were not any, or vice versa. In conclusion, the findings of the Dounreay analysis were difficult to evaluate robustly as the choice of radii and time periods for their study area “are arbitrary” (p. 266). Any clusters of cases in one area and time period could be eliminated simply through an alternative choice of radii or time periods. The second of the health examples is provided by Odoi and colleagues (2003). They were investigating the impact of the MAUP on the spatial distribution of human giardiasis (a parasitic infection causing diarrhea) in Canada. The study sets out to explicitly examine the impact of alternative spatial scales on the identification of infection clusters and whether the most appropriate statistical framework for assessing the clustering was using global or local statistics. Their analysis demonstrated that using a fine spatial scale with relatively small units enabled the detection of clusters that were hidden at the higher spatial scale. They also identified that local statistical measures provided more clustering detail than the global measures and as such were more appropriate for the exploratory analysis of patterns in spatial data.

59.3.2 The Importance of Spatial Autocorrelation

Tobler’s First Law of Geography states that all things are related, but near objects are more related than distance objects (Tobler 1970). More formally, the degree of similarity is known as spatial autocorrelation, a concept developed by Michael Dacey in the 1950s at the University of Washington (see Getis 2010 for a comprehensive review). Cliff and Ord (1981) make the link between spatial autocorrelation and the MAUP more explicit, and note that the size of the cells in the areal unit system is important in determining the strength of the spatial autocorrelation. All other things being equal, larger areal units will have lower levels of autocorrelation than smaller ones. In other words, at different spatial scale, different patterns and degrees of spatial autocorrelation will be present and will impact on the structure of the data that are being analyzed.

Returning to the work of Fotheringham and Wong (1991) after assessing for the significance of the changes in parameter estimates, they investigated whether there was a link between these changes and spatial autocorrelation in the variables included in the analysis. Their conclusion was that there was little link between the severity of the MAUP and the degree of spatial autocorrelation in a (pair of) variable(s). They reinforced this conclusion by citing the examples of the percentage of black individuals and the percentage of home owners as displaying regression parameters that behaved very similarly under aggregation in terms of the significant change magnitude but that possessed very different spatial autocorrelation structures.

The work of Flowerdew and Green (1994) provides a way into understanding the properties of data with spatial autocorrelation. Using simulated data, they explore

the outcomes of multiple realizations of areal units at a given scale. The use of simulated data was important as it enabled them to analyze data with known spatial autocorrelation properties in comparison with real data where spatial autocorrelations are not known and may be impacted by other (unmeasured) biases as well. Green and Flowerdew aggregated their basic grid of raw simulated data into new areal units in three ways: (a) randomly; (b) systematically, based on the value of one of the simulated variables; and (c) spatially, by combining spatially contiguous blocks. The new zones that were constructed aspatially with random aggregation show no change in the subsequent correlation or regression outcomes (although the standard error is increased as a consequence of having fewer data points); the systematic aggregation increases the correlation coefficient but has no effect on the regression parameter, while spatial aggregation alters both coefficients. In conclusion, they argue that the effects of spatial autocorrelation may “result from contiguous processes affecting the distribution of one or more of the variables being analysed, or the spatial distribution of other variables which have effects on these.” This explicitly expresses the realization that the variables of areal units may display linked characteristics.

Developing their work on spatial autocorrelation further, Green and Flowerdew (1996) and Flowerdew and colleagues (2001) extend their analysis to consider the impact of spatial autocorrelation between variables as well as within variables, a phenomenon which they term “cross-correlation.” They define cross-correlation as the relationship not only between variable X and variable Y at a specific point in space but also being between X and Y at neighboring points in space. In Green and Flowerdew (1996), they continue using the simulated data but this time aggregated into spatially contiguous zones. They then model the relationship between the simulated X and Y firstly using a standard regression model and then using a model that incorporates the simulated cross-correlation between X and Y. Green and Flowerdew call the cross-correlation a regional effect, and they introduce a regional term into the regression model so that there is a regression coefficient for the local effect and a regression term for the regional effect. Having used simulated data for an initial exploration, attention is then turned to repeating the analysis with real data derived from the UK population census. Setting up an investigating into unemployment and ethnicity, Green and Flowerdew find evidence that confirms their cross-correlation hypothesis and demonstrates the usefulness of the local and regional regression approaches. In Flowerdew et al. (2001) they illustrate the same concept using the example from Fotheringham and Wong (1991, see above). They theorize that cross-correlation can occur because the relationship between the “attractiveness of housing (and hence its value and the likely income of the residents) may depend not just on race and class in the immediate vicinity but also on such characteristics in neighboring areas” (Flowerdew et al. 2001, p.91). Within this work is the useful conclusion that while the presence of spatial autocorrelation is important in determining the incidence of the scale effect in correlation coefficients, it does not impact on the regression coefficients. The regression coefficients are altered when cross-correlation is present between the X and Y variable.

Arbia (1989) introduced the term “systematic spatial variation” to create a formal framework to understand the relationship between the MAUP and spatial autocorrelation using Cliff and Ord’s work (1981) as a starting point. Using data relating to the residential location of population organized on a 32 by 32 lattice, Arbia simulated the MAUP by aggregating the grid into combinations of 16 by 16, 8 by 8, 4 by 4, and 2 by 2. The results of the investigation demonstrate that with aggregation there is an increase in the level of variance and that as the level of aggregation increases, the estimates of the variance of the data become more unreliable as the number of observations diminishes with fewer degrees of freedom. Arbia concluded the effects of the MAUP under aggregation were the result of the relationships between near objects. Building on this finding, Manley et al. (2006) demonstrate that spatial autocorrelation structures rarely match the boundaries of the zones that have been used to represent the data and that these differences between the spatial extent of the autocorrelation is, in part, one of the causes of the MAUP.

Over time, more complex models were applied to the MAUP. For instance, Amrhein and Flowerdew (1989) investigated the effects of MAUP in relation to Poisson regression. The results of their analysis demonstrated that within the Poisson model there is little zonation effect to be found. However, this is not a cause for celebration by the spatial analyst because a methodology to overcome the MAUP has been identified: the lack of effect is the consequence of the analytical technique, not because the results are free from the MAUP. The finding of Amrhein and Flowerdew is important because they add a new dimension to the MAUP discussion. They demonstrate that the choice of model for an analysis is just as critical as the zonation and scale choice itself. This conclusion does not, however, mean that the world of the analyst dealing with spatial data is bleak as might initially be presumed. Amrhein (1995) uses the finding above to develop six heuristics for analysts and suggest that certain statistics and results (for instance, the standard deviation of coefficients, or the Pearson correlation coefficient) exhibit greater changes due to MAUP (scale) than other statistical methods (for instance, mean or the variance).

The work investigating spatial autocorrelation, and the related cross-correlation, has demonstrated that the MAUP is likely to be caused by the interrelated nature of the spatial variables being represented in the areal units. Thus, when aggregation is undertaken and the spatial structure of the data has a direct influence on the resulting zonations the MAUP occurs. Manley et al. (2006) further demonstrated the complexity of this problem by analyzing British Census data and showing that spatial autocorrelation rarely coincides with the boundary lines of areal units and when aggregation is undertaken it frequently incorporates small zones with differing degrees of spatial autocorrelation.

59.3.3 Exploring the MAUP Through Zone Design

A cursory overview of the statistical investigations into the MAUP would suggest that the vast majority of effort into explaining the MAUP has been concerned with the scale effect. In fact, the zonation issue has also been tackled extensively, and in

some regards, with more success than the scale issue. The zonation issue research has largely focused on two aspects: how can zonations be created that are appropriate to the analytical task and what are the properties of zonation that lead to the MAUP occurring. The ability to provide multiple realizations of zonal systems within one analysis space enables the scale effect to be investigated further, as many different zonations can be derived as scale changes.

If zoning systems are problematic, then it is useful to consider why and how zoning systems may be (re)designed. The rationale behind is summed up by Openshaw and Rao (1995): “[t]he new opportunity provided by [the increasing availability of digital] boundaries is not to demonstrate the universality of MAUP effects, or to manipulate results by gerrymandering the spatial aggregation used, but it is to design new zoning systems that may help users recover from MAUP.” Openshaw (1978) presented two extremes of zone design approaches to illustrate the problem. A conventional statistical approach within which spatially aggregated data can be viewed as fixed, or a model that assumes that the “undefined parameters [are] fixed, and the identification of an appropriate zoning system has to be made in some optimal manner.” The first view is unacceptable due to the interdependence between the choice of zone and results achieved. From a statistical standpoint, the second solution is as poor as the first one was from a geographic perspective, as it could serve to remove the comparability between studies.

The process of zone design presents a compromise through the creation of the system that satisfies (or at least suffices) a set of criteria. One ideal outcome for a good zonal system would be a set of zones that was as simple as possible, homogenous (against a single or set of variables defined by the user), and compact. In contrast, Openshaw (1978) increased the complexity of the problem and suggested that shape (as distinct to compactness) and population size are also important elements to include. Depending on the task for which the zones are required, each of these criteria may be made more or less important. One of the first attempts at automated zone design was undertaken by Stan Openshaw (1978) with the Automatic Zoning Procedure, implemented in the Automatic Zoning Program (AZP). In more recent research, the process of zone design has become integrated with the mainstream literature around Geographical Information Systems (GIS) and enabled users to define their own zonal units. AZP was extended and became the Zone Design System (ZDES) and has been employed in a wide range of zonal scenarios. One prime example is explored in Openshaw and colleagues (1998) which commented on the first fully automated basic spatial unit (bsu) design process undertaken for the publication of the 2001 UK Census data. As Openshaw and colleagues point out, one of the major barriers to successful zone design is the realization that the problem is not one that can be tackled in the traditional software programming sense, where a global optimal solution is identifiable – if there was a global optimal solution, it is not clear how it would be identified, and in many cases there is no optimal solution. Rather, there is a range of suitable solutions which present sufficient solutions given the criteria that have been inputted.

Other systems have been developed specifically for zonal data analysis and redesign. An alternative to ZDES, is AZM (Automated Zone Matching). AZM “[i]mplements zone design on a set of zones described by polygon and arc attribute tables exported from Arc/Info or generated by users’ own programs. [The program is designed to optimize] the match between two zonal systems, or the aggregation of a set of building block zones into output areas with a range of user-controlled design parameters” (Martin 2003). AZM uses the AZP procedure outlined by Openshaw (1978) and is conceptually similar. However, unlike ZDES, the AZM program was not designed specifically for the purpose of zone design. The primary function of the program is to provide a means to enable two incompatible zone coverages to be aggregated into a higher-level zone system that enables comparison (Martin 2003). However, through the input of two identical coverages, it can be used to perform an aggregation function (Martin (2003)). Nevertheless, the advantages of being able to control the aggregation process with regard to shape, key variable homogeneity, and population size mean that it is suited to the design of analytically appropriate zonal systems. In other words, zonal systems that better reflect the required uses of data, as opposed to purely “random” aggregations where there is little or no control over one or all of these factors, are not relevant in the context of research where desired scales of aggregation are required.

Finally, evidence of the potency of understanding zone design and exploiting it was presented by Boyle and Alvanides (2004). Using a case study involving the City of Leeds, and measures of deprivation, they demonstrate that it is possible to change the ranking of Leeds relative to other cities across the UK by using different boundary systems. This is of particular importance, as the European Commission was offering what are termed structural funds to aid the reduction of inequalities at a local level within member countries. Using the 1998 Index of Local Deprivation (ILD) based on the 1991 Census, as published, Leeds appeared 56th out of 57 cities. However, simply by redrawing the boundaries using alternative population thresholds to define the city area, the ranking could be changed to 11th. Applying another different criteria for the aggregation, whereby the scores were taken for wards, not local authority districts, enabled a further change in the ranking, making Leeds the 3rd most deprived city in England. The initial ranking of 56th would not have secured funding while the final ranking of 3rd would ensure a large flow of money into the city. Both of these examples highlight the potential difficulties, opportunities, and concerns that research using aggregated data should address.

59.4 Conclusion

This chapter has provided an overview of the modifiable areal unit problem (MAUP). With the growth of spatially coded data available, the potential for analysts to be confronted with areal units in analysis is increasing dramatically. Knowledge of the potential pitfalls of conducting analysis containing areal unit data is vital when dealing with areal unit data in analysis. This is true both when the areal units are the objects of the analysis as it is when the areal unit data are included to

provide context to other sorts of information. In many cases, it is important to acknowledge the presence of the MAUP in analysis while accepting that the results may be conditional on the scale and zonation scheme employed.

Previous research has demonstrated that it is unlikely that a global solution to the MAUP will ever be found: indeed, to do so is to deny the inherent spatiality of the data that is under investigation, and the removal of the MAUP would be to remove the very object of interest! Previous research has also demonstrated that spatial autocorrelation and cross-correlation are likely to be very important in understanding the degree and severity of the MAUP. As such, these are key topics that the (spatial) analyst using aggregate data should be aware of and acknowledge in their analysis. Therefore, when dealing with spatially organized data, the analyst must adopt a geographically informed process of hypothesis formation. Analytical scale should become a primary factor that is explicitly considered rather than an issue that is implicitly dealt with and all too frequently assumed away in the name of pragmatism. In many cases, this will require the analyst to adopt an approach whereby multiple scales of measurement and analysis should be considered, or a highly rigorous spatial framework for an analysis constructed. This chapter is all too brief to provide a comprehensive view of all the work that has been conducted into the MAUP. Nevertheless, it hopefully sheds sufficient light on the subject and processes to provide the reader with the means to adopt a more critical and nuanced approach to their analysis.

information and knowledge, waiting to be discovered. The field of spatio-temporal data mining (STDM) emerged out of a need to create effective and efficient techniques in order to turn the massive data into meaningful information and knowledge. This chapter reviews the state of the art in STDM research and applications, with emphasis placed on three key areas, including spatio-temporal prediction and forecasting, spatio-temporal clustering and spatio-temporal visualization. The future direction and research challenges of STDM are discussed at the end of this chapter.

60.1 Introduction

With automatic sensor networks and crowd sourcing now being used extensively to monitor a diverse range of phenomena, the amount of data being collected with both spatial and temporal dimensions has increased dramatically. Data collected at two or more locations and times make up space-time series, examples of which include daily temperature series at meteorological stations, monthly crime rates of world capital cities and daily traffic flow on urban roads. These space-time series are massive and continually growing. Spatio-temporal data mining (STDM) is the extraction of unknown and implicit knowledge, structures, relationships, or patterns from these massive datasets. STDM techniques and tasks include spatio-temporal forecasting, spatio-temporal association rule mining, spatio-temporal sequential pattern mining and spatio-temporal clustering and classification, amongst others (Miller and Han 2009). More recently, spatio-temporal visualization has become another hot topic for STDM as we begin to explore new ways of representing spatio-temporal data that go beyond the static map.

Early research efforts on spatio-temporal forecasting focused on adapting existing statistical regression models from the fields of time series analysis, spatial analysis and econometrics to deal with spatio-temporal data. Such models are typically geared towards teasing scarce information from homogenous datasets and have been overwhelmed by the increasing volume and diversity of spatio-temporal data that is now being collected. Increasingly, researchers and practitioners are turning towards less conventional techniques, often with their roots in the machine learning and data mining communities, that are better equipped to deal with the heterogeneous, nonlinear and multi-scale properties of large scale spatio-temporal datasets. For instance, methods such as artificial neural networks (ANNs) and support vector machines (SVMs) are now being successfully applied to spatio-temporal forecasting problems.

The association (or co-location) rule mining is to infer the presence of spatial features in the neighbourhood of other spatial features (Shekhar et al. 2011). They are spatial extensions of association rules, which were developed by the retail industry to examine the behavior of consumers. A spatio-temporal co-location rule implies a strong association between locations *A* and *B* that if the attributes of *A* take some specific value at a point in time, then with a certain probability, at the same point in time, the attributes of *B* will take some specific value. A related

STDM task is mixed drove co-occurrence pattern (MDCOP) mining. MDCOPs are subsets of two or more different object types whose instances are often located close to one another in space and time (Shekhar et al. 2011). The drawback of these methods is that only contemporaneous associations are considered so they do not account for the evolution of a spatial process over time.

A logical extension to association mining is to analyze spatio-temporal sequential patterns. This involves finding sequences of events (an ordered list of item sets) that occur frequently in spatio-temporal datasets. Sequential pattern mining algorithms were also first introduced to extract patterns from customer transaction databases. A spatio-temporal sequential pattern means that if at some point in time and space, the attributes in A take some specific value, then with a certain probability at some later point in time, attributes at B will take some specific value. Sequential pattern mining implicitly incorporates the notion of spatio-temporal dependence; that the events at one location at one time can have some causal influence on the events at another location at a subsequent time. A similar concept to sequential patterns are cascading spatio-temporal patterns, which are ordered subsets of events that are located close together and occur in a cascading sequence (Shekhar et al. 2011).

Clustering involves grouping unlabeled objects that share similar characteristics. The goal is to maximize the intraclass similarity and minimize the interclass similarity. Clustering can be used for classification, segmentation and outlier detection, and here clustering is a general term for all these tasks. Widely used spatial clustering techniques e.g., K-means and K-medoids, have been extended to spatio-temporal clustering problems. Designing an effective spatio-temporal clustering algorithm is a difficult task because it must account for the dynamics of a phenomenon in space and time. For instance, when clustering moving objects, a cluster may change its spatial location from one time step to the next but still be the same spatio-temporal cluster. Rules for capturing this type of behavior are difficult to encode in algorithms.

Mining interesting patterns, rules and structures from spatio-temporal data is only part of the task of STDM. The results are not useful if they are not easily understood. For instance, finding a spatio-temporal cluster in a patient register dataset is not useful in itself. On the other hand, confirming this spatio-temporal cluster as a disease outbreak and visualizing it using a platform that epidemiologists and medical professionals can understand is very useful indeed. As a result, space-time visualization has emerged as another important facet of STDM. It explores the patterns hidden in the large data sets by using advanced visualization and animation techniques. This includes conventional 2D maps as well as newly developed 3D space-time cube methods, which can show hotspots and isosurfaces of spatio-temporal phenomena. Integration of data exploration, analysis and visualization in a single platform takes this one step further. The STARS platform (space-time analysis of regional systems, Rey and Janikas 2010) is an excellent example of this that allows exploratory and explanatory analysis and visualization of regional data with spatio-temporal extent. However, despite significant progress, how to visualize large volumes of data in real time and to best make use of the third dimension are problems that are yet to be adequately solved.

This chapter is organized around three main tasks of STDM; space-time modeling and prediction, space-time clustering and space-time visualization. In the following section, we review spatio-temporal autocorrelation and its implications for space-time modeling. Section 60.3 is devoted to space-time modeling and prediction, by either statistical (parametric) approaches or machine learning (non-parametric) approaches. Section 60.4 gives a brief review of space-time clustering and outlier detection, and is followed by an introduction to space-time visualization in Sect. 60.5. The final section summarizes the directions of future research in STDM.

60.2 Spatio-Temporal Autocorrelation

An observation from nature is that near things tend to be more similar than distant things both in space and in time. For instance, the weather tomorrow is more likely to be similar to today's weather than the weather a week ago, or a month ago and so on. Similarly the weather 1 mile away is likely to be more similar than the weather 10 miles away or 100 miles away. These phenomena are referred to respectively as temporal and spatial dependence. The presence of dependence in spatial and temporal data violates the stationarity assumption of classic statistical models such as ordinary least squares (OLS) and necessitates the use of specialized modeling and forecasting techniques. Testing for dependence is typically accomplished using an autocorrelation analysis. Autocorrelation is the cross-correlation of a signal with itself and can be measured in temporal data using the temporal autocorrelation function (ACF, Box and Jenkins 1970) or in spatial data using an index such as the familiar Moran coefficient.

These measures are global, implying a degree of fixity in the level of autocorrelation across the space/time such that it can be described by a single parameter. However, this is often unrealistic. Many time series exhibit nonlinear characteristics that make stationarization difficult. Similarly, spatial data often exhibit structural instability over space, which is referred to as heterogeneity. Heterogeneity has two distinct aspects; structural instability as expressed by changing functional forms or varying parameters, and heteroskedasticity that leads to error terms with non-constant variance (Anselin 1988). Ignoring it can have serious consequences including biased parameter estimates, misleading significance levels and poor predictive power. Anselin (1988) provides some methods for testing for heterogeneity. Additionally, a number of local indicators of spatial association (LISA) have been devised. These include a local variant of Moran's I and Getis and Ord's G_i and G_i^* statistics, which measure the extent to which high and low values are clustered together.

Although sharing many commonalities in techniques and concepts, the fields of time series analysis and spatial analysis have largely developed separately from one another. The behavior of a variable over space differs from its behavior in time. Time has a clear ordering of past, present and future while space does not and because of this ordering isotropy has no meaning in the space-time context. In time, measurements can only be taken on one side of the axis; hence estimation involves

extrapolation rather than interpolation. Temporal data also has other characteristics, such as periodicity, that are not common in spatial data and scales of measurement also differ between space and time and are not directly comparable.

When a variable Z is observed over time at two or more locations, it is both a spatial series and a time series and can be referred to as a space-time series $z = \{z(s, t) | s \in S, t \in T\}$ in spatial domain S and temporal interval T . A space-time series may exhibit spatio-temporal dependence which describes its evolution over space and time. If the spatio-temporal dependence in a dataset can be modeled then one essentially has predictive information. A number of indices have been devised to this end including space-time (semi) variograms (Heuvelink and Griffith 2010) as well as space-time eigenvector filtering (Griffith 2010). Two indices are described here, the space-time autocorrelation function (ST-ACF), that measures global space-time autocorrelation, and the cross-correlation function (CCF), that measures local space-time autocorrelation between two locations. These indices are extensions of the temporal autocorrelation function and are selected as they are easily interpretable and have a practical application in established space-time modeling frameworks.

60.2.1 The Global Measure

The ST-ACF measures the N^2 cross-covariances between all possible pairs of locations lagged in both time and space (Pfeifer and Deutsch 1980). Given the weighted l^{th} order spatial neighbours of any spatial location at time t and the weighted k^{th} order spatial neighbors of the same spatial location s time lags in the future, the space-time cross-covariance can be given as:

$$\gamma_{lk}(s) = E \left\{ \frac{[W^{(l)}z(t)]' [W^{(k)}z(t+s)]}{N} \right\} \quad (60.1)$$

Where N is the number of spatial locations, $W^{(l)}$ and $W^{(k)}$ are the $N * N$ spatial weight matrices at spatial orders l and k , $Z(t)$ is the $N * 1$ vector of observations z at time t , $z(t+s)$ is the $N * 1$ vector of observations z at time $(t+s)$ and the symbol $'$ denotes matrix transposition. Based on Eq. (60.1), the ST-ACF can be defined as:

$$\rho_{lk}(s) = \frac{\gamma_{lk}(s)}{[\gamma_{ll}(0)\gamma_{kk}(0)]^{\frac{1}{2}}} \quad (60.2)$$

ST-ACF has been used in STARIMA to calibrate the order of moving average (MA), which define the range of spatial neighbourhoods which contribute to the current location at a specific time lag (Pfeifer and Deutsch 1980). The MA orders are fixed globally both spatially and temporally and a single parameter is estimated for it in practical application such as in Kamarianakis and Prastacos (2005), and Cheng et al. (2011b).

60.2.2 The Local Measure

The cross correlation function (CCF) (see, for example, Box and Jenkins 1970) treats two time series as a bivariate stochastic process and measures the cross covariance coefficients between each series at specified lags. It provides a measure of the similarity between two time series. The CCF is useful if one has reason to believe that the level of autocorrelation in a spatio-temporal dataset is not fixed in time and space. Given two time series X and Y , the CCF at lag k is given as:

$$\rho_{xy}(k) = \frac{E[(x_t - \mu_x)(y_{t+k} - \mu_y)]}{\sigma_x \sigma_y} \quad k = 0, \pm 1, \pm 2, \pm \dots \quad (60.3)$$

The CCF measures cross-correlations in both directions, as denoted by subscript k , therefore the temporal lag at which the CCF peaks can be used to determine a transfer function between two series. This is, however, dependent on sufficient spatial and temporal resolution in the data. A peak at lag zero indicates that the current resolution does not capture the direction of influence of one location on another, but the series behave very similarly at the same time (Cheng et al. 2011a). As examples, the global and local measures of road network in central London are shown in Figs. 60.1 and 60.2.

60.3 Space-Time Forecasting and Prediction

Space-time models must account for the combined problems of spatial and temporal data mentioned in the preceding sections. Uptake of space-time models has traditionally been limited by the scarcity of large scale spatio-temporal datasets (Griffith 2010). This is a situation that has been reversed over recent decades and we are now inundated with data and require methods to deal with them quickly and effectively. The models that are currently applied to space-time data can be broadly divided into two categories; statistical (parametric) methods and machine learning (non-parametric) methods. These are described in turn in the following subsections.

60.3.1 Statistical (Parametric) Models

The state of the art in statistical modeling of spatio-temporal processes represents the outcome of several decades of cross-pollination of research between the fields of time series analysis, spatial statistics and econometrics. Some of the methods commonly used in the literature include space-time autoregressive integrated moving average (STARIMA) models (Pfeifer and Deutsch 1980) and variants, multiple ARIMA models, space-time geostatistical models (Heuvelink and Griffith 2010), spatial panel data models (Elhorst 2003), geographically and temporally weighted regression (Huang et al. 2010) and eigenvector spatial filtering (Griffith 2010).

Fig. 60.1 (a) CCF and (b) coefficient of determination (CCF^2) between unit journey times of three pairs of road links in central London in the AM peak period (7–10am) (Cheng et al. 2011a)

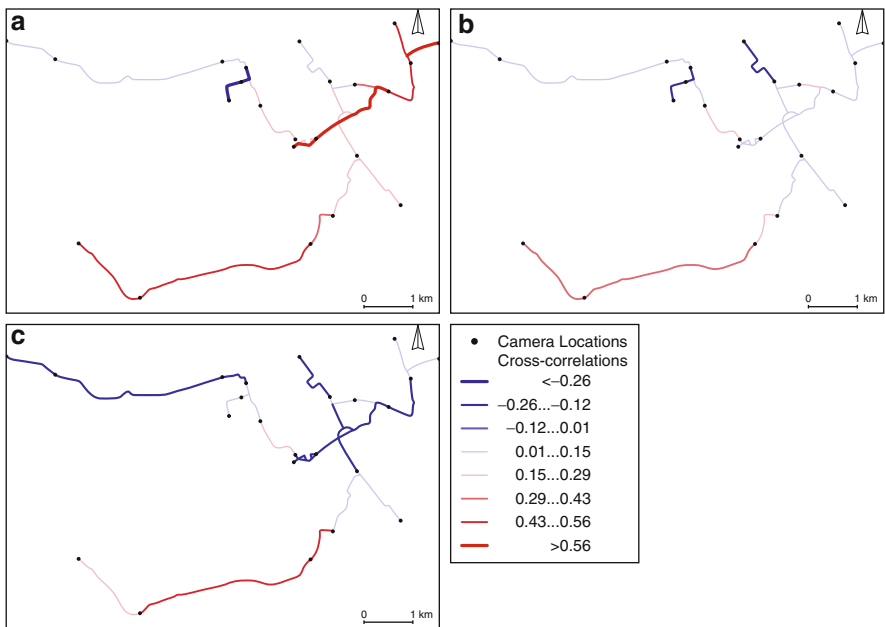

Fig. 60.2 Average CCF between links and their first-order neighbours at temporal lag zero in (a) the AM peak; (b) interpeak; and (c) PM peak (Cheng et al. 2011a)

60.3.1.1 Space-Time Autoregressive Integrated Moving Average

Space-time autoregressive integrated moving average (STARIMA) is a family of models that extend the ARIMA time series model to space-time data (Pfeifer and Deutsch 1980). STARIMA explicitly takes into account the spatial structure in the data through the use of a spatial weight matrix. The general STARIMA model

expresses an observation of a spatial process as a weighted linear combination of past observations and errors lagged in both space and time. A fitted STARIMA model is usually described as a STARIMA (p,d,q) model, where p indicates the autoregressive order, d is the order of differencing and q is the moving average order. The application of STARIMA models has been fairly limited in the literature, with examples existing in traffic prediction (Kamarianakis and Prastacos 2005) and temperature forecasting (Cheng et al. 2011b).

Some important special cases of the STARIMA model should be noted; when $d = 0$ the model reduces to a STARMA model, furthermore, a STARMA model with $q = 0$ is a STAR model and with $p = 0$ is a STMA model. Although the STARIMA model family accounts for spatio-temporal autocorrelation, it has not yet been adequately adapted to deal with spatial heterogeneity and parameter estimates are global. The implication of this is that the space-time process must be stationary (or made stationary through differencing/transformation) for STARIMA modeling to be effective.

60.3.1.2 Spatial Panel Data Models

Panel data is a term used in the econometrics literature for multi-dimensional data. A panel contains observations on multiple phenomena (cross-sections) over multiple time periods. When panel data include a spatial component they are referred to as spatial panel data. Although the term describes the data itself, there are a range of models that have been developed to work with spatial panel data that originate specifically from spatial econometrics that are referred to as spatial panel data models. Methodologically, they are often very similar to those encountered in the spatial statistics literature.

Aspatial panel data models are modified to account for spatial dependence in one of two ways; either with a spatial autoregressive process in the error term; a spatial error model (equivalent to a spatial moving average), or with a spatially autoregressive dependent variable; a spatial lag model (Elhorst 2003). In their standard form, spatial panel data models are global models and do not account for spatial heterogeneity and, as in the spatial statistics literature, this has become a focus of research in recent years. Elhorst (2003) defined a set of spatial panel data models that account for heterogeneity in different ways. The uptake of spatial panel data models has been much more widespread than those mentioned in Sect. 60.3.1 and there have been applications in liquor demand prediction and US state tax competition, amongst many others.

60.3.1.3 Space-Time GWR

Recently, there has been a great deal of interest in extending geographically weighted regression (GWR) to the temporal dimension. In their geographically and temporally weighted regression (GTWR) model, Huang et al. (2010) incorporate both the spatial and temporal dimensions into the weight matrix to account for spatial and temporal nonstationarity. The technique was applied to a case study of residential housing sales in the city of Calgary from 2002 to 2004 and found to outperform GWR and temporally weighted regression (TWR) as well as OLS.

60.3.1.4 Space-Time Geostatistics

Space-time geostatistics is concerned with deriving space-time covariance structures and semivariograms for the purpose of space-time interpolation and forecasting. The aim is to build a process that mimics some patterns of the observed spatiotemporal variability, without necessarily following the underlying governing equations (Kyriakidis and Journel 1999). The first step usually involves separating the deterministic component $m(u, t)$ of space time coordinates u and t . Following this, a covariance structure is fitted to the residuals. The simplest approach is to separate space and time and consider the space-time covariance to be either a sum (zonal anisotropy model) or product (separable model) of separate spatial and temporal covariance functions. Although simple to implement, these models have the disadvantage that they do not consider space-time interaction. They assume a fixed temporal pattern across locations and a fixed spatial pattern across time. Additionally, it is not straightforward to separate the component structures from the experimental covariances. For example, an experimental spatial covariance will be influenced by temporal variability resulting from the time instant at which the data was measured.

The second approach is to model a joint space-time covariance structure. This approach is generally accepted to be more appropriate. Combinations of the two approaches have also been described in the literature (Heuvelink and Griffith 2010). Once an appropriate space-time covariance structure has been defined, one can use standard Kriging techniques for interpolation and prediction; Space-time geostatistical techniques are best applied to stationary space-time processes. Highly nonstationary spatio-temporal relationships require a very complicated space-time covariance structure to be modelled for accurate prediction to be possible. Despite being spatio-temporal in nature, the main function of space-time geostatistical models is space-time interpolation and they encounter problems in forecasting scenarios where extrapolation is required (Heuvelink and Griffith 2010).

60.3.2 Machine Learning (Non-parametric) Approaches

In parallel to the development of statistical space-time models, there was a multidisciplinary explosion of interest in non-parametric machine learning methods, and many of these have been successfully adapted to work with spatio-temporal data due to their innate ability to model complex nonlinear relationships. There is a wide range of machine learning algorithms available, in this section we focus on two of the most popular; the artificial neural network and the support vector machine.

60.3.2.1 Artificial Neural Networks

Artificial Neural Networks (ANNs) are a family of non-parametric methods for function approximation that have been shown to be very powerful tools in many application domains (see Fischer 2006 for example), often dealing with complex real world sensor data. They were initially inspired by the observation that biological learning is governed by a complex set of interconnected neurons. The key

concept is that, although individual neurons may be simple in structure, their interconnections allow them to perform complex tasks such as pattern recognition and classification.

Since its inception, the term ANN has become an umbrella term for a broad class of flexible non-linear models for regression and classification with a range of different architectures. ANNs have been widely applied in spatial and temporal analysis. Kanevski et al. (2009) have applied various types of ANN to spatial and environmental modeling problems including radial basis function neural networks (RBFNN), general regression neural networks (GRNN), probabilistic neural networks (PNN) and neural network residual Kriging (NNRK) models and have gained excellent results. The authors note that the strength of ANNs is that they learn from empirical data and can be used in cases where the modeled phenomena are hidden, non-evident or not very well described. This makes them particularly useful in modeling the complex dependency structures present in space-time data that cannot be described theoretically. Hsieh (2009) also provides a good review of ANN methods applied to spatial problems.

60.3.2.2 Support Vector Machines

Another widely used machine learning technique is the support vector machine (SVM, SVR in the regression case). SVMs are a set of supervised learning methods originally devised for classification tasks that are based on the principles of statistical learning theory (Vapnik 1999). SVMs make use of a hypothesis space of linear functions in a high dimensional feature space, trained with a learning algorithm from optimization theory. The key to their strong performance is that the learning task is formulated as a convex optimization problem meaning that, for a given set of parameters, the solution is globally optimal provided one can be found. Therefore, SVMs avoid the problem of getting stuck in local minima which are traditionally associated with ANNs. This has led to SVMs outperforming most other systems in a wide variety of applications within a few years of their introduction.

SVMs have been successfully used to model time series in a number of application areas including financial time series and traffic flow prediction. Compared to time series analysis, the uptake of SVM in the spatial sciences was initially slow but has seen a rapid increase in popularity in the past 5 years or so. The book “Machine Learning for Spatial Environmental Data” (Kanevski et al. 2009) provides a good introduction to some of the machine learning methods currently being used to model spatial data. Recently, SVMs have been applied to spatio-temporal avalanche forecasting (Pozdnoukhov et al. 2011). The approach involves incorporating the outputs of simple physics based and statistical approaches to interpolate meteorological and snowpack related data over a digital elevation model of the region. The decision boundary is used to discriminate between safe and dangerous conditions.

60.3.2.3 Other Methods

ANNs and SVMs are two methods that are widespread in temporal and spatial analysis, however, the field of machine learning is huge and a comprehensive

review is beyond the scope of this chapter. Various other methods have been used including nearest neighbour regression, kernel (ridge) regression, Gaussian processes, self-organizing maps (SOM), principal components analysis (PCA) and regression trees, which are introduced in Hsieh (2009). This list is non-exhaustive and readers are also referred to the text of Kanevski et al. (2009) for detailed introduction in the context of spatial data.

60.3.3 Summary

In this section, the complex, nonlinear, non-stationary properties of spatio-temporal data and their implications for space-time models were outlined. The question is which model should one choose for a given spatio-temporal dataset? The answer to this depends on the data. In the literature, space-time analysis is typically applied to data with low spatial and/or temporal resolution which is acquired after the event. In the tradition of spatial analysis, the practical use of such data is to elicit causal relationships between variables that can give some valuable insights into the underlying processes. In this case, the use of parametric statistical models may be preferable because of their explanatory power and interpretability.

However, these days, more and more data sources are becoming available in (near) real time at high spatial and temporal resolutions. Extracting meaningful relationships from such data is a task that is secondary to forecasting and it is likely that machine learning approaches, with their greater flexibility, will play an ever increasing role. Generally, machine learning methods have a wider field of application than traditional geostatistics due to their ability to deal with multi-dimensional nonlinear data. They are also well suited to dealing with large databases and long periods of observation. In particular, the SVM approach is favorable because it avoids the curse of dimensionality faced by other methods. One of the future research directions in this area lies in improving the interpretability of the structure and output of machine learning algorithms. Another way is to use a hybrid framework with both statistical and machine learning approaches (Cheng et al. 2011b).

60.4 Space-Time Clustering

60.4.1 Introduction

Another very important task of STDM is to extract meaningful patterns and relationships from massive spatio-temporal data that are not necessarily explicit. In this situation, we may wish to search for structure in the dataset without an a priori hypothesis. Hypotheses can be then be formed and refined a posteriori from the results. This is known as unsupervised learning. One of the most important unsupervised learning tasks in STDM is clustering. This involves grouping space-time series into clusters, where the similarity of data within a cluster and the dissimilarity between the clusters are high. Clustering can also be used to detect outliers.

A spatial outlier is a spatially referenced object whose thematic attribute values are significantly different from those of other spatially referenced objects in its spatial neighborhood. It represents an object that is significantly different from its neighborhoods even though it may not be significantly different from the entire population. A spatial-temporal outlier is a spatial-temporal object whose thematic attribute values are significantly different from those of other spatially and temporally referenced objects in its spatial or/and temporal neighborhoods. Identification of ST-outliers can lead to the discovery of unexpected, interesting, and implicit knowledge, such as local instability or deformation (Cheng and Li 2006). Nowadays spatial and spatio-temporal clustering has been widely used to understand the spatial patterns hidden in spatial databases with applications in epidemic studies, crime hotspot analysis and social networks.

The three domains of space-time series data can be used to define the similarity between observations for clustering. The first is the thematic domain, where the attributes define the characteristics of the object. The second is the spatial domain, which is used to describe the location of the object. Finally, the temporal domain is used to store the timing of the object. These domains are used to answer the questions *what*, *where* and *when* respectively. Initial research on clustering focused on the thematic domain, with methods such as k-means, k-medoids and their variants being popular. Research into clustering using the spatial domain gained popularity in the early twenty-first century. Initial research on spatial clustering has focused on point data. Popular algorithms such as DBSCAN and BIRCH are the outputs of this research area. The spatial distance or the spatial density derived from the spatial locations of the points is considered for clustering. Clustering has also been conducted by combining spatial adjacency with thematic domains or by combining the spatial distance with the thematic distance. Temporal-thematic clustering is mainly applied to group time series data, in order to know whether customers are changing over time, or to determine if credit card fraud transactions change over time.

Very few algorithms consider the spatial, temporal and thematic attributes seamlessly and simultaneously in the clustering. Capturing the dynamicity in the data is the most difficult challenge in spatio-temporal clustering, which is the reason that traditional clustering algorithms, in which the clustering is carried out on a cross-section of the phenomenon, cannot be directly applied to spatio-temporal phenomena. The arbitrarily chosen temporal intervals may not capture the real dynamics of the phenomena since they only consider the thematic values at the same time, which cannot capture the influence of flow (i.e., time-lag phenomena). It is only recently that this has been attempted. We pay particular attention to spatio-temporal scan statistics, a method that has shown promising performance in a range of STDM tasks such as health, crime and transport studies.

60.4.2 Spatio-Temporal Scan Statistics

Spatio-temporal scan statistics (STSS) is a clustering technique that was originally devised to detect disease outbreaks (Neill 2008). The goal is to automatically detect

regions of space that are “anomalous,” “unexpected,” or otherwise “interesting.” Spatial and temporal proximities are exploited by scanning the entire study area via overlapping space-time regions (STRs). Each STR represents a possible disease outbreak with a geometrical shape which is either a cylinder or rectangular prism. The base corresponds to the spatial dimension and the height corresponds to the temporal dimension. The dimensions of the STR are adjustable parameters. For instance, the maximum spatial dimension (e.g., the circular base of a cylindrical STR) can represent the maximum possible boundary of an outbreak, and the height of the STR could be the maximum allowable time to detect the outbreak. The dimensions of the STR are allowed to vary in order to detect outbreaks of varying sizes.

The initial proposition of STSS is based on the comparison of the disease rates inside and outside of a STR. If the disease rate inside the STR is significantly higher than outside the STR, then a possible disease outbreak is detected. However, this does not take into account the temporal variations (e.g., seasonal trends), which are inherent in epidemiological data. More recently, an expectation based approach was proposed to accommodate the temporal trend, where the observed value of an STR is compared with its expected value based upon historical data. Based on the statistical distribution that the data is assumed to follow, comparison is made via a likelihood ratio score function. If a STR has a likelihood ratio score bigger than 1, the STR is a potential disease outbreak. To reduce the false-alarm rate (reporting a disease outbreak where in reality there is no outbreak), the significance of the potential STRs is further tested via Monte Carlo simulation. If the STR is found to be significant at this stage, then a disease outbreak is recorded (Neill 2008)

STSS has the significant drawback that the entire study region has to be scanned, which is computationally intensive and limits the method’s scalability. Although previous research has shown that this problem can be tackled via efficient spatial-indexing methods. The assumption that a disease outbreak is a regular geometrical shape is also not realistic (e.g., disease might have spread via the river, thus affecting the people near the river bed) and remains as a limitation of the method. This problem might be tackled by generating irregularly shaped STRs.

60.5 Space-Time Visualization

Representing a phenomenon that evolves over space and time has emerged as a contentious issue within the GIS community. The contentious issue comes from the fact that most geographic phenomena change over time; for example, forest fires, storms, water contamination and also traffic congestion, but representing time on a map is still difficult. It is because GIS has its roots in mapping, which originally was designed to represent static phenomena, not dynamic process. Geographic visualization enhances traditional cartography by providing dynamic and interactive maps. Many new techniques on visualizing time on maps have been proposed. These techniques can be divided into three broad types: (static) 2D and 3D maps, and animation.

60.5.1 2D maps

There are various ways to represent time on static 2D maps, either as a single static map or multiple snap shots. Since all time steps are shown at the same time, the map-readers don't need to retain events temporarily in their minds thus preventing lapses of certain critical information. However, this technique can only present a few time steps at a time due to the limitation of the available map media (computer screen, paper, etc.).

This section will discuss some interesting static map techniques. The techniques are divided according to the type of data to be presented: geometric change of spatial objects (movement, size, shape, etc.), attribute change of spatial objects, and travel time.

60.5.1.1 Representing Geometric Change of Spatial Objects

Monmonier (1990) presents movement of spatial objects by drawing movement paths or pinpoints of objects on a 2D plane. Arrows are added to represent directions of movements. This technique is called a "dance map" since it is similar to a diagram of foot paths in a ballroom dance. Dance maps can display both discrete and continuous movement. When data are captured at fixed time intervals, a dance map can display the rate of movement (or rate of change) very well. Color or variety in sizes of objects can be added to the map, but the number of objects is limited by occlusion.

Another visualization technique presented by Monmonier (1990) is the *chess map* (map series). Each map contains a snap shot representing a time slice. A series of maps are laid out continuously in the manner of a chess board for users to compare events between time slices, allowing the comparison of many different time slices at a single sitting. The disadvantage of chess maps is that a large space is required to present multiple maps at the same time. In addition, the users must determine by themselves as to how the changes occurred, and at which time slices.

60.5.1.2 Representing Thematic Attribute Change of Spatial Objects

A *change map* shows changes or differences against a reference time period, as an absolute value or percentage, such as population increase every 10 years compared with 1990 (Monmonier 1990). The change map is good for representing quantitative attributes. Readers do not have to calculate the amount of change by themselves.

Another way to show the change is to add "small charts on maps" to visualize time series data on maps. The advantage of small charts on maps is that map readers are informed of the locations of the data on the maps as well as how their attributes change over time. However, when plotting many charts simultaneously, the base map can become overcrowded. Moreover, the charts can be easily overlapped when the data locations are very close to one another. An example of small charts on maps is given in Andrienko and Andrienko (2007).

Visual variables (colors, sizes, texture) can be applied to represent variation in attributes at different locations. The classic example of this technique is Minard's map showing Napoleon's doomed campaign to Moscow in 1869. Time was displayed as an axis on the map (parallel to the axis of the geographical position), and the number of remaining soldiers was shown by the thickness of the lines. Another good example is spatial treemaps (Slingsby et al. 2010) that represent traffic variables (traffic speed and traffic volume) of areas of London. Each grid cell on the map represents a borough. The level of brightness of each cell on spatial treemaps is used to represent the value of a traffic variable (speed and volume). Time is also mapped onto small cells within each area. This technique allows the visualization of a large number of time points, since it exploits every pixel on the map to represent data.

Rank Clock has recently been used to visualize the dynamics of city size changes (<http://www.bartlett.ucl.ac.uk/casa/pdf/paper152.pdf>), where the time is arranged as a clock, the thematic attribute (the size of the city) shows as a dot along the time line. By linking all the dots of a spatial unit over time, the trajectory of rank change is shown.

2D Space-time coloured pixels is widely used to study patterns of traffic congestion in space-time. It was used to display data from loop detectors. The space-time coloured pixels consists of two axes: a device position axis and a time axis. Each pixel represents the magnitude of traffic parameter, in colours, measured from a monitoring device at a particular time. Any anomaly of the detectors can also be shown easily by this approach.

60.5.1.3 Travel Time

The previous two subsections use time as a reference for other types of data (changes in geometry and in attributes of spatial objects). Here we pay special attention for travel time representation since time itself is the data to be represented and special techniques are developed for this purpose. There are two techniques that are used to present travel time on maps.

A *cartogram* is a map that distorts geographic space on maps to represent attributes of spatial data. For example, the tube map of London arrange all the tube lines in six zones in order to show the distance to the centre of London (Zone 1), which is not the exact physical (geometric) locations of the tube lines and stations. Using this technique, travel time on transportation networks can be represented using distance on a map, an example of which is the travel time tube map that distorts real geographic layout of tube lines in London in order to show travel time between stations.

The "isochrone" is another technique that is employed to represent travel time. Isochrones are similar to contour lines on a map, but an isochrone line connects points of equal travel time from a given origin (Brunsdon et al. 2007). The isochrone is a great alternative to the cartogram as it does not distort the underlying map.

60.5.2 3D Visualization

60.5.2.1 3D Space-Time Cube

The 3D space-time cube (or, alternatively, space-time aquarium) was proposed by Hagerstand (1970). A 3D space-time cube consists of two dimensions of geographic locations on a horizontal plane, and a time dimension in the vertical plane (or axis). The space-time cube is normally applied to represent trajectories of objects in 3D space-time dimension, or “space-time paths.” Trajectories are normally from GPS data nowadays, and they are represented as lines in the 3D space-time.

3D space-time cube has two main limitations. Firstly, the 3D display makes it difficult to refer space-time paths to geo-locations and time. Secondly, the space-time cube has difficulty in displaying large amounts of data. However, interactive techniques can be used to reduce cluttering when displaying a large amount of data. With interactive functions, users can decide which data to display and can zoom and rotate the cube on its axes. Data aggregation (such as generalized space-time path) can also improve visualization on 3D space-time cube.

60.5.2.2 3D Isosurface

An isosurface is a three-dimensional analog of an isoline. It is a surface that represents points of a constant value (e.g., pressure, temperature, velocity, density) within a volume of space. Isosurface has been employed in various applications such as medical imaging, fluid dynamics, astrophysics, chemistry and quantum mechanics. Isosurfaces are popularly used to visualize volumetric datasets, which consist of a 3D location with one scalar or vector attribute. The data sets are structured as (x,y,z,v) , where (x,y,z) are the spatial coordinates and v is an attribute. The 3D isosurface has also been applied to visualize incident data, which are structured as (x,y,t) , where (x,y) are two dimensional spatial coordinates and t is the time when the incident occurred (Brunsdon et al. 2007). Isosurfaces have great potential to show the development of space-time processes such as congestion on the traffic network.

60.5.2.3 3D Wall Map

The 3D wall map is a 2D road map with an additional time dimension to display change. Each layer represents the situation at a time. Cheng et al. (2010) employed the technique to represent travel delay during the morning peak in central London at four consecutive Mondays in October 2009. The layout of the link map represents the real geographical layout of the road network. The colours between layers represent the unit journey time (minutes per kilometre), with yellow and red colours showing the highly congested areas (travel time more than 5 min per kilometre) (Fig. 60.3).

60.5.3 Animated Maps

The first computer based animation map was created by Tobler in 1970 (Tobler 1970). He used 3D animated maps to display simulated urban growth data

Fig. 60.3 Wall map of travel delay (mins/km) of outbound roads during the morning peak on 5,12,19,26 October 2009 (Cheng et al. 2011a)

in the Detroit region of the US. However, animated maps were not widely used for many years due to the difficulty in distributing and playing back large data files. However, with improvements in computing power and internet technology over the past three decades, animation maps have become a very active area of research and are now distributed widely on the internet. Weather maps and traffic maps are two of the many examples.

An animated map has two outstanding advantages. The first one is that an animation map can be used as an alternative to a static map. It can be employed to emphasize key attributes by using, for example, blinking symbols “to attract attention to a certain location on the map” (Kraak and Klomp 1995). The second advantage is that it provides additional visual variables called “dynamic variables” such as “duration,” “rate of change,” “order of change,” “frequency,” “display time,” and synchronization (MacEachren et al. 2004).

60.5.4 Visual Analytics: The Current Visualization Trend

Visual analytics is an outgrowth of the field of scientific and information visualization. It refers to “the science of analytical reasoning facilitated by interactive visual interfaces” (Thomas and Cook 2005). The emergence of visual analytics has been driven by the fact that we have no proper tools to leverage large amounts of data. Visual analytics is an iterative process that involves information gathering, data pre-processing, knowledge representation, and decision making. Normally, unknown data are visualized in order to give a basic view of that data, then users will use their perception (intuition) to gain further insights from the images

produced by visualization. The insights generated by this human perception are then transformed into knowledge. After users have gained certain knowledge, they can generate hypotheses that will be used to carry out further analysis using available data analysis and exploration techniques. The results from analytical process will be visualized for presentation, and further gain in knowledge.

Visual analytics is much more than simple visualization. It can rather be seen as an integral approach to combining visualization with human factors, and data analysis (Keim et al. 2008). Visual analytics is becoming more important to many disciplines including scientific research, business enterprise, and other areas that face problems of overwhelming avalanche of data. GIS, also, is now facing this massive data problem. The concept of visual analytics was introduced into GIS, namely “Geovisual Analytics”. Geovisual analytics has its specific focus on space and time; posing different specific research problems, and demands special approaches in solving generic research problems of Visual Analytics.

60.6 Conclusions

Since the concept of knowledge discovery from databases (KDD) was proposed in 1988, tremendous progress has been made in data mining and spatial data mining (Miller and Han 2009; Shekhar et al. 2011). STDM is only possible based upon the progress in those areas, along with GIS and geocomputation. This chapter introduces the fundamentals of STDM, which consists of space-time prediction, clustering and visualization.

As for space-time prediction, we have discussed the statistical (parametric) models, including families of STARIMA models, space-time geostatistical models, spatial panel data models, and space-time GWR. The challenge in statistical models lies in the non-stationary and non-linearity of space-time data. How to calibrate the spatio-temporal autocorrelations in the models is the bottleneck of statistical approaches. For low spatio/temporal resolution data, use of parametric statistical models may be preferable because of their explanatory power and interpretability. Due to their ability to deal with multi-dimensional nonlinear data machine learning methods are becoming more popular for large datasets. We have briefly introduced artificial neural networks (ANNs), support vector machines (SVMs), and other methods (Kernel-based approach and self-organized maps) for space-time analysis. However, the interpretability of machine learning is low, and a hybrid framework with both statistical and machine learning approaches might be helpful for this.

Space-time clustering can be used to extract meaningful patterns (clusters) in the data. It can also be used to detect outliers or emerging phenomena (epidemic outbreak or traffic congestion). Considering the spatial, temporal and thematic attributes seamlessly and simultaneously, and the dynamicity in the data is the most difficult challenge in spatio-temporal clustering. Spatio-temporal scan statistics (STSS) sheds lights on this aspect, though efforts are needed to improve computation efficiency and to reduce the false alarm rate.

Space-time visualization explores the patterns hidden in the large data sets by using advanced visualization and animation techniques. This includes conventional static 2D maps as well as newly developed 3D wall maps and isosurface, which shows the hotspots in space-time. Recently “Visual Analytics” and “Geovisual Analytics” have emerged as an iterative process (or tools) that involves information gathering, data pre-processing, knowledge representation/visualization, and decision making. Still, real-time visualization of dynamic processes is still very challenging due to large volume and high dimensions of the data. For examples, methods are needed to show the evolution and dissipation of crime or traffic congestion in space and time simultaneously.

However, the field of STDM is far from mature, and further research is needed in the following areas:

- a. New methods and theory are needed for mining crowd sources such as data contributed by citizens and volunteers. These are often extremely noisy, biased, and nonstationary. One example of such data is the trajectory data obtained from smart phones or other sensors. This area is relevant to the recent development of citizen sciences and VGI in particular.
- b. Theory and methods need to be developed to extract meaningful patterns from those individual sensors and put them under the framework of networks and network complexity such as transport and social-networks made up of those individual. Under network, the interaction and dynamic flows should be considered in mining spatio-temporal patterns. This aspect is relevant to complexity theory and network dynamics in particular.
- c. STDM for emergency and tipping points detection, leading to the generation of, actionable knowledge, i.e., finding the emergent patterns and tipping points of economic crises and disease epidemics. It is important to find outliers, but more important is finding the critical points before the system breaks down so that mitigating action can be taken to avoid the worst scenarios such as traffic congestion and epidemic transmission.
- d. Another challenge of STDM is how to calibrate, explain and validate the knowledge extracted. A good example of this is the calibration of spatial (or spatio-temporal) autocorrelation. Higher order spatial autocorrelation models have been developed, but the pitfalls have also been found (LeSage and Pace 2011). Nonstationarity and autocorrelation is fundamental to our observation (or our empirical test) of reality, it is hard to prove that the higher order autocorrelation comes from the first to the second, then to the third; or from the first to the third directly, which makes the explanation unconvincing. Furthermore, validation is difficult – so far Monte Carlo simulation is the main tool for simulation, which is also based upon a statistical distribution, which is hardly provable. This makes machining learning more promising in future STDM.
- e. Technically, grid computation and cloud computation allow data mining to be implemented at multiple computer sources. Even so, when the data volume is increased, the capacity of software and hardware is still limited. How to scale the algorithm to larger networks will always be a challenge for data mining given the

increase of data volume is far quicker than the improvement in the performance of data processors.

Please notice that the content of this chapter is mainly around spatial data in point, line and lattices, but not on image data, which is another broad area of research. Also, due to the limit of length, we do not include the progress on space-time simulation, which includes agent-based modeling (ABM) and cellular automata (CA). ABM has been used across many disciplines to demonstrate the impact of individual decisions and choices on the nature of a system (Gilbert 2007). Such examples include the individual behavior of birds in flocks, ants in colonies and people in crowds – all entities are acting independently yet contribute to a larger body. There is great potential within ABM to replicate and predict system changes over space and time. In (Manley et al. 2011), the agent-based simulation has demonstrated the link between individual choice and behavior in abnormal conditions with the formation and movement of urban road congestion. CA is a discrete model studied in computability theory, mathematics, physics, complexity science, theoretical biology and microstructure modeling. It consists of a regular grid of cells, each in one of a finite number of states, such as “On” and “Off.” It has been widely used in urban planning and landuse change modeling.

Abstract

This chapter outlines the key ideas of Bayesian spatial data analysis, together with some practical examples. An introduction to the general ideas of Bayesian inference is given, and in particular the key rôle of MCMC approaches is emphasized. Following this, techniques are discussed for three key types of spatial data: *point data*, *point-based measurement data*, and *area data*. For each of these, examples of appropriate kinds of spatial data are considered and examples of their use are also provided. The chapter concludes with a discussion of the advantages that Bayesian spatial analysis has to offer as well as considering some of the challenges that this relatively new approach is faced with.

61.1 Introduction

Bayesian analysis has seen an enormous increase in popularity over recent years. There are a number of possible reasons for this. Firstly, a framework in which prior beliefs may be incorporated can offer certain advantages. Particularly, one can examine a new study in the light of findings of previous studies – something which cannot be done in a classical framework. Secondly, inferences drawn are based on posterior distributions for parameters of interest. Some find this a more intuitive basis for inference than classical significance tests and confidence intervals. Indeed, one author considering the teaching of elementary statistics observed that some of his students misinterpreted classical inference in a way that coincided with Bayesian inference (Berry 1997). Thirdly, a probability distribution for a parameter contains more information than a classical confidence interval. For example, a bimodal posterior or a highly skewed posterior would offer a more subtle interpretation of the outcome of a study than a simple interval or point estimate.

To recall the basic ideas of Bayesian inference, an individual supplies information *prior beliefs* and some unobservable parameter (or set of parameters) θ in the form of a *probability distribution* or *probability density function* $f(\theta)$. If the observable data \mathbf{x} has a likelihood function $L(\mathbf{x}|\theta)$ then Bayes theorem can be used to obtain the relationship

$$f(\theta|\mathbf{x}) \propto f(\theta)L(\mathbf{x}|\theta) \quad (61.1)$$

thus giving an expression for the probability distribution of the unobservable θ given the observable data \mathbf{x} . This is a very different framework to the classical or *frequentist* approach to statistical inference above θ . Although the latter makes use of $L(\mathbf{x}|\theta)$, θ itself is treated as a deterministic, but unobservable, quantity. As such, $f(\theta)$ and $f(\theta|\mathbf{x})$ are not considered as relevant concepts, and instead, hypotheses as to whether statements about θ are true are used as the basis for inference. The need to supply $f(\theta)$ in Bayesian inference is a notable qualitative distinction between the two approaches, as it requires the analyst to supply a subjective set of beliefs about θ as part of the analysis process – although these beliefs could represent a state of impartiality (e.g., by supplying a uniform distribution for θ). In this situation the prior distribution is often referred to as a *noninformative prior*.

One practical difficulty with this approach is that Eq. (61.1) only defines the posterior distribution up to a constant of proportionality. To normalize the distribution (so that the integral over all θ values is one), the equation

$$f(\theta|\mathbf{x}) = \frac{f(\theta)L(\mathbf{x}|\theta)}{\int f(\theta)L(\mathbf{x}|\theta)d\theta} \quad (61.2)$$

is used.

However, the integral in the denominator of Eq. (61.2) is not always analytically soluble, which in the past has led to some difficulties with carrying out Bayesian

analysis in practice. Fortunately, recent advances in computational techniques have addressed this issue. In particular, the advent of Markov Chain Monte Carlo (MCMC) simulation-based approaches has allowed Bayesian approaches to be applied in a wide variety of situations where analytical results are intractable. The ideas of Bayesian inference, in general, and of MCMC methods are covered in ► [Sect. 9, “Spatial Econometrics”](#) in this major reference work. The aim of this chapter is to focus on how these ideas can be applied to the analysis of *spatial* data. In many ways there is nothing special about Bayesian techniques for spatial data – essentially the principles underlying the inferential process (stemming from Bayes’ theorem) are the same as those used for any kind of data. However, although Bayesian analysis of spatial data may have the same overarching framework, there are distinct characteristics of the kinds of *model* to which it is applied and also to the kinds of *data structure* one is likely to encounter. Thus, in this chapter, models in which the random components are spatially correlated and the ways in which Bayesian inference is made about spatial characteristics of the modeled processes will be considered. Firstly, the kinds of spatial data with which Bayesian methods are commonly used will be outlined. Next, examples of how Bayesian methods are applied for each type of data will be given. Finally some practical considerations will be considered.

61.2 Kinds of Spatial Data

Elsewhere in this book, a comprehensive list of spatial data types is provided. However, not all of these data types may be analyzed in a Bayesian framework using techniques that are well established at the time of writing. In particular, there are few Bayesian methods that may be applied to arc- or line-based data. Following the typology of Fischer and Wang (2011), some kinds of data for which well-established Bayesian approaches exist are now listed:

- *Point data*: These are data consisting of a set two or three dimensional point coordinates in Euclidean space. The points themselves are considered as random and typically interest lies in modeling a stochastic *spatial point process* that could have generated the data.
- *Point measurement data*: These are data consisting of a set of spatial points, as before, but here each point has an attached *attribute*. Typically the attribute is some kind of measurement, such as a temperature taken at that location or the price of a house sold at that location. Here, in general it is only the measured attribute that is assumed to be a random component of the model, the locations being treated as fixed, controlled values – effectively part of the design of the data collection procedure. Typically, the spatial component of models for this kind of data arises from an assumption that correlations between the attributes is in some way dependent on the relative locations of the points.
- *Field data*: These are data that relate to variables which are conceptually continuous (the field view) and whose observations have been sampled at an

pre-defined and fixed set of point locations. Arguably, those have a great deal in common with point measurement data – although those are defined *only* at a fixed set of points, while field data relate to a *sample* of point measurements of a mapping from *all* points in space to an attribute value. In this case, a measurement (such as temperature) could have been taken at *any* point in space.

- *Area data*: These are data consisting of a set of spatial regions – typically represented as polygons. In most studies, the polygons provide a partition of a geographical study area, that is, their union completely covers the study area, and no pair of polygons intersects, except in some cases on their boundaries. In the latter situation, regions with boundaries touching are said to be *adjacent*. As with point-based measurement data, an attribute is associated with each entity – the entities now being regions instead of points. Also in common with point-based measurement data, the regions are considered to be fixed (not arising from a random process), and the only component assumed random in models of these data is the attribute. In this case, the spatial aspect of the model is achieved by relating the correlation structure of the random attributes to the relative position of regions – in particular, they often make use of the adjacency or otherwise of each pair of regions in the data set.
- *Spatial interaction data*: These data (also termed origin-destination flow or link data) consist of measurements or counts, each of which is associated with a pair of point locations, or pair of areas. For example, travel to work data, listing the number of people traveling from a given origin (home) zone to a given destination (workplace) zone, fall into this category.

In this chapter, attention will be focused on point data, point measurement data, and area data – as in Cressie (1993), although the technique suggested for point measurement data may also be applied to field data.

61.3 Bayesian Approaches for Point Data

A key model for point data is the *spatial Poisson process*. In such a process, location of points occurs independently of one another, with the *intensity* of occurrences in location $s = (s_1, s_2)$ being given by $\Lambda(s)$. For any area A within the region of study, the number of occurrences has a Poisson distribution with mean

$$\int_{s \in A} \Lambda(s) ds \quad (61.3)$$

In such models, it is informative to estimate $\Lambda(s)$ since mapping this function allows regions of high intensity to be mapped, and related features, such as areas of high variability in intensity, or locations of peak intensity can be investigated. One very simple method of estimation is to use a *pixel-* or *regular lattice-*based approach. Suppose the study area is partitioned into a number of small, identical

tessellating polygons (typically squares or regular hexagons), Δ_k for $k \in \{1, \dots, n\}$. If λ_k is the mean value of $\Lambda(\mathbf{s})$ for $\mathbf{s} \in \Delta_k$, then

$$\lambda_k = \frac{1}{A} \int_{\mathbf{s} \in \Delta_k} \Lambda(\mathbf{s}) \mathbf{d}\mathbf{s} \quad (61.4)$$

where A is the area of each Δ_k . If the value of A is reasonably low, so that each Δ_k occupies a very small proportion of the study area, it is reasonable to assume that $\Lambda(\mathbf{s})$ does not vary much within each Δ_k , so that the lattice based approximation

$$\Lambda(\mathbf{s}) = \lambda_k \text{ for } \mathbf{s} \in \Delta_k \quad (61.5)$$

may be used. Now, if c_k is the number of points occurring in Δ_k , then c_k has a Poisson distribution with mean $A\lambda_k$. For simplicity, assume for now that spatial units are chosen such that $A = 1$ – this simplifies equations, without any loss of generality. With this assumption in place, c_k has a Poisson distribution with mean λ_k . At this stage, a Bayesian approach may be applied to estimate λ_k , since the Poisson distribution of c_k gives

$$\Pr(c_k | \lambda_k) = \exp(-\lambda_k) \lambda_k^{c_k} \quad (61.6)$$

and so if the prior probability density function for λ_k is $f(\lambda_k)$, then the posterior distribution $f(\lambda_k | c_k)$ is related to the prior and the likelihood function by

$$f(\lambda_k | c_k) \propto f(\lambda_k) \exp(-\lambda_k) \lambda_k^{c_k} \quad (61.7)$$

In particular, if the prior for λ_k is a gamma distribution, proportional to $\lambda_k^{\alpha-1} \exp(-\beta\lambda_k)$ for $\lambda_k > 0$, and zero otherwise, and where the constant of proportionality is independent of λ_k , then we have

$$f(\lambda_k | c_k) \propto \exp(-(1 + \beta)\lambda_k) \lambda_k^{c_k + \alpha - 1} \text{ if } \lambda_k > 0, \text{ and zero otherwise} \quad (61.8)$$

which is also a gamma distribution for λ_k , with updated parameters $\beta' = \beta + 1$ and $\alpha' = \alpha + c_k$. In particular, in the case where $\alpha = \beta = 0$, we have $f(\lambda_k) \propto \lambda_k^{-1}$. This is an example of an improper prior distribution – although it is not a well-defined probability function itself, the corresponding posterior distribution *is* well defined, being a gamma distribution with parameters $\alpha = c_k$ and $\beta = 1$. In this case, the expected value of the posterior distribution for λ_k is just c_k . This value may be used to provide a point estimate of λ_k for each area Δ_k .

As an example, consider the inventory data of the Zurichberg Forest, Switzerland (see Mandallaz (2008) for details), which lists the locations (and types) of trees in the forest. These data are provided with the kind authorization of the Forest Service of the Canton of Zurich. Figure 61.1 shows the raw tree

Fig. 61.1 Raw trees data from the Zurichberg Forest (RHS) and estimates of $\Lambda(s)$ based on a hexagonal grid and noninformative priors for the finite elements λ_k (LHS)

location data and the estimated values of $\Lambda(s)$ using the above approach, with the Δ_k zones being elements of a hexagonal tessellating grid.

One characteristic of this kind of estimate is that although it is only a minor generalization of the raw data (it simply estimates the intensity in Δ_k as being proportional to the observed count of events in that area, c_k), the underlying Bayesian theory also provides a posterior distribution, so that one could, for example, estimate other features of the posterior distribution for λ_k such as the upper 95th posterior percentile for each λ_k , or the summed intensity over some arbitrary region of the forest. In either case, posterior distributional features could be estimated (possibly via simulation) in addition to point estimates. As an example, consider the problem of estimating the average intensity over the entire forest. Assuming there are n Δ_k elements covering the forest, this quantity is

$$\frac{1}{nA} \int_{s \in \mathcal{F}} \Lambda(s) ds \text{ where } \mathcal{F} = \bigcup_{k=1, \dots, n} \Delta_k \tag{61.9}$$

If length units are chosen such that $A = 1$ as before, this is equal to

$$\frac{1}{n} \sum_{k=1, \dots, n} \lambda_k \tag{61.10}$$

which is the mean of all of the λ_k values. For brevity, this will now be denoted as $\bar{\lambda}$. If each λ_k has a posterior distribution as set out in Eq. (61.8), then it can be seen that

$$f(\bar{\lambda} | \{c_k, k = i, \dots, n\}) \propto \bar{\lambda}^{n\bar{c}-1} \exp(-n^{-1}\bar{\lambda}) \text{ if } \bar{\lambda} > 0, \text{ and zero otherwise} \tag{61.11}$$

Fig. 61.2 Posterior probability distribution of mean intensity of trees in forest. 99 % HDR is also indicated

where \bar{c} is the arithmetic mean of the c_k 's. Thus the posterior distribution of $\bar{\lambda}$ is also gamma, with parameters $n\bar{c}$ and n^{-1} . Thus, the posterior distribution of $\bar{\lambda}$ is shown in Fig. 61.2.

To obtain an interval estimate of $\bar{\lambda}$, the $a\%$ *Highest Density Region* (HDR) (Hyndman 1996) can be found. This is the region in the set of possible values of $\bar{\lambda}$ such that the posterior probability that $\bar{\lambda}$ lies in the region is $a/100$, and the posterior probability density of any point within the region is higher than any point outside of the region. For the Zurichberg Forest data, the 99 % HDR is the interval (0.757, 0.814). This is indicated on Fig. 61.2.

The above example used a prior probability density distribution that assumed independence between the individual discretized intensity levels λ_k . This assumption is manifested in certain characteristics of the intensity estimates. In Fig. 61.1 the estimates show quite a large amount of spatial “roughness,” that is, there are a number of Δ_k zones whose mean intensity estimates λ_k are very different in value from their neighbors. However, there may be reason to expect that in fact these values should vary smoothly. If this is the case, Bayesian inference can be a useful tool since such expectations of smoothness can be expressed via the prior distribution.

An important issue is now to define roughness. In terms of any function $G(s)$, rather than the discrete approximation, one possible measurement of roughness is the expression

$$\mathcal{R}(G) = \int_{s \in \mathcal{F}} \left(\frac{\partial^2 G}{\partial s_1^2} + \frac{\partial^2 G}{\partial s_2^2} \right)^2 ds \tag{61.12}$$

where $s = (s_1, s_2)$. Note that the two partial second derivatives in Eq. (61.12) measure rate of change of slope and that if both of these have high positive or

high negative values, this indicates sharp maxima or minima – hence, squaring the sum of these and integrating over the study area is a measure of the propensity of $G(\mathbf{s})$ to have sharp peaks and pits and is therefore a plausible measure of roughness. Note also that $\mathcal{R}(G) = 0$ if and only if

$$\frac{\partial^2 G}{\partial s_1^2} + \frac{\partial^2 G}{\partial s_2^2} = 0 \quad (61.13)$$

that is, if $G(\mathbf{s})$ is a solution of Laplace's equation – frequently referred to as a *harmonic function*. Harmonic functions exhibit the *mean value property*

$$G(\mathbf{s}) = \frac{1}{2\pi r} \oint_{\mathbf{t} \in P(\mathbf{s}, r)} G(\mathbf{t}) d\mathbf{t} \quad (61.14)$$

if G is a harmonic function, and $P(\mathbf{s}, r)$ denotes a circular path of radius r centered on the location \mathbf{s} , provided that all of $P(\mathbf{s}, r)$ lies strictly within the region in which $G(\mathbf{s})$ is defined. In less mathematical terms, this states that the value of a harmonic function at a given point is equal to the mean value of that function taken over a circular path centered on that point. Again, this can be thought of as a condition of smoothness. Returning to Eq. (61.12), $\mathcal{R}(G)$ can be thought of as a measurement of the discrepancy between G and a harmonic function, and, that considered from this viewpoint, this provides an alternative interpretation of this quantity as a measure of roughness.

61.4 A Roughness-Based Prior

In the previous section, a measurement of roughness was proposed. In this section, this measure will be used to construct a Bayesian prior encapsulating subjective expectations of smoothness in $\Lambda(\mathbf{s})$ which will be combined with observed point data to obtain a posterior distribution for intensity. To do this, the roughness of some function G that is related to Λ may be used to construct a prior probability density function for the value of $\mathcal{R}(G)$ with an exponential form suggested:

$$f(\mathcal{R}(\Lambda)) \propto \kappa \exp(-\kappa \mathcal{R}(G)) \quad (61.15)$$

defined for positive $\mathcal{R}(G)$. The mean of this prior distribution is κ^{-1} so that low values of κ suggest that a high degree of roughness is expected.

Here, G will be related to Λ by $G(\mathbf{s}) = \sqrt{\Lambda(\mathbf{s}) + 3/8}$ – this is chosen since the transformation gives a distribution close to normal and has a variance-stabilizing effect, when the counts in the zones Δ_k have a Poisson distribution (Anscombe 1948; Mäkitalo and Foi 2011). In practice, as in the previous example, a finite

Fig. 61.3 Diagram showing notation for numerical values of neighbors of zone Δ_k (the central hexagonal zone)

element approach is used to estimate $G(s)$. In particular, it can be shown that $\mathcal{R}(G)$ can be approximated by

$$R = \text{const} \sum_{k=1,n} \left(g_k - \frac{1}{6} \sum_{i=1,6} g_{k(i)} \right)^2 \tag{61.16}$$

where $g_{k(i)} = \sqrt{\lambda_{k(i)} + 3/8}$ indicates the mean value G associated with each of the neighboring tessellating zones to Δ_k as set out in Fig. 61.3. Provided δ is reasonably small, these mean values $\{g_k, g_{k(1)}, g_{k(1)}, g_{k(1)}, g_{k(1)}, g_{k(1)}, g_{k(1)}\}$ are close to the sampled values of G at points annotated on the figure.

To see how this estimate is derived, firstly assume that each of the lines emanating from the central g_k has a length δ . To estimate $\partial^2 G / \partial s_1^2$ and $\partial^2 G / \partial s_2^2$ at the point (s_1, s_2) , a quadratic surface of the form

$$Q(s_1 + t_1, s_2 + t_2) \approx \gamma_0 + \gamma_1 t_1 + \gamma_2 t_2 + \gamma_{11} t_1^2 + \gamma_{12} t_1 t_2 + \gamma_{22} t_2^2 \tag{61.17}$$

is fitted to the values g_k and $g_{k(1)}, \dots, g_{k(6)}$ at the (t_1, t_2) locations corresponding to the central point and six hexagonally arranged lines in Fig. 61.3, respectively, using least squares approximation. The locations of the seven points are

$$\left\{ (0, 0), \left(\frac{\sqrt{3}}{2}\delta, -\frac{1}{2}\delta\right), (0, -\delta), \left(-\frac{\sqrt{3}}{2}\delta, -\frac{1}{2}\delta\right), \left(-\frac{\sqrt{3}}{2}\delta, \frac{1}{2}\delta\right), (0, \delta), \left(\frac{\sqrt{3}}{2}\delta, \frac{1}{2}\delta\right) \right\} \tag{61.18}$$

and the corresponding Q values are $\{g_k, g_{k(1)}, g_{k(2)}, g_{k(3)}, g_{k(4)}, g_{k(5)}, g_{k(6)}\}$. Using this approximation and applying second partial derivatives, we obtain the approximations $\partial^2 G / \partial s_1^2 \approx \gamma_{11}$ and $\partial^2 G / \partial s_2^2 \approx \gamma_{22}$, so that

$$\frac{\partial^2 G}{\partial s_1^2} + \frac{\partial^2 G}{\partial s_2^2} \approx \gamma_{11} + \gamma_{22} \quad (61.19)$$

It may be checked that, when the values for the point locations and intensities are substituted into the formula for the least squares fitting, we have

$$\gamma_{11} + \gamma_{22} = -2 \left(\frac{1}{6} \sum_{i=1,6} g_{k(i)} - g_k \right) \quad (61.20)$$

and note also, from the Taylor expansion of $G(\mathbf{s} + \mathbf{t})$, that this approximation tends asymptotically to the true value as δ tends to zero. Finally, it is interesting to note that this result can be used to derive a discrete version of the mean value property, with the circular path around a point being approximated by the centroids of the neighboring hexagonal lattice elements.

Now, returning to the definition of roughness in Eq. (61.12), the approximation in Eq. (61.16) may be obtained. Entering this expression for R (as an approximation for \mathcal{R}) into Eq. (61.15) yields a roughness-penalty-based prior distribution for each g_k :

$$\Pr(g_k | g_{k(1)}, \dots, g_{k(6)}) \propto \kappa \exp \left(-\kappa \sum_{k=1,n} \left(g_k - \frac{1}{6} \sum_{i=1,6} g_{k(i)} \right)^2 \right) \quad (61.21)$$

It may be noted that this distribution takes the form of a *intrinsic conditional autoregressive* (ICAR) model (Besag 1974; Besag and Kooperberg 1995) – with precision parameter κ . This is an improper prior, as it does not have a well-defined multivariate distribution for the vector \mathbf{g} ; however, in conjunction with certain likelihood functions (e.g., multivariate normal), the posterior probability density is well defined. Thus, a prior distribution for the g_k values is constructed, and therefore, one for the λ_k values can be derived. However, this prior distribution requires the parameter κ to be provided. One possibility – if the analyst has a clear idea of the degree of roughness to expect – is to specify a particular value in advance. However, in many situations one cannot realistically do this, and another approach – demonstrated here – is to specify a *hyperprior* for the quantity. In this case, Eq. (61.21) is assumed to be conditioned on κ as well, with the prior for κ being an improper prior equal to a small constant.

Having constructed this prior distribution for the parameters, it is now necessary to consider the posterior distribution. Since we are working with the *transformed* parameters $g_k = \sqrt{\lambda_k + 3/8}$, the counts in each zone Δ_k will also be transformed using the same function, that is, c_k , the count of trees in each Δ_k , will be

transformed to $c'_k = \sqrt{c_k + 3/8}$. Anscombe (1948) suggests that Poisson counts from a distribution with mean λ_k transformed in this way have an approximately normal distribution with mean g_k and variance $1/4$. Making use of this approximation, a degree of algebraic manipulation shows that the conditional posterior distributions for the g_k 's and κ are then given by

$$\begin{aligned} \Pr(g_k | g_{k(1)}, \dots, g_{k(6)}, \kappa) &\propto N\left(\frac{1}{24} \sum_{i=1, \dots, 6} g_{k(i)} + \frac{c'_k}{\kappa}, \frac{1}{\sqrt{\kappa + 4}}\right) \\ \Pr(\kappa | g_1, \dots, g_n) &\propto \text{Gamma}\left(n, \sum_{k=1, \dots, n} (g_k - \frac{1}{6} \sum_{i=1, 6} g_{k(i)})^2\right) \end{aligned} \quad (61.22)$$

where $N(\cdot)$ and gamma denote the normal and gamma distributions with the standard parameterizations. This specification of posterior probabilities lends itself to a Markov chain Monte Carlo (MCMC) approach. Rather than estimate the parameters of interest analytically, this approach draws simulated samples from the posterior distribution of the parameters of interest. Essentially, if estimates of all parameters except one are provided, the remaining one is then drawn from one of the conditional distributions shown in Eq. (61.22). Cycling through the parameter space, provided each parameter is drawn from the correct conditional distribution, a draw of all parameters from the full posterior distribution is obtained. If a large number of such multivariate draws are provided, then the empirical distribution may be used to estimate features of this posterior probability distribution. In this case, an MCMC approach is used to estimate and map the posterior mean of each λ_k , which is achieved by transforming the simulated distribution of the g_k 's, via the inverse Anscombe transform $\lambda_k = g_k^2 - 3/8$. The results are shown in Fig. 61.4.

A further advantage of the MCMC approach is that estimation of quantities related to the λ_k values may be estimated in a very natural way, by simply computing these quantities for the simulated posterior λ_k value and viewing the resulting distribution of the computed quantities. For example, a quantity of interest may be the *slope* of $\Lambda(\mathbf{s})$. This is defined to be the magnitude of the vector $\nabla\Lambda(\mathbf{s})$. As before, a discrete approximation will be used – and this may be obtained from the coefficients of the quadratic expression Q in Eq. (61.17). In fact

$$\begin{aligned} \frac{\partial\Lambda}{\partial s_1} &\approx \gamma_1 \\ \frac{\partial\Lambda}{\partial s_2} &\approx \gamma_2 \end{aligned} \quad (61.23)$$

so that

$$|\nabla\Lambda(\mathbf{s})| = \sqrt{\left(\frac{\partial\Lambda}{\partial s_1}\right)^2 + \left(\frac{\partial\Lambda}{\partial s_2}\right)^2} \approx \sqrt{\gamma_1^2 + \gamma_2^2} \quad (61.24)$$

Fig. 61.4 Posterior mean estimates of trees in forest, based on implementing the MCMC algorithm set out in Eq. (61.22)

It may be checked that by using a least squares estimation of Q ,

$$\begin{bmatrix} \gamma_1 \\ \gamma_2 \end{bmatrix} = \frac{1}{3} \begin{bmatrix} \frac{\sqrt{3}}{2} \lambda_2 + \frac{\sqrt{3}}{2} \lambda_3 - \frac{\sqrt{3}}{2} \lambda_5 - \frac{\sqrt{3}}{2} \lambda_6 \\ \lambda_1 + \frac{1}{2} \lambda_2 - \frac{1}{2} \lambda_3 - \lambda_4 - \frac{1}{2} \lambda_5 + \frac{1}{2} \lambda_6 \end{bmatrix} \quad (61.25)$$

which may be used to obtain an estimate of the slope. Applying this to the MCMC simulations obtained earlier yields the map in Fig. 61.5. This shows the regions in which the tree density undergoes most change. As a final approach, one could designate any area where the slope exceeds 1.5 to be a *transition zone*. The idea of this is to identify boundary regions around the forest, for example, these could equate to *ecotones* (Holland and Risser 1991; Allen and Breshears 1998). Again, a function is applied to the simulated λ_k values to obtain a binary variable T_k , which takes the value one if λ_k exceeds 1.5, and zero otherwise. By counting the number of times (in 1,000 simulations) that T_k is equal to one, an estimate of the posterior probability that each zone Δ_k is part of a transitional area may be estimated. In addition, the posterior standard deviations are also illustrated (Fig. 61.6).

61.5 Bayesian Approaches for Point-Based Measurement Data

In this section, analysis of a set of data points will be considered, with each point having an attached attribute. In this case, the spatial point locations will not be treated as random, for example, they may be points where a set of measurements were taken, such as soil conductivity or rainfall levels or the rental or sale prices of

Fig. 61.5 Posterior mean estimates of slope of $\lambda(\mathbf{s})$

Fig. 61.6 Posterior mean estimates of T_k (left) and associated standard deviations (right – see text)

houses at a given set of addresses. The attributes will, however, be treated as a random spatial process. Typically, this will be done by specifying a *variogram* or *correlation function* specifying the degree of correlation between the attributes associated with a pair of points. For a *stationary process*, this correlation will depend only on the distance between the point pairs – so that measurements associated with any pair of points separated by a given distance will have the

same correlation, regardless of their absolute spatial location. Analyzing data using a model of this kind, particularly with a view to interpolating measured values, is referred to as *kriging* – based on the early work in this area developed by Matheron; see (Matheron 1970, 1973) for example.

The underlying idea here is that the attribute values are observations from a *field* defined as a real-valued random function over a space S . The randomness can occur in two ways. Firstly, the function itself is modeled as a Gaussian random process, with a value $E(z) = m(\mathbf{s})$, where $E(z)$ is the expected value of the attribute value z and $m(\cdot)$ is a function of location $\mathbf{s} \in \mathbf{S}$. For *ordinary kriging* this function is just a constant value, μ . For a fuller discussion, see Cressie (1993). The covariance between two values at locations \mathbf{s}_1 and \mathbf{s}_2 is given by $\sigma^2\rho(\mathbf{s}_1, \mathbf{s}_2)$, where $\rho(\mathbf{s}_1, \mathbf{s}_2)$ is the correlation between the z -values at \mathbf{s}_1 and \mathbf{s}_2 – and if the process depends only on the distance between the points, as stated above, then the $\rho(\cdot)$ function can be written in the form $\rho(|\mathbf{s}_1 - \mathbf{s}_2|)$, or $\rho(d)$ if $d = |\mathbf{s}_1 - \mathbf{s}_2|$. The relationship is often expressed in the form of a *variogram*:

$$\gamma(d) = \sigma^2(1 - \rho(d)) \quad (61.26)$$

A number of possible functional forms for γ are frequently used. Some following examples include

Exponential	$\gamma(d) = \sigma^2 \left[1 - \exp\left(-\frac{d}{h}\right) \right]$	
Spherical	$\gamma(d) = \sigma^2 \left(\frac{3d}{2h} - \frac{d^3}{2h^3} \right)$, if $d < h$; σ^2 otherwise	(61.27)
Gaussian	$\gamma(d) = \sigma^2 \left[1 - \exp\left(-\frac{d^2}{2h^2}\right) \right]$	

In each of these cases, the parameter h controls the amount of correlation between attribute values at locations separated by a given distance. Although the exact interpretation differs for each of the functions, it is generally the case that larger values of h suggest correlation persists at larger distances. Note that the list above is not exhaustive, but also that arbitrary specification of these functions is not possible – in general, functions must be chosen such that for any set of points in S , the covariance matrix implied by the function must be positive definite.

When analyzing this kind of data, there are generally two key issues requiring investigation. Firstly, the calibration of the variogram function, in the particular forms above, implies the estimation of the parameters h and σ^2 . The second issue is the use of this model for interpolation. Although the Gaussian process is sampled at a finite number of locations, it is often useful to estimate values of $E(z)$ at other locations. In particular, given that there is a vector of observed attribute values \mathbf{x} , interpolation at a new point \mathbf{s} can be thought of as estimating the conditional mean of z at this location, given \mathbf{x} – written as $E(z|\mathbf{x})$. In both cases, although the primary aim may be the investigation of parameters, being able to make statements about

the precision or accuracy of these statements is of importance. The original approach to kriging calibrates the variogram using point estimates for the parameters, and then “plugs them in” to the expression for $E(z|\mathbf{x})$. However, more recently, attention has focused on approaches that allow for uncertainty in the variogram parameter estimates. In terms of interpolation, these provide a more realistic picture of kriging estimates – although the original approaches provide expressions for variance in $E(z|\mathbf{x})$, these are conditioned on the parameter values in the variogram. In reality these parameters are generally estimated and subject to uncertainty due to the sampling process – and this in turn adds uncertainty in the estimates for $E(z|\mathbf{x})$.

A Bayesian approach – such as that given by Diggle et al. (1998) – is one way of addressing this issue. Prior probability distributions are supplied for the variogram parameters, and on the basis of observations, a posterior distribution function is derived. In the reference above, as in the previous section, an approach using Markov chain Monte Carlo simulations is used.

The technique is illustrated here with a set of house price data obtained from Nestoria (<http://www.nestoria.co.uk>) – a web site providing listings of houses currently for sale. Here a set of 260 semidetached three bedroom houses were downloaded for the Liverpool area of the United Kingdom. This set contains all three bedroomed semidetached houses listed on 28th December 2011, excluding those whose price was not published in the listings. (A very small number of houses are listed as “price on application”.) Prices were scaled to units of thousands of pounds, to avoid rounding errors in calculations; thus, an asking price of \$199,950 would be recorded as \$199.95 k. Here, house locations are recorded as latitude and longitude and then transformed to the OS National Grid projection coordinates in meters. A plot of the data is given in Fig. 61.7. From this, it may be seen that there is a degree of spatial clustering in this data, for example, a group of higher-priced houses are visible to the north, and another group of lower-priced houses may be seen to the southern part of the area.

Here, an exponential variogram model is used – with a uniform prior on $[0, 30]$ km for h and a reciprocal prior for σ^2 . Calibration is via the MCMC approach, as outlined in the previous section. This is achieved using the *geoR* package for the R statistical programming language. As an example of the variogram calibration aspects of the analysis, the posterior distribution curve for the parameter h is shown in Fig. 61.8. Note that since *geoR* uses discrete approximations for distributions, this takes the form of a histogram. This shows that the posterior distribution for h peaks at around 4 km, although it has quite a long tail. In a classical inference approach, this kind of insight into inference about h is rarely provided, as in general it is just a two-number confidence interval that is provided.

In Fig. 61.9 the correlation derived from the variogram associated with each of the possible values for h is shown. For each h , the correlation curve is drawn with an intensity corresponding to the posterior marginal probability of that value of h . Reading off vertically from the x -axis suggests posterior probabilities of correlation associated with a given value of h . From this it can be seen that there is very little correlation between pairs of observations separated by more than about 20 km.

Fig. 61.9 Posterior estimates of the correlation curve

Fig. 61.10 Posterior predicted mean house price values based on Bayesian kriging

Moving on from inference about the variogram, as stated above, it is also possible to make inferences about the values of $E(z|\mathbf{x})$ where there are no observations. In this case, the technique is used to evaluate such values at regular points on a grid, so that “house price surfaces” can be drawn, outlining regional trends in house prices around the city of Liverpool. Again, the `geoR` package in R (Ribeiro and Diggle 2001) is used to achieve this. Results are shown in Fig. 61.10. As these are also the results of MCMC simulation, it is possible to visualize the accuracy of the estimates, by showing a corresponding surface of the standard deviations of the posterior distributions of the estimates of $E(z|\mathbf{x})$ at each location on the grid.

Fig. 61.11 Posterior predicted standard deviations of house price values based on Bayesian kriging

These are illustrated in Fig. 61.11. Note that in this figure, lower values of the posterior standard deviation (and hence greater confidence in the estimation) occur at locations close to the data points. To see this, compare Figs. 61.7 and 61.11.

61.6 Region-Based Measurement Data

In this section, data associated with regions (such as states or counties that may be represented by polygons) will be discussed. This section will be somewhat briefer than the previous two – a key reason for this is that the approach seen in Sect. 61.3 is quite similar to those that may be applied here. This is because, for point data, a discrete grid approximation was used, and this is essentially applying Bayesian approaches to region-based data, providing the “regions” form a regular lattice. A number of models have been developed to describe multivariate distributions where each variable is a quantity associated with a region. For example, if z_i is associated with region i , then the simultaneous autoregressive model (SAR) is

$$z_i = \mu_i + \sum_{j=1}^n b_{ij}(z_j - \mu_j) + \varepsilon_i \quad (61.28)$$

where $\varepsilon_i \sim N(0, \sigma_i^2)$ independently, and $\mu_i = E(z_i)$ and b_{ij} are constants, with $b_{ii} = 0$. Frequently, if w_{ij} is an indicator variable stating whether regions i and j are adjacent (with the convention that $w_{ii} = 0$), then the b -values are modeled as $b_{ij} = \rho_s w_{ij}$ and the values of μ_i and ρ_s are parameters to be estimated. Note that here the s is not intended as an indexing subscript; it simply denotes that this parameter is associated with the SAR model. In the simplest case for μ_i , we may assume it takes

a constant value μ and also that σ_i^2 takes the constant value σ^2 – so that all that is needed is to estimate the three values μ , σ^2 , and ρ_s .

A related model is the conditional autoregressive (CAR) model which specifies the distribution of z_i conditionally on all of the other z -observations, denoted by z_{-i} :

$$z_i|z_{-i} \sim N\left(\mu_i + \sum_{j=1}^n c_{ij}(z_j - \mu_j), \tau_i^2\right) \quad (61.29)$$

where, similar to before, $c_{ii} = 0$. Again, a common form of model for c_{ij} is $c_{ij} = \rho_c w_{ij}$. Assuming that the μ_i 's and τ_i^2 's are fixed for all regions, again we have a model with just three parameters, μ , τ^2 , and ρ_c . In each of these cases, Bayesian analysis can be carried out in a fairly intuitive way. For both the CAR and SAR models, it is possible to rearrange the model equations to the form of multivariate distributions of \mathbf{z} , the column vector of z_i observations. For the SAR model, we have

$$\mathbf{z} \sim N\left(\mu\mathbf{1}_n, \sigma^2(\mathbf{I}_n - \rho_s\mathbf{W})^{-1} [(\mathbf{I}_n - \rho_s\mathbf{W})^{-1}]^T\right) \quad (61.30)$$

where $\mathbf{1}_n$ is a column vector of n 1's, \mathbf{I}_n is the $n \times n$ identity matrix, and \mathbf{W} is the matrix of w_{ij} values. Similarly the factorization theorem – see Besag (1974), for example – gives for the CAR model:

$$\mathbf{z} \sim N\left(\mu\mathbf{1}_n, \tau^2(\mathbf{I}_n - \rho_c\mathbf{W})^{-1}\right) \quad (61.31)$$

Using similar prior distributions to those from Sect. 61.3 combine with either Eq. (61.29) or Eq. (61.28) to provide the likelihood functions enables a multivariate posterior distribution for σ^2 , ρ_s (or ρ_c), and μ to be derived and simulated. With this in mind, it is relatively straightforward to simulate posterior distributions for either of the sets of three distributions or for some priors to derive the distributions theoretically.

61.7 Conclusions

The above discussion demonstrates that it is possible to apply Bayesian inference to a number of spatial problems. Here, problems have been broadly classified in terms of the form of geographical information used as the basis of the analysis: point-based data, point-based measurement data, and region-based measurement data. In each case some form of Bayesian analysis is proposed. However, the list here is by no means exhaustive. For example, it may be possible to apply kriging and variogram-based methods (Oliver 2010) to regional data either by assigning a centroid point to each region or – perhaps more realistically – by expressing

regional values as the average or sum of points defined on a random field defined within that region. Also it is possible to extend these models – whereas in this chapter the expected value of the observed measurements has been modeled as a constant value, it is possible to adopt a regression approach and to express this quantity as a function of explanatory variables. Bayesian analysis provides a useful inferential tool for calibrating all of these models; they provide a relatively rich set of tools for drawing inference relating to model parameters and particularly when using MCMC tools, for drawing inferences relating to functions of these parameters, or predictive distributions for future observed variables. There are other forms of spatial data, and these may also be usefully analyzed using Bayesian techniques. For example, linear or network data have not been considered here, but such data forms may also be usefully analyzed using models which lend themselves to Bayesian analysis.

However, perhaps a greater challenge for spatial analysis is the ability to assess *which* model for a given data set is the most appropriate or whether a particular model is entirely inappropriate. The use of inferential tools as stated above is applied within a framework where the “true” model is a member of a family of models, for example, when analyzing regional data although the specific values of μ , ρ_c , and σ^2 may not be assumed, it is taken as given that the model can be specified in the general framework of a CAR model. However, how might one decide whether this is more appropriate than a SAR model? This is not a simple matter of testing “nested” models, when one set of models is a subset of another and inference can be based on posterior distributions of the parameters in the larger subset, but a matter of comparing structurally distinct models. Indeed, how does one choose between either of these models and a kriging-based model as suggested earlier. A number of ideas have been proposed for this in a Bayesian framework, but this area of research is relatively new; the *deviance information criterion* (DIC) of Spiegelhalter et al. (2002) is one attempt to address this – although some debate has been raised – see, for example, Ando (2007) who discusses a tendency for the DIC to favor models with larger numbers of parameters and proposes a modification to address this.

Another issue related to this is that of model appropriateness. Some recent criticism has been aimed at CAR and SAR based models – Wall (2004) notes that although the **W** matrix suggests that there is some spatial structure in the model, the actual variance-covariance matrices in Eqs. (61.30) and (61.31) can provide counterintuitive relationships between distances between regions and correlations, stating that

... although these covariances are clearly just functions of **B** or **C**, in general there is no obvious intuitive connection between them and the resulting spatial correlations.

(Here **B** and **C** are matrices of b_{ij} and c_{ij} coefficients). Although the Bayesian approach allows us to make relative assessments of the most appropriate parameter values within the modeling framework, it is also important to determine whether *any* combination of parameters would be meaningful. These observations are highly significant; a great deal of work (Bayesian and otherwise) has used models of this kind and has in general accepted that they have encapsulated spatial dependency in a reasonable way.

In summary then, it is argued that Bayesian analysis has a great deal to offer to spatial analysis and provides a richness of inferential tools, particularly via MCMC, that allow insights to be made that may not otherwise be possible or at least achieved as easily or intuitively. However, there are still a number of challenges, although arguably many of those – such as the issues of model appropriateness or model selection – are problems that face *all* kinds of statistical inference.

Abstract

Two classes of models that have made major breakthroughs in regional science in the last two decades are cellular automata (CA) and agent-based models (ABM). These are both complex systems approaches and are built on creating microscale elemental agents and actions that, when permuted over time and in space, result in forms of aggregate behavior that are not achievable by other forms of modeling. For each type of model, the origins are explored, as are the key contributions and applications of the models and the software used. While CA and ABM share a heritage in complexity science and many properties, nevertheless each has its own most suitable application domains. Some practical examples of each model type are listed and key further information sources referenced. In spite of issues of data input, calibration, and validation, both

modeling methods have significantly advanced the role of modeling and simulation in geography and regional science and gone a long way toward making models more accountable and more meaningful at the base level.

62.1 Introduction

Models are simplifications of real-world systems that are amenable to tests and simulations of the reactions of the real systems to changes in their state and function. For extant and complicated regional systems, such as the United States Interstate Highway system, experiments on society would be unacceptable (closing highways to measure traveler delays, for example) – yet the computer allows such experiments *in silico*. Models, of course, are only of value if their structures are based on knowledge or data about an actual system and if they give results which are reasonable and credible. Foremost among the challenges of modeling is the fine-tuning of models so that they achieve the best results (calibration), of meaningfully converting a system's components into structural and behavioral equivalents within the model (design), of the model's effective use of computing power (tractability), of the ability to match actual or expected results (performance), and of their ability to create accurate predictions (validity). Regional science has employed a large number of modeling approaches over time, yet in the last three decades, two paradigms of modeling have emerged that have made achievements against these challenges and that have led to breakthroughs in model performance and accuracy for regional systems. These two approaches are cellular automata (CA) models and agent-based models (ABM).

In this chapter, we examine these two modeling approaches. Both have been termed “individual-based modeling approaches” in ecology, and this reflects the fact that both types of models are bottom-up – that is, they model the primitive or elemental level of behavior associated with a system. Aggregate patterns are achieved by summing the results of many individual actions, which has led to the related terms “disaggregated models” and “micro-simulation models.” Both these approaches are similar in that they are simple, easy to program and implement, and use an iterative approach. Both require initial conditions to be set and have challenges around calibration procedures. Cellular models are preferred when geographic space can be represented in the form of a geographic grid, such as the cells in a raster Geographic Information System. They are also favored when model states and the probabilities of transitions among those states are known and stable. They are most suitable for dissipative processes, such as land use change and urban growth. On the other hand, agent-based models are superior when the basis of a model is a behavioral unit, such as a person, household, business, landholder, or farmer (the “agent”), and when the modeled process consists of interactions over time among one or more types of agents that produce a spatial form, such as land use, crop choice, or habitat type. It has been said that the two modeling forms differ only in the fact that in CA the agents remain in place and interact only with their neighbors. This statement, however, ignores

both major and subtle differences between the two modeling approaches, such as their means of calibration and validation. We return to this contrast in the concluding section.

62.2 Complexity and Models of Complexity

Complex systems theory was originally developed in physics and has origins in Lorenz's work on weather forecasting, which in turn reflect chaos theory and work on the three-body problem by Poincaré in 1890. Initially, Lorenz observed that a system's behavior in the long term reflects the initial conditions of the system, such as the locus of an attraction point being a function of where a point subject to the attraction started its path. The values of variables that separate different system behaviors are called thresholds, and crossing them leads to nondeterministic and nonlinear behavior. Complexity is that behavior phase which is neither static nor deterministic. An early demonstration of complexity was in sand piles. When sand is poured from a nozzle, it forms a pile, which grows in a simple linear fashion. However, at some point in its growth, the sides of the pile are subject to failure. Even though the exact failure gradient is known, it is impossible to tell when a failure will take place and how much of the sand pile it will take down. Such behavior has been called self-organized criticality.

As chaos and complexity theory became more known, largely due to the Santa Fe Institute and the work of scholars like Murray Gell-Mann and John Holland, applications in many different fields became commonplace. Complexity has a natural link to the science of fractals and self-similarity, as noted by Batty (2000). Many of the fields that adopted the complex systems approach were related to physical geography, such as meteorology, fire modeling, and ecological succession. However, Batty and Longley's (1994) demonstration of the fractal nature of cities led to some degree of acceptance within urban and human geography. Many systems in human geography exhibit complexity, including land use change, residential segregation, urban growth, road network growth, and intercity interactions.

Important concepts in complexity theory are that dynamical systems – those subject to feedbacks – exist in three aggregate states or phases: chaos, stability, and complexity. In chaos, no discernable rules, structures, or even heuristics apply, such as in the business cycle or the stock market. In stability, behavior is linear or can be modeled by polynomials, that is, the change is differentiable and solvable with differential equations, equilibrium theory, and optimization. Complexity, however, is marked by periods (time) or subregions (space) of both stability and chaos. A system can move from one aggregate behavior state to another (a phase change), but each behavior type is robust (resilient) against perturbation to some degree (Waldrop 1993). Tipping a system beyond a threshold provokes a phase change, and the system then trends away from the original state. An example often used is a lake, which is subject to inputs of phosphates. The ecosystem of the lake is able to counter the impact of the phosphates up to a certain concentration. Beyond that, even by a fraction, the lake cannot return to its initial state, and eutrophication takes

place, leading to a new ecosystem based on the higher phosphate levels and different plant and animal species. An unknown, possibly large, proportion of human and natural systems exhibit such complexity.

The attraction of both cellular automata and agent based models is they represent some of the simplest frameworks possible for demonstrating complex systems behavior. Largely for this reason, the models were quickly adopted and used to test many new types of urban and economic systems models. John Holland has suggested a defining condition for identifying complex systems and complexity, which he has termed emergence (Holland 1998). Emergence has been criticized as too subjective a criterion by which to identify complexity but is said to exist in a system when new and unpredicted patterns or global-level structures arise as a direct result of local-level procedures. The structure or pattern that emerges cannot be understood or predicted from the programmed or assumed behavior of the individual units alone. An example of emergence in CA is the glider (see Sect. 62.3). An example in the SLEUTH CA urban model (Clarke et al. 2007) is the aggregation of new settlements at the junctions of roads, a behavior nowhere inherent in the model's programmed behavior.

62.3 Cellular Automata: Origins

A cellular automaton (plural cellular automata) is a discrete model originally theoretical, but now implemented in disciplines from physics to biology, geography to ecology, and computer science to regional science. CA have been defined as "discrete spatio-temporal dynamic systems based on local rules" (Miller 2009). As noted above, they are the simplest modeling framework in which complexity can be demonstrated. Using CA, extremely complex behavior and emergence can be demonstrated with terse conditions and minimal rules. They are inherently attractive as spatial models because they map closely onto the raster grid in a geographic information system, because they use only local interactions among cells, and because of their simplicity. Nevertheless, they are capable of modeling and simulating extraordinarily complex behavior (Batty 2000) and of demonstrating emergence.

A CA has four elements: (i) a grid of cells, each of which can assume a finite number of states; (ii) a neighborhood, over which a change operator applies, usually the Moore (8-cell) neighborhood surrounding a cell in the grid; (iii) a set of initial conditions, that is, an instance of the states for each and every cell in the system; and (iv) one or more rules, which when applied change the state of a cell based on properties or states of the neighborhood cells. The model advances by applying the rules to every cell one at a time, then swapping the changed grid with the initial grid, and by repeating this procedure.

CA were invented by Stanislaw Ulam, while he was employed at the Los Alamos National Laboratory in the 1940s. At the same time, John von Neumann was working on the problem of self-replicating systems. Von Neumann proposed the kinematic model, a robot that could rebuild itself from spare parts. Ulam recommended that von

Fig. 62.1 A 2D cellular automaton Game of Life. Configuration shows a glider gun, a cell form that remains static and sends out streams of gliders. Gliders and glider guns are emergent behavior from the simple rules of the Game of Life

Neumann develop his idea around a mathematical abstraction, such as the one he was using to study crystal growth on a lattice network. Like Ulam's lattice network, von Neumann's cellular automata used a two-dimensional grid, with his self-replicator implemented algorithmically, working within a CA with a 4-cell neighborhood and with 29 states per cell. This CA is now termed a von Neumann universal constructor. At about the same time, Norbert Wiener and Arturo Rosenblueth developed a CA model and mathematical description of impulse conduction in cardiac systems, implying broad applicability of the theory. By the 1960s, CA were being studied as a simplification of dynamical systems – models developed to simulate natural systems with feedbacks, such as air flow, turbulence, and weather, and human systems such as cities and economies. In 1969, Gustav Hedlund compiled many CA results into a seminal paper on the mathematics of CA (Hedlund 1969).

Nevertheless, CA remained largely a mathematical curiosity until John Conway's creation of a CA game, the Game of Life. Martin Gardner drew popular attention to the game in a 1970 issue of his games column in *Scientific American* (Gardner 1970). Life was a two-state, two-dimensional CA with only four rules: (i) Any live cell with fewer than two live neighbors dies (death), (ii) Any live cell with two or three live neighbors remains alive (survival), (iii) Any live cell with more than three live neighbors dies (overcrowding), (iv) Any dead cell with exactly three live neighbors becomes alive (birth). Despite the game's simplicity, it can create astonishing variety in its long-term patterns. An "emergent" phenomenon is the "glider," a cell arrangement that perpetuates itself by continuous movement across the grid (Fig. 62.1). It is possible to arrange the automata so that gliders interact to perform computations, and it has been proven that the Game of Life can emulate a universal Turing machine, thus completing von Neumann's line of research.

62.4 Cellular Automata: Key Contributions

In the 1980s, Stephen Wolfram published a series of papers systematically investigating an unknown class of one-dimensional cellular automata, which he called *elementary cellular automata* (Wolfram 1986). The demonstration that what is now termed “complex systems behavior” can be simulated from the simplest of CA led to a host of explorations within the social and physical sciences into the range of what CA could simulate. Wolfram continued this work, and in 2002 published *A New Kind of Science* (Wolfram 2002). In the book, Wolfram argues that discoveries about cellular automata are not isolated facts but have significance for all disciplines of science. Using a one-dimensional CA, Wolfram demonstrated that virtually any mathematical function can be simulated, and he explored applications across disciplines. Wolfram proposed a four-class set of possible CA. In Class 1, nearly all patterns quickly evolve into a stable homogenous set and randomness disappears. In Class 2, nearly all patterns quickly evolve into an oscillating structure, with some randomness remaining. In Class 3, nearly all patterns evolve into pseudo-random or chaotic structures. Any regular structures are quickly eliminated by randomness, which dissipates through the entire system. In Class 4, nearly all initial patterns evolve into structures that interact in complex and interesting ways. Wolfram has conjectured that many class 4 cellular automata are capable of universal computation. This has been proven for Conway’s Game of Life and for Wolfram’s Rule 110. Rule 110 is a unique achievement, defined as a one-dimensional CA that for the input neighboring configuration set $\{111, 110, 101, 100, 011, 010, 001, 000\}$ yields the equivalent outputs $\{0,1,1,0,1,1,1,0\}$. Of the 88 possible unique elementary cellular automata, Rule 110 is the only one for which Turing completeness has been proven, making it arguably the simplest known Turing complete system. Rule 110 exhibits Class 4 behavior, which is neither completely stable nor completely chaotic. Localized structures appear and interact in various complicated-looking ways, demonstrating the properties of emergence and phase change. There have been several attempts to place CA into other formally rigorous classes, inspired by Wolfram’s classification. For instance, Culik and Yu proposed three well-defined classes (and a fourth one for the automata not matching any of these) called Culik-Yu classes.

From the perspective of geocomputation, Batty (2000) surveyed the variants of CA possible for simulating urban and similar systems. He pointed out that strict CA models are on one end of a computational spectrum and that at the other end are simple Cell Space models, really no different than raster grids with a finite set of states that transition over time. He distinguished between cell space models, which are not at all CA models in the strict sense, and the concept of relaxing the CA assumptions. Key among the relaxations is the incorporation of action-at-a-distance, which is excluded by strict CA’s use of the von Neumann or Moore neighborhoods only. CA development in modeling of urban areas and other geographical realms are covered in a literature review, and some useful information sources are listed (Batty 2000, p. 119).

Beyond mathematics, CA applications have been less concerned with definitional rigor and more with making CA adjust to geographical variation. Approaches have included automatic learning methods to empirically derive rules from observed patterns, self-modification or rule changes triggered by aggregate system behavior, and the addition of “ghost” states, that fall between strict classes (e.g., “urban,” “non-urban,” and “under development” as land uses). Sante et al. (2010) note eight ways that formal CA models have been modified for use in urban growth modeling: using irregular spaces, nonuniform cell spaces, extended neighborhoods, nonstationary neighborhoods, complex transition rules, nonstationary transition rules, by adding growth constraints, and using irregular time steps. Theoretical work has also examined the synchronous versus asynchronous application of the rules.

Applications of CA models in regional science have been commonplace. Most frequently, the models work on land use maps, often simplified to urban and nonurban states. Rules are derived and models calibrated using past data states, that is, by hindcasting. Land use maps derived from remotely sensed data at different time periods have commonly been used as data inputs, and other data are often zoning restrictions, transportation networks, and topography. Geographic Information Systems are used to compile and georegister the map layers, and to receive the modeling results. CA models have been applied at many scales, following the research on fractal urban forms pioneered by Michael Batty (Batty 2005), but most CA models use data at resolutions between 30 and 100 m. An early model by White and Engelen (1993) added action-at-a-distance by changing the Moore neighborhood assumption. Clarke et al. (1997) created the SLEUTH model, a CA that incorporated weighting of probabilities and self-modification, feedback from the aggregate to the local. Wu and Webster’s modeling of the rapid growth in Southern China was another significant contribution (Wu and Webster 1998). Sante et al. (2010) tabulated 33 urban CA models and compared their characteristics, and provided a useful summary of the theoretical and applied CA modeling surrounding geography, urban planning, and regional science. Silva has considered complexity theory in planning more generally, using CA as the specific example (Silva 2010).

Sante et al. (2010) also offered a classification of CA transition rules. Type I rules are those of classical CA, that is, transitions can only occur based on the states of neighboring cells. Type II rules are based on potentials or probabilities altered by the land or environmental status of a cell. Type III rules are pattern development rules, which adjust the states based on shape or the existence of a network, such as roads. Type IV rules use computational intelligence methods to determine the rules from prior system behavior. Typical are Case-Based Reasoning, neural networks, data mining and kernel-based methods. Type V rules use fuzzy logic and uncertainty reasoning, while Type VI rules include those not compatible with types I–V.

62.5 Cellular Automata: Applications

Examples of cellular models in popular use include DINAMICA (See: www.csr.ufmg.br/dinamica), SLEUTH (See: www.ncgia.ucsb.edu/projects/gig), and

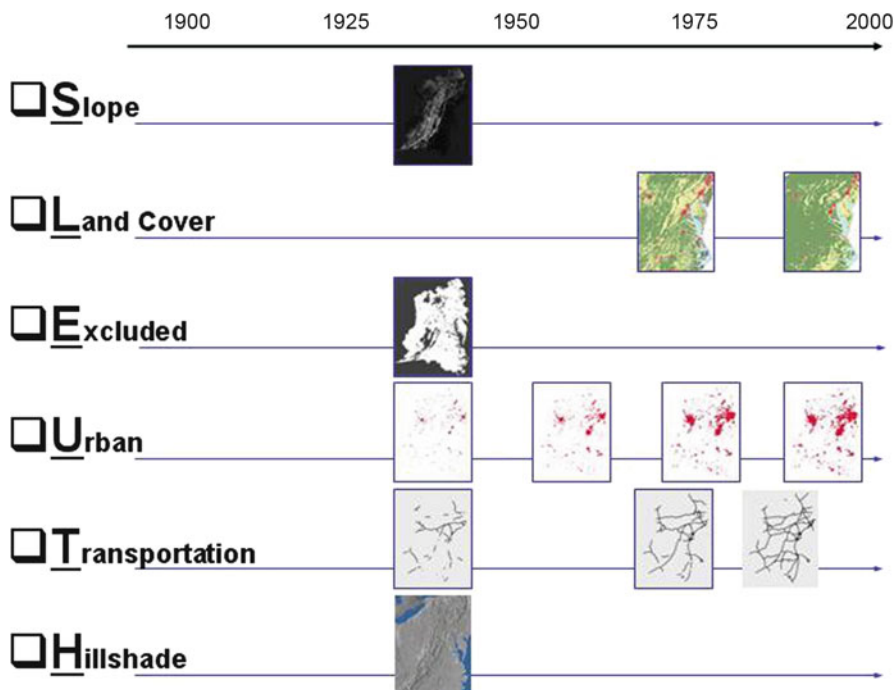

Fig. 62.2 Input data for the SLEUTH model. Minimum layers are topographic slope, two land use maps, one exclusion map, four urban extent maps, two transportation maps, and a hill-shaded background image. Data shown are for the Environmental Protection Agency's Mid Atlantic Regional Assessment study area

Simland (Wu 1998). Influential critical reviews of CA research include those by Batty (2005), Torrens and O'Sullivan (2001), and Benenson (2007). An important early theoretical framework was that of Takeyama and Couclelis (1997), and additional attempts at synthesis have been made by Benenson and Torrens (2004) and by Torrens and Benenson (2005). Nevertheless, interest in and use of the CA suite of models continues unabated, with applications of several of the models at many scales, across regions, for whole nations, and on all continents other than Antarctica.

A representative CA model that has been long-lived in relation to others is the SLEUTH model. SLEUTH is an acronym for the data input layers required by the model (Fig. 62.2). The model was developed by the author and a host of collaborators with funding support from the United States Geological Survey, the National Science Foundation, and the Environmental Protection Agency. There are three retrospectives on SLEUTH's now 15 years of use (Clarke et al. 2007; Clarke 2008a, b). SLEUTH actually consists of two CA models tightly coupled together and coded within the same open source C-language program: the Clarke Urban Growth model and the Deltatron Land Use Change model.

Fig. 62.3 At each cycle in the CA model, five sets of behavior rules are enforced. These are controlled by the factors and parameters shown and are applied in sequence for each one “year” iteration of the model

The former is a classic CA, using a Moore neighborhood and simple sequential rules (Fig. 62.3), but using weighting for probabilities, Monte Carlo simulation, and self-modification – in which aggregates, such as the overall growth rate, feedback into the parameters controlling the rule sets. The latter differs in that it takes its input of quantity of transformation from the Urban Growth model and applies CA in change space rather than geographic space. In doing so, it relaxes the single time-step rule and allows persistence and aging of cells for longer than one time step. SLEUTH has over a hundred applications at many scales and for different cities worldwide. A typical forecasting result is shown in Fig. 62.4.

62.6 Agent-Based Models: Origins

Agent-based models (ABM) are a class of computational models for simulating the actions, behavior, and interactions of autonomous individual or collective entities, with the goal of exploring the impact of one agent or a behavior type on the system as a whole. Miller (2009) notes that the agents are independent units that attempt to fulfill a set of goals. The agents can be countries, landowners, residents, renters, farmers, shoppers, vehicles, or even people out for a walk. Unlike with CA, the purpose of ABM is often the exploration of variants in system behavior due to agent characteristics (such as the proportion of agents of different types) or rules, rather than resulting aggregate structures or maps. Multiagent models include more than one agent; for example, a habitat model may include plants, animals that eat the plants, and predators that eat the animals. ABMs combine game theory, complex

Fig. 62.4 Land use in the Santa Barbara, California, region. *Top*: In 1998, the base year for modeling with SLEUTH. *Bottom*: In 2030, as forecast by SLEUTH for the Santa Barbara Regional Impacts of Growth Study (2003). *Black*: unclassified; *Red*: urban; *yellow*: agriculture; *orange*: rangeland; *green*: forest; *blue*: water; *purple*: wetland; *Tan*: barren land

systems theory, evolutionary programming, and stochastic modeling. In ecology and biology, ABMs are termed “individual-based models.”

ABMs simulate the actions and interactions of multiple agents, in an attempt to emulate the overall system behavior and to predict the patterns of complex phenomena. Agents behave independently, but react to the environment, the aggregate properties of the system, and other agents. So, for example, a farmer agent in the Brazilian Amazon may clear land as he becomes more profitable, in response to a change in crop price, or because his neighbor is clearing his land. Agents are usually assumed to behave with bounded rationality, acting in their own interests such as reproducing, increasing profit, or increasing status, usually by simple heuristic rules. For example, the previously mentioned farmer may decide to have a child or build a house when profitability reaches a certain level. Agents can also “learn,” that is, avoid previously failed decisions while favoring successful ones. They can also adapt, that is, change behavior based on properties of the system.

An ABM consists of (i) agents specified at specific model scales (granularity) and types; (ii) decision-making heuristics, often informed by censuses and surveys in the real world; (iii) learning or adaptive rules; (iv) a procedure for agent engagement, for example, sample, move, interact; and (v) an environment that can both influence and be impacted by the agents. Creating a model involves examining or surveying a system to extract the agents’ behavior and influential factors, quantifying these elements, then coding the model in an environment that allows control, examination of maps and time sequences, and metrics of system behavior and performance. Many ABMs are programmed in coding languages with Java being the most common, while others use one or more of the software tools,

both open source and proprietary, in which the system and rules have to be specified. While there are many examples of software for ABM, relatively few of them are compatible with GIS or produce maps or images. Also of use is the ability to do Monte Carlo simulations and to let the models iterate to a steady state.

ABMs share their origins with CA in the work of von Neumann, Ulam, and Conway. A pioneering agent-based model in urban systems was Thomas Schelling's urban residential segregation model (Schelling 1971). Though not computational, the work embodied the basic concept of agent-based models as autonomous agents interacting within a fixed environment and with an observed aggregate outcome. In the 1980s, interest in game theory led to Robert Axelrod's experiments with the game "Prisoner's Dilemma," showing that strategies evolved and coevolved over time among players. Craig Reynolds' research on models of flocking behavior yielded the first biological agent-based models with embedded social characteristics. Modeling biological agents using ABM became known as artificial life. This led to artificial societies, artificial cities, computational economics, etc. Important software tools for ABM were StarLogo, SWARM, and NetLogo in the 1990s, and since then Ascape, Repast, Anylogic, and MASON (Railsback et al. 2006). Examples of early models include *Construct* by Kathleen Carley and *Sugarscape* by Joshua Epstein and Robert Axtell. These explored the coevolution of social networks and culture and the role of social phenomena such as segregation, migration, pollution, sexual reproduction, combat, and the transmission of disease. An early book on ABM in social simulation was Nigel Gilbert's *Simulation for the Social Scientist* (1999). A key research journal has been the *Journal of Artificial Societies and Social Simulation*.

62.7 Agent-Based Models: Key Contributions

A survey of the recent ABM literature is that of Niazi and Hussain (2011). A key survey in Geography was that of Parker et al. (2003), resulting from a workshop (Parker et al. 2002). Also influential was a series of papers published by the Santa Fe Institute (Gimblett 2002). Agent-based modeling has been extraordinarily interdisciplinary. ABM has been applied to model organizational behavior, logistics, consumer behavior, traffic congestion, building and stadium evacuation, epidemics, biological warfare, and population demography. In these cases, a system encodes the behavior of individual agents and their interconnections. In some geographical applications, the models have been informed by field work, interviews, or from censuses that are used to derive behavioral characteristics and choices using qualitative methods. Agent-based modeling tools are then used to test how changes in individual and collective behavior impact the system's aggregate behavior. In some cases, agents are allowed to learn from past choices, avoiding decisions with negative outcomes, for example.

The following ABM development environments include the ability to ingest, output, and use spatial data: Anylogic, Cormas, Cougaar (via OpenMap),

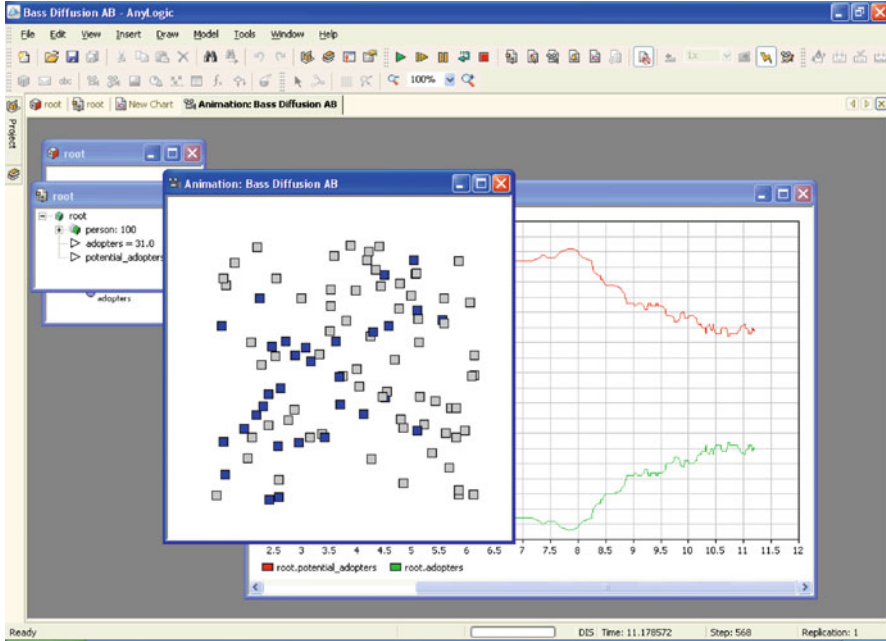

Fig. 62.5 User Interface for the Anylogic 6 Agent-Based modeling software (Source: http://www.coensys.com/agent_based_models.htm)

Framsticks, Janus (using JaSIM), MASON, Repast, SeSAM, Netlogo, and VisualBots. Some of these, and other nonspatial packages, contain model libraries that include CA examples such as Game of Life, HeatBugs, demographic models, epidemiological models, and flocking. Many include the means to display charts, graphs, and maps and menus to input control variables and rules (Fig. 62.5).

62.8 Agent-Based Models: Applications

Recent topics in regional science that have been modeled with ABMs include crowd behavior during riots and outdoor events (Torrens 2012), innovation in businesses (Spencer 2012), commuting behavior (McDonnell and Zellner 2011), ecology and habitats, disease, and land use change. The most recent research on agent-based models has demonstrated the need for combining agent-based and complex network-based models. This has included a desire for models with reusable components, tools for proof of concept and design, descriptive agent-based modeling for developing descriptions of agent-based models by means of templates and complex network-based models, and a need for better validation. The latter point has been repeatedly used in critiques of ABM: their very nature makes

Fig. 62.6 Israeli and Arab residential patterns of the Israeli towns of Yaffo and Ramle from the Israeli census, and their Schelling model simulations (Source: Hatna and Benenson (2012))

calibration and validation using data descriptive of real systems rather difficult, if not impossible. For example, a programmed behavior type will indeed emerge when enough agents are given enough time, so experiments with agents could be considered circular reasoning. Truly emergent behavior or new knowledge should be unanticipated during model construction.

An example of a common ABM application is the Schelling model (Schelling 1971). This simple model of segregation, originally proposed as a game simulation, has been used as the basis of many agent-based models and theoretical discussions about ABMs. The model illustrates how individual tendencies regarding neighbors can lead to segregation in cities. The model has been extensively used to study residential segregation of ethnic groups where agents represent householders who relocate in the city. A concise statement of the model is that by Benenson et al. (2009), in which are enumerated the six behavior rules, assuming the model to be an ensemble of agents of two types, B and W, dispersed over a grid. The rules are: (i) at every iteration, the agents can move to a vacant cell; (ii) the decision to move to a cell is based on the fraction in the neighboring cells of the opposite type of agent; (iii) this fraction should be below a tolerance proportion; (iv) if this fraction is exceeded, then an agent moves; (v) the agent searches within a finite distance for cells that are below the tolerance threshold, and if none exists, does not move; (vi) vacated cells become available for other agents. In most applications, these rules produce residential segregation, depending on the two constants that must be determined. Benenson and his colleagues have repeatedly experimented with

real-world data and the Schelling model. [Figure 62.6](#) shows Jewish-Arab residential patterns of the Israeli towns of Yaffo and Ramle from the Israeli census, and their ABM equivalents (Hatna and Benenson [2012](#)).

62.9 Conclusions

Cellular automata and agent-based models have both represented a new approach in modeling, that of complex adaptive systems. In this approach, models are micro-simulations, run at the atomic level, and aggregate behavior emerges as a consequence of large numbers of agent interactions. The complex systems approach has favored CA and ABM over Forrester-type systems dynamics models and steady-state and equilibrium models. CA and ABM share in common their individual basis. In CA, the modeled entities are cells that remain static while spatial and other processes move across or through them. In ABM, the agents can move in space, interact with each other directly, and interact with other agent types. In both cases, a large number of independent autonomous lowest level actors create the overall landscape. The models can include extra data, such as environmental control layers, and parameters that influence the agents, such as prices or demands.

CA models have been criticized as oversimplifications of reality, and those that have relaxed the rules have been criticized as not pure CA. CA are extremely sensitive to their initial conditions, and are very consumptive of CPU time. Since most use square grids, they are subject to error due to incorrect choice of map projection, and directional bias. In the long run, they are subject to equifinality arguments, since in most cases all developable land becomes developed, regardless of the exact sequence of development. They have also been criticized as difficult to implement and data hungry.

Bithell et al. (2008, p. 625) have noted that ABM have the potential to create integrated models that cross disciplines, so that similar computational methods can be used to control the spatial search process, to deal with irregular boundaries, and display the changing of systems where the “preservation of heterogeneity across space and time is important.” They note that a principal challenge of ABM is to find sets of rules that best represent the beliefs and desires of human as agents, so that they reflect the cultural context, yet still allow system exploration. Clifford (2008, p. 675) noted that ABMs are most appropriate where decisions or actions are distributed around specific locations, and where structure is seen as emergent from the interaction among individuals. For this new and exploratory modeling framework, he calls for “a rediscovery and reappraisal of the richness and depth of insight in the model-building enterprise more generally.” Some have attempted to link ABM with other bodies of theory, for example, Neutens et al. (2007) have linked ABM and time-space geography. Andersson et al. (2006) have attempted to link networks, agents, and cells to model urban growth. Lastly, O’Sullivan and Hakley (2000) have suggested that using ABM encourages a modeling bias toward an individualist view of the social world, thereby missing many forces that shape

real economic and human systems top down, such as planning and government. Read (2010, p. 329) noted that agent-based models “sometimes provide only a veneer of, rather than substantive engagement with, social behavior.”

Both CA and ABM have enjoyed popularity in the regional modeling arena in the last 20 years due to their simplicity, ease of use and accuracy. When machine learning or optimization is involved, the models can produce simulations that are of excellent accuracy. However, the models are often only as good as the data with which they are trained or tested, and are highly sensitive to the context of these data. Relatively few CA or ABM models are highly ported across different applications. Even fewer have been rigorously tested for accuracy, repetition, and parameter sensitivity and validated using independent data. A major criticism of both model types is that while the simulations are accurate and engaging, they lack any causative description or policy-related link to actual system behavior. Thus, while they can create useful future scenarios or forecasts, the means by which the actual system can be steered toward that outcome is not forthcoming. CA models are best used for spatially distributed process simulation, such as spread and dispersal, and when the geometry, scale, and basic behavior of a system are known. ABM is suited to simulations with no prior precedent, no past data, or when system knowledge is absent. These applications are usually more exploratory than when CA are used. Nevertheless, both modeling methods have significantly advanced the role of modeling and simulation in regional science and gone a long way toward making models more accountable and more meaningful at the base level. Their joint impact on research and understanding of human systems has been profound.

Abstract

Spatial microsimulation is an excellent option to create estimated populations at a range of spatial scales where data may be otherwise unavailable. In this chapter, we outline three common methods of spatial microsimulation, identifying the relative strengths and weaknesses of each approach. We conclude with a worked example using deterministic reweighting to estimate tobacco smoking prevalence by neighborhood in London, UK. This illustrates how spatial microsimulation may be used to estimate not only populations but also behaviors and how this information may then be used to predict the outcomes of policy change at the local level.

63.1 Introduction

Social science research increasingly aims to explore the effects of government policy on individual behavior. Although detailed data are available about individuals from disparate surveys and sources (such as health records), what is often not known/readily available is the spatial location of these individuals within a city or country. Microsimulation can link data from multiple sources to model behavior at the individual level, to identify groups within a population who may need additional support or assistance before changing an aspect of public policy. Microsimulation may also be applied spatially to estimate small-area population effects of public policy prior to implementation. In this way, governments may be better prepared for local changes that follow rollout of a new tax or urban planning scheme. Additionally, the knowledge of how particular behaviors vary spatially can lead to more efficient allocation of services: garbage collection in areas of highest waste generation and hospitals located in proximity to areas with more traffic accidents or greater prevalence of long-term illness.

The focus in this chapter is spatial, rather than individual, microsimulation. Spatial microsimulation creates a “synthetic” population (compiled from anonymized individual-level data) which realistically matches the population, as defined by the population census, in a geographical area for a given set of criteria (constraints). A diverse set of research and policy applications utilize spatial synthetic populations, including health (Brown and Harding 2002; Smith et al. 2011), transportation (Beckman et al. 1996), and water demand estimation (Williamson and Clarke 1996).

The accurate representation of populations within geographical areas may have great significance for microsimulation modeling when the outputs are intended to inform policy. The US and UK Censuses collect comprehensive sociodemographic data on individuals, but to protect confidentiality, data are aggregated to larger geographic scales. At a coarse geographic scale (such as US state or county), more attribute detail is available, including cross tabulation of attributes such as tables of age-sex-ethnicity distribution of the population. At a fine geographic scale (e.g., UK output areas with average populations of 250), detailed population attributes are not available, only univariate tables of age, sex, or ethnicity. The lack of detailed data at the local level has led to research focused on creating realistic synthetic populations within a predefined geographical area, estimating combinations of attributes and/or data not available within census datasets, effectively filling in the blanks.

Within this chapter, both microsimulation and spatial microsimulation are defined. Using the main application areas as examples, we highlight the strengths and weaknesses of the approach. The focus then moves onto the main algorithms that are used within spatial microsimulation: deterministic reweighting, conditional probabilities, and simulated annealing. An exemplar of the application of spatial microsimulation is provided through a case study involving the estimation of smoking prevalence in local areas within London, UK. Finally, a general discussion is presented offering suggestions for areas of future development.

63.2 Defining Spatial Microsimulation

Microsimulation is the generation at time $t = 0$ of a population sample P made up of n individuals $[P^1, P^2, \dots, P^n]$ where each individual, i , has a number of initial attributes $[a^i_1, a^i_2, \dots, a^i_m]$. The population is then updated to later times, t , so the attributes of individual i become functions of time $[a^i_1(t), a^i_2(t), \dots, a^i_m(t)]$. This allows the population to be used to model the effects of policy changes on individuals. While detailed statistics on each individual attribute are often available for the whole population (e.g., number of males/females, number of people in a given age band), information about the codependencies of attributes is not (e.g., how many people in the 20–30 age band are male/female), or there is no information on policy-relevant outcomes such as household expenditure on childcare, or individual-level health behavior such as physical activity or smoking. What is often available is a sample of the population which does contain all these attributes. In microsimulation, the initial population is often taken from population samples in large-scale surveys.

Spatial microsimulation is a type of microsimulation that recognizes the key role of geography in many of the processes being modeled. Each respondent from a survey dataset, which includes the attributes we want to estimate for the population, is given a probability (weight) to live in a specific location or spatial area (e.g., a ward), based on the known population structure of each area from the census. As discussed above, one of the key challenges for spatial microsimulation is the creation of a realistic initial population. Often population samples are only available at the coarse spatial resolution (e.g., at country/regional level) and not at the fine spatial scale required. At the fine scale, only statistics on the individual attributes are available. Spatial microsimulation techniques therefore need to generate a realistic population in each area, j .

Mathematically, the population of area j can be written as $P_j = [w_{ij} P^i]$ where the weight w_{ij} represents the number of people in the population of area j , characteristic i , with the attributes of person P^i from the sample or synthetically generated population. To ensure the proportions of each individual attribute are correct in the area, the w_{ij} need to be chosen so the mean absolute error (MAE) given by $\sum_{km} |T_j^{km} - T_j^{km}(obs)|$ is minimized for each area j . Here, T_j^{km} is the modeled number of people in area j with attribute k taking the value m , and $T_j^{km}(obs)$ is the equivalent number observed. The modeled value is given by $T_j^{km} = \sum_i w_{ij} \delta_i^{km}$ where δ_i^{km} takes the value of one if attribute k takes the value m for person i and zero otherwise. Ideally, the MAE would be zero for all areas, but in practice, this is not always attainable given just an initial sample of the whole population. Much of the focus of the rest of this chapter will be discussing methods for obtaining the weights w_{ij} .

63.3 Static and Dynamic

Microsimulation models are categorized as either static or dynamic. In static microsimulation, a large representative sample has rules (normally drawn from data analysis or the literature) applied to it to generate the synthetic demographic and economic characteristics expected at one point in time. Spatial population

simulations are focused on what the consequences of external information bring to the population; it does not model the changes in the population itself. The defining characteristic of static microsimulation is that there is no direct change of the individuals within the model during the simulation time period, instead we focus on adding attributes to the existing population dataset. A typical “what-if?” scenario would be: “If there had been no poll tax in 1991, which communities would have benefited most and which would have had to have paid more tax in other forms?” (See Ballas et al. 2005; Gilbert and Troitzsch 2005). Further examples of static microsimulation in this area are presented below in Table 63.1.

In dynamic microsimulation, individuals change their characteristics as a result of endogenous factors within the model; the populations update over time. Various degrees of direct interaction between micropopulation units can be found in dynamic microsimulations, for example, processes such as birth and marriage. These models rely on accurate knowledge of the individuals and the dynamics of such interactions. In a dynamic microsimulation, the updating of the dynamic structure is performed by “aging” the population through the application of transition probabilities (i.e., what is the probability of an individual getting married or having a baby?). The changes in the population itself are modeled with changes in an individual in 1 year having an effect on the characteristics in subsequent years. A typical future-oriented dynamic microsimulation scenario would be as follows: if the current government had raised income taxes in 1997, what would the redistributive effects have been between different socioeconomic groups and between central cities and their suburbs by 2011? (O’Donoghue 2001; Ballas et al. 2005; Gilbert and Troitzsch 2005).

Static and dynamic microsimulation each has benefits and drawbacks. Static models tend to be simpler programs than dynamic models, and because they are less computationally demanding, simulations can be run quickly. There is a general acceptance that dynamic models provide a more realistic long-term estimate of individual-level behavior (O’Donoghue 2001). However, the process of generating realistic behavior involves potentially unlimited interactions/interdependencies of the individuals when updating; this can result in dynamic microsimulations being computationally demanding (Ballas et al. 2005).

63.4 Microsimulation as a Tool for Policy

One of the most important advantages of microsimulation is that it enables us to examine the impact of policy changes on individuals even with sparse data. This distinguishes microsimulation from alternative methods, such as Bayesian estimation (Congdon 2006) (for details of general Bayesian methods, see Brunson, this volume) or multilevel modeling for small-area population estimation (Moon et al. 2007). These two approaches to small-area population estimation require cross-tabulated data at the spatial scale of the simulation output, limiting the scale of any simulations. The key advantage of microsimulation is that it has no such requirement and may be carried out from a series of univariate tables through an iterative process of recalculating weights.

Table 63.1 Name and description of examples of microsimulation models within the four main domain areas (Adapted from Birkin and Wu 2012)

Model name and domain	Origin	Description and example applications
(a) Tax benefits		
POLIMOD	UK	Demonstrates how VAT, National Insurance Contributions, and local taxes are calculated under different assumptions; entitlement to retirement pension and other non-means-tested social security benefits
STINMOD	Australia	Static microsimulation model of the tax and transfer systems. The rules of government programs are applied to individuals and aggregated to calculate outcomes for income units, families, or households
EUROMOD	Europe	Tax-benefit model that covers 15 countries. It provides estimates of the distributional impact of changes to personal tax and transfer policy at either the national or the European level
(b) Pensions		
PRISM	UK	Dynamic microsimulation of income from social security, earnings, assets, public and private occupational pensions, and retirement savings plans
SfB3	Germany	Analysis of pension reforms, the effect of shortening worker hours, distributional effects of education transfers, and interpersonal redistribution in the state pension system
DYNACAN	Canada	Projects the incidence, average levels, and variation in private pensions into the future as a function of birth year, age, and gender
(c) Health care		
PBS	Australia	Expenditure on pharmaceuticals by different types of households, resultant government outlays under the Pharmaceutical Benefits Scheme, and the remaining patient co-payment contributions
LifeMOD	UK	Model the lifetime impact of the welfare state through examination of health status over the life course and implications for health-care financing in the UK
LifePaths	Canada	A dynamic longitudinal microsimulation model of individuals and families which simulates the discrete events that together constitute an individual's life history
DRACULA	UK	Simulate response of traffic to different network layouts and control strategies; measure network performance from outputs of the average travel time, speed, queue length, fuel consumption, and pollutant emission
Paramics	US	Microscopic simulation of a range of real-world traffic and transportation problems handling scenarios ranging from a single intersection to a congested freeway or the modeling of an entire city's traffic system
VisSim	Germany	Models traffic flow in urban areas as a discrete, stochastic, time step-based microscopic model, with driver-vehicle-units as single entities. The model contains a psychophysical car following model for longitudinal vehicle movement and a rule-based algorithm for lateral movements (lane changing)

Table 63.2 Name and description of examples of spatial microsimulation models

Model	Origin	Description
SVERIGE	Sweden	Dynamic population model designed to study human eco-dynamics. Simulates spatial location and mobility of individuals. Developed for Sweden
SimBritain	UK	Dynamic simulation attempting to model British population at different geographical scales up to the year 2021
HYDRA	UK	Grid-enabled decision-making support system for health service provision
SMILE	UK	Dynamic spatial microsimulation model designed to analyze the impact of policy change and economic development on rural areas in Ireland

Spatial microsimulation has further advantage over other microsimulation models in its ability to explore spatial relationships and analysis of the spatial implications of policy scenarios. These advantages are reflected in the different applications where microsimulation has been applied. [Table 63.1](#) presents an overview of the main subject domains and models that microsimulation can be found within, while [Table 63.2](#) presents examples of spatial microsimulation models.

Many of the models in [Tables 63.1](#) and [63.2](#) share a common feature; they are concerned with the idea of “what-if?” simulations whereby the impact of new or alternative policy rules on the whole system or individual parts/components can be assessed. A simple example might be, “What would happen to the economic situation of local households if there is a change in child benefit tax?”

63.5 Spatial Microsimulation Algorithms

There are several established methods used for spatial microsimulation, specifically: deterministic reweighting (Smith et al. 2011), conditional probability (Monte Carlo simulation) (Birkin and Clarke 1988), and simulated annealing (Openshaw 1995; Voas and Williamson 2001). These methods were selected due to their common application in geography (see Voas and Williamson 2001; Ballas et al. 2005). Further details of each of these algorithms, including mathematical derivations, can be found in Harland et al. (2012).

63.5.1 Deterministic Reweighting

The deterministic reweighting algorithm was introduced by Ballas et al. (2005) and has been widely used in microsimulation models for health-care research. As described in Smith et al. (2011), the deterministic reweighting algorithm proportionally fits each individual record in the sample to the observed counts in each of the constraint tables (univariate tables which define the “known” population within an area based on a set of attributes) iteratively until each of the constraint variables have been included. Each iteration of reweighting first applies Eq. (63.1) to calculate an initial new weight which is subsequently

reweighted to reflect the observed population count in the subsequent constraint tables using Eq. (63.2) and then a scaling factor is included in Eq. (63.3):

$$nw_o^c = oldwt^c \frac{tot_o^c}{tot_s^c} \quad (63.1)$$

$$NW_o^c = \sum nw_o^c \quad (63.2)$$

$$\frac{tot_o^c}{NW_o^c} nw_o^c \quad (63.3)$$

where nw_o denotes new weight for individual in area o ; NW_o total weight for all individuals in area o ; c is constraint subcategory, such as “male” in the gender constraint table; tot_o^c total population in constraint c in area o defined by a population census; tot_s^c total population in constraint c in survey data; and $oldwt^c$ is initial starting weight for individual, based on predefined survey weights, or may be set to equal one.

For each zone, the sample is cloned with the initial starting weights and then reweighted using the procedure outlined above. Each time an individual is “cloned” into an area, the additional attributes associated with them beyond the constraints are also included. Each person in the survey is given a weight, or probability, of living in each area based on the census constraint tables for each area, and this weight adjusts as the algorithm cycles through the constraints. Through this process, a more extensive population profile is made available. The local population profile will include decimal values of the weights, so outcomes are expressed as proportions of the base population rather than individuals replicated with attributes. Perfect matching between the synthetic totals and sample totals from the reweighting algorithm cannot be reached for every zone. The more dissimilar the characteristics of a zone are from the distribution of characteristics in the sample, the greater the resulting error, as this method assumes all of the areas are relatively homogeneous. A zone with a high ethnic minority population will differ to the average distribution of ethnic minority groups in the sample, making such a zone less likely to match the constraint table perfectly. Therefore, despite this algorithm having no stochastic element and being completely deterministic, the order in which constraints are applied can produce different resulting populations as each new weight produced is a product of the weight calculated using the preceding constraint information. One way to adapt this algorithm so the estimates are more accurate is to group together similar areas and run them through the model together (Smith et al. 2011). This is illustrated in the example at the end of this chapter.

63.5.2 Conditional Probabilities

The conditional probabilities model is an adaptation of the synthetic estimation procedures first introduced by Birkin and Clarke (1988). It was originally designed to generate a synthetic population where no survey data

existed. With the availability of more survey information, the algorithm has evolved to execute equally well using a sample.

The algorithm initiates by creating a population with the characteristics of the first constraint and the associated probability calculated from the constraint table. For example, the first constraint is gender and the number of males and females in the first geographical zone are 120 males and 180 females. Therefore, 120 individuals are created with an associated characteristic of male, and a further 180 individuals are created with a characteristic of female.

The second constraint is marital status with three categories: married, single, and divorced/widowed. The probability of married, single, and divorced/widowed people appearing in the zone is first derived from the sample. It is simply the count of individuals in each category from the second constraint, divided by the total number of individual records appearing in the first constraint. If the sample contained 1,000 records of which 400 were male, of the males 160 were married, the joint probability of a male being married would be $160/400 = 0.4$. The remaining joint probabilities are calculated for the male sample and result in being male and married, $p(\text{male, married})$, is 0.4, $p(\text{male, single})$ is 0.4, and $p(\text{male, divorced/widowed})$ is 0.2. The male portion of the synthetic population is iterated through, with a random number greater than zero and less than or equal to one generated for each individual. If the random number is less than 0.4, a characteristic of married is added to that individual; if the random number is between 0.4 and 0.8, a characteristic of single is added to the individual; and finally, if the random number is greater than 0.8, a characteristic of divorced/widowed is added to the individual. This process is repeated for the female category from the first constraint.

Once all individuals in the current zone have been assigned the second constraint characteristics, the totals for each of the three categories are calculated and compared to the totals observed in the marital status constraint table. The initial starting probabilities are adjusted to represent the discrepancies between the observed constraint totals and those calculated from the synthetic population. For example, if 100 married people were expected in this zone but only 80 had been created, the initial male probability of being married, $p(\text{male, married})$, of 0.4 would be boosted using Eq. (63.4), as would the corresponding female probability, $p(\text{female, married})$:

$$np_c(x, y, z, \dots, n) = op_c(x, y, z, \dots, n) \frac{T_c^{constraint}}{T_c^{synthetic}} \quad (63.4)$$

where $np_c(x, y, z, \dots, n)$ is the new joint probability calculated and $op_c(x, y, z, \dots, n)$ the old or initial joint probability. $T_c^{constraint}$ is the total number of individuals in category c of the current constraint, and $T_c^{synthetic}$ the total number of individuals in category c of the synthetic population.

For the male population, Eq. (63.4) would become $0.5 = 0.4 \frac{100}{80}$ giving a new $p(\text{male, married})$ of 0.5. Each joint probability for the second constraint is adjusted

and the characteristic assignment process repeated. This process is iterated through until changes in the joint probabilities fall below a predefined threshold. Each constraint is added individually using this technique until all the required constraints have been incorporated, and then the next zone is calculated starting from the initialization of the synthetic population using the values from constraint one. Once this process is complete, the synthetic population can be saved if no additional attributes from the sample are required. However, if the researcher is interested in examining attributes from the sample not included in the constraints, usually because they are not available, then an additional final Monte Carlo sampling stage is required. For each individual in the synthetic population, the sample is entered at a random point and iterated through until the first record exactly matches the constraint attributes generated for the synthesized individual. When a matching record in the sample has been found, the extra attributes are copied to the synthetic record.

63.5.3 Simulated Annealing

As outlined by Davies (p. 6, 1987), “Simulated annealing is a stochastic computational technique derived from statistical mechanics for finding near globally-minimum-cost solutions to large optimisation problems.” The essence of the procedure is to start by creating a population as a random extract from the sample file, and by aggregating for the various constraints, the goodness of fit of the population to the constraining tables can be evaluated. From this population, an individual member is selected at random and replaced with another individual that is also selected at random from the sample. The aggregation and goodness of fit evaluation is repeated, and if the fit is improved, then the new individual replaces the old.

The feature which distinguishes simulated annealing, for example, in contrast to hill-climbing algorithms, is the incorporation of the Metropolis algorithm allowing both backward and forward steps to be taken when searching for an optimal solution (Otten and van Ginneken 1989). So even if the replacement leads to deterioration in the model fit, it will be allowed by the model as long as a certain threshold is exceeded. This threshold is often characterized as a “temperature” step – or annealing factor – as this method was originally conceived as a means to simulate the annealing process by which metals are cooled. As the algorithm proceeds, the (temperature) thresholds are reduced, and so, backward steps become progressively more unlikely, so that ultimately only climbing moves are permitted toward an optimized outcome.

Simulated annealing is similar to deterministic reweighting to the extent that weights are applied to members of a sample. However, in simulated annealing, these weights are zero or one representing selection or exclusion, whereas in deterministic reweighting, the weights are fractional. Simulated annealing is a heuristic hill-climbing algorithm rather than an iterative process (deterministic reweighting) or sequential estimation method (conditional probabilities). One of the

most important differences is that simulated annealing evaluates individual moves simultaneously against all of the constraining tables, whereas in both of the other techniques, this evaluation takes place constraint by constraint.

63.6 Which Algorithm?

Each spatial microsimulation algorithm/method possesses its own inherent advantages and disadvantages. The following section evaluates the strengths and weaknesses of each method in the context of issues to consider before selection of an algorithm.

First, how much preprocessing is required to obtain a robust fit-for-purpose output? As both the deterministic reweighting and conditional probabilities algorithms reweight the resulting populations using one constraint at a time, building on the results from the previous constraint, they are sensitive to the constraint order specified within the model; the first constraint will have the greatest impact on the final “weight” assigned to an individual to live in an area.

The primary difference between deterministic reweighting and conditional probabilities is the lack of a stochastic process in deterministic reweighting. As the deterministic process will give the same result every time, the impact of slight modification to the constraint variables will be clear from the results. To model the prevalence of type 2 diabetes using a deterministic method and estimate the impact of an aging population on diabetes prevalence, the age constraint may be adapted to reflect an aging population. The model is then rerun to estimate diabetes prevalence under this aged population distribution. In contrast, the simulated annealing algorithm places equal weight on each constraint (although this can be changed at the researcher’s discretion), and thus, the constraint order is of no consequence to the outputs.

The number of constraints that can be specified is related to the speed of execution of each algorithm. The deterministic reweighting algorithm reweights the sample using all of the constraint information in a specified order. As more constraints are added, the difference in sample and constraint frequency distributions can become more pronounced, especially at finer geographies where constraint populations are small. Therefore, less robust results may be produced as additional constraints are included in the model. The conditional probabilities model suffers with similar issues; however, these are less pronounced due to the joint probabilities for constraint combinations being adjusted in isolation. However, increasing the number of constraints increases both the processing time and the likelihood of being unable to converge on a suitable joint probability for a constraint combination. Simulated annealing also suffers from a time performance penalty as the number of constraints is increased although the rate increase is less severe than for the other two algorithms.

One of the major advantages that the conditional probabilities method has over the other two algorithms is that if a sample is unavailable, a synthetic population can be created using only the aggregate information from the

constraint tables. However, as the algorithm here requires a sample from which to extract the initial joint probabilities, an alternative source for this information is required in the absence of a sample otherwise erroneous individuals, such as married children, could be produced. A major advantage of the simulated annealing approach, as discussed above, is the inclusion of the Metropolis algorithm. However, the drawback to added search power is the associated higher computational times. Neither the conditional probabilities method nor the deterministic reweighting method can take backward steps when searching for a solution.

Finally, both the conditional probabilities and the simulated annealing methods contain a stochastic element that results in the creation of a different population configuration each time the model is run. This allows the model to consider and produce alternative and potentially more realistic populations. Deterministic reweighting does not have this capability. However, because deterministic reweighting produces the same result with each model run, the impacts of any starting constraint change are more easily quantifiable and can be important for policy evaluation, as discussed above.

There is only one example of these methods being compared and systematically evaluated within the published literature. Harland et al. (2012) compared the outputs of spatial microsimulation algorithms at varying spatial scales. While simulated annealing performed very well in each of the experiments that were performed, no clear winner was advocated. An interesting finding was that the simulation of attributes that are particularly influenced by spatial locations is best undertaken using the deterministic reweighting algorithm. This method allows the constraint order to be tailored to best represent a particular cluster of zones and is more accurate when the purpose is to model one distinct outcome rather than recreating a generic population (Smith et al. 2011). The following case study uses the deterministic reweighting algorithm to estimate one such outcome, estimation of smoking prevalence in London.

63.7 Case Study: Estimating Smoking Prevalence Locally

The application of spatial microsimulation to health outcomes is a valuable extension to the earlier models of tax policy and population estimation. Local-level public health data are more readily available due to electronic patient records and regular data collection as part of the funding scheme in the UK; however, these data only reflect individuals who are registered with a general practice or visit the hospital. Patient records are protected by strict information governance, and patient right to privacy or confidentiality prevents widespread access to or use of records which may inadvertently identify an individual. Within the UK data, governance prohibits most spatial mapping of individual health data below the Lower Super Output Area level [=LSOA] (about 1,500 individuals). Even when the data exists, it may not be used for spatial analysis if there is risk of reidentifying patients when their location is combined with demographic

characteristics. Small-area estimation of health outcomes/behaviors offers a solution to restricted spatial analysis and can be accomplished by combining detailed health surveys with population census data with spatial microsimulation.

Small-area estimation of health data may be carried out using a variety of statistical methods and frameworks. Here we focus on spatial microsimulation using a deterministic reweighting algorithm, although as mentioned previously, there are numerous alternatives including multilevel modeling (Moon et al. 2007) and Bayesian methods (Congdon 2006). In the example to follow, we will show that the microsimulation algorithm requires only univariate population data tables at the geographic level of interest. The population census restricts multivariate (cross-tabulated) tables at lower levels with the aim of protecting identity. For this reason, spatial microsimulation has been used to estimate health outcomes down to the output area level, which typically includes about 150 individuals. If we knew how smoking prevalence varied spatially, we would be able to allocate smoking cessation services and associated resources more effectively.

There are few complete population health censuses available beyond local bespoke surveys. More frequently, countries will have national-level health surveys (such as the Health Survey for England or New Zealand Health Survey) repeated either annually or every set number of years. These national surveys are conducted with a representative sample of the population and often include hundreds of variables to provide comprehensive profiles of respondents' health. As part of the data collection process, the surveys will also collect information on basic social and demographic characteristics of respondents. This data allows respondents from the health survey to be "linked" to people from the census who share the same demographic traits. This process will be illustrated in an example of smoking prevalence estimation among adults in London (2001 Census population: 7,172,090).

Data to produce the smoking estimates will come from the 2008 Health Survey for England [=HSE] ($n = 12,648$ respondents). In this example, we will use logistic regression to identify the social and demographic variables present in both the HSE and the 2001 Census that are best predictors of cigarette smoking among adults in England. There must be consistency in the variables between both datasets: the census provides the spatially defined population at the output area level, and the HSE gives us the probability of an individual who fits a given social and demographic profile to be a smoker. For the sake of simplicity, this example will be limited to four predictor variables (constraints).

The logistic regression model is run using SPSS 18.0. A series of potential predictor variables are identified from literature on smoking behavior: age, sex, ethnicity, social grade, marital status, employment status, and housing tenure. Smith et al. validated this method to predict smoking accurately in New Zealand (2011) using age, sex, ethnicity, and income data from the New Zealand Health Survey and the New Zealand Census of Population. After running a series of logistic regression models and comparing model fit, the four best predictors of smoking status from the HSE were identified as age, sex, marital status, and social grade. The constraints variables are categorical (Table 63.3).

Table 63.3 Constraints in the smoking model

2008 HSE data Constraint		<i>n</i>	%
Sex	Male	5,897	46.6
	Female	6,751	53.4
Age	0–17	3,069	24.3
	18–24	575	4.5
	25–34	1,096	8.7
	35–44	1,321	10.4
	45–54	1,305	10.3
	55–64	1,234	9.8
	65+	4,048	32
Social grade	AB	5,193	41.1
	C1C2	4,946	39.1
	DE	2,509	19.8
Marital status	Single	4,873	38.5
	Married	5,505	43.5
	Separated	211	1.7
	Divorced/widowed	2,059	16.3

NB The social groups in the UK are defined as follows: *A* is upper middle class (higher managerial, administrative, or professional), *B* is middle class (managerial, administrative, or professional), *C1* is lower middle class and *C2* skilled working class (junior managerial, skilled manual laborers), *D* is working class (semi- and unskilled workers), and *E* are those at the lowest level of subsistence (pensioners, widows)

There are a total of 4,765 LSOAs in London. The constraint tables are created with the total counts of individuals in each LSOA, which must sum to the same total population in each LSOA for each constraint variable. This must be checked carefully as some people will not answer all of the questions in the census. To ensure that there are the same total counts for each LSOA in each constraint, the numbers are proportionally adjusted to sum to the total provided in the basic population table for the LSOA. For example, in the first LSOA, the total population is known to be 1,600. However, only 1,540 people answered the marital status question. To adjust for the known total population (1,600), the number of people in group AB (670) is divided by the total count in the social grade table (1,540) then multiplied by 1,600:

$$670/1,540 \times 1,600 = 696.1$$

This is repeated for all of the categories in social grade, in each LSOA.

As discussed previously in the spatial microsimulation literature, with the deterministic reweighting algorithm applied here, the model will smooth all of the areas to look similar to each other. This will increase the error in prevalence estimates for areas which are unique, because the local population will look very different from the “general” population. One way to minimize the tendency to

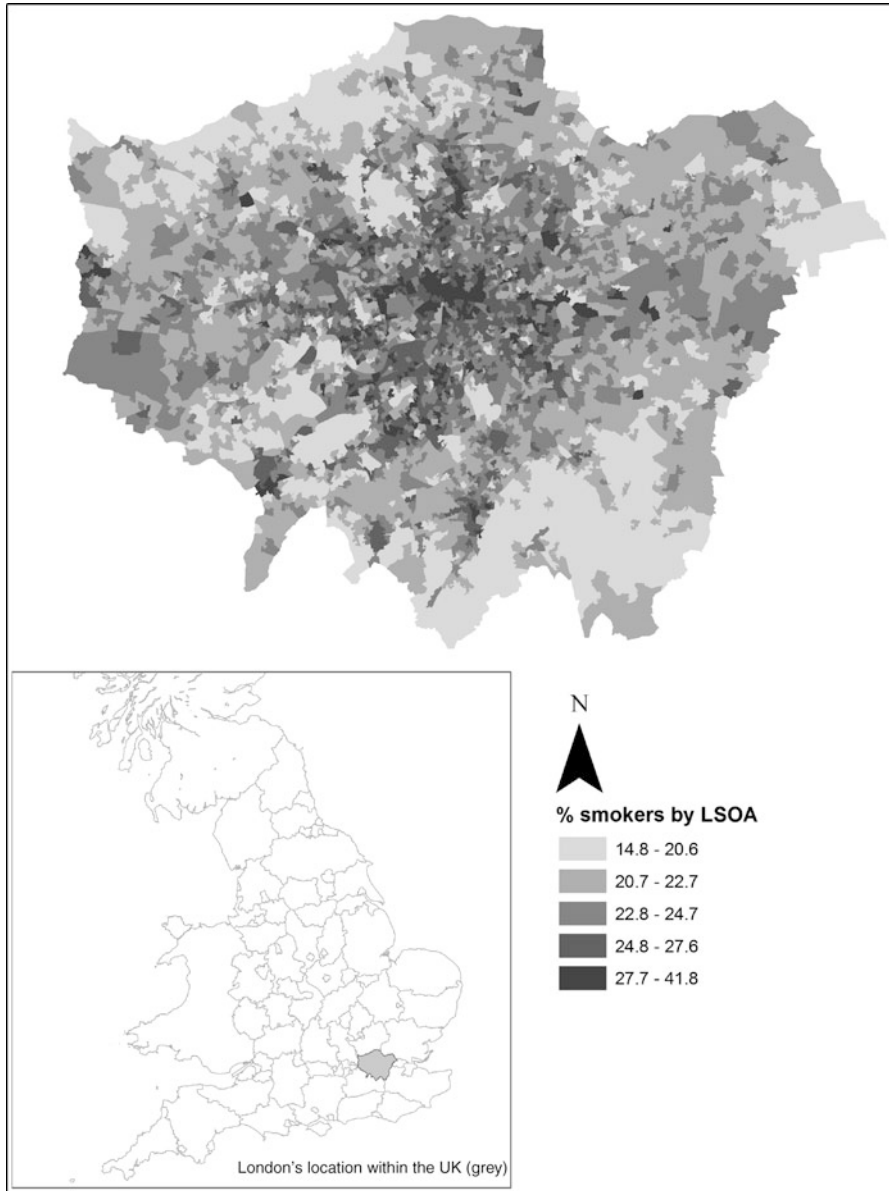

Fig. 63.1 Estimates of smoking prevalence of adults in LSOA's in London

higher levels of error in dissimilar places is to first identify the LSOAs which have a similar population profile in terms of the constraint variables used to predict the health behavior. This may be done by running a k-means cluster analysis (Smith et al. 2009). In this example, the LSOAs are clustered based on the percent of

Table 63.4 Error between microsimulation model and estimates from NHS information centre (2005–2008 data)

Westminster	–2.59

the population in the 18–24 age range and social groups D or E and the percent who are unmarried. All of these groups are most likely to be smokers within the constraint data.

There are a total of five clusters based on these population characteristics. The model is then run five times, once for each of the clusters. The results are decimal values of people as smokers or nonsmokers, or children under the age of 18. The final counts of smokers are then used to calculate the prevalence of smoking among adults in each LSOA. The estimates are mapped at the LSOA level for London in [Fig. 63.1](#). Estimated prevalence ranged from 14.8 % to 41.8 % by LSOA.

The results are validated against estimates created by the National Health Service (NHS: this is the main health-care provider in the UK) Information Centre (IC), based on HSE data from 2005 to 2008. The NHS estimates are available only at the primary care organization (PCO) level, of which there are 31 in London. We aggregated the estimates from the microsimulation model to the PCO level and measured the difference in prevalence between the NHS estimates and our estimates. The mean absolute difference was 2.85 % overall, with a range of values from -6.86 % to 9.34 % (Table 63.4). The greatest error was in Barking and Dagenham PCO (9.34 %). The error is reasonable given the available data and the time difference between our estimates and those created by the NHS IC.

The estimate error may also be measured against real-world data, where available (see Smith et al. 2011), or against a similar outcome such as diabetic amputations when predicting prevalence of diabetes (Congdon 2006). Alternatively, the error may be tested against another known value that is related to both the constraint variables and the outcome.

As this deterministic reweighting example shows, there are basic steps to the simulation process that must be conducted every time:

- Identify viable aspatial dataset for the health outcome/behavior (here, the HSE).
- Conduct statistical analyses to identify the optimal predictor variables for the outcome that are available from a spatial dataset (here, the census).
- Using the statistical information on predictors of the health outcome, cluster the areas based on the proportion of area populations that are in the highest subgroup of each constraint (i.e., Which social grade contains the greatest proportion of smokers? Marital status group?).
- Ensure that the constraint tables are prepared with the same count of people in each area across all variables.
- Run the model and validate against available data, similar outcome, or a related variable present in both the spatial and aspatial data.

63.8 Conclusions

Comprehensive socioeconomic data is not, for reasons of confidentiality, available at the individual level within any locality. This lack of detailed data has motivated research into spatial microsimulation with the intention of creating realistic synthetic populations that are representative of the geographical areas to which they represent. These populations can then input into simulation models that allow policy makers to understand the small-area impact in policy or demographics.

This chapter has provided a brief overview of spatial microsimulation, focusing on the main algorithms that are typically employed. A case study of prevalence of smoking in London was presented using deterministic reweighting to show the value that this approach can bring to informing policy on health outcomes. It is clear from this example that spatial microsimulation has a great deal to offer for social simulation modeling.

However, there remain many possible directions for future research. In terms of improving the modeling technique, there is no overarching consensus to which algorithm (reweighting/synthetic reconstruction technique) is the most appropriate or accurate for different domain applications or at which spatial level. This requires further research on validation of the synthetic population estimates produced by researchers. It also requires researchers to be honest about areas in which spatial microsimulation is not successful!

There are several criticisms that can be leveled at microsimulation. They are data hungry, computationally intensive, only model one-way interactions (the impact of policy on individuals), and weak in handling behavioral modeling. Several of these limitations can be overcome by hybridization with other individual-based models, in particular, agent-based models (see Crooks and Heppenstall 2012).

This is perhaps one of the most exciting areas of future research for spatial microsimulation. Realistic individual-level populations can be generated that mimic specific characteristics about a geographical area, or a specific application; for example, populations can be generated that contain characteristics of particular interest to health or education researcher. These populations can be turned into individual agents that form part of a larger modeling effort (see Wu and Birkin 2012). Hybridization allows the incorporation of both different types of behavior and detailed interactions between individuals, something which microsimulation alone is not capable of. The value of hybridization with agent-based models is that it would allow both researchers and policy makers to ask more sophisticated questions of social simulation models and in turn receive more accurate and realistic forecasts.

Acknowledgments This work was funded by the ESRC funded grant “Modeling Individual Consumer Behavior” (RES-061-25-0030) and MRC Population Health Scientist Fellowship (G0802447). The modeling framework used was developed by Kirk Harland.

Abstract

Spatial networks organize and structure human social, economic, and cultural systems. The analysis of network structure depends on the development of

measures and models of networks, which in turn rely on mathematical graph theory. Key concepts and definitions from graph theory are reviewed and used to develop a variety of graph structural measures, which can be used to investigate local and global network structure. Particular emphasis is placed on high-level network structural features of centrality, cohesive subgraphs, and structural equivalence. Widely used models for spatial networks are introduced and discussed. Pointers to empirical research on real-world spatial networks are provided.

64.1 Introduction

It has become commonplace to think of ourselves as inhabitants of a “networked world.” The most obvious contemporary manifestation is the Internet, augmented in recent years by web 2.0 technologies that enable online social networks and by mobile technologies which maintain those connections even while people move through global transport networks from city to city and continent to continent. If “[t]he most profound technologies are those that disappear” (Weiser 1991, p. 94), then the Internet is by any measure profound, so much so that we only notice it – it only becomes visible – when it is unavailable. Of course, most networks are much older and more obviously geographical than the Internet. Significant infrastructure from transport systems and telecommunications to the supply of electricity and water is in the form of networks. Arguably, when it comes to understanding the aggregate geographies of the human world, whether from a social, economic, or cultural perspective, it is networks which structure, constitute, and organize those patterns.

Manuel Castells (1996) foresaw (but only just!) this development in his *The Rise of the Network Society*. Castells suggests that the network society alters social, economic, and cultural relationships, creating a global “space of flows” not directly associated with any particular location on the Earth’s surface. Less radically, other scholars have argued that a key determinant of the relative importance of world cities is not their geographical location per se but their location in economic, transport, social, and cultural networks. For example, Taylor et al. (2011), using network measures, rank the relative importance of cities to argue that London is an “alpha++” city outranking many more populous cities such as Tokyo (alpha+), Seoul (alpha), or Los Angeles (alpha). What makes London rank above other cities is not its particular individual characteristics or geographical location, but its position in relation to other cities, in other words its position in multiple overlapping networks of relationships between cities worldwide.

However, we are getting ahead of ourselves. Whether or not we consider a network analysis of world cities (or anything else) to be informative, before we can deploy such methods, we must define terms and develop measures. As in any field of quantitative study we need measures to enable repeatable descriptions of the objects of study and models to allow us to determine if the measurements we make of empirical cases are interesting. In the next section, basic concepts, definitions,

and measures from graph theory are introduced. There follows a consideration of higher-level concepts of graph structure and associated measures. Throughout these sections pertinent aspects of spatial networks are discussed. Following from this, we introduce some models for spatial networks and comment on their properties. We then consider some significant findings from the rapidly growing literature applying these methods to real spatial networks. The article ends with some pointers to possible future directions.

Note that we do not consider here the numerous problems in computer science, operations research, and transport analysis (particularly traffic assignment and related problems) which are closely associated with the analysis of spatial networks. Interested readers should consult reference works in these fields and related chapters in this major reference work.

64.2 Spatial Networks and Graphs

In their stimulating and still relevant text *Network Analysis in Geography*, Haggett and Chorley (1969) follow Kansky (1963) in moving quickly from considering spatial networks to the analysis of mathematical graphs. Real spatial networks are complicated physical entities, with numerous elements, themselves often complex entities, such as multilane highways or airports with several runways (see Fischer 2004 for how these complications may be handled in a GIS setting). Our primary interest in the analysis of spatial networks lies in understanding how the network as a whole structures connectivity so as to centralize some locations, marginalize others, and, in general, differently position locations with respect to one another. It makes sense to strip away the messy complication of real spatial networks and work with the simpler, abstract representation of a mathematical graph.

We therefore begin with definitions from *graph theory*, which provides a foundation for the analysis of networks. A *graph* is a mathematical abstraction which can represent any set of elements somehow related to one another. Wilson (1996) provides a succinct introduction to the key terms and concepts discussed below. More advanced references delve into this field of discrete mathematics (Gross and Yellen 2006), which is fundamental to computer science (see, e.g., Jungnickel 1999), and is increasingly considered fundamental across all the sciences (Newman 2010).

64.2.1 Basic Definitions

A graph G consists of a finite, nonempty set $V = \{v_i\}$ of *vertices* and a finite nonempty set $E = \{e_i\}$ of distinct, unordered pairs of distinct elements in V , called *edges*. The number of elements in V , commonly denoted n , is the *degree* of G . The number of edges in E is often denoted m . Figure 64.1 shows a typical small graph with $V = \{a, b, c, d, e, f, g, h\}$, $E = \{ab, bc, cd, cf, de, dg, dh, eg, fg, gh\}$, $n = 8$, and $m = 10$.

Fig. 64.1 A typical graph

The edge $v_i v_j$, or e_{ij} , is said to *join* (more commonly link or connect) the vertices v_i and v_j , and these vertices are considered *adjacent*. We say that e_{ij} is *incident* with v_i and v_j and that v_i is a *neighbor* of v_j . The *neighborhood* $N(v_i)$ of v_i , often written simply N_i , is the set of vertices adjacent to v_i . Two edges incident with the same vertex are *adjacent* edges. In Fig. 64.1, $N_b = \{a, c\}$, and edges ab and bc are adjacent.

Given the ubiquity of graphs (or networks), it should come as no surprise that there is considerable confusion around terminology, with different fields adopting different terms in various contexts. Vertices are often referred to as *nodes* and represent the entities in a network, such as cities, people, cell phone towers, airports, and railroad stations. Edges are commonly referred to as *links* or *connections* and represent relationships between nodes, such as movements of goods, services or people, existence of airline routes, and mutual intervisibility. We can think of graphs as mathematical abstractions of networks which exist in the real world, in much the same way that variables represent measurements of real phenomena – this is the distinction between vertices and nodes, edges and links, and so on. In this section, while introducing formal definitions from graph theory, we adopt the proper mathematical terms, but elsewhere may return to widely used synonyms (such as network, node, and link).

The structure $G = (V, E)$ described so far is a *simple graph*, which has limited relevance to the representation of complicated real-world networks. We may also want to include cases where vertices may be joined to themselves by a *loop* $v_i v_i$, and multiple edges may also be allowed if we drop the requirement that edges be distinct. More significantly, *directed graphs* (sometimes referred to as *digraphs*) consist of a set of vertices V and a set of *arcs* A or *directed edges*, each of which consists of an *ordered* pair of vertices in V , implying directionality in the relationship between the vertices. This departure from the simple graph allows us to consider relationships where flows in each direction may be different (or even nonexistent in one direction), and is obviously an important consideration when we consider many real-world infrastructure or distribution networks.

Another variant on the simple graph is the *weighted graph* where each edge has an associated value or weight often denoted w_{ij} , representing some attribute of the relationship between the vertices it joins. The most obvious attribute of interest in many geographical applications is the length of the edge, measured either as a distance or perhaps duration. More generally, edge weights may represent some

cost associated with movement along the edge. Less obviously, but equally applicable, are edge weights that somehow represent the strength of the relationship between the vertices they join. The volume or value of trade between two countries and the number of flights daily between two airports are just two examples among many possibilities. In many cases, weights relating to the strength of a relationship between the incident vertices will reflect rates of flow or the capacity of the associated edges.

64.2.2 Vertex Degree, Graph Density, and Local Clustering

Even the limited graph theoretic concepts introduced so far allow us to develop useful descriptive measures of graph structure. Most obviously, the number of edges incident with a vertex is its *degree* denoted $deg(v_i)$ or k_i . The average vertex degree is a useful summary measure of graph structure, given by

$$\bar{k} = 2m/n \quad (64.1)$$

since each edge is incident with two vertices. This measure is equivalent to Kansky's β index (1963) differing only by a constant multiplier. The *degree list* of a graph is the set of vertex degrees often arranged in order of increasing degree. For the graph in Fig. 64.1, the degree list is $\{1, 2, 2, 2, 2, 3, 4, 4\}$. In large graphs representing complex real-world networks, it is more useful to examine the *degree distribution* of the vertices, an aspect considered in more detail in later sections, although, as we shall see the degree distributions of many spatial networks are strongly constrained by their spatial embedding. If all vertices have the same degree k , it is *regular* of degree k , or *k-regular*. In practice, this is unlikely to occur in spatial networks, but may provide a useful benchmark or null model for assessment of how regularly structured is an observed network.

For a simple graph with n vertices, the maximum number of edges that could exist is given by $\binom{n}{2} = n(n-1)/2$. Comparing the actual number of edges in the graph to this maximum provides a measure of how strongly connected the graph is overall, namely, its *density*, $\rho = m/\binom{n}{2} = 2m/n(n-1)$. A graph's density is the fraction of all possible edges which *could* exist which actually *do* exist. The graph in Fig. 64.1 has density $2 \times 10/(8 \times 7) = 0.357$. Because the number of possible edges in a graph grows approximately with the square of its degree, whereas in most spatial networks the number of edges grows roughly linearly with graph degree, most spatial networks have low density, and only a small proportion of all the possible connections exist. This generally arises either because of distance decay effects or due to planarity constraints. We consider both issues in more detail below.

Because of the constraints on overall graph density in spatial networks, it is often more interesting to consider the local density or clustering of a spatial network.

This is a measure of how strongly connected the graph is in the neighborhood of each vertex. The *clustering coefficient* of a particular vertex is given by

$$C(v_i) = \frac{2m_i}{k_i(k_i - 1)} \quad (64.2)$$

where m_i is the number of edges joining vertices in the neighborhood of v_i . This is a direct localized equivalent to graph density and provides information about how well connected the network is locally. The distribution of the clustering coefficient in a network provides useful information about its structure. One interpretation is that it gives the probability, given that two vertices v_j and v_k are neighbors of v_i that v_j and v_k are themselves neighbors. Many spatial networks exhibit high clustering coefficients compared to nonspatial networks, which is unsurprising: if two vertices in a spatial network are neighbors, it implies that they are near one another, and if two vertices share a common neighbor, since they are probably also near one another, there is a high chance that they will be neighbors of one another.

64.2.3 Spatial Embedding and Planarity

Thus far, there has been no explicit consideration of the spatial aspect. Where we are concerned with spatial networks, vertices will have an associated spatial entity, often conveniently considered to be a point location, but potentially also a more complex spatial entity such as a region – for example, in a trade network, vertices may represent regions or countries.

Two types of spatial embedding of a graph are possible. The most obvious spatial networks are those where both vertices and edges are spatially embedded. Examples include transport and infrastructure networks, where the graph edges are physically realized in space, with direct implications for any associated weights or directional restrictions. Less obviously, spatial embedding of edges imposes a constraint on the overall network structure, that of *planarity*. A planar graph is one which can be drawn in two dimensions with no edges intersecting except at vertices on which they are both incident. For many infrastructure networks, this is approximately true, although bridges and tunnels in ground-transport networks are an obvious (but generally minor) exception. The planarity constraint significantly alters the overall structure of graphs, and we consider its implications in the following paragraphs.

A second form of spatial embedding is where vertices have associated spatial locations, but edges represent nonspatial relationships. An example is a spatially embedded social network. Individuals in the network have some spatial location – perhaps their home address – but edges might represent friendship or acquaintanceship relationships with no corresponding physical realization. A less obvious example is when the vertices in the graph represent spatially extended entities – such as metro lines – and edges represent a relationship such as “has an

interchange with.” Such networks rarely constitute the primary object of analysis, although they may easily arise as *dual graphs* in some analyses. In considering such a network to be a spatial network, we implicitly assume that the distance between vertices (whether direct Euclidean distance or over intervening spatial networks – see below) has an effect on the probability of their existence. In other words, we expect that vertices more remote from one another are less likely to be joined than those that are closer together.

Where the distinction matters, we will refer below to fully embedded or vertex-embedded spatial networks, reserving the term spatial networks to refer to networks of either kind.

The fundamental difference between spatial networks with spatially embedded edges, which are (approximately) planar, and spatial networks not affected by this constraint lies in the limits it places on the overall density of the graph both globally and locally. A fundamental result is Euler’s formula for planar graphs

$$n - m + f = 2 \tag{64.3}$$

where n and m are the number of vertices and edges as before, and f is the number of *faces* or regions in the plane which the graph divides the space into. We consider the overall region in which the graph is embedded as face, so that for the graph in Fig. 64.1, $f = 4$, that is, the whole space and the regions *cdgf*, *deg*, and *dhge*. Euler’s result is easily proved when we consider starting from a graph consisting of one vertex and no edges, so that $n = 1$, $m = 0$, and $f = 1$ when Eq. (64.3) clearly holds (see Fig. 64.2). Adding any edge while maintaining planarity, either (i) joins two existing vertices without intersecting an existing edge, so increasing both m and f by one, while leaving n unchanged, or (ii) adds a new vertex and joins it with an edge, increasing both n and m by one with no change in f . In either case, Eq. (64.3) remains true.

Euler’s formula has important implications for the possible density of planar graphs. Since every face requires at least three edges, and each face can share an edge with at most one other face, we know that $m \geq 3f/2$. Combining this result with Eq. (64.3) we arrive at

$$m \leq 3n - 6 \tag{64.4}$$

Combining this result with Eq. (64.1) tells us that the upper bound on the mean degree of a planar graph is $\bar{k} \leq 6$. Kansky (1963, p. 18) recognizes this in providing alternative formulations of his γ index (equivalent to graph density) for planar and nonplanar graphs.

Understanding this result, it is much easier to understand why area maps are so distinctively structured and why the Voronoi tessellation and associated Delaunay triangulation exhibit such characteristic structure. Since the spatial network constructed from the adjacency relations of a set of polygonal regions must necessarily be planar, the mean number of neighbors of each region cannot exceed 6. In graph terms, this bound on the number of edges in a planar graph

Fig. 64.2 How a planar graph grows as edges are added. Either the number of faces f (upper path) or the number of vertices n (lower path) must increase, but not both

and thus on many spatial networks, means that almost all spatially embedded networks are *sparse*, with $m \ll n^2$ and $\rho \propto 1/n$ as $n \rightarrow \infty$. In terms of local clustering, planarity also implies that any vertex with $k_i > 4$ must have $C_i < 1$ since it is impossible for any graph of more than four vertices to be fully connected.

64.2.4 Shortest Paths, Distances, and Network Efficiencies

A particular sequence of edges $\{v_0v_1, v_1v_2, \dots, v_{r-1}v_r\}$ forms a *walk* of length r . If the vertices in a walk are distinct, then it is a *path*, and a path that begins and ends at the same vertex forms a *cycle*. The *distance* between vertices v_i and v_j , d_{ij} is the length of the shortest path among the set of all possible paths between v_i and v_j . Any one path between v_i and v_j of length d_{ij} is a *geodesic*. The largest distance between any two vertices is the *diameter* of the graph.

In a directed graph, walks may only proceed in the direction of constituent arcs. In a weighted digraph, the length of a path is generalized from the above definitions by summing the weight of its constituent edges, and the distance between two vertices is the length of the shortest path, as before. Given that the weights associated with the arcs in each direction between any two vertices are not necessarily the same (that is, $w_{ij} \neq w_{ji}$), there is no guarantee that the distances between vertices in a directed graph will be symmetric. Note also that where graph weights do not represent a “traversal cost,” such as when they represent link capacities or trade volumes, numbers of people, or other similar measures, then it does not make sense to accumulate edge weights in this way.

The (graph) distances between any two nodes or between all pairs of nodes in a spatial network are of considerable interest, particularly in how they compare to the corresponding straight line (Euclidean) distances between the corresponding node locations. If a network provides a path between two nodes whose distance is close to the straight line distance, then the network is efficient for that particular journey. On the other hand, if the network requires a much longer and more circuitous path to be taken between two locations, it is inefficient. A measure of the network efficiency for a single particular path is the *route factor* defined by Black (see 2003), following Nordbeck (1964) as

Fig. 64.3 The minimum spanning tree of a set of points

$$Q_{ij} = \frac{d_G(v_i, v_j)}{d_E(v_i, v_j)} \quad (64.5)$$

where d_G and d_E are graph-based and Euclidean distances, respectively, between locations i and j . We can average this quantity over a particular node

$$\bar{Q}_i = \frac{1}{n} \sum_j Q_{ij} \quad (64.6)$$

or over the whole network

$$\bar{Q} = \frac{1}{n(n-1)} \sum_{j \neq i} \bar{Q}_{ij} \quad (64.7)$$

The route factor provides one perspective on the efficiency of a network as-built. Another perspective is to consider how cheaply a set of locations might be connected. A *tree* is a graph which includes no cycles, in which $n = m + 1$. The *minimum spanning tree* of a set of vertices is the tree which minimizes the total weight of the edges in the tree, and when the weights relate to the cost of providing the associated node-to-node links, it represents the cheapest way to connect every node to every other. However, such a network is unlikely to be efficient from the point of view of a user of the network as measured using the route factor, since it will certainly involve many very circuitous shortest paths (see Fig. 64.3). Such a network is also vulnerable to failure, since losing just one edge will leave it disconnected. In practice, real networks will have more edges than the minimum spanning tree.

64.3 Higher-Order Structure in Networks

The measures we have considered so far generally focus on the overall structure of a network in a general way or on the structure at a particular location. Summary measures or distributional properties of these measures are generally useful, but they often fail to reveal structural aspects of networks which arise out of the totality of all the spatial relationships in the network. In this section, we briefly consider measures of such higher-order structure.

64.3.1 Network Centrality

Consideration of distance in networks leads naturally to questions of the most accessible or central locations in the network. An obvious approach is to calculate the mean distance from a node to every other node in the network:

$$\bar{d}_i = \frac{1}{n} \sum_j d_{ij} \quad (64.8)$$

where d_{ij} is the graph distance between vertices v_i and v_j as previously defined. Using this *centrality* measure, the most central node in a network is that with the minimum d_i . While this is an obvious measure of network centrality, there are many alternatives. One which has received considerable attention in recent years, because of its close relationship to movement on the network and to how subregions of the graph are connected to one another (see below) is *betweenness centrality*. The betweenness centrality of a vertex v_i is the proportion of the shortest paths between all other pairs of vertices $v_j \neq v_k$ in which v_i appears. If $g_{jk}(v_i)$ is the number of shortest paths from v_j to v_k in which v_i appears, and g_{jk} the total number of shortest paths from v_j to v_k , then

$$c_{between} = \sum_{j \neq k} \frac{g_{jk}(v_i)}{g_{jk}} \quad (64.9)$$

This measure has the nice property that it can be readily extended to edges also, simply being the proportion of all shortest paths on which each edge lies. Betweenness centrality provides an indication of the extent to which each vertex or edge has the potential to control movement or communication in the graph, assuming that there is “everywhere-to-everywhere” movement in the system. This measure is directly related to approaches that rely on random walk models. The most central vertices and edges measured in this way are those which will experience the most traffic when a population of random walkers move around the system.

64.3.2 Network Modules or Subgraphs

A class of measures which remains difficult to define precisely, but which has a clear intuitive interpretation, has recently come to the fore, as researchers attempt to determine how a network can be broken into cohesive subgraphs or regions, now most often referred to as *communities*. Fortunato (2010) provides a comprehensive overview of developments in this field. The general definition of a community is that the member vertices of a community are more strongly connected to one another within the community, than they are to vertices outside the community. This definition is not very precise, however. To take it to the extreme, we could argue that any joined pair of vertices are more closely connected to one another than they are on average to the rest of the graph (unless the graph is fully connected). A less extreme definition is to consider as communities, small, fully connected subgraphs or *cliques* (from their origins in social network analysis, see Wassermann and Faust 1994), but due to spatial constraints, cliques are unlikely in fully embedded spatial networks and so unlikely to be useful.

We obviously need a more flexible definition. Many have been suggested in the social networks literature (see Wassermann and Faust 1994, pp. 257–267), but most suffer from serious computational challenges in identifying them in graphs of any size, because of the exponential growth in the number of subsets of the vertex set V as graphs get larger. An important breakthrough has been in the development of more computationally tractable methods, beginning with the Girvan-Newman algorithm (Girvan and Newman 2002). Many of these methods are based on heuristic approaches, which successively remove edges of low betweenness centrality while repeatedly recalculating some measure of the quality of the resulting graph decomposition. Other methods aim to identify hierarchically nested communities and can consequently deal with very large networks with millions of nodes. Fortunato (2010) provides comprehensive details and references. It is notable that none of these methods are explicitly spatial, although where edge existence and/or weight is dependent on spatial proximity, this should not be a cause for concern.

The net result of these considerations is that the current working definition of a graph community is a circular one: graph communities are those subgraphs in a graph identified by a community-detection algorithm. This places considerable importance on the analyst's ability to meaningfully interpret any communities so identified, a situation analogous with that in the cluster analysis of multivariate statistical data.

Vertex centrality and community structure for a typical spatial network are illustrated in Fig. 64.4. In Fig. 64.4a vertex centrality calculated from the total path length from each vertex to every other while considering the Euclidean length of the graph edges is shown, with the darkest shaded vertices the most central. As is often the case, the most central vertices are those that are most geographically central to the network, as we might expect. By contrast, in Fig. 64.4b the betweenness centrality based only on the network topology is shown. Because, in topological terms, the vertices to the west of the central part of this network provide a shortcut around the densely packed central region, these vertices are highlighted

Fig. 64.4 Centrality and network communities illustrated. See text for details

by this centrality measure. Finally, Fig. 64.4c shows a possible community structure in this network where seven distinct regions in the network have been identified based on their mutual connectivity.

64.3.3 Structural Equivalence

A final graph structural characteristic likely to be of interest is the concept of *structural equivalence* among vertices or edges. This concept is easily grasped, but precise definitions are mathematically challenging and detection of structurally equivalent sets of vertices remains difficult. The idea is that vertices that are structurally equivalent have similar relationships to the rest of the graph as one another, an idea whose origins lie in social network analysis where structural equivalence is related to social roles (Lorrain and White 1971). Graph communities are a special case of structurally equivalent vertices, which share the property of being in the same community. In a transport network, we might expect major junctions on arterial routes to constitute an equivalence class. However, pinning down how this concept can be realized in practice has proved difficult, and detection of structurally equivalent (or more usefully structurally similar) sets of vertices is computationally challenging – consider that while community detection can assume that the subgraphs of interest are connected subsets of the graph, no such assumption can be made for structural equivalence classes. While the concept of structural equivalence is an attractive one for the analysis of spatial networks, progress in this area remains rather limited.

64.4 Generating Networks: Spatial Network Models

While measures of network structure are important tools in improving our understanding of spatial networks, it is equally important to develop models for

network formation. This was recognized by Haggett and Chorley in their coverage of [network] “Growth and Transformation” (1969, pp. 261–318), an extensive chapter and a very modern treatment. A recent review paper (Barthélemy 2011) provides a useful overview of many different spatial network models. Here we briefly review some of the available models and consider their general properties.

An important null model for any network is the Erdős–Rényi (E–R) model (see Erdős and Rényi 1960), which has been much studied. The E–R graph is generated as follows: create a set of n vertices, then consider every possible pair of vertices, and with probability p join them with an edge. Many of the expected properties of E–R graphs are well known. Of particular interest are the expected mean clustering coefficient and mean path length of vertices in the graph, once the network is sufficiently dense to be connected with no isolated clusters, an event which happens quite suddenly close to $p = \ln n/n$. The expected clustering coefficient $\langle C \rangle$ is given by p since p is the probability that any two vertices will be connected, and so is also the likely proportion of the neighbors of any vertex that will be connected. The expected shortest path length $\langle d \rangle$ in the E–R graph is approximated by $\ln n / \ln \bar{k}$.

64.4.1 Spatial Networks From Point Patterns

Perhaps the most obvious way to generate a spatial network is to begin with a point pattern and then to apply some geometric rules by which points are connected to one another (or not). This *geometric graph* model admits considerable variety in the outcomes depending on both the underlying point pattern and on the geometric rules applied. It also has the property that if we make the “rule” for joining nodes independent of the distance between them, then it is equivalent to the E–R random graph. More reasonable rules will be familiar from the construction of spatial weights matrices (see, e.g., pages 200–205 in O’Sullivan and Unwin 2010).

A distance criterion where two nodes are joined if they are closer together than some threshold distance. In Fig. 64.5a nodes nearer than 5 units apart are connected.

A nearest neighbor criterion where each node is joined to its nearest k neighbors. In Fig. 64.5b each node is joined to its 4 nearest neighbors.

An attribute-distance rule where depending on some attribute of the nodes and their separation distance they are joined or not. The simplest form of this rule is where the attribute is a radius of influence r_i , and nodes i and j are joined if $r_i + r_j < R$ where R is a threshold distance. An example is shown in Fig. 64.5c. Such a simple rule might be meaningful in the context of trees in a forest influencing one another, but in regional science, a more likely formulation will be based on an interaction measure such as $m_i m_j d_{ij}^{-\alpha}$ where the m values represent activity or population at each location and α is a constant controlling the rate at which likely connection falls away with distance.

A pure geometric rule such as those governing the Delaunay triangulation or closely related Gabriel graphs (see Okabe et al. 2000) shown in Fig. 64.5d, e, respectively.

Fig. 64.5 Examples of geometric networks as described in the text. The region is 40 units east–west and 60 north–south, and the point pattern is inhomogeneous Poisson with greater intensity at the center of the region. Point symbols in (c) are scaled so that if the circles of two points intersect, they are joined in the network

A *global rule* such as that governing construction of the minimum spanning tree, where the edges are those which together connect the network with the minimum total path length. An example is shown in Fig. 64.5f.

As is clear from Fig. 64.5, the various geometric rules produce quite different networks. An important distinction is that the Delaunay, Gabriel, and minimum spanning trees are planar, whereas the other networks are not. At the same time that they do not guarantee planarity, the distance and distance-attribute models may also leave some nodes unconnected. It is unusual for real-world spatial networks to leave isolated regions, and so it may be that hybrid models where a distance criterion is applied subject to a connectivity and/or planarity requirement are more reasonable in some cases. One approach is to start with a network substrate, such as the minimum spanning tree or Gabriel graph, and add additional edges according to a distance criterion.

64.4.2 Spatial Small Worlds

Small-world networks are so-called after the commonly encountered apparent contradiction in social networks that while they are locally highly connected (i.e., they have high clustering coefficients), they also have globally short paths (i.e., the mean path length is low). It is apparent that this result does not hold for graphs generated by the E–R model. As noted, E–R graphs become connected when $p = \ln n/n$ when $\bar{k} \simeq \ln n$. For a network with 1,000 nodes, this gives us $\langle C \rangle = p = 0.00691$, $\bar{k} \simeq 6.91$, and $\langle d \rangle \simeq 3.57$. Increasing n to 10^6 reduces $\langle C \rangle$ to 1.38×10^{-5} while $\langle d \rangle$ only increases to 5.26. Clearly, although E–R networks are small worlds with short path lengths, they do not have the high local connectivity that makes this property in social networks surprising.

Watts and Strogatz (1998) presented an alternative network model that is both highly clustered locally, yet has short mean path lengths. Their approach is to start with a regular lattice and “rewire” it by breaking links and reconnecting them to other nodes selected at random from anywhere in the network. They show that only small numbers of rewiring events are necessary to dramatically reduce the mean path length in a lattice. Although Watts and Strogatz present their work for one-dimensional lattices, the basic idea is readily extended to more realistic spatial settings.

In two dimensions, a regular lattice is a grid of nodes with each node connected to its four nearest neighbors. The expected path length between any two nodes selected at random scales with $n^{1/2}$, and, in general in a D -dimensional lattice path lengths will scale with $n^{1/D}$. *Spatial small-world* models, rather than rewire the lattice, typically introduce additional “shortcut” links with the probability of the shortcuts dependent on the distance between the vertices they join. The probability that a shortcut e_{ij} exists might be proportional to $d_{ij}^{-\delta}$ where δ is a parameter chosen in a particular case. As δ is increased while holding constant the overall number of additional links added, the networks produced by models of this kind transition from random to small-world to regular lattice properties. This is readily understood in qualitative terms. For low values of δ , any length shortcut is equally likely – in effect, nodes are undifferentiated from one another – and the network has distance properties similar to a random network. High values of δ heavily penalize the provision of longer shortcuts, leaving the lattice’s overall $n^{1/D}$ distance-scaling property intact. Many transportation networks lie somewhere on this continuum, depending on how we incorporate shortcuts such as urban orbital highways, high-speed rail links, and airline routes into the more densely connected local transport network.

64.4.3 Growing Spatial Networks: Preferential Attachment

The examples above apply a connection or rewiring rule to a preexisting set of nodes. Arguably, a more realistic approach is to grow a spatial network from an initial individual node, by progressive addition of new nodes and edges, according to some rules governing how new nodes are attached to existing ones. Once again, the baseline case is a nonspatial network growth model known as the *preferential*

attachment model, attributable to Albert et al. (1999), which has spawned a large literature on “scale-free” networks (see Caldarelli 2007). The basic idea is that nodes are added to a network and attach themselves preferentially to those nodes that already have larger numbers of connections. The resulting networks have heavy-tailed distributions of vertex degrees meaning that a small number of very strongly connected nodes dominate the network structure.

Planar networks clearly cannot exhibit such characteristics, and physical constraints in most spatial networks prevent an unrestricted preference for attachment to the most well-connected existing nodes. Preferential attachment models that consider space, require each new node to have a spatial location, and the probability of attachment to existing nodes is then a function of both the degree of existing nodes and the distance between the new node and the existing nodes; this is similar to the attribute-distance geometric models considered previously, but with progressive addition of nodes rather than an all-at-once calculation. Models of this general structure often produce the hub-and-spoke structures characteristic of many distribution networks. Again, as with spatial small-world networks, the rate at which the probability of a connection decays with distance is important in determining overall characteristics of the resulting networks.

64.4.4 Dual Graphs: New Graphs from Old

An important idea for models of networks is the dual transformation, whereby an initial graph is transformed to a new graph by switching between nodes and edges or (in a planar graph) between faces and nodes. The *line graph* $L(G)$ of G is the graph whose vertices correspond to the edges of G and where two vertices are joined when their corresponding edges are adjacent. This dual transformation is shown in Fig. 64.6 and as in the case illustrated results in a denser graph with more variety in the vertex degree distribution than the original “primal” graph. The line graph dual transformation is often applied to the more obvious primal network representation of a system, such as the road intersection and segment network, because the richer structure provides more opportunities for insight into key features of the network. Figure 64.6b–d shows a simple example. In a planar graph, a similar dual transformation entails treating each face of the graph as vertex in a new graph, and joining those vertices whose faces are adjacent in the original graph. This is the relationship between the familiar Voronoi tessellation and the Delaunay triangulation (see Okabe et al. 2000).

64.4.5 Matrix and Adjacency List Representation of Graphs

Before closing the discussion of network analysis measures and models, it is important to note that even simple analysis of graphs requires careful consideration of how they are stored for computational purposes. There are two distinct approaches, which is preferable being largely a function of the graph density.

Fig. 64.6 Different graphs from the same network: (a) the line graph dual transformation, *white squares and gray lines* are the original graph and *black circles and dashed lines* are the line graph; (b) a primal graph for a road network; (c) line graph from the same road network; and (d) named road graph from the same road network

An obvious approach, given its close relationship to spatial weights matrices, is the graph *adjacency matrix* $\mathbf{A}(G) = a_{ij}$ where $a_{ij} = 1$ if the edge e_{ij} exists and 0 otherwise. The row order of \mathbf{A} is unimportant, but the row and column ordering must be the same. The *incidence matrix* \mathbf{B} is an alternative matrix representation that records the incidence of edges and vertices and is an $n \times m$ matrix where $b_{ij} = 1$ if e_j is incident with v_i , and 0 otherwise. A useful relationship between the incidence matrix and adjacency matrix is that

$$\mathbf{B}\mathbf{B}^T = \mathbf{A}^* \quad (64.10)$$

where \mathbf{A}^* is the adjacency matrix, modified such that the elements in the main diagonal are equal to the degree of the corresponding vertex. Another useful transformation is that the adjacency matrix $\mathbf{A}(L)$ of the line graph of G is given by $\mathbf{B}^T\mathbf{B} - 2\mathbf{I}_m$ where \mathbf{B} is the incidence matrix of G as defined above and \mathbf{I}_m is the $m \times m$ identity matrix.

However, many spatial networks have very low densities. This makes adjacency matrices an inefficient representation because many 0 entries are stored even though they record no useful information. Therefore, an *adjacency list* representation is often more appropriate and simply consists of a list of all the edges in the graph. Depending on the implementation details, it may also be necessary for vertices to be explicitly listed, or for the number of vertices in the graph to be stored, before the edges are listed. Appropriate modifications of such data structures can readily accommodate directed or weighted graphs.

Many tools and software platforms used for the analysis of graph data make use of both matrix and adjacency list representations, and, given the sparseness of many

spatial networks, it is important that an efficient *sparse matrix* implementation be available. For many analyses, the ability to quickly convert back and forth between (dense or sparse) matrix and adjacency list representations is necessary for efficient analysis.

64.5 Properties of Real-World Spatial Networks

Armed with the measures and models introduced above, it is possible to investigate the properties of real-world spatial networks. This remains an active area of research in many fields, and we restrict the discussion in this section to pointing to interesting examples and useful review materials, which enable a rapid introduction to specific fields.

64.5.1 Road Networks

Road networks are the most immediately obvious network encountered in everyday life. The primal representation of a road network, where vertices are the road intersections and edges are the road segments between them, generally exhibits rather uninteresting structure. Across large areas of a given city, the road network approximates to a two-dimensional lattice, and the range of vertex degrees is limited by geometry: it is unusual for road junctions to connect more than five or six road segments. However, when we range across larger scales, the road hierarchy in most regions introduces shortcuts in the form of highways with limited connections to the lattice of local roads. Spatial small-world networks capture this structure relatively well.

More interesting features of road networks may emerge when the primal representation is converted to the line graph dual or when *named roads* are treated as the units of analysis (i.e., the vertices in the graph) and intersections between named roads are the graph edges. Either of these transformations admits greater variety in the vertex degree distribution, and can enable the topologically most central roads to be identified, which may be of greater interest than more traditional approaches in some cases (see Jiang 2006). Perhaps the most interesting work in this area has been recent efforts to model a variety of urban street networks using rather simple models based on the preferential attachment principle but taking spatial constraints into account (Courtat et al. 2011).

64.5.2 Transport Networks

Transport networks cover a wide range of modes other than road-based. Relative to road networks, the most obvious feature of other modes is their point-to-point or station-connection structure. These features introduce greater potential for departures from planarity, particularly when airline networks and shipping routes

are considered. In analysis of an extensive database of world airline routes, Barrat et al. (2004) demonstrate that this network has many interesting properties, including small-world characteristics, and distinctive scales related to regional and global service areas. This paper and others focusing on airline networks and the various findings in this area are well covered in the spatial networks review paper by Barthélemy (2011, pp. 13–17).

A comprehensive overview of developments in the analysis of all kinds of transport networks is provided by Rodrigue et al. (2009) where coverage extends beyond the more structural forms of analysis discussed in this chapter to cover how transport networks structure the regional and global economy and how they impact urban mobility and related issues of transport policy and planning. The grounding of earlier work in real-world histories provides a striking contrast with recent work in a journal special issue “Evolution of Transportation Network Infrastructure” (see Levinson 2009) where more exploratory analyses of different network growth models are highlighted.

64.5.3 Other Spatially Embedded Networks

It is appropriate given its importance in inspiring much of the recent explosion in work on networks to point to work on the Internet. This is representative of a wide range of work on infrastructure networks of all kinds. It is easy to forget that the Internet relies like other networks on physical plant of various kinds and that considerations such as efficiency of service provision, costs of installation, and vulnerability to disruption are critical concerns for the Internet backbone as they are for other infrastructure such as electricity and water supply. A comprehensive overview of network analysis work on the Internet is provided by Pastor-Satorras and Vespignani (2004). More geographically grounded perspectives that focus attention on the spatial embedding of Internet infrastructure focus on how the structure of the Internet relates to local geographical factors and to other infrastructure networks, often showing that places that are well connected by airlines, roads, and other systems tend also to be well provided with Internet connectivity (Malecki 2002). Once again, the interplay between exploratory analysis of overall structure and more grounded approaches is critical to progress in understanding in this field.

Finally, we briefly consider spatially embedded social networks, perhaps the fundamental building block of all the other networks considered. An excellent overview of how space and social networks may be mutually reinforcing and how these effects can be modeled is provided by Butts and Acton (2011). They strongly argue for the benefits of analysis that attends to both network aspects and spatial aspects. Among the most promising areas for future development in this field are coevolutionary networks (Gross and Blasius 2008) where network structures and the attributes of nodes and edges mutually influence one another over time, and the wide-ranging study of how processes such as disease spread or the diffusion of ideas occur on networks (see Newman 2010, pp. 627–676).

64.6 Conclusions

Many, perhaps most, features of the human world can be considered to be embedded in space and networked to one another at various spatial scales either (more or less) permanently or in constantly changing ways. This chapter has deliberately focused on basic concepts and models that are useful for the analysis of such networks, particularly emphasizing the rapid growth of ideas in the recently emerged “science of networks.” While much of this material has been developed in statistical physics and allied fields, it is apparent that the insights yielded by these approaches build on much earlier work on networks in geography and regional science, extending it and applying fundamental ideas to larger and more dynamic networks than before. Even so, claims that work in these areas heralds a new dawn for the social sciences (see, e.g., Watts 2007) seem overdone. On the contrary, it is probable that the best and most insightful work will continue to demand the application of measures, methods, and models from network science reviewed here, in combination with detailed, well-grounded empirical research on the development and structure of networks in specific contexts in space and time.

Abstract

We review some of the special properties of spatial data and the ways in which these have influenced developments in spatial data analysis. We adopt a historical perspective beginning in the early twentieth century before moving to the development of spatial autocorrelation statistics in geography’s Quantitative Revolution. Phases of development after the Quantitative Revolution are divided into emergence of spatial econometrics, the development of exploratory methods for spatial data analysis, and local statistics for handling heterogeneity. We then consider more recent advances in the areas of spatial data mining, the “new” geostatistics, and Bayesian hierarchical statistical modeling of spatial data.

65.1 Introduction

Spatial statistics is used for the *analysis* of spatial data, that is, “the reduction of spatial patterns to a few clear and useful summaries” (Ripley 1981, p. 1), and for *comparing* such summaries “with what might be expected from theories of how the pattern might have originated and developed” (Ripley 1981, p. 1). In order to test theoretical expectations against data collected through observation, statistical models are often necessary. There are, of course, many different types of models that are critical to the progress of science, but statistical models are formalizations of theory in terms of random variables and their associated probability distributions. We might compare several different models to see which one best fits the data; we might take a single model and see how well it fits the data.

There are several different types of spatial data encountered in geography and regional science. *Point pattern* or *point process* data arise where each data value refers to the location of a discrete object the size of which is sufficiently small relative to the study area that it can be treated as a point (e.g., the location of factories in a region). Interest may focus on how the points are distributed within the region (e.g., are the factories in a particular economic sector spatially clustered or random?). If interest focuses on say the distribution of an attribute attached to each point (e.g., are the factories that have been closed in the last 12 months clustered given the distribution of factories in that sector?), we refer instead to a *marked point process*. Some variables that originate as point data are reported as discrete-valued *regional counts* (e.g., the number of residential burglaries recorded by UK Census Output Area (COA)) or their attributes as continuous-valued *regional averages* (e.g., average household disposable income) or *rates* (e.g., the number of burglaries per 100 households) or *ratios* (e.g., area-standardized disease-specific mortality ratios obtained by dividing the observed number of deaths due to a particular disease in each area by the expected number of cases given the area’s population size and its age and sex composition). The reporting areas may be irregular in shape as in the above examples or form a regular grid. When *regional data* refer to small areas (such as COAs or a fine grid), then there may be interest in constructing a density map which is a smoothed representation of the data (e.g., a population density map, a burglary risk map). Some spatial data are *point samples from a continuous surface*, where the point *sampling* has been performed according to some design (e.g., random, stratified random, systematic). The data may refer to levels of surface soil contamination or ground level atmospheric pollution. There may be interest, for example in *geostatistics*, in constructing a map of the attributes spatial variability or interpolating to points or areas on the map where no data have been collected. Spatial data may also take the form of *objects* that have both location and extent and which may or may not fill the space. Interest may focus on modeling the distribution of the objects such as vegetation or land use patches. As a final example, data may refer to the nodes or vertices of a *network* (e.g., a rail, road, or airline network). On the vertices of the network are recorded origin–destination or (directed) flow data such as numbers of people or tonnage of goods moving between two nodes or line segments on the network in a period of time.

Analysis may be concerned to understand population migration or trade *flow data*, for example, using origin- and destination-specific factors and the distance between the origins and destinations (Fischer and Wang 2011).

In any analysis, it may be necessary to combine data of different types: regular areas, irregular areas, and point data, as illustrated, for example, in Elliott et al. (2009). Different data types raise different problems for statistical analysis and modeling, and for a more formal definition of a number of different forms of spatial data, see Cressie (1991, pp. 8–9)

Obtaining useful summaries of spatial data is complicated because single numbers (such as the mean and standard deviation for summarizing aspects of the distribution of data values) are not sufficient for describing the spatial variation in data values. Maps and graphs, perhaps several of both, are required in order to describe both the distributional and spatial variation in the data. Spatial data may show different patterns of variability on different parts of the map and at different scales.

Statistical analysis and modeling of spatial data introduces other considerations. The classical theory of statistical inference assumes data are obtained by randomly *sampling* from the population (so that the data set can be considered representative of the population), and observations are independent and identically distributed (i.i.d.). For this reason, the underlying probability models of classical statistics are i.i.d. But in the case of spatial data, even if sample observations have been collected by a process of random *sampling*, if sample values are sufficiently close together in geographical space, they will not be independent because the population from which the data have been drawn is said to be *spatially autocorrelated*. Data values are not independent; the structure of that dependence may not be the same everywhere on the map (nonstationarity), and there may also be small pockets of high (or low) data values (*disease clusters*, crime, or unemployment hot spots). The mean value of an attribute may not be the same everywhere on the map. In addition to nonindependence, data values across a map may not be uniform in the sense of coming from some common underlying distribution. They may display what is termed *spatial heterogeneity*. These two often-encountered characteristics of spatial data introduce special considerations when undertaking statistical modeling including the need to construct valid (or “permissible”) models to describe spatial variability which can then be used for inference with spatial data.

When data are collected in the form of counts or rates by area, there may be further issues to consider. If area data values are averages, rates, or ratios and if in addition areas possess large populations, then such summaries may obscure or conceal *within-area heterogeneity* – subpopulations within areas with markedly different averages (or rates or ratios). On the other hand, if the areas possess small populations, while such a framework might preserve more of the underlying spatial variability in the data (and each small area might be homogeneous), individual area estimates will typically have much larger standard errors. As a further consequence of this, if the map is partitioned into areas, some of which have large while others have small populations, then the data may be *heteroscedastic* – that is, each observation has been drawn from a different probability distribution with

a different variance. If area data values refer to an ecological covariate (i.e., expressing a property of an area that is not reducible to measures at the individual level, e.g., social capital, area deprivation, social cohesion), then the values of this variable will depend on the scale of the partition and the configuration of the boundaries (the zoning). This is one example of the “*modifiable areal unit problem*” which states that the results of spatial analyses and modeling are conditional on the particular partition through which we observe spatial variation. These and other challenges that confront the analysis of spatial data have been reviewed at some length elsewhere (see Haining (2009)).

This chapter provides an overview of some of the major developments in spatial statistics with particular relevance to geography and regional science. It is divided into four sections. The first section briefly reviews the statistical origins of what is now called spatial statistics and describes how and why one area of spatial statistics came to be part of geography’s *Quantitative Revolution* in the 1950s, 1960s, and early 1970s. The second section discusses the emergence of *spatial econometrics* and its links (and overlaps) with spatial statistics. What characterizes *spatial econometrics* and in what sense does it stand apart from, indeed distinct from, the field of spatial statistics? The third section considers the emergence of *exploratory spatial data analysis* in the 1980s and follows this with the development of “local statistics” for analyzing spatial *heterogeneity*. The fourth section is an overview of some recent developments in the field: *spatial data mining*, what I shall term the “new” *geostatistics* and Bayesian hierarchical spatial statistical modeling. The purpose of this chapter is to show the reader the development path of spatial statistics and how this can be seen as a response to the distinctive properties and challenges presented by spatial data.

65.2 Where Did It All Start?

65.2.1 The Statistical Origins

The roots of spatial statistics can be traced back to at least the early twentieth century and the involvement of classically trained statisticians in analyzing the data from agricultural uniformity trials carried out at Rothamsted in England. In such analyses, a component of yield variation is due to processes operating at a scale greater than the size of the spatial units used to report the data so that crop yields in adjacent plots tend to be similar. Classically trained statisticians became interested in the problem of how to carry out field trials (which might be testing different management methods and crop varieties in relation to soil type) using experimental designs that would control for such attributes and hence yield stronger inference.

The analysis of agricultural yield data was also motivation for the seminal paper by Whittle (1954) in which he made explicit the link between the problem of analyzing such data and two-dimensional stochastic models. In that paper, he defined the *simultaneous spatial autoregressive (SAR) model* on

a regular square lattice in which if $X(i,j)$ denotes the random variable at location (i,j) of a regular square lattice then

$$X(i,j) = a[X(i-1,j) + X(i+1,j)] + b[X(i,j-1) + X(i,j+1)] + e(i,j) \quad (65.1)$$

where a and b are parameters and $e(i,j)$ is a normally distributed white noise (i.i.d.) process. Whittle's paper notes that unlike time series modeling, spatial process modeling needs to allow for dependence to extend in all directions (not just from past to future as in time series modeling) and that in two dimensions, the dependence structure on the north–south axis might differ from that on the east–west axis. Twenty years later, Besag (1974) in an equally seminal paper presented the theory of conditionally specified spatial models (for continuous- and discrete-valued random variables) and included in his set of models the *conditional spatial autoregressive (CAR) model* for normally distributed random variables. For readers interested in the differences between these models, see, for example, Haining (2003 pp. 297–304).

A slightly earlier strand of development, predating Whittle's work, saw the publication of papers addressing the problem of how to test for what is now referred to as *spatial autocorrelation*. In each case, the null hypothesis of no *spatial autocorrelation* is tested against a nonspecific alternative that the observations are autocorrelated. The tests, *Geary's c test*, based on squared differences between observations in adjacent areas; *Moran's I test*, based on the cross product between observations in adjacent areas; and Krishna Iyer's *join count test* for nominal level data, based on counting the number of adjacent areas in the same class or in different classes, are reviewed in Cliff and Ord (1973). None of these early tests made any allowance for the topological and/or geometrical structure of the areas making up the areal system other than whether pairs of areas were adjacent (shared a common border) or not.

These developments were applicable to the case of area data. *Geostatistics* was developed for spatial data collected as point or block samples from a continuous surface and with a quite different aim in mind. Matheron (1963) developed a comprehensive theory of optimal *interpolation* in geographical space on the basis of sample data. In purely geographical terms, we might think of this as a theory for drawing maps of continuous phenomena on the basis of a scattered sample of observations. Spatial variation in any particular set of data was described by estimating the *semi-variogram* (a squared difference statistic) and then finding a best fit model for this empirical *semi-variogram* from the set of "permissible" models. A rich array of models is available for describing spatial variation. For further discussion of this area of spatial statistics and its antecedents, see Haining et al. (2010) which also includes comparative comments with the literature cited above.

65.2.2 From Statistics into Geography and Regional Science

It was during the *Quantitative Revolution* in the 1950s and 1960s that some aspects of this statistical theory began to filter into geography. Researchers in sociology had

already recognized (in some cases long before geography's *Quantitative Revolution*) that the theory and tools of classical statistics could not be applied uncritically to the analysis of geographical data (see, e.g., Neprash (1934) as well as other papers in the same journal supplement). It was not until the 1960s that the "problem" of *spatial autocorrelation* began to be examined carefully by geographers and a key deficiency of the earlier tests devised by Moran, Geary, and Krishna Iyer, their topological invariance, confronted.

Geography's *Quantitative Revolution* was not merely a methodological revolution – the aligning of geography's methods with those used by the quantitative sciences – it was also a revolution in terms of how the subject matter of geography should be addressed. It was a revolution in the sense that geographers became interested in the development of theory. But it would be theory that would only survive so long as it withstood rigorous attempts to refute it through empirically grounded research. Models represented the translation of theory into a form that would enable empirical testing to be performed, and although not the only form of model building that entered the geographical literature, statistical modeling was a key element in this agenda. So herein lay the nub of the problem. Because of the importance of statistical modeling to theoretical geography, these issues could not be set to one side. And there were of course precedents to believing that none of these problems were insuperable, least of all coping with the effects of spatial dependence. Time series analysis had undergone a transformation in the first half of the twentieth century and now underpinned the practice of econometrics which in turn supported the testing of economic theory. Geographical statistics was in need of a similar transformation.

It was the work of Cliff and Ord that reported important breakthroughs in constructing statistics for testing for *spatial autocorrelation* on the sorts of irregular areal frameworks social scientists most frequently worked with. In Cliff and Ord (1973), they developed the inference theory for modified versions of *Geary's c* and *Moran's I* statistics introducing a "weighting" term into the formulation of the statistic that allowed adjacency to be specified much more generally than had hitherto been possible. The reader interested in this aspect of geography's history should refer to the special issue of the journal *Geographical Analysis* (2009(4)).

Two areas of geography benefitted most directly from this innovative work. The first was in the application of the regression model. *Regression models* enable data analysts to empirically test the relationship between a dependent variable and a set of explanatory or independent variables. This statistical model has in the past and indeed continues to play a very important role in developing and testing theory in many areas of quantitative science. In the case of classical least squares *regression modeling*, population inference (hypothesis testing, parameter estimation) is based on the assumption that model errors are i.i.d., and failure to satisfy this assumption results in underestimation of type I errors in hypothesis testing. Regression residuals are estimates of model errors, and Cliff and Ord (1973) provide an inference theory for testing for nonindependence of model errors using the least squares residuals.

The second area to benefit was the testing of specific types of spatial theory. Cliff and Ord (1973) considered the area of spatial *diffusion modeling* where different theoretical processes were simulated and then compared with observed outcomes. But, among many other complications associated with this approach, evaluating the correspondence between simulated output and empirical observation must compare not only the frequency distribution of numbers of adopters by area but also the spatial arrangement of the counts.

Another example was in the area of economic geography and the analysis of those economic processes that by definition are embedded into geographical space (e.g., urban and regional development, location theory, land use change, regional and international trade, spatial price competition). During the *Quantitative Revolution*, those economic geographers who went in search of stronger theoretical perspectives began to take a close interest in the work of location theorists. They also began to engage with the newly emerging field of regional science. Early books on the tools and methods of regional science paid little attention to statistical modeling, but in the 1970s, the field of *spatial econometrics* began to emerge becoming to regional scientists what econometrics had become to economists. The purpose behind its development was to provide the statistical tool kit to enable regional scientists to test spatial economic theory. We now turn to discuss this development.

65.3 Spatial Econometrics

Anselin (1988), and again most recently in his extended review of the field in 2010, credits Jean Paelinck with first use of the term *spatial econometrics* in an address to the Dutch Statistical Association in 1974. The term was used to “designate a growing body of the regional science literature that dealt primarily with estimation and testing problems encountered in the implementation of multiregional econometric models” (Anselin 1988, p. 7). Another significant date in the development of the field is 1979 when Paelinck and Klaassen’s (1979) “*Spatial Econometrics*” was published. Anselin (2010) chooses that year as “the historical starting point for *spatial econometrics*” (p. 3).

Anselin (2010), as others had done before him, argues that *spatial econometrics* and spatial statistics should be seen as distinct. The distinction is defined by the types of problems that are tackled. Whereas spatial statistics is fundamentally data driven, *spatial econometrics* (like econometrics), is fundamentally theory driven. *Spatial econometrics* has been developed explicitly to fit *spatial regression models* to test spatial economic theory – in this sense moving away from Paelinck’s original definition of the field.

Providing spatial econometricians do not cut themselves off from the rich vein of statistical theory and models generated by spatial statisticians, then there may be advantage to be gained from distinguishing between *spatial econometrics* and spatial statistics. But the justification for the distinction is not entirely convincing.

In contrast to earlier days in geography's *Quantitative Revolution*, statisticians today see many opportunities for fruitful interaction on broad classes of spatial problems and would not accept the view that their model building is purely data driven, by implication "atheoretical." As Cressie and Wikle (2011, p. 14) have recently observed, "...Statistics has become more a Science than a branch of Mathematics. ..."

Spatial econometrics today is principally concerned with how to specify, fit, and then carry out diagnostic checks on *regression models* when working with locationally (or spatially) referenced data. The data can be cross-sectional (purely spatial) or *spatiotemporal* with measurements on one or several variables. Underlying these models are usually theories about how distance (to a particular location such as a city center), spatial configuration (the spatial distribution of objects within a space, such as whether areas of poverty are scattered or ghettoized within an urban area), or spatial gradients (between neighboring areas in terms of socio-economic characteristics) help to explain variation in a dependent variable. What is observed (e.g., area crime rates, regional economic performance) is not necessarily an outcome purely of circumstances *within the places themselves* because what is observed, and the variation we want to explain, may be the outcome of processes that operate across geographical space (e.g., different forms of interaction).

Methodologically *spatial econometrics* focuses on two properties commonly encountered when handling geographical data: spatial dependence (autocorrelation) and spatial *heterogeneity*. We shall consider approaches to the handling of spatial *heterogeneity* in the next section and focus here on just the handling of spatial dependence in *spatial econometrics*.

Typically, spatial dependence is handled by specifying lagged variables in the *regression model*. In the case of lagging the dependent variable, a model might be specified of the form

$$Y(i) = b_0 + b_1X_1(i) + \dots + b_kX_k(i) + \rho \sum_{j \in N(i)} w(i,j) Y(j) + e(i) \tag{65.2}$$

$$\sum_{j=1}^n w(i,j) = 1; \quad i = 1, \dots, n$$

where the $\{e(i)\}$ are i.i.d $N(0, \sigma^2)$, b_0 is the intercept coefficient, and b_1, \dots, b_k are the regression coefficients on the independent variables X_1 to X_k . The parameter ρ is the spatial interaction parameter for the weighted average of the dependent variable ($Y(i)$). For any given site i , this weighted average takes in the values at sites neighboring i but excluding site i ($N(i)$). Thus, $w(i,j) > 0$ if $j \in N(i)$ and $w(i,i) = 0$ for all i . Models specified in this way and in which the influence of neighboring sites is usually stronger the closer they are to i ($w(i,j) > w(i,k)$ if j is closer to i than k is to i) have a long history in the statistical modeling of certain types of economic interaction processes including price competition effects. Clearly, other forms of weighting could be constructed to reflect the structure of economic interactions across space (Haining 1990).

Lagging may also be specified on one or more of the independent variables as in, for example, the model

$$Y(i) = b_0 + b_1 X_1(i) + \dots + b_k X_k(i) + b_{r,\text{lag}} \sum_j c(i,j) X_r(j) + e(i)$$

$$\sum_{j=1}^n c(i,j) = 1; \quad i = 1, \dots, n \quad (65.3)$$

where in this case $Y(i)$ is modeled to have an association with the independent variable X_r as a function not only of X_r 's value at i but also its value at neighboring locations. (For this reason, we use the notation $c(i,j)$ (rather than $w(i,j)$) to distinguish the spatial averaging in Eq. (65.3) from that in Eq. (65.4).) This type of model is sometimes encountered in house price modeling where characteristics of the neighborhood where the house is located and nearby neighborhoods may impact on price. This type of spatial averaging or smoothing may also be encountered in environmental epidemiology where the air pollution level in neighboring areas is treated as a risk factor because people move about in their day-to-day lives and are thus exposed to levels of air pollution in areas other than where they reside.

In the absence of well-defined explanatory variables to include in the model, the spatial lagging may be applied to the errors

$$Y(i) = b_0 + b_1 X_1(i) + \dots + b_k X_k(i) + u(i)$$

$$u(i) = \theta \sum_{j \in N(i)} w(i,j) u(j) + e(i) \quad (65.4)$$

$$\sum_{j=1}^n w(i,j) = 1; \quad i = 1, \dots, n$$

where the terms in Eq. (65.4) are as defined above and θ is now the spatial interaction parameter associated with the errors. Forms of this model and Eq. (65.2) have been used in the modeling of origin–destination *flows* (Fischer and Wang 2011, pp. 64–67).

As Anselin (2010) points out, the methodology associated with the fitting of this class of models has continued to evolve. He reviews in some detail the notable strides that have been made both in the rigor with which these and other models can be fitted and in the availability of software to implement the fitting. One problematic aspect in this evolutionary development is the specification of the *weights matrix* $\{w(i,j)\}$. Adjacency is the default option for many analysts in specifying the *weights matrix* with two areas being defined as *neighbors* if they share a common border. Most software makes this an easy option to implement. But adjacency may not always be appropriate depending on the model to be fitted and whether, for example, there is a need to capture other forms of spatial relationship including

hierarchical dependency structures and complex patterns of spatial competition (Haining 1990). Another approach is to define the elements of the *weights matrix* based on the similarity of the areas in terms of one or more covariates when borrowing data spatially to strengthen small area inference, for example, social and other interpersonal networks may be used to underpin spatial relationships based on the presence or absence of social relationships. Lu et al. (2007) define, as part of a Bayesian *hierarchical model*, an intrinsic conditional autoregressive model where the weights, $w(i,j)$, are Bernoulli distributed with parameter $p(i,j)$ and where $\text{logit}(p(i,j))$ is a linear function of a set of covariates ($z(i,j)$) based on known features of the pair of areas i and j .

The links between methodological advance and the evolution of spatial economic theory are only touched upon in Anselin (2010) – in that sense, his review is concerned with theoretical *spatial econometrics* (statistical methods) rather than applied *spatial econometrics* (economic models). Over time, applied *spatial econometrics* has tended to become synonymous with *regression modeling* applied to spatial data where *spatial autocorrelation* and *spatial heterogeneity* in particular are present and need to be accommodated. Its treatment of spatial effects reflects the growing “legitimization of space and geography” (Anselin 2010, p. 8) in the quantitative social sciences more generally. But the subfield perhaps needs to be more than that if it is to justify its separate identity from spatial statistics and fully justify its “econometric” label. A close link with mainstream economic theory would seem essential in order to provide economic legitimacy to models (systems of equations) within which geography and spatial relationships have been, in economic terms, rigorously embedded (Fingleton (2000)).

65.4 New Kinds of Geographical Exploration

65.4.1 Exploratory Spatial Data Analysis

Exploratory data analysis (EDA) is a collection of techniques for summarizing data properties, detecting patterns in data, identifying unusual or interesting features in data, detecting errors, distinguishing accidental from important features in a data set, and formulating hypotheses from data. *EDA* might also be used in later phases of analysis, for example, in assessing model fit. Techniques are typically visual (charts, graphs, and figures) and/or numerical (resistant statistics, i.e., statistics not greatly affected by a small number of extreme values). *Exploratory spatial data analysis* (ESDA) extends the definition of *EDA* to spatial data, extending the set of visual tools to include the map and the set of numerical tools to include, for example, spatial *cluster detection* statistics (Haining 1990, 2003).

GIS or GIS-like software, for example, GeoDa, have provided excellent platforms for these tools (see www.geodacenter.asu.edu). Advances in computer technology have had a particularly big impact on *ESDA* with the development of new visualization techniques such as *brushing* (highlighting cases in one graph such as a segment of a boxplot and seeing them highlighted in another graph or on a map),

dynamic brushing (brushing using a moving window), and various forms of *dynamic interactivity* (allowing the user to modify the graphics themselves to better explore data properties, e.g., rescaling and rotating three-dimensional plots).

A significant challenge in undertaking these forms of analysis with area data (where data values refer to areal aggregates such as census tracts) is the problem of comparability especially when dealing with small numbers of events (e.g., numbers of cases of a disease by small area). In many areas of *scientific visualization*, different data values are directly comparable (e.g., the results of experiments, data values taken from time windows of the same length). But area data across a region often refer to polygons of different physical sizes and with different baseline populations. This raises two distinct problems for *ESDA*. Comparing rates and ratios across such a map is potentially misleading. A rate computed for an area with a small denominator population has a larger error variance than a rate computed for an area with a large denominator population. This may necessitate using different sized symbols or other visual devices to distinguish between high- and low-precision data values. Extreme rates (and ratios, such as standardized ratios where an observed count is divided by an expected count) are most often found when the denominator population is small, but statistically significant rates (relative to some baseline) are most often found when the denominator population is large (see, e.g., Haining 2003, pp. 194–199). Sometimes, the areas with the largest populations are physically the smallest (e.g., the census tracts in urban as compared to rural areas) and may be hard to see depending on the scale of the map. One solution to this is the cartogram, where, for example, each area is physically transformed so that its size is proportional to its population. As computer technology has advanced, it has become possible to develop many different forms of cartogram, some that more closely reflect the area as the viewer is used to seeing it which may help him or her to better navigate and hence read the map. For numerous examples of *cartograms* see, for example, www.worldmapper.org and www.sasi.grouph.ac.uk/maps.

65.4.2 The Local Revolution

We noted above that spatial *heterogeneity* is a property often present particularly when analyzing spatial data over a large geographic area. *Heterogeneity* may be illustrated in the following terms. Assume we are dealing with the counts associated with the number of new cases of a disease in each of n areas during an interval of time. Suppose the generating process for these counts is dependent on an underlying set of risk parameters $(\lambda_1, \dots, \lambda_n)$. If all the λ_i are identical, then the risk surface is said to be homogeneous. If for at least some areas ($i \neq k$), $\lambda_i \neq \lambda_k$, then the risk surface is said to be spatially heterogeneous.

Clusters of cases might arise from a process in which events occur independently of each other but where there is spatial variation in the levels of the risk factors across the map. So, an unusually large number of observed cases in area k may be the product of a high value of λ_k which may be due, in turn, to high levels of the relevant

risk factors in area k that determine the value of λ_k . If adjustment is made for these factors, then the existence of the cluster may be accounted for. Clusters of cases might also be due to a contagion process where although the underlying risk map may be uniform, when one case occurs, it triggers others giving rise to a spatially clustered pattern. Examples of this type of process include repeat offending in the same neighborhood for cases of burglary and the occurrence of cases of an infectious disease. This is referred to as *global heterogeneity*, extra variation in the data that can be analyzed using a global model. This *heterogeneity* may be spatially uncorrelated, but it may be spatially correlated if, for example, the spatial scale of the process exceeds the size of the observational units used to collect data.

However, there is often interest in identifying the specific locations of local clusters (hot spots) of cases in an area referred to as *local heterogeneity*. Kulldorff's scan test, a likelihood-based test statistic, has been widely adopted to test for the presence of spatial clusters in point as well as area data (Kulldorff 1997). This test uses moving windows (circles) of varying size. Each of these many circles represents a possible cluster. The test measures the unusualness of each potential cluster using a local likelihood ratio statistic which compares a null hypothesis that cases occur in the population at risk with equal probability whether individuals are inside or outside the circle against an alternative hypothesis that cases inside the circle have a higher probability of occurrence than those outside the circle. The circle with the highest local likelihood ratio statistic is considered the most likely cluster. The question posed is "how unusual is this most unusual collection of events?" (Waller 2009, p. 312). By using Monte Carlo hypothesis testing, the scan test is able to answer this question avoiding the *multiple testing problem*. In addition to the scan test that looks for clusters wherever they might be on the map, another class of techniques tests for whether there is an unusually large number of cases around a specific location such as a point source of pollution or other source of possible contamination. This is referred to as a *focused test* (see, e.g., Haining 2003, pp. 263–5).

That *heterogeneity* may be present in the relationship between a dependent variable and the set of independent variables that explain its spatial variation underlies another important set of local spatial statistical techniques. Such a *regression model* might take the form

$$Y(i) = b_0 + b_1(i)X_1(i) + \dots + b_k(i)X_k(i) + e(i) \quad i = 1, \dots, n \quad (65.5)$$

where the terms are as defined for Eq. (65.2), but now the regression coefficients depend on i so that parameter values differ for each observation. Additional modeling assumptions have to be introduced in order to fit a model of this type as otherwise there is insufficient data to estimate the parameters.

Consider the hedonic *regression modeling* of house prices in an area large enough to encompass different climatic regimes so that house buyers attach different values to housing attributes depending on location with respect to these different regimes. If the geographic area can be partitioned into different areas, then a *spatial regimes* model may be used in which model parameters are allowed to differ

from one area to another (but not within areas) using dummy variables in the regression that distinguish between the different areas (Anselin 1988). Spatial *heterogeneity* however might show a form of variation where the parameters vary continuously across the study area, rather than discretely, preventing any prior partitioning. In this case, other methods might be implemented, and the interested reader is referred to Jones and Casetti (1992) for the *expansion method* and to Fotheringham et al. (2000) for the method of *geographically weighted regression (GWR)*. In the case of the *expansion method*, the parameters are expressed as a function of a finite number of other variables called expansion variables (z). To take a simple example of the *spatial expansion method* where parameter variation is treated as a function of spatial location, then we might assume

$$b_1(i) = \varphi_0 + \varphi_1 z_1(i) + \varphi_2 z_2(i) \quad i = 1, \dots, n \quad (65.6)$$

where φ_1 and φ_2 are parameters and the variables z_1 and z_2 are the coordinates defining the centroid of each area i . In this case, the spatial expansion is a linear or first-order trend surface which is the additional modeling assumption about how the regression parameters vary spatially. Higher-order trend surfaces could be used or indeed other types of variables. By contrast, *GWR* is based on obtaining local estimates of each parameter where a separate model is fitted to each area. For any $b_j(i)$, for example, data at i are used as well as data from areas close to i but giving most weight to those data values nearest to i . Many possible weighting functions (spatial kernels) can be specified. The additional modeling assumption is that the data in nearby areas to any i carry information about the value of the parameter in i (a form of *spatial autocorrelation*). For a comparative overview of these and other methods for allowing local variation in *regression model* parameters, including *spatially varying coefficients models*, see Lloyd (2011, pp. 109–143).

Heterogeneity may be associated with other properties of the attribute such as its spatial dependency structure. The spatial dependency structure might be different on different parts of the map. Again, depending on the nature of the spatial correlation, there may be a single, global, model of spatial variation that can accommodate the apparent *heterogeneity*. However, there may be circumstances where a global model of spatial variation will not provide a useful model for the data, for example, where there is either theoretical or empirical evidence (or both) that data from particular parts of a map reflect the outcome of special and distinctive local processes. In *geostatistics*, for example, different *variograms* may be needed for different map segments in order to implement kriging.

65.5 Into the Twenty-First Century

In this section, we reflect on some of the areas of spatial statistics which are shaping and will probably continue to form a significant part of the research agenda in spatial statistics in the coming years. We look at the following areas: *spatial data mining*, the “new” *geostatistics*, and *Bayesian spatial hierarchical modeling*.

65.5.1 Spatial Data Mining

Spatial data mining is the process of discovering interesting but potentially useful patterns in spatial databases. It therefore shares at least some of the objectives of ESDA described in an earlier section. But *spatial data mining* is concerned with the development of automated methods that can be applied to large (and very large) spatial databases. Extracting patterns from large databases underpins decision making in many organizations including those concerned with public health, crime and disorder, land use and transportation, and environmental management.

In common with the relationship of ESDA to EDA, *spatial data mining* when compared to other forms of (nonspatial) *data mining* has the special challenge of recognizing spatial relationships and spatial *neighbors* and taking into account the special properties of spatial data. The location and spatial extension of objects need to be embedded into algorithms. “Neighbor relations” need to be examined for many objects within the same analysis and the term “neighbor” interpreted in many different ways for a thorough interrogation. Moreover, given the size of databases and hence the time taken to process data, it has to be possible to achieve efficient implementation for the purposes of, among others, detecting spatial clusters, spatial outliers and co-location, and relationship patterns among different classes of point, line, and polygon objects such as the distribution of an animal species and wildlife habitats. This is one aspect of the “process of stimulus and convergence” between Geographic Information Systems (*GIS*) and spatial data analysis which began in the 1960s and discussed by Goodchild and Haining (2004): “it is more difficult to analyse the vast amounts of (spatial) data available. . . , and to test new theories and hypotheses without computational infrastructure; and the existence of such infrastructure opens possibilities for entirely new kinds of theories and models, and new kinds of data” (p. 382). *GIS* has an important role to play in providing the necessary computational infrastructure for spatial *data mining*. For further discussion as well as numerous examples of *spatial data mining*, see Miller and Han (2009).

65.5.2 The “New” Geostatistics

Traditionally, *geostatistics* has been viewed as a tool to enable physical and environmental scientists to analyze sample data obtained from a continuous surface. But more recently, the methods of *geostatistics* have been adapted to predict and map *regional data* in the form of small area counts. Oliver et al. (1998) use *binomial co-kriging* to analyze the risk of childhood cancer in the English West Midlands. Population size variation across the areal units is taken into account with pairs of areas with larger populations (and hence more reliable rates) given more weight in the estimation of the *variogram*. If the population at risk is large and the probability of having the disease is small so that the *small number problem* arises, *Poisson kriging* can be used.

Geostatistical change of support methods have been used to create maps that help to reduce the visual bias that can arise when mapping data where the subareas

vary in physical size. Areas that are physically large can visually dominate a map. The methodology involves deconvolution of the *variogram* obtained from areal data in order to construct a point support *variogram*. Area-to-point kriging is used to provide point support predictions. Population size variation is allowed in estimating the deconvoluted *variogram*. See Haining et al. (2010) for many references on the methodology including area to area kriging for irregularly shaped areas which can be used to tackle other change of support problems.

Geostatistics is also being used to model spatial variation in a dependent variable in terms of a set of independent variables where the data refer to irregular areas. Kerry et al. (2010) use the spatial components from area to area factorial *Poisson kriging* to identify the most important spatial scales at which crime rates vary and to identify which explanatory variables are statistically significant at those different scales. This represents another important extension of *geostatistical* theory, one that offers insights into the scale-dependent nature of relationships.

65.5.3 Bayesian Hierarchical Modeling

We conclude this section with comments on some new approaches to modeling spatial data. In the last 10–15 years, *Bayesian models* have emerged as important tools in geography and regional science research, made possible by important breakthroughs in computational methods and the availability of inexpensive high-speed computers and of software for fitting spatial models (e.g., WinBUGS and facilities in R and MATLAB). In earlier years, spatial modeling was overwhelmingly *frequentist* or likelihood based: data values, \mathbf{x} , are assumed a random sample from \mathbf{X} , a random variable with a specified probability distribution depending on a set of fixed parameters, ϕ . The likelihood function for ϕ given the data \mathbf{x} is then defined, $L(\phi|\mathbf{x})$, and parameter estimates are based on maximizing the likelihood function. Hypothesis testing is based on likelihood ratios for different values of ϕ . Inference is based on repeated *sampling*.

With *Bayesian* inference, however, the parameters are also random variables with their own distribution. This means that in addition to specifying the distribution of \mathbf{X} for the observed data \mathbf{x} , it is necessary to also specify the distribution of ϕ , called the prior distribution, which depends on a further set of parameters. These parameters in turn can be modeled by prior distributions (hyper-priors). The combination of these conditional distributions produces the posterior distribution, and by *sampling* the posterior distribution, inference summaries can be obtained such as the posterior mean, credible intervals (the *Bayesian* version of the *frequentist's* confidence interval), and probabilities of interest (such as the probability of a risk parameter exceeding a critical threshold). In *Bayesian* analysis, instead of handling spatial dependency effects in the data model for \mathbf{X} , which complicates the likelihood and often makes model fitting by maximum likelihood difficult (for an early discussion of this, see Whittle 1954), these effects can be handled in the prior distribution instead and fitted using the software referred to above. There are now many examples of this type of modeling (see, e.g., Le Sage 2000; Lu et al. 2007).

Specifying probability models in terms of a sequence of linked conditional models offers a means of modeling complex systems in ways that quantify the inherent uncertainties within scientific research relating to the data (level 1), the specification of the model (level 2), and model parameters (level 3). “Hierarchical statistical modelling represents a way to express uncertainties through well defined levels of conditional probabilities” (Cressie and Wikle 2011, p. 15). Cressie et al. (2009) provide a discussion and application of *hierarchical models* in *ecological analysis*.

Spatial effects are typically handled through a spatially structured random effects term as the following example illustrates. Suppose the researcher is modeling small area disease counts where $x(i)$ is the number of cases in area i . The data model (level 1) specifies $x(i)$ as the realization of a Poisson random variable ($X(i)$) with intensity parameter $\lambda(i) = E(i)\theta(i)$ where $E(i)$ is the number of cases expected in area i given its population composition and $\theta(i)$ is the area-specific relative risk in area i . This level of the *hierarchical model* expresses the uncertainty in the data given the model specification including its parameters. At level 2, we define the model that reflects our understanding of what determines area level relative risk. For example, we may set

$$\text{Log}[\lambda(i)] = \text{Log}[E(i)] + b_0 + b_1Z_1(i) + \dots + b_kZ_k(i) + u(i) + s(i) \quad i = 1, \dots, n \quad (65.7)$$

where Z_1, \dots, Z_k define a set of k area-specific covariates with parameters b_1 to b_k that explain variation in relative risk and $\{u(i)\}$ and $\{s(i)\}$ are random effects. The $\{u(i)\}$ are i.i.d. normal random effects, and the $\{s(i)\}$ are given an *intrinsic conditional spatial autoregressive* (ICAR) specification (Haining 2003). These two terms model the scientific uncertainty in the model specification (e.g., competing theoretical understandings of the determinants of relative risk, our understanding of exposure to risk factors) as well as the effects of *overdispersion* and *spatial autocorrelation* in the spatial variation in relative risk and hence in the spatial distribution of the counts. At level 3, for a fully *Bayesian* analysis, the parameters at level 2 are treated as random variables and given probability distributions. As noted in an earlier section of this chapter, this could be extended to include the weights that define which areas are treated as *neighbors* in the ICAR specification. Choices about probability distributions could be informed by scientific understanding, but they might also be a way of allowing for uncertainty in our knowledge (Cressie et al. 2009). For an extension of these models to the multivariate case including multivariate spatial effects, see, for example, Gelfand and Vounatsou (2003).

65.6 Conclusions

One of the earliest items on the agenda of the USA’s National Center for Geographic Information and Analysis (NCGIA) was spatial *data quality* emphasizing its fundamental importance to the development of good science. Understanding data uncertainty, arising from all the stages by which a complex geographical

reality is translated into spatial data, remains at the heart of good spatial science. In the light of the preceding comments, it should also link closely with modeling. At about the same time, attention was also being drawn to the importance of software development for spatial data analysis. In addition to progress in these two areas, the field of spatial data analysis has grown in many other ways. But static, cross-sectional in time, spatial data analysis is restricted to analyzing and modeling the “here and now” of some wider process. A series of spatial analyses over time can shed light on change but in other respects remains limited. The understanding that has been gained by the progress made in spatial statistics forms an essential element in the emergence of *spatiotemporal* data analysis. With the huge growth in space-time data sets and the potential they offer to advance scientific understanding, this represents one of the key areas for future growth.

Abstract

In this chapter, we discuss key concepts for exploratory spatial data analysis (ESDA). We start with its close relationship to exploratory data analysis (EDA) and introduce different types of spatial data. Then, we discuss how to explore spatial data via different types of maps and via linking and brushing. A key technique for ESDA is local indicators of spatial association (LISA). ESDA needs to be supported by software. We discuss two main lines of software developments: GIS-based solutions and stand-alone solutions.

66.1 Introduction

In his groundbreaking book from 1977 on exploratory data analysis (EDA), Tukey (1977) made several statements that are still relevant today, more than 35 years after the publication of this book:

- “The greatest value of a picture is when it *forces* us to notice what we never expected to see.” (p. vi)
- “Today, exploratory and confirmatory can — and should — proceed side by side.” (p. vii)
- “Exploratory data analysis is detective work — numerical detective work — or counting detective work — or graphical detective work.” (p. 1)
- “Unless exploratory data analysis uncovers indications, usually quantitative ones, there is likely to be nothing for confirmatory data analysis to consider.” (p. 3)
- “Exploratory data analysis can never be the whole story, but nothing else can serve as the foundation stone — as the first step.” (p. 3)

Tukey’s expectations (and limitations) on EDA can easily be extended to exploratory spatial data analysis (ESDA), that is, the exploratory analysis of data with a spatial (geographic) component. As early as 1981, Ripley (1981) followed the distinction between exploratory and confirmatory data analyses in the preface of his book on spatial statistics: “The techniques presented are designed for both of John Tukey’s divisions of exploratory and confirmatory data analysis” (p. vi).

The exact definition of ESDA slightly differs from source to source, but all agree that ESDA is an obvious extension of EDA. Commonly found topics that are covered by ESDA include the visualization and exploration of data in a spatial (geographic) framework. ESDA utilizes many methods, tools, and software components from the field of interactive and dynamic statistical graphics, such as brushing and linked views/linked windows. Typically, one or more map views are linked with one or more statistical displays of the data. Modifications to one of the views will result in modifications of all linked views. Questions of interest that ESDA can answer may be whether a cluster of points that can be seen in a scatterplot is related to nearby spatial locations or whether a particular geographic region (say, the coastal region of a country) exhibits different characteristics than the mountainous region that can be seen in a linked statistical view. Moreover, ESDA can help to create new hypotheses about the underlying spatial data that can later be investigated in more detail in a follow-up study. Also, ESDA methods should be applied before any advanced modeling and testing of statistical hypotheses. Anscombe (1973) has provided some striking examples which could happen when a linear regression line is blindly fitted to some unsuitable data set. The same is the case if some methods from spatial statistics are blindly applied to some spatial data set when no prior exploration took place. We should keep in mind that spatial data often are large and diverse data sets, rather than homogeneous data sets. A large number of different methods usually could, and should, be used, including, simple numerical summary statistics. Coming back to Tukey, the goal or expected outcome of the exploration usually is unknown in advance. Moreover, it should be noted that ESDA is more than just an extension of EDA as additional techniques

and methods are needed that incorporate the specific spatial structure of the data. A frequent goal of ESDA is the exploration of spatial autocorrelation. We speak of positive spatial autocorrelation when nearby observations on average are more similar than what a random assignment would yield and of negative spatial autocorrelation when nearby observations on average are more distinct than what a random assignment would yield.

In the next section, we will discuss the main types of spatial data and following that, consider basic visualization and exploration techniques via maps. We then discuss two of the key concepts of ESDA: exploration via linking and brushing and local indicators of spatial association (LISA). A section on software for ESDA follows. We then finish with a brief conclusion and outlook on possible future work.

66.2 Types of Spatial Data

There exist four main types of spatial data:

- a. In spatial point patterns, the location of an event is of interest itself. Point patterns can be the locations where a patient died from a particular disease or where some specific animal species has been observed. A question of interest might be to explore the spatial patterns of the deaths, for example, at which locations deaths have been due to disease A and at which locations deaths have been due to disease B.
- b. Lattice data, sometimes also called area, areal, or grid data, are data that have been aggregated over some small geographic area. Often, a distinction is made between regular lattices (such as encountered for remote sensing data) or irregular lattices (such as states, counties, or health service areas). In a scenario where different economic regions are compared, a question of interest might be to explore how variables such as educational level, age, and racial composition of the population relate to unemployment in that region.
- c. Geostatistical data, sometimes also called spatially continuous data, are data that could, at least theoretically, be observed at any spatial location. However, cost and time determine at how many locations such data actually are collected. Examples of this type of data range from precipitation and temperature measurements to air pollution measurements and readings of minerals in the earth. A question of interest might be to visualize the distribution of nitrates in the soil in a specific region before fitting a smooth surface to the data.
- d. Origin–destination flow data, sometimes also called link or spatial interaction data, are data that consist of measurements, each of which is associated with a pair of point locations or a pair of areas. Examples for this type of data are home address and workplace address for inhabitants of a particular city or originating and destination airports for airline travel. A question of interest might be to explore from which originating airports most passengers, most flights, or most cargo arrives at a particular destination airport.

Cressie (1993) addressed the first three types of spatial data, both from a theoretical as well as from an applied perspective. When an additional temporal

component is available, that is, spatial data are collected over time; we speak of spatiotemporal data. Origin–destination flow data are discussed in detail in Fischer and Wang (2011, Part II). To a considerable extent, the underlying type of spatial data set determines which ESDA techniques are most suitable. Many of the ESDA techniques discussed in this chapter are suitable for more than one type of spatial data.

66.3 Basic Visualization and Exploration Techniques via Maps

The first step to explore spatial data often is to display the data on a map and then to produce several variations of the initial map. Credit needs to be given to John Snow (1813–1858), a British anesthesiologist, who was the first who mapped disease data. His investigation of the 1854 cholera outbreak in London pioneered the field of epidemiology. Nowadays, some consider him the “*father of epidemiology*” but the name “*grandfather of ESDA*” might suit him equally well. The 1854 London cholera outbreak started on August 19, 1854. It lasted about 6 weeks and resulted in more than 575 deaths. Snow (1936) observed: “. . . Mortality in this limited area probably equals any that was ever caused in this country, even by the plague.” Snow’s hypotheses were that cholera was transmitted from person to person via a fecal–oral route and that the drinking water of the Broad Street pump was the cause of the cholera outbreak. Snow utilized his map and empirical evidence to convince the Board of Guardians to remove the handle of the Broad Street pump. A mere 48 fatal attacks occurred, following the removal of the handle of the Broad Street pump, indicative that the water feeding the Broad Street pump could indeed be the source of the cholera epidemic.

As demonstrated by Snow, the visualization of spatial locations, that is, spatial point patterns, can provide valuable insights into such a data set. Moreover, if additional information is available for the locations such as age, gender, and case/control, this information can be displayed via different colors, symbols, and symbol sizes in the map display.

66.3.1 Choropleth Maps

For lattice data and geospatial data, several types of map displays exist and can be used for exploration. Best known, and most widely used, are choropleth maps. However, choropleth maps highly depend on choices made by the map creator. Even if the geographic boundaries are fixed as is the case for lattice data, Monmonier (1996, Chaps. 4 & 10) worked out different visual effects depending on whether the data are split into equal–interval classes or into quartile (or other quantile) classes. The same choices that affect histograms, that is, the starting point of a class interval and the width of each class interval, also affect choropleth maps.

Moreover, color choices in choropleth maps have a considerable effect on our perception. A small dark area in an overall bright map may (or may not) be

perceived as well as a small white area in an overall dark map. Excellent options for color choices for maps and statistical plots can be obtained from the *ColorBrewer* software tool (Harrower and Brewer 2003), accessible at <http://colorbrewer2.org>.

Finally, if geographic boundaries are not fixed in advance, choropleth maps can be easily affected by the modifiable areal unit problem (MAUP) (Openshaw 1984). Depending on the boundaries that are used for the aggregation (such as summation or averaging), rather different results for the sums, percentages, or averages may be obtained. Monmonier (1996, Chap. 10) demonstrated the MAUP for the locations of Snow's cholera data set. Therefore, it is necessary to explore what happens when spatial data get aggregated in different ways.

Given these different sources for biases when looking at choropleth maps, it is necessary to create and explore a variety of these maps to explore and understand the underlying spatial patterns. A single choropleth map that is the result of some default setting in a map-producing software package rarely will reveal all details of the underlying spatial data set. Andrienko et al. (2001) discussed how to conduct an exploratory analysis of spatial data via a combination of interactive maps and data mining.

66.3.2 Linked Micromap Plots

Linked micromap (LM) plots (Symanzik and Carr 2008; Carr and Pickle 2010) were introduced as an alternative to choropleth maps, especially to overcome some of the limitations of choropleth maps. The basic idea behind LM plots is to link geographic region names and their statistical values with their locations that are shown in a sequence of small maps, called micromaps. A typical LM plot (see Fig. 66.1) consists of three to five columns. The first column usually shows the maps, the second column lists some identifier (such as country or state names), and the third to the fifth columns contain statistical plots. Each small map highlights a few locations, typically five in a single map. The data are sorted according to some statistical criteria, for example, from highest to lowest (or vice versa), or from highest increase to lowest increase between years 1 and 2. Thus, the topmost map shows locations with the five largest (or smallest) observations according to the sorting criteria, the next map shows the five locations with the next largest (or smallest) observations, and so on. In case of any spatial association, locations with high or low observations tend to be plotted on the same map or on neighboring maps. The columns with the statistical plots may contain dot plots for each location, confidence intervals, time series plots, or box plots that are based on data for each particular location.

Micromaps have been used in print for applications as diverse as for comparisons of changing population density and population growth by state and for the visualization and interpretation of birth defects data in Utah and the United States. Typically, a published micromap is the result of many iterations where the authors experimented with different sortings and arrangements of the data panels and multiple possible layouts of the map panel.

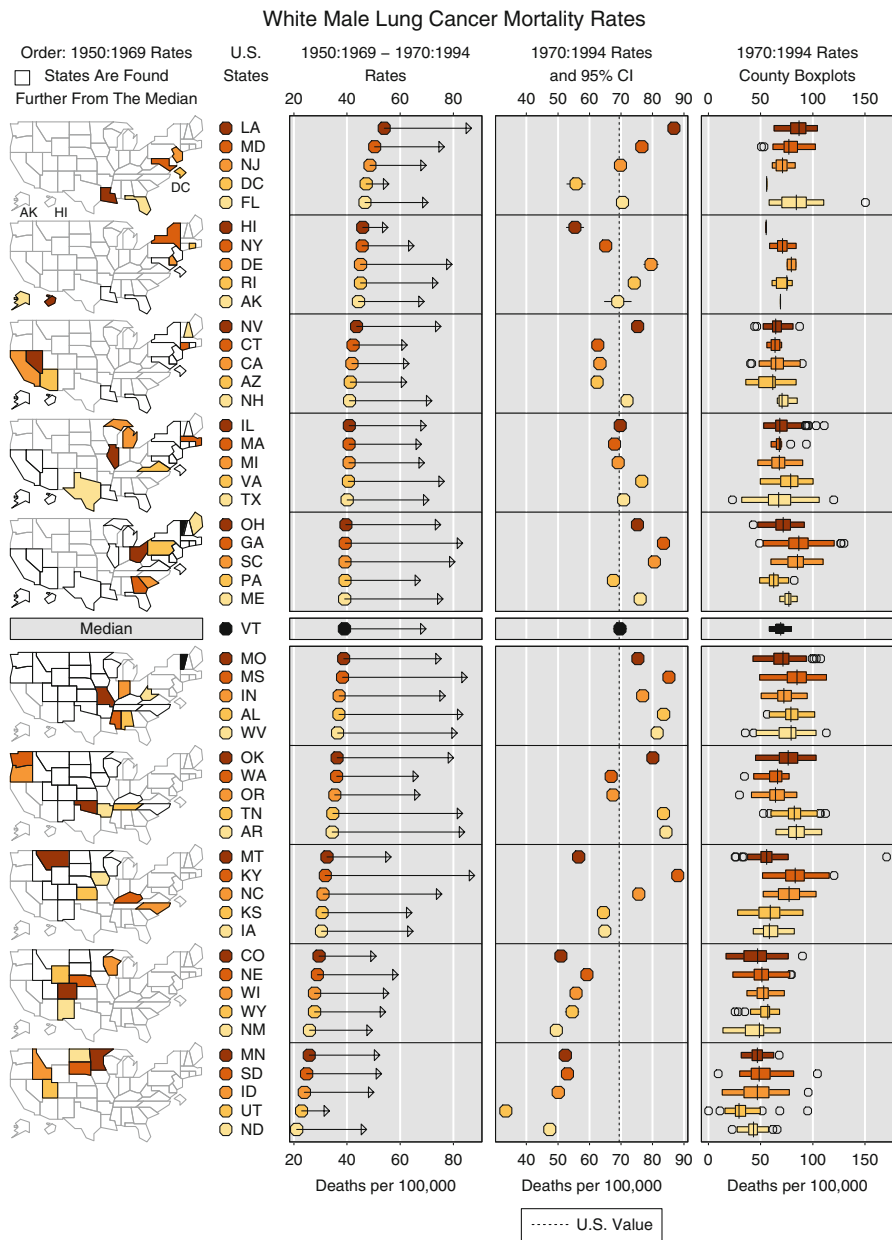

Fig. 66.1 LM plots, based on data from the NCI Web page, showing summary values for white male lung cancer mortality rates in the United States for the years 1950–1969 and for the years 1970–1994 in the *left data panel*, rates and 95 % confidence intervals in the *middle data panel*, and box plots for each of the counties of each state in the *right data panel* (Previously published as Fig. 1.6 in Symanzik and Carr (2008, p. 285))

While LM plots initially were constructed only for a static representation of the underlying data on paper or a computer screen, interactive versions may be introduced to allow an exploration of the underlying data from multiple perspectives. The US Department of Agriculture (USDA) – National Agricultural Statistics Service (NASS) Research and Development Division released an interactive micromap Web site (<http://www.nass.usda.gov/research/sumpant.htm>) in September 1999 for the display of data from the 1997 Census of Agriculture. This Web site still is accessible today. The National Cancer Institute (NCI) released an interactive micromap Web site (<http://www.statecancerprofiles.cancer.gov/micromaps>) in April 2003 for accessing their cancer data (Wang et al. 2002; Carr et al. 2002). This Web site is still accessible today and it is permanently updated with new data. While printed (static) LM plots are most suitable when the number of geographic regions ranges from about 10 to about 100, interactive LM plots may be suitable for several hundred geographic regions. Micromaps at the county level for the 254 counties of Texas at the NCI micromap Web site can reveal some very strong patterns, based on the data selection.

Figure 66.1 shows a static LM plot with three statistical columns based on data derived from the NCI Web site. The rows in the figure are sorted according to the 1950–1969 white male lung cancer rates in the United States (US) that reveal some strong geographic pattern with high rates in the eastern, southern, and western United States. A next step could be to resort the rows with respect to highest 1970–1994 rates, then with respect to highest absolute increases from the 1950–1969 to the 1970–1994 rates, and finally with respect to highest relative increases from the 1950–1969 to the 1970–1994 rates. Moreover, the second and third data column might be used to display data from possible confounding variables at the state level, such as smoking rates, gender composition, or educational level. After the exploration of several such LM plots, a researcher likely will have observed many known facts about the spatial distribution of male lung cancer, but, hopefully, some unexpected patterns and relationships also will have emerged.

66.3.3 Conditioned Choropleth Maps

Conditioned choropleth maps (CCmaps) (Carr et al. 2000; Carr and Pickle 2010) were introduced as a tool for the exploration of spatial data that consist of geographic locations, one dependent variable, and two independent variables. Via sliders, a researcher can interactively partition each of the two independent variables and the dependent variable into three different intervals each. A 3×3 set of panels containing nine partial maps shows the color-coded level (high, medium, low) of the dependent variable for those geographic locations that relate to high values of variable one and high values of variable two in map one, for those geographic locations that relate to high values of variable one and medium values of variable two in map two, and so on. For example, in an agricultural setting, variable one might be the amount of fertilizer, variable two might be the amount of

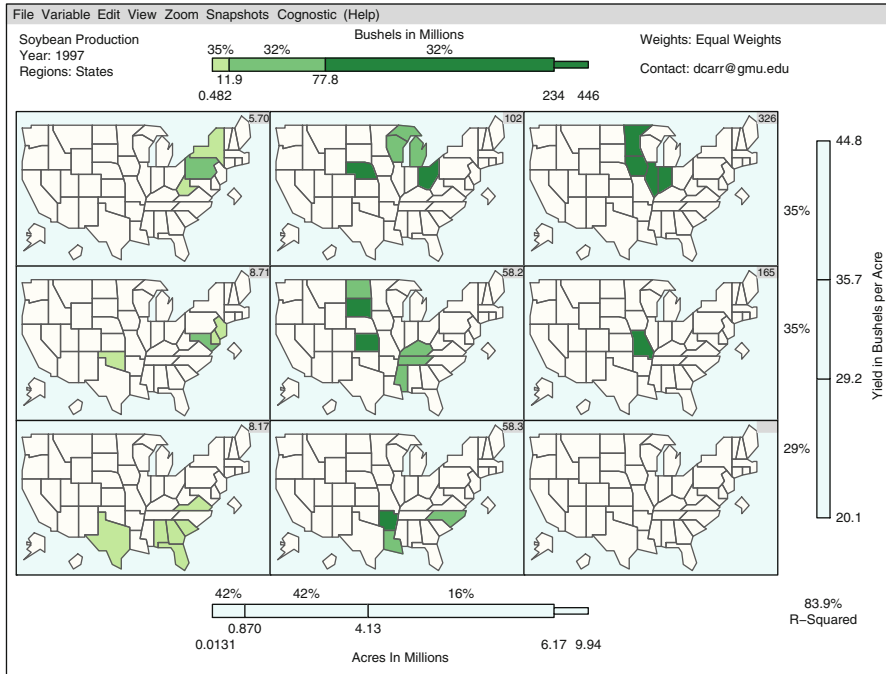

Fig. 66.2 CCmaps, based on data from the USDA–NASS Web page, related to soybean production in the United States. The plot shows the dependent variable production (*top slider*) that is conditioned on the two independent variables acreage (*bottom slider*) and yield (*right slider*) (Previously published as Fig. 1.7 in Symanzik and Carr (2008, p. 289))

precipitation, and the dependent variable might be the yield of a crop. One might expect that high values for fertilizer and precipitation result in a large yield. The nine maps show the relationship among the three variables in a geographic framework, thus allowing the consideration of the underlying spatial structure of the data and not only the statistical relationships. Cutoff values can be changed interactively, thus allowing the investigation of many possible settings. CCmaps are useful tools for the interactive generation of statistical hypotheses for medical, epidemiological, and environmental applications.

In Fig. 66.2, the 1997 soybean production in the United States is conditioned on acreage and yield. In an interactive environment, slider settings can be further modified to identify geographic areas of interest on the nine maps.

66.4 ESDA via Linking and Brushing

While in the previous section map views were interactively manipulated in a rather direct way, we will discuss in this section how map views and associated statistical

displays can be interactively manipulated via linked views and brushing. This is commonly understood as the classical idea of EDA and ESDA. For a detailed discussion of concepts for interactive graphics, such as brushing, linked brushing, linked views, focusing, zooming, panning, slicing, rescaling, reformatting, rotations, projections, and the grand tour, the reader is referred to Symanzik (2004, Sect. 10.3). Main statistical plot types that can be frequently found as components of linked views include histograms, scatterplots, scatterplot matrices, the grand tour, parallel coordinate plots, bar charts, pie charts, spine plots, mosaic plots, ray-glyph plots, and cumulative curves (such as the Lorenz curve). Most of these plot types also were discussed in Symanzik (2004, Sect. 10.3). Figure 66.3 shows one map view that has been linked with two scatterplots. In addition, plots for spatial data, such as variogram–cloud plots (see Fig. 66.4) and spatially lagged scatterplots, can be components of the linked views.

The overall idea of brushing is to mark different subsets of the data in a particular plot with different colors, symbols, sizes, or point or line styles. This is usually done based on the visual appearance of patterns in a specific plot, for example, outliers that seem to be far away from the remaining points in a histogram or scatterplot, or clusters that seem to be well separated from each other. In the next plot that is being produced, the original assessment will be reevaluated, additional points may be marked, or points may be marked differently.

In the framework of linked brushing and linked views, the brushing information is carried over from one plot to the next. For example, outliers that are marked in a histogram or scatterplot will be marked in a similar way (with the same colors, symbols, sizes, or point or line styles) in all related plots, in particular on a map view as well. Monmonier (1989) introduced the term geographic brushing in reference to interacting with the map view of geographically referenced data.

In Fig. 66.3, the US cities with the highest index for education have been brushed in the left scatterplot, and cities with a high crime index have been identified by name in the same scatterplot. The map view shows the locations of these cities with the same color and symbols as in the scatterplot. Moreover, the scatterplot on the right reveals that a high crime index is associated with a high recreation index while a high education index is associated with a medium recreation index. Nothing striking is noticeable when comparing the brushed values for education and crime with the arts index. Extensions of brushing for spatial data, such as moving statistics, or brushing, applied to origin–destination flow data (Liu and Marble 1997), exist.

In advanced software environments, brushing can take place in any of the linked views, including the map view. So, when locations in a specific geographic region are marked, the other statistical views will reveal whether there is some possible statistical relationship among the data from the selected locations as well, for example, whether the statistical values are similar to each other or whether the statistical values span the entire range of the underlying data distribution.

Linked brushing is not always one-to-one between the different displays. In a variogram–cloud plot, the absolute difference (or a related measure) of a variable of interest is calculated for all pairs of spatial locations, and this measure

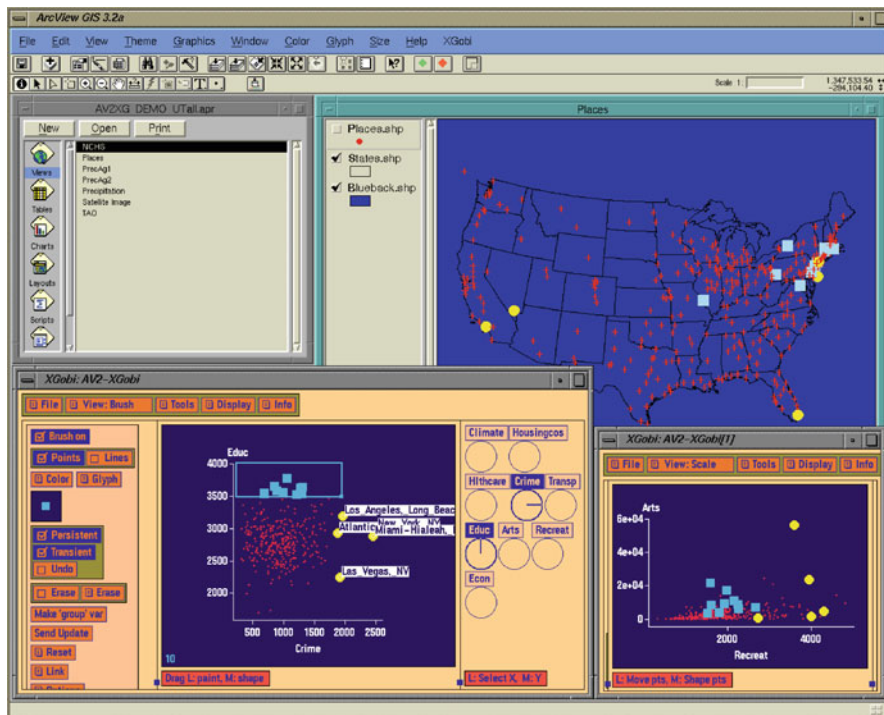

Fig. 66.3 Screenshot of the “Places” data in ArcView/XGobi. A map view of 329 cities in the United States is displayed in ArcView at the top. The two XGobi windows at the bottom are showing scatterplots of crime (*horizontal*) versus education (*vertical*) (*left*) and recreation (*horizontal*) versus arts (*vertical*) (*right*). Locations of high crime have been brushed and identified, representing some of the big cities in the United States. Also, locations of high education (above 3,500) have been brushed, mostly representing locations in the northeastern United States. All displays have been linked (Previously published as Fig. 10.1 in Symanzik (2004, p. 299))

is plotted against the Euclidean distance between the two associated points (up to a cutoff distance chosen by the researcher). Thus, when brushing one point in a variogram–cloud plot, this needs to be translated to a pair of spatial locations that are brushed in the map view.

Figure 66.4 shows such a link for precipitation measurements in the northeastern United States. In this figure, the highest values in the variogram–cloud plot (up to the cutoff distance) have been brushed. The map view shows two points, that is, spatial locations, that are connected to several other spatial locations. The location in the northeast likely is a spatial outlier as its precipitation measurements are considerably different (either higher or lower) than those from all nearby locations. A next step would be to explore additional variables for these locations, starting with elevation. The location in the southwest likely is not a spatial outlier; rather, there is some considerable local variation happening in this region as this location is only connected to some, but by far not all, locations in its neighborhood.

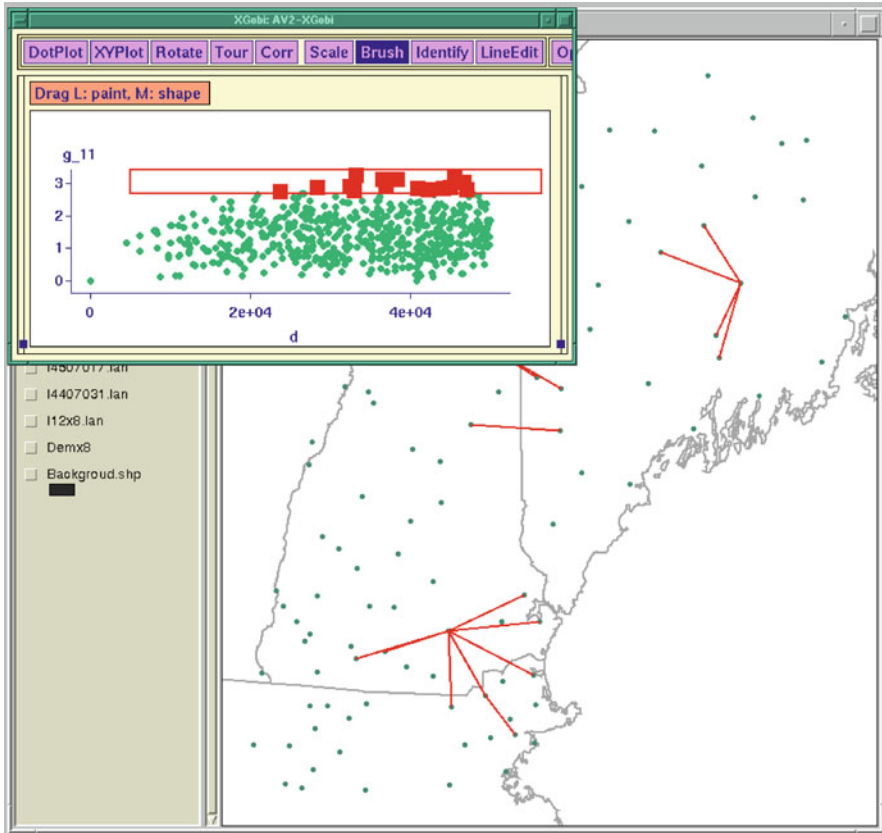

Fig. 66.4 Example of a variogram–cloud plot that is linked to a map view, based on precipitation data for the northeastern United States. In the *upper left* XGobi window, we have brushed (using a *solid rectangle*) the highest values in the variogram–cloud plot. In the *lower right* ArcView map view, each pair of locations, related to a point that has been brushed in XGobi, has been connected by a line (Previously published as Fig. 2 in Symanzik et al. (2000, p. 477). Reprinted with permission from the *Journal of Computational and Graphical Statistics*. Copyright 2000 by the American Statistical Association. All rights reserved)

66.5 Local Indicators of Spatial Association (LISA)

Moran's I statistic is a well-known measure for spatial autocorrelation at the global level for lattice data. Anselin (1995) introduced a local Moran statistic, a local Gamma statistic, a local Geary statistic, a Moran scatterplot, and other LISA statistics to assess the spatial association at a location i . The LISA statistics allow to identify local spatial clusters and to assess local instability. Moreover, the LISA statistics allow to assess the influence of a single location on the corresponding global statistic, a feature that is as important as being able to identify influential points in a regression framework.

LISA statistics are probably the most frequently applied ESDA technique, with applications in areas as diverse as regional sciences, spatial econometrics, epidemiology, social sciences, and criminology. Despite its wide use, one should keep in mind that LISA statistics are exploratory in nature, and, usually, additional steps are required to confirm the initial results derived from LISA statistics.

66.6 Software for ESDA

ESDA is highly dependent on software that supports various types of statistical displays, map views, and that allows linked brushing. Two main approaches have been developed during the last 25 years: Conducting ESDA in software environments where a geographic information system (GIS) is linked to statistical software packages and in stand-alone statistical software solutions. A more detailed overview of various software solutions for ESDA has been provided in Symanzik (2004, Sect. 10.6.1).

66.6.1 ESDA and GIS

Fotheringham (1992) pointed out that it is not necessary to conduct an exploratory spatial data analysis within a GIS, but that in many circumstances, using a GIS to do so might simplify the exploration of the data and provide insights that otherwise might be missed. Therefore, over the next decade, several researchers developed software that linked GIS with statistical software, or they added statistical features to existing GIS.

In Anselin (1994), a series of ESDA techniques were discussed in the context of a GIS, with the primary focus on exploring the spatial nature of the underlying data. These techniques could be classified as techniques based on the neighborhood view of spatial association (such as Moran scatterplots and LISA statistics) and as techniques based on the distance view of spatial association (such as spatially lagged scatterplots and variogram–cloud plots). Various software links between GIS such as Arc/Info, ArcView, and Grassland and one or more statistical software packages implemented several of these techniques. Some of the links that were developed and maintained over a longer time period were links between Arc/Info, respectively, ArcView, and SpaceStat (Anselin et al. 1993; Bao and Anselin 1997) and links between ArcView, XGobi, and XploRe (Cook et al. 1996; Symanzik et al. 2000). One major limitation of such software links is that whenever one of the individual software packages is modified with respect to the functionality of the link, the other software packages have to be modified accordingly.

66.6.2 Stand-Alone Software for ESDA

In contrast to linking GIS and statistical software, several software developers focused on the development of stand-alone statistical software that also support map views of the spatial locations that are linked with statistical displays. Some of

the best known examples are Spider (Haslett et al. 1990), REGARD (Unwin et al. 1990; Unwin 1994), and, more recently, GeoDa (Anselin et al. 2006). One major limitation of stand-alone software for ESDA is that the functionality that is usually available in a GIS has to be reimplemented in a statistical software package.

In recent years, R (R Development Core Team 2011) has become the *lingua franca* of statistics. Since its appearance around 1996 (Ihaka and Gentleman 1996), R has been further advanced by thousands of creators of contributed packages (almost 4,000 in May 2012) that provide all kinds of additional functionality beyond the original R base functionality. This includes packages for maps, color selections, EDA and ESDA, and advanced statistical functionality for spatial data, such as the following:

- *maptools* (<http://cran.r-project.org/web/packages/maptools/index.html>) that allows to read and manipulate geographic data, in particular ESRI shapefiles
- *maps* (<http://cran.r-project.org/web/packages/maps/index.html>) that provides access to a variety of maps
- *RgoogleMaps* (<http://cran.r-project.org/web/packages/RgoogleMaps/index.html>) that allows to query the Google server for static maps and to use one of the Google maps as a background image to overlay statistical plots from within R
- *RColorBrewer* (<http://cran.r-project.org/web/packages/RColorBrewer/index.html>), the R implementation of <http://colorbrewer2.org>, for good color choices for maps and other plots
- *iplots* (<http://cran.r-project.org/web/packages/iplots/index.html>), an R package in the spirit of Spider and REGARD, for interactive plots in R, including maps
- *splancs* (<http://cran.r-project.org/web/packages/splancs/index.html>) for the exploration and analysis of spatial and space–time point patterns,
- *spatstat* (<http://cran.r-project.org/web/packages/spatstat/index.html>) for the exploration and analysis of spatial data, mainly spatial point patterns
- *spdep* (<http://cran.r-project.org/web/packages/spdep/index.html>) for the analysis of spatial dependence at a local and global scale, including Moran and LISA statistics
- *geoR* (<http://cran.r-project.org/web/packages/geoR/index.html>) for the exploration and analysis of geostatistical data
- *gstat* (<http://cran.r-project.org/web/packages/gstat/index.html>) for modeling, prediction, and simulation of spatial and spatiotemporal geostatistical data
- *spgrw* (<http://cran.r-project.org/web/packages/spgrw/index.html>) for computing geographically weighted regression

While the Web pages listed above provide detailed user guides and information how to use each of these packages, Bivand (2010) demonstrated how many of the ESDA techniques described in this chapter can be performed in R. An extended overview of additional R packages for the reading, exploration, visualization, and analysis of spatial data can be found at <http://cran.r-project.org/web/views/Spatial.html>.

66.7 Conclusions

In this chapter, we have provided an overview of techniques, methods, and software solutions for ESDA. Most of the developments took place during the

last 25–30 years. Due to the rapid development of computer hardware, including high-quality graphic displays, over the last few decades, ESDA techniques are nowadays easily accessible for many researchers on a wide variety of hardware platforms.

A current hotspot for ongoing development of ESDA techniques is R and its thousands of contributed packages. For a few decades, software packages for exploratory data analysis were relatively weak for confirmatory data analysis (using John Tukey's terms here), and vice versa. However, R is continuously getting stronger for both types of data analyses, and it is able to handle a large variety of GIS data formats. It can be expected that in the near future, exploratory and confirmatory data analyses will be conducted almost simultaneously in R or some similar software environment. Once a researcher detects something of interest in a spatial data set via ESDA, a confirmatory analysis can immediately follow, and once a confirmatory analysis has been conducted, ESDA can be used to further explore the spatial fit of the fitted model, its residuals, and so on.

A trend in recent years has been to provide access to spatial data for everyone via Web interfaces. This includes the previously introduced Web sites for interactive micromaps (<http://www.nass.usda.gov/research/sumpant.htm> and <http://www.statecancerprofiles.cancer.gov/micromaps>), but, even more, Web-based software such as *gapminder* (Rosling and Johansson 2009), accessible at <http://www.gapminder.org/>. The Google version, called *Google Public Data Explorer*, accessible at <http://www.google.com/publicdata/directory>, might become a tool that provides easy and fast access to EDA and ESDA techniques for millions of Web users.

Abstract

Spatial autocorrelation in health events may be the signature of underlying causal factors of direct scientific and practical interest but may also be due to pedestrian or nuisance factors that obscure meaningful spatial patterns. The problem is to discern spatial patterns that inform our understanding of the health events themselves from those that are of little interest. This chapter provides a framework for advancing knowledge when the causes of observed health event clusters are unknown.

67.1 Introduction

We begin with background and trends in health data, electronic health and mobile health, and clustering as pre- versus post-epidemiology. Motivations for clustering are presented, with the scope of inference and what can be learned from spatial disease patterns. The approach of Strong inference is described and proposed as a useful framework for the analysis of health event clusters. This touches on explanations for patterns, which can be due to nuisance factors and covariates, as well as to underlying causes of disease. Coverage is then given to sources of autocorrelation in health events, which are extensive, and range from the signature of underlying disease processes to covariates and risk factors that may or may not be of interest, to treatment effects, access to care, and geographic variation in pathogen and host genetics, as well as other causes. Each of these may be an explanatory hypothesis describing the origin of a health event cluster. Complicating factors include latency and temporal lag processes, location uncertainty, and using location as a proxy. Next, the types of data that may be analyzed are presented, ranging from case locations, case-control data, mobility histories, and data aggregated into rates. What goes into the denominator is an important consideration when using rates, and alternatives, such as the stage of diagnosis that have readily estimated denominators, are considered. Consideration is given to the kinds of data that may be analyzed, including incident cases and deaths, case-control data, symptoms, volunteer geographic information and crowd sourcing, and residuals from spatial models. Examples of data models for these different types are next. The conclusion revisits important problems and future prospects, including sources of false negatives in cluster analyses, the use of location as a surrogate for exposure or as a proxy for another variable, and the development of experimental methods and sampling frameworks for the emerging era of “big data.” “Big data” refers to massive data sets that collect over time and that are difficult to analyze using common database management tools; these pose a true challenge in spatial analysis. Very large data sets have been around for quite some time; what distinguishes “big data” is the heterogeneity of its sources that include retail transactions, photos and surveillance videos, data from logs and sensors, as well as unstructured text posted on the Web, such as blogs and social media.

67.2 Background and Trends

Once identified, health event clusters may be used to guide public health response, to site clinics and screening facilities in order to better serve at-risk communities, to guide application of health interventions, and to formulate health policies. The accurate and timely identification of spatial and temporal patterns in health events is therefore of some importance (Kingsley et al. 2007).

Pre- Versus Post-Epidemiology. Health event clustering has been referred to as “pre-epidemiology” since it has often relied on encountered data that were not

collected using an experimental design suited to cluster detection. This has limited its inferential power to the extent that clustering has been viewed as an expensive activity that does little to increase our understanding of the causes of disease (Neutra 1990). As the field has advanced, clustering has been applied to data that come from traditional experimental designs such as case-control studies, and techniques have been developed for systematically excluding hypotheses that might explain observed disease patterns. One then seeks to allocate the risk not explained by the known risk factors to specific places, groups of study participants, and times. This supports the construction of new hypotheses regarding underlying causal factors and may be thought of as “post-epidemiology” as the analyses are conducted after, or as an adjunct to, traditional epidemiological analyses. The key is that the data being analyzed have been collected as part of a sampling design that controls for known risk factors and covariates.

Application Areas. Initially, health event cluster analysis was primarily a response mechanism for replying to cluster alarms raised by a concerned public. This was a retrospective analysis in that the techniques were applied to existing data to evaluate whether there was a statistically significant excess of disease. Surveillance is used when one wishes to analyze a stream of health data in order to detect an increase or change in baseline risk. Syndromic surveillance is a special case of surveillance that uses health indicators that may not have been fully vetted via diagnoses, laboratory confirmation, or other means. Here the objective is the timely identification of disease outbreaks, such as might arise under a bioterrorist attack or from local emergence of a novel flu strain. Syndromic surveillance has evolved as data on indicators of disease, such as pharmaceutical prescriptions and over-the-counter sales of cough, diarrhea, and other medications, have become increasingly available. Meaningful use guidelines for syndromic surveillance in public health using electronic health record data collected in emergency department and urgent care settings are being proposed at the time of this writing (Johnson et al. 2012). As noted above, techniques for analyzing volunteered geographic information on disease are now being developed. With the advent of mobile devices, such as cell phones, mobility traces coupled with information on health outcomes may be clustered to assess relationships between mobility patterns, specific places, and health events.

The Changing Landscape of Public Health Data. The availability of georeferenced data in health analysis is expanding rapidly due to several technological and policy trends. First, there is increased availability of user-generated, location-enabled health data as segments of the population become comfortable with sharing information through smart phones, Web browsers, and other means and as search engine keywords and social media are used to assess near real-time trends in health-related symptoms, medications, and outcomes. The confluence of crowd sourcing (e.g., “reflexive consumerism” where patients review hospitals and professionals on the Web) and volunteer geographic information (VGI, where individuals report activities at their location) is enabling significant advances in disaster response, epidemiology, and exposure assessment science (Goodchild and

Alan Glennona 2010). For example, by coupling technologies for near real-time sensing of pollutants with location-enabled devices such as mobile phones, VGI can be used to generate model-based high spatial resolution exposure estimates. This makes possible validation of individual-level exposure estimates as a person goes about their daily activities.

Second, the US health-care system and the Department of Health and Human Services are investing heavily in interoperable electronic health records expected to revolutionize health care and disease control and surveillance. Recent national legislations such as the Health Information Technology for Economic and Clinical Health (HITECH) Act and the Affordable Care Act (ACA) include provisions requiring the collection of detailed electronic data in standardized format for insurance and care equity purposes (Weissman and Hasnain-Wynia 2011). Many of the data records for these systems include personal identifiers – names, addresses, and related health information – that can be used to construct georeferenced databases on patients, providers, and health-related resources such as screening facilities.

Third, advances in spatiotemporal epidemiology facilitate reconstruction of geocoded residential histories of patients. The feasibility of developing reliable geospatial data retrospectively for large, epidemiological studies has been demonstrated, and revisiting completed studies using spatial epidemiological methods is now possible. In an era of fiscal constraints, expensive, large epidemiological studies are less likely to be funded. Application of spatiotemporal analysis to completed case-control, cohort, and longitudinal studies holds enormous promise for gaining new insights into disease causation that leverages existing investments in health research.

67.3 Scientific Inference from Patterns of Health Events

Health event clusters may loosely be defined as statistically significant excesses of health events in space, in time, or in space-time. There also is space-time interaction, as when nearby health events occur at about the same time. Cluster existence, location, and timing can inform decisions regarding different questions, such as:

1. Is an observed pattern of health events statistically unusual? (Is apparent clustering real?)
2. Where are populations with elevated disease rates? (Where are local excesses found?)
3. Are areas with elevated health events found in proximity to geographic features thought to be associated with disease causality? (Is there focused clustering about pollutant sources?)
4. Is the observed spatial pattern of health events consistent with certain hypothesized disease processes, and not consistent with others (what is the underlying cause)?
5. Are there reasonable new hypotheses that might explain the observed disease patterns (what is the best explanation for the cluster)?

Several of these questions can be addressed using an inferential process where plausible generating processes for an observed pattern are considered and then excluded. This can be done in a haphazard fashion, but it usually is best to systematically enumerate the set of plausible hypotheses that might give rise to an observed pattern of health events and to then exclude members of this set by conducting a series of experiments that may include statistical tests and models for evaluating space-time disease patterns. This inferential framework seeks to accomplish a mapping of health event patterns to the spatial processes that might give rise to them, and is called Strong inference.

67.4 Strong Inference for Health Events

In 1964 Platt coined the term “Strong inference” (Platt 1964) to describe a useful construct for systematically evaluating explanatory hypotheses that plausibly might explain observed patterns in a data set. It involves, first, enumeration of the explanatory hypotheses that might give rise to the pattern; second, formulation of falsifiable predictions that can be used to systematically test each of these hypotheses; third, undertaking the tests of predictions; and, fourth, winnowing out the hypotheses whose corresponding predictions are found to be false. The remaining hypotheses then must include, or together explain, the observed data patterns. The initial set of explanatory hypotheses may be expanded as the experiments are conducted. What is key is that the predictions framed for each hypothesis be falsifiable (e.g., can be tested using a statistic for spatial clustering) and that the set of explanatory hypotheses be properly framed.

67.5 Sources of Spatial Autocorrelation in Health Events

Spatial autocorrelation is characteristic of almost all geographic data and can reflect the magnitude and spatial scale of underlying causal processes (Getis 2010). This raises a very important question. What are the sources of spatial autocorrelation in health events? These may need to be included in the set of explanatory hypotheses for an observed pattern and include spatial autocorrelation in underlying risk factors, covariates, reporting, diagnosis, health-care policies, physician behaviors, and interpolation autocorrelation, as summarized below. This is by no means an exhaustive list but includes factors that likely should be considered in many spatial analyses of health events.

Multifactorial Causes of Disease. It is important to recognize that many health outcomes may be caused by several different disease processes and that a given exposure mechanism may result in different disease outcomes. For example, risk factors for myocardial infarction include genetic predispositions, diet, body weight, exercise habits, medication compliance, and access to care, among others. And specific exposures, such as smoking, are associated with elevated risk for a host of health outcomes, including bladder, throat, and lung cancers, asthma, pneumonia, and emphysema, among others.

Spatial autocorrelation in health events may arise whenever the host of factors underlying disease expression are themselves spatially structured. Genetic predispositions for disease may be inherited, giving rise to spatial autocorrelation in disease risk whenever family members cohabit and tend to live near one another; ambient air pollutant concentrations tend to be highly spatially autocorrelated; and so on.

Comorbidity and Competing Causes of Death. It is unusual for chronic diseases to be the sole disease process occurring in a patient, especially as the age of the subject increases. This makes sense when one considers the multifactorial nature of most diseases. At the population level, smoking will increase the risk of both lung and bladder cancers; at the individual level, a smoker may have comorbid conditions such as emphysema and lung cancer. The expression of infection processes is often mediated by immune response and the health status of the individual. Hence, risk of infection increases as the physical condition of the individual declines. Individuals and populations are thus both subject to competing causes of death. Prior to the advent of antibiotics in the 1940s, respiratory and childhood infections were major sources of mortality in most developed countries. As antibiotics became widely available, the major source of mortality became chronic diseases such as heart conditions and cancer. These were “unmasked” once respiratory and childhood infections were removed as a competing cause of death. Spatial autocorrelation in health events thus may arise when there is underlying geographic variation in comorbid conditions and/or risks for competing causes of death.

Geographic Variation in Exposure and Behaviors That Mediate Exposure. Health events associated with environmental exposures are mediated by exposure routes including eating, drinking, breathing, dermal exposures, and ionizing radiation. When considering health outcomes associated with exposure to specific risk factors, such as arsenic, one needs to consider relevant exposure routes and mechanisms, such as consumption of foods and beverages containing biologically active forms of arsenic. Exposure-mediating behaviors are often modifiable risk factors, since what one smokes, drinks, and eats are to a certain extent individual choices that can be changed. When evaluating spatial patterns in health outcomes associated with environmental exposures, one needs to consider both environmental concentrations as well as the exposure routes whereby the compound under consideration enters the body. Both of these (environmental concentrations and exposure routes and mechanisms) may themselves be spatially structured. For example, the amount of water people drink varies with age, decreasing as one gets older; with occupation (farm workers requiring more water than office workers); with altitude; and other factors.

Socioeconomic and Demographic Factors. One definition of “covariate” is a variable that has an effect (e.g., is associated with the outcome) that is not of direct interest. When modeling health events such as disease incidence, socioeconomic and demographic factors such as age may be considered as covariates, since age, for example, does not of itself cause disease. Yet, these are of considerable importance when evaluating spatial disease patterns, since the risk of most health outcomes including cancer, heart disease, and infections is typically associated with socioeconomic status, sex, race, and age. One thus may need to account for spatial

patterns in covariates when assessing the significance of a clustering of health events. Rather than asking “Are the health events clustered?” one instead may ask “Is there significant clustering of health events above and beyond spatial patterns in covariates?” Neutral models (described later) have been developed to address this question.

Genetics. Microevolutionary processes such as selection, isolation by distance, and migration give rise to spatial autocorrelation in genetic structure and genetic variance in geographically distributed populations. While we often think of human populations as being very well mixed, interbreeding freely over large geographic distances, this is often not the case. Population genetics in North American, European, and Asian populations have been demonstrated to be spatially autocorrelated and associated with language and dialect. This makes sense when one considers that children speak the language of their parents and family and that family members tend to live in geographic proximity of one another, even though some may travel far from their homes. Familial clusters are often observed for many cancers, both because of behavioral factors mediating common exposures such as secondhand smoking and diet but also because of within-family genetic similarity in oncogenes and tumor suppressor genes. For example, one hypothesis for explaining the excess of breast cancer incidence on Long Island is the higher incidence of mutations of BRCA genes in local populations thought to be descended from European populations. BRCA1 and BRCA2 are tumor suppressor genes, and mutations of these genes have been linked to breast and ovarian cancers.

For infectious diseases the pathogen, whether a virus or a bacteria, undergoes a population bottleneck whenever there is infection transmission to a susceptible person. Only a few (e.g., several thousands) of the pathogen may be required for infection to take hold, and together these may have a genetic composition that is quite different from the overall pathogen population. A mutation that occurs during a bottleneck can become fixed in the pathogen population infecting that host (person). When this mutation is associated with changes in infection transmission or severity of the infection, it can have important consequences for the spread of infection, as well as for morbidity, mortality, and resistance to treatment. Such mutations can give rise to new pathogen strains, and the occurrence of these strains may be observed as outbreaks of the new strain, initially occurring in localized populations. This has been documented for diverse infectious diseases including cholera, tuberculosis, HIV, and influenza.

Perhaps one of the best known instances of interactions between infection and genetics is selective pressures for the sickle cell trait that foster resistance to malaria infection. In sickle cell disease, the red blood cells are misshapen, leading to circulatory problems and early death of red blood cells, resulting in anemia. The disease has a genetic basis, with alleles that code for the sickle cell trait and for abnormal hemoglobin, resulting in different forms of the disease of varying severity. But when one sickle cell allele is present, it confers some resistance to malaria infection. This confers a substantial selective pressure in populations residing in malarial regions. The sickle cell trait and sickle cell anemia, thus, vary

geographically with higher penetration of the sickle cell gene in populations residing where malaria is endemic.

Vector-borne diseases and parasites often have complex life histories, involving infection transmission and amplification among humans and one or more host organisms. Well-known examples include malaria, Lyme disease, and West Nile virus, among others. Here, spatial structure in the genetics of the pathogen can arise due to the interactions between population bottlenecks and mutations, as noted above for infectious diseases. The genetics of the host species can also influence the origin and spread of different pathogen strains.

Environment/Vector-Pathogen Ecology. Environmental patchiness in habitats suitable for vector and host organism survival is an important determinant of where and when vector-borne and parasitic infections occur. In the northeastern and midwestern United States, the white-tailed deer (*Odocoileus virginianus*) is an important host species for Lyme disease, which is transmitted by a bite from infected blacklegged ticks. Infection transmission events can only occur where both infected ticks and susceptible people are present. Blacklegged tick habitat includes wooded, brushy areas that provide food and cover for intermediate host species such as white-footed mice and white-tailed deer. But infection transmission to humans only occurs when people are in areas where infected ticks are present and feeding. Thus, the occurrence of Lyme disease is highly associated with geographic overlap of human activity spaces with habitat suitable for both intermediate hosts and the tick itself. Infection transmission is highly structured temporally as well, occurring in those months when the tick is searching for blood meals in the spring and fall.

Heterogeneity in Population Density, Rate Stability, and the Small Numbers Problem. Health events that occur in small areas may be expressed as a rate, such as an incidence or mortality rate. Rates are calculated from a numerator, such as the number of incident lung cancer cases in white males, and a denominator, such as the population at risk (e.g., white males) for lung cancer. The rate is calculated by dividing the numerator by the denominator, and this is where the “small numbers problem” arises. The variance in the rate depends critically on the size of the denominator. When the denominator is small, variance in the rate is high; when the denominator is large, variance in the rate is small. Hence, the appearance of an apparently large rate might be due entirely or in part to the small numbers problem (e.g., a small denominator with a resulting large variance in the rate estimate), and the true, underlying risk might be entirely unremarkable. A simple protocol for evaluating whether the small numbers problem is having an impact on estimated rates is as follows. First, create a map of the rate and a scatterplot of the rate (on the x-axis) and the population at risk (on the y-axis). Next, inspect the scatterplot for the “greater than” signature (e.g., “>”) such that variance in the rate is larger at small population sizes (Fig. 67.1). Finally, brush select on the scatterplot to see where the areas with high rates and low population sizes appear on the map. These are the places with apparent high rates that may be unstable due to the small numbers problem.

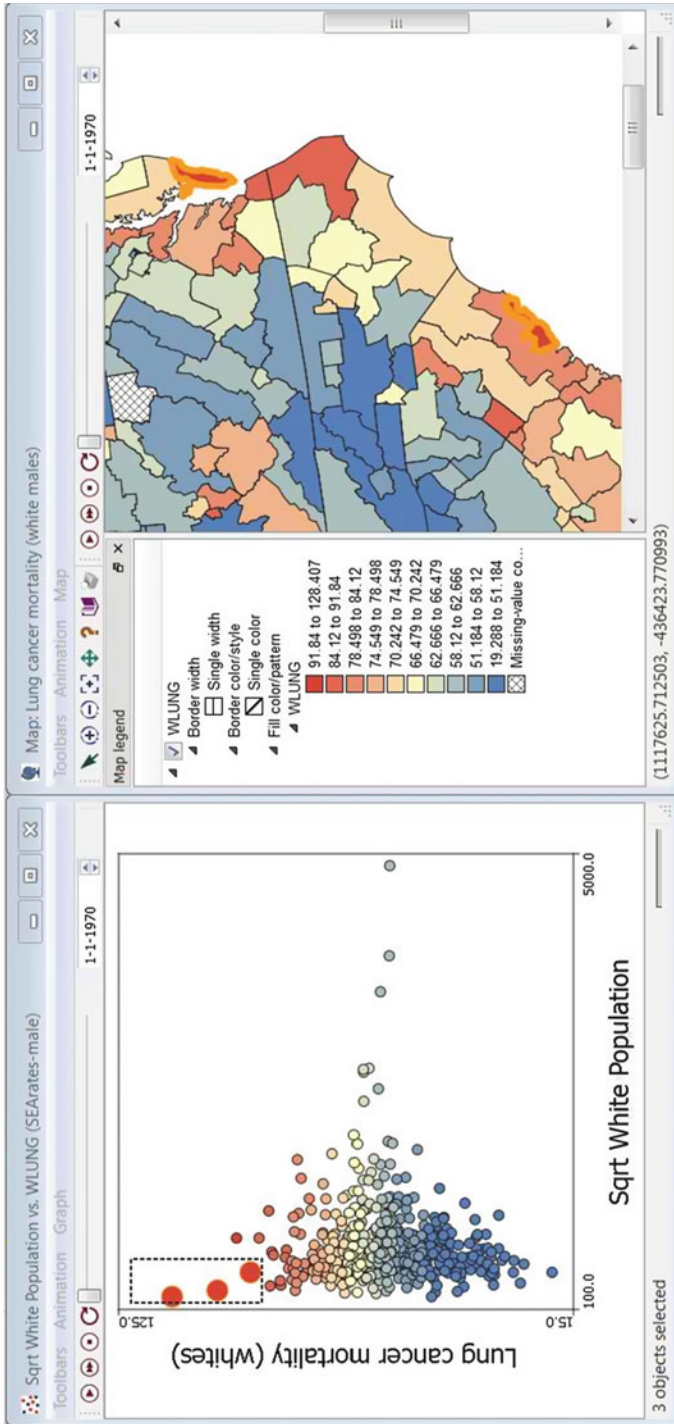

Fig. 67.1 Simple diagnostic for the small numbers problem. A plot of the lung cancer mortality rate for white males (y-axis) versus the square root of the white male population (x-axis) demonstrates the “>” signature, with higher variance in the rate at small population sizes. Brush selection on the scatterplot (the three large red circles in dashed rectangular box) locates the areas with high mortality rates that may be unstable since they have small denominators. Calculated in BioMedware SpaceStat software

Variability in rates due to the small numbers problem, if not corrected for, can give rise to artifactual spatial structure in the estimated rates. For example, the three areas with high rates brush selected in Fig. 67.1 are high spatial outliers. When clustering rates, it therefore is important to use statistical techniques that either stabilize the rates by constructing local populations with similar denominator sizes or that account for denominator size when assessing statistical significance.

Constructing Local Populations with Similar Denominator Sizes. A classic example of the former approach is Turnbull's test, which uses spatially adaptive kernels to construct local populations with common denominator sizes (Turnbull et al. 1990). This method scans populations within the study area for clusters of cases. A circular window is centered on each region in turn and expanded to include neighboring regions until the total aggregated population within the window equals a user-defined threshold, R . One can think of this as "borrowing strength" from neighboring areas to construct local populations comprised of the same at-risk population size. These circular windows may overlap, and the counts within the windows will not be independent. The test statistic, M_R , is the maximum number of cases observed among all windows of population size R .

Accounting for Denominator Size When Assessing Statistical Significance. A widely used example of the latter approach is the heterogeneous Poisson model, which is used to specify null spatial models for inferential statistics and as the point of departure for more complex modeling approaches. A Poisson disease process is described by a parameter, lambda (λ), often referred to as the intensity, and the counts of the health events in local areas are assumed to be samples from a Poisson distribution with a given intensity and population size in each local area:

$$y_i \sim \text{Poisson}(\lambda_i, E_i) \quad i = 1, 2, \dots, A \quad (67.1)$$

Here, y_i denotes the observed count of health events (e.g., incident cases or deaths) in area i , A is the number of areas (e.g., counties or census tracts) under consideration, and E_i is the expected count of health events based on the size of the population at risk in area i after correction for known risk factors and covariates (e.g., age structure). λ_i , then, is an area-specific relative risk variable, defining the relative disease risk in the population residing in area i . This model is *heterogeneous* since the disease risk (the λ_i) may vary from one area to another.

A null hypothesis frequently used when evaluating counts of clusters of health events in local areas is that the underlying disease risk is the same from one area to another so that area-specific elevations in risk are absent. Here the null hypothesis could then be written:

$$H_0 : \lambda_1 = \lambda_2 = \dots = \lambda_n; i = 1, \dots, A \quad (67.2)$$

Global, Focused, and Local Tests for Clusters of Health Events. We then might proceed by evaluating the "omnibus" alternative hypothesis of rejecting the null hypothesis (here "–" is negation):

$$H_1 : \neg(H_0). \quad (67.3)$$

In health event clustering, this corresponds to what is known as a global test for clustering such that rates are elevated somewhere in the study area, but the null hypothesis does not specify which areas are elevated. Focused cluster tests use more detailed alternative hypotheses that state that certain areas might have elevated risk. These might be chosen, for example, to be near a known source of carcinogens. Local tests search for elevated risk in specific areas, but do not require prior knowledge or specification of which areas might have elevated risk.

Interpolation Autocorrelation. Smoothing rates in an attempt to adjust for rate instability can introduce spatial autocorrelation due to interpolation. Smoothing introduces nuisance autocorrelation whenever the kernels or models used to accomplish the smoothing overlap. Examples include inverse distance and empirical Bayesian interpolation. Here, the spatial scale of the autocorrelation introduced by smoothing will depend on the kernel size. When assessing clusters, it may be inappropriate to cluster rates after first smoothing them, since the smoothing step can introduce artifactual local similarity in rates attributable to interpolation rather than to underlying disease processes. One thus may wish to use smoothing when displaying maps of the rates, but employ techniques that explicitly account for denominator size when evaluating clustering.

Access to Screening, Care, and Treatment. Access to health-care and screening facilities can give rise to spatial autocorrelation in health events since both screening and treatment influence health outcomes. For example, several studies have demonstrated that access to breast cancer screening facilities is significantly associated with geographic differences in stage at diagnosis, with late-stage cancers more frequent in populations distant from breast cancer screening facilities. Poorer populations are particularly impacted by access to screening, since availability of transport and travel times may pose barriers to seeking health screening. An example is the use of mosquito nets, malaria incidence, and distance to clinics that distribute the nets (Enayati and Hemingway 2010). In agrarian rural areas of Malawai with poor roads, a distance of 10 km to the nearest clinic where mosquito nets are distributed may involve a full day round trip. Not surprisingly, studies have demonstrated that households nearer to clinics have higher mosquito net usage rates than households that are distant. A useful intervention then is to distribute the mosquito tents directly to the households.

Neighborhood/Contextual Effects. Neighborhood and related contextual effects can have negative impacts on human health status that exceed the impacts of covariates such as socioeconomic status and access to care that themselves may vary dramatically from one neighborhood to another (Spielman and Yoo 2009). Hypotheses suggest that perception of personal safety and quality of the neighborhood living environment can result in chronic stress that leads to reduced immune function and increased disease susceptibility, elevated blood pressure, and heart disease. One mechanism is the interaction between chronic stress, elevated cortisol, and immune system status, such that chronic stressors are associated with

suppression of both cellular and humoral measures of immune system function. Neighborhoods thus may be associated with spatial autocorrelation in health effects through direct effects such as socioeconomic determinants (e.g., income and health insurance), environmental factors (such as air quality), as well as contextual effects that impact stress and immune function.

Differences in Response to Health-Care Policy. Policies related to health care, treatment, drug development and deployment, and care delivery can have substantial impacts on health outcomes that may differ from one geographic area to another. In the United States, the states have a fair amount of flexibility in how they implement national policies. For example, the Center for Disease Control (CDC) is required to conduct the Behavioral Risk Factor Surveillance System (BRFSS), which is an ongoing telephone health survey system, tracking health conditions, and risk behaviors in the United States annually since 1984. Data are collected monthly by all 50 states, the District of Columbia, Puerto Rico, the U.S. Virgin Islands, and Guam. A core portion of the health survey questions come from the CDC, but states can supplement the survey with their own optional modules, and the BRFSS variables may thus vary from one state to another.

In addition, health policies can have differential impacts on physician behaviors that are not immediately apparent when the policies are drafted. For example, a recent study explored geographic variation in the use of physician-administered chemotherapeutic agents under Medicare Part B in response to a major reform of Medicare's reimbursement system (Jacobson et al. 2011). Physician prescription behavior in response to the payment change varied from state to state. Some states increased treatments with certain chemotherapeutic agents by 4 %, and a few actually reduced treatment rates. The state-to-state differences are statistically significant, with the null hypothesis that the change in chemotherapy treatment was the same across states rejected at $p < 0.001$ level.

Healthy Worker and Geographic Attractors. The "healthy worker effect" describes the reduced disease risk observed among employed individuals in many industries that cuts across different diseases. This can give the false appearance of no differences in risk between workers employed in a given industry when compared to the larger population, even though substantial occupational risks may be present (Fornalski and Dobrzyński 2010). Workers tend to follow employment opportunities, and the establishment of large manufacturing facilities can attract a cohort of healthy workers, resulting in an apparent deficit of disease risk in neighborhoods where these workers reside. A related phenomenon is that of the "geographic attractor" that arises after health conditions are diagnosed. Here, individuals decide to move nearer hospitals, clinics, and treatment centers to ease health-care access. When they die, the place of death is recorded as their last known residence, leading to an apparent excess of disease near treatment facilities.

Outbreaks/Spread of Infection. Infectious diseases transmitted through the air, sexual contact, fomite transmission, by drinking water contaminated with pathogens, and other means often require infected and susceptible individuals to be in close proximity to one another. This is true for pathogens with limited life spans outside the human body (e.g., influenza viruses), but is less true for those with

a dormant phase that can survive outside the body for extended periods (such as anthrax spores). For highly infectious pathogens transmitted from person to person, we may observe an initial outbreak from an index case (the first case to appear in a local population) that is followed by a spatial “wave” of infection that moves outward from the location of the index case. This may be followed by an endemic phase characterized by the maintenance of lower levels of infection in the population characterized by local outbreaks or by the infection spreading rapidly and dying out. Geographic pattern in the spread of infection is mediated by complex interactions between the probability of infection transmission, the contacts between infected and susceptible individuals, the life history of infection including the duration and timing of the infective stage, mobility of infected and susceptible individuals, timing of the rise and waning of immunity, the virulence of infection, as well as other factors (Sattenspiel and Lloyd 2010).

Immunity. When considering spatial autocorrelation in the spread of infectious diseases, the geography of immunity can be an important consideration. Issues include the waning of immunity, herd immunity, vaccination behaviors, and vaccine availability and distribution (Funk et al. 2010). When pathogens enter the body, the immune system develops antibodies to fight the infection. Immune response is said to wane as the concentrations of antibodies specific to that pathogen decrease over time. When immunity has waned sufficiently, the person may then become infected once again. This process can result in the appearance of clusters where members of a local population are infected, become immune, and then a resurgence of infection as immunity wanes, resulting in space-time patterns in infection.

Vaccination confers immunity without having to undergo a full-blown infection. *Herd immunity* is the protection from infection that arises when a sufficiently large proportion of the population has been vaccinated. Infection transmission halts when enough individuals are vaccinated and are immune, conferring protection even to those who have not been vaccinated. Vaccination itself often follows geographic distribution and adoption patterns. Hence, the vaccine distribution strategy can impact the timing of when immunity is conferred by vaccination and thus the geographic spread of infection. Vaccination itself can have intriguing side effects in terms of disease ecology. The eradication of smallpox is one of the great public health triumphs of our time, in which the global distribution and administration of the smallpox vaccine eradicated the disease in human populations. Immunity to smallpox confers partial immunity to a related infection, monkeypox. Once smallpox was eradicated, the smallpox vaccination program stopped, and outbreaks of monkeypox infections are now increasing (Rimoin et al. 2010).

Geographic Variation in Positional Error. That errors in case ascertainment and incomplete reporting can complicate the detection of disease clusters is well known (Kingsley et al. 2007). Positional error can also impact cluster detection, in at least two ways. First, geographic confounding arises when geographic variation in risk factors is associated with geographic variability in positional error. The potential for this is larger than one might expect as positional error in geocoded place of residences is larger in rural areas, a gradient similar to certain environmental risk factors and socioeconomic and demographic variables. Second, positional error decreases the

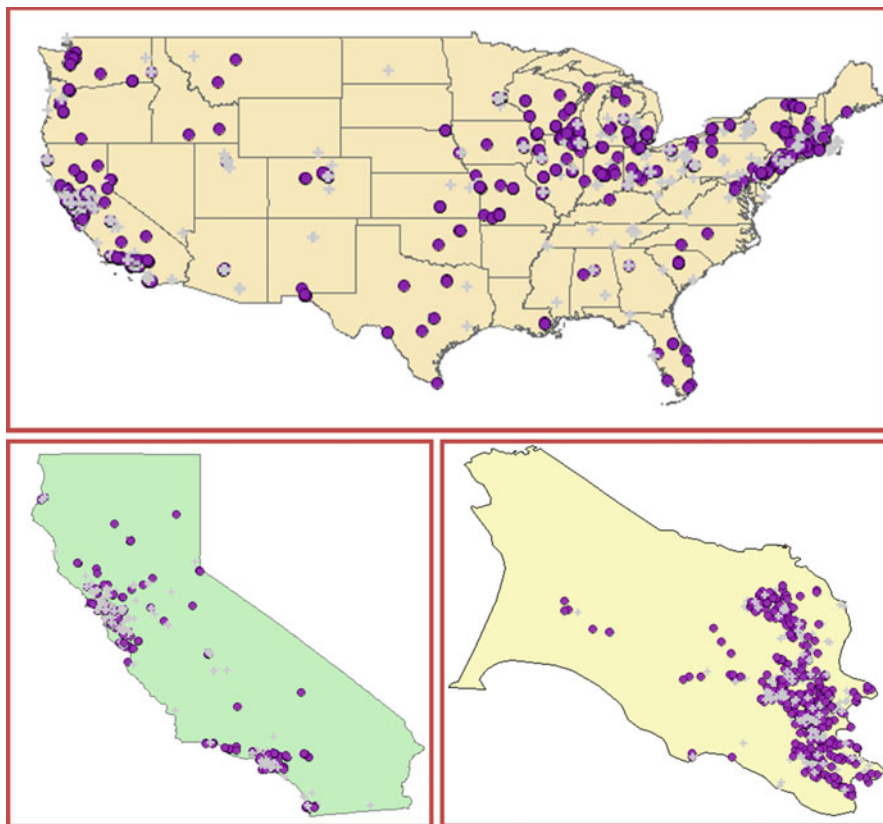

Fig. 67.2 Locations of places of residence of breast cancer cases (*circles*) and controls (*plus symbols*). Geographic locations of place of residence may vary dramatically from that observed at time of diagnosis in Marin county (*lower right*) to where women lived over their life course in the US (*top*) and California (*lower left*) (Source: Jacquez et al. 2011)

power to detect true clusters. Hence, our ability to detect clusters will vary geographically when gradients in positional errors are present.

Migration/Latency. Both chronic and infectious diseases have a latency between causative exposures and diagnosis. For cancers, this latency can be a decade or more, for infectious diseases such as influenza, it may be days. Because humans are mobile, the geographic pattern of where individuals were when they were exposed may differ dramatically from where they were when they were diagnosed. Consider the example of breast cancer. Breast cancer is a complex disease thought to have long latencies on the order of decades, although a small proportion of cases do appear in childhood and adolescence. The geographic pattern of where women lived over their life course differs dramatically from where they lived when they were diagnosed (Fig. 67.2). For many health outcomes, geographic patterns in cases at time of diagnosis may differ dramatically from that observed at disease onset.

67.6 Role of Neutral Models

The above paragraphs provided an overview of some of the sources of spatial autocorrelation in health events. When exploring disease patterns and clusters, many of these sources of geographic variation may not be of direct interest, for example, we often may wish to account for spatial heterogeneity in population density when searching for the signature of causative exposures underlying clusters of disease. Here, the idea is to search for clusters of health events above and beyond that attributable to geographic variation in population density. This concept can apply to any source of geographic pattern that may not be of direct interest; those members, for example, of the set of possible explanations that are described earlier under “Strong inference” and enumerated in [Sect. 67.5](#).

When clustering health events, one then incorporates geographic variability in covariates and other factors not considered to be of interest into the null hypothesis. Mechanistically, this usually is accomplished using approximate randomization that includes observed variation patterns in those factors not of direct interest into the null spatial model. Models that accomplish this have been referred to as “neutral” rather than “null” models, to capture the idea that they account for more than just “complete spatial randomness.” Neutral models thus correspond to plausible system states that can be used as a reasonable null hypothesis (e.g., “background variation”) in disease cluster tests. The problem then is to identify spatial patterns above and beyond that incorporated into the neutral model, enabling, for example, the detection of clusters *above and beyond* background or regional variation in the risk of developing disease.

A typology of neutral models that account for factors often encountered in analyses of health events defines neutral models type I–VI. These neutral models are realistic in that they account for the spatial autocorrelation, nonuniform risk, and spatially heterogeneous population sizes that may be present in the absence of the cluster process. Model I is complete spatial randomness (CSR) that is still widely used in health analysis even though it usually does not correspond to any plausible state of the system being studied. Model II reproduces the spatial autocorrelation that may be present in the observed data. Model III incorporates nonuniform variability in the underlying risk that may be attributable to risk factors and covariates that are not of direct interest. Models IV to VI account for the impact of population size and variability on the stability of observed rates and are used to address the small numbers problem.

Neutral models thus play a critical role in scientific inference in disease pattern analysis since they allow one to systematically incorporate different sources of geographic variation, including spatial autocorrelation, into the hypotheses being evaluated. In the framework of Strong inference, one conducts a series of statistical analyses systematically evaluating each of the hypotheses in the set of alternative explanations for the observed spatial patterns of health events. These are each incorporated into the neutral model of a given spatial cluster test, and if the test is significant, that hypothesis is rejected; if it is not significant, that hypothesis is retained in the set of plausible explanations for the observed spatial pattern.

An alternative mechanism when knowledge of the system is sufficient is to construct more formal, detailed models using (spatial) regression within a maximum likelihood or Bayesian framework, or other modeling approaches. The variability captured by the model is then attributable to the predictor variables, and clustering may then be applied to the regression residuals to quantify spatial pattern not captured by the model itself.

67.7 Data: What to Cluster?

Several different types of health events are commonly analyzed, including incident cases and deaths, diagnoses and stage at diagnosis of cancers and other conditions, symptoms, volunteered or crowd-sourced data, Web search terms, pathogen strains, mobility traces, and model residuals.

Incident cases may come from disease reporting systems such as cancer, birth defect, and infectious disease registries. This information may include date of diagnosis, place of residence at time of diagnosis, place of diagnosis, and patient identifiers. The patient identifiers and place of residence can be very useful in a spatial analysis, as they support linking of the diagnostic information to other data on Medicare usage, socioeconomic status, and behavioral risk factors, among others. This data linking may be accomplished by the registry, in order to protect access to data and confidentiality, or it may be accomplished by the researchers. Geographic bias may be introduced when case reporting varies from one geographic area to another, in which case areas with more complete reporting may appear as aberrant spatial clusters due to sample bias.

Incident death data often is of higher quality and can be more complete than case data, as all deaths must be reported to state and public health agencies. These typically include cause of death, identifiers for the deceased, and place of residence at time of death. As noted earlier, competing causes of death may result in underreporting of comorbid conditions, as when a person dies of lung cancer but also has Alzheimer's. Here, the cause of death may be attributed to lung cancer. Both incidence and mortality data may lag one or more years between when the health events occurred and when the data are available from the registry/reporting agency. This allows for case validation, data entry, and checking for completeness.

Diagnoses and stage at diagnosis are used to conduct surveillance, to identify populations with advanced stages of disease, and to aid in the siting of screening facilities. Diagnoses for infectious diseases of public health interest such as influenza, HIV, sexually transmitted diseases, and others may be reported to local and state health agencies and from there to centralized reporting facilities such as the Centers for Disease Control. This information may be timely for infectious diseases, allowing weekly assessment of outbreaks and infection trends. Cancer staging information may be available describing tumor status from localized (in situ) to metastasized/advanced and provide important advantages for spatial analyses. First, they may be used to assess disparities in stage at diagnosis, which

can provide insights into differential access to screening facilities and/or differences in exposures and genetic predispositions. Second, they also have the advantage of providing ready-to-use denominators, since the population at risk will be the total number of diagnoses summed across stages.

Symptoms may be quite useful for undertaking syndromic surveillance that seeks to identify the early onset of infectious diseases, outbreaks, and bioterrorism attacks. Here, the incoming data may be of uncertain quality, including over-the-counter sales at pharmacies for symptom-related products such as antihistamines, cold medicines, and diarrhea medications. More recently, syndromic surveillance approaches have been applied to data from Google Web search terms and to crowd-sourced and volunteered information on disease outbreaks, with surprising accuracy in terms of the predictive ability, even though a practical means for validating the incoming data is frequently absent (Adams 2011). This is expected to be a growth area in applied spatial analysis in public health, as it can provide near real-time data streams at nominal expense.

The genetic similarity of *pathogen strains* can be closely associated with how far apart the infected individuals are on the chain of infection, due to the population bottlenecks that occur with each transmission event and to the increasing number of replications of the pathogen as distance on the chain of infection increases. Replications increase genetic change as replication errors and genetic mutations accumulate. This can lead to strong spatial autocorrelation in within-patient pathogen strain genetics, such that nearby infected individuals tend to be infected with similar pathogen strains. Polymerase Chain Reaction and other technologies for rapid molecular genotyping of pathogen strains are now being used for hospital infection surveillance and outbreak detection (Ecker et al. 2009). The emergence of antibiotic- and drug-resistant pathogen strains is thought attributable to strong selective pressures posed by antibiotic treatment, and distinct multidrug-resistant pathogen strains are known to emerge in specific clinics and geographic settings. Hence, spatial patterns in pathogen genetics can provide useful information regarding pathogen emergence, history, and infection transmission. Coevolutionary theory for pathogens and their hosts results in distinct predictions regarding how pathogen and host genetics may change through time in different places, although complex pathogen life histories and other microevolutionary processes can obscure the expected similarities.

Spatial autocorrelation in the *residuals* from spatial models treating health events as dependent variables and various risk factors and covariates as independent variables (risk models) is often used as a model diagnostic. Spatially autocorrelated residuals violate assumptions of regression (iid, independent and identically distributed residual errors) and may indicate a missing predictor that is itself spatially structured or a spatial process, such as migration, that is not present in the model. For risk models, the residual is the difference between the observed risk (e.g., incidence and mortality rate) and the modeled risk. When the residual is positive, the model underpredicts the observed risk; hence, local populations with positive residuals have excess risk beyond that explained by the model.

67.8 Data Models and Clustering Methods

There are several reviews of cluster and cluster modeling of health events including inferential statistics, geostatistics, regression, and Bayesian techniques (Goovaerts 2009; Lawson and Banerjee 2009; Rogerson 2006; Waller and Gotway 2004; Aldstad 2010). Here we provide a quick overview of several data models and corresponding clustering methods. The reader may wish to visit the above references and other chapters in this handbook for further details on clustering methods.

Individual health events, such as the place of residence and time of diagnosis for a case of leukemia, provide the basic datum of the form:

$$x_i, y_i, t_i \quad (67.4)$$

This represents health events as points in space-time and assumes events have no duration and may be assigned to discrete locations. Each record usually corresponds to a disease case, and there are n total health events (cases). This data model has been criticized as overly simplistic, since it ignores disease latency and assumes individuals do not move from place to place.

This data model underlies many tests for space-time interaction in health events. Interaction tests search for patterns such that nearby health events occur at about the same time, a pattern taken to be indicative of contagious processes (e.g., infection) and local elevations in disease risk that occur over discrete times. Examples of tests for interaction include the Mantel, Knox, and k-NN tests. Here, we give a quick definition of Mantel's test.

The Mantel test calculates s_{ij} and t_{ij} as the spatial and temporal distances, respectively, between two health events i and j . These distances may be scaled to reduce the impact of larger distances on the test statistic. Mantel's statistic is the sum of the products of the space and time distances:

$$Z = \sum_{i=1}^n \sum_{j=1}^n s_{ij} t_{ij} \quad (67.5)$$

This often is scaled to yield a correlation:

$$r = \frac{1}{(n^2 - n - 1)} \sum_{i=1}^n \sum_{j=1}^n \frac{s_{ij} - \bar{s} t_{ij} - \bar{t}}{s_s s_t} \quad (67.6)$$

Here, \bar{s} is the average space distance, \bar{t} is the average time distance, and s_s and s_t are the standard deviations of the spatial and time distances, respectively. The standardized measure is a matrix correlation that is in the range -1 to 1 , with large positive values indicating significant interaction such that nearby health events occur at about the same time and with negative values indicating avoidance, so that nearby health events tend to occur in temporal isolation.

Counts, for example, of the number of incident cases in each area, arise when denominator information is lacking, preventing the counts from being converted

into rates. Here, the underlying data model may be written simply as f_{it} , which is the count of health events in area i over a defined temporal support (e.g., count of incident cases of leukemia in county i in 2010). Since areas will differ in size of the at-risk population, spatial analysis of counts across areas will not be particularly informative at a single point in time. Count data through time are useful for surveillance when one is interested in assessing whether to sound a “cluster alarm” when the counts increase relative to a historic baseline (Höhle and Paul 2008), assuming the size of the underlying at-risk population is relatively static. *Rates* are comprised of a numerator and denominator with the count of the number of health events in the numerator and the population at risk in the denominator. Examples include incidence, mortality, morbidity, and accident rates. Raw rates may be of little use in spatial analyses since they do not correct for important covariates, such as age. It is not informative, for example, to search for clusters of childhood leukemia in retirement communities where only those 55 and older may reside. Rates therefore are often age-standardized, and standardization may be accomplished for many of the covariates identified earlier (Greenland 2004). There are many techniques for analyzing clustering of data defined by numerators and denominators, and these often employ a heterogeneous Poisson model with uniform risk as the underlying null hypothesis, as described earlier. Among the most widely used are spatial scan statistics that may use circular-, elliptical-, and flexibly shaped scanning kernels (Kulldorff et al. 2007; Tango and Takahashi 2005). Boundary analysis approaches that work at higher spatial resolution in that they are sensitive to changes across the area edges are also available (Lu and Carlin 2005). Spatially explicit *health disparity* statistics may be used when numerator and denominator data are available for two groups, one a target (such as black males) and the other a reference population (such as white males). These statistics seek to identify statistically significant differences in local population means for the two groups. Examples include the analysis of racial disparities in lung cancer mortality in US Congressional districts (Gallagher et al. 2009).

Data from *case-control* studies are often modeled as marked spatial point processes with two states: case and control. One then can write a data model as

$$x_i, y_i, c_i \tag{67.7}$$

Here, x_i , y_i are the geographic coordinates of the health event for study participant i , and c_i is a case-control identifier defined as

$$c_i = \begin{cases} 1 & \text{if participant } i \text{ is a case} \\ 0 & \text{if participant } i \text{ is a control} \end{cases} \tag{67.8}$$

Several techniques have been proposed for cluster analysis and surveillance analysis with case-control data; these all account for geographic heterogeneity in population density. Cuzick and Edwards test (1990) is based on nearest neighbor relationships:

$$T_k = \sum_{i=1}^n \sum_{j=1}^k c_i c_j \quad (67.9)$$

Here, T_k is the test statistic, which is large when cases tend to be nearest neighbors of other cases; k is the number of nearest neighbors being considered, analogous to a kernel size but defined by the local number of nearest neighbors to evaluate (e.g., ten nearest participants to case i); and the inner summation iterates over the k nearest neighbors of participant i .

The cases and controls are assumed to be sampled from the same underlying spatial distribution; hence, there should not be clustering of the cases relative to the controls. If there is, this may be the signature of an underlying spatial process such as infection/contagion, localized exposures to factors that increase disease risk, case attractors (such as clinics as mentioned earlier), and geographic sampling bias. When analyzing data from case-control studies, it is important that the sampling strategy *not* be geographically stratified, as this will tend to obscure true clustering of cases relative to controls. To see this, suppose the controls are sampled proportionately to the cases in subparts of the study area, such as townships. For every case that occurs in a township, the sample is geographically stratified to draw a control from that township. This makes it impossible to detect a geographic clustering at the township scale. The data model is static and ignores mobility of the study participants, a need that is addressed using mobility histories.

Mobility histories model traces of location-enabled devices, such as smart phones, as well as residential histories of study subjects and industries. For example, residential histories can be represented as space-time step functions (Fig. 67.3). To identify the location and timing of significant clustering of cases relative to controls using this data model, a spatially and temporally local case-control cluster statistic may be defined as

$$Q_{i,t}^{(k)} = c_i \sum_{j=1}^k \eta_{i,j,t}^{(k)} c_j \quad (67.10)$$

This quantity is the count, at time t , of the number of k nearest neighbors of case i that are cases, and not controls. Individuals i and j have case-control identifiers, c_i and c_j , as defined earlier. The term $\eta_{i,j,t}^{(k)}$ is a binary spatial proximity metric that is one when participant j is a k nearest neighbor at time t of participant i ; otherwise, it is zero. Since a given individual i may have k unique nearest neighbors, the $Q_{i,t}^{(k)}$ statistic is in the range $[0, k]$. When i is a control, $Q_{i,t}^{(k)} = 0$. When i is a case, low values indicate cluster avoidance (e.g., a case surrounded by controls), and large values indicate a cluster of cases. When $Q_{i,t}^{(k)} = k$, at time t all of the k nearest neighbors of case i are cases.

With this local statistic defined, several global, local, and focused cluster tests that account for residential mobility can be defined by integrating over a person's life course, over space (a time slice), and over time. When integration is accomplished

Fig. 67.3 Residential histories as space-time step functions. The axes x and y define a geographic domain (e.g., longitude and latitude decimal degrees), the t axis represents time (e.g., date). The study extends from time t_0 to time t_T . The residential histories for persons i and j are shown as step functions through space-time. For example, person i begins the study residing at location x_i, y_i, t_0 . They remain at that geographic coordinate until the instant before time t_1 , when they move to x_j, y_j, t_1 . The duration of time they reside at this first place of residence is ω_0

over a subject’s residential history, we think of this as a “life course” statistic that assesses a tendency to have other cases rather than controls nearby through time.

$$Q_i^{(k)} = \int_{t=t_0}^T Q_{i,t}^{(k)} dt \tag{67.11}$$

A time-specific statistic that provides an overall measure of case clustering when all of the participants are considered together is given in Eq. (67.12). It is the sum, over all cases, of the subject-specific and time-specific measure of case clustering in Eq. (67.10).

$$Q_t^{(k)} = \sum_{i=1}^{n_1} Q_{i,t}^{(k)} \tag{67.12}$$

Analogous to Cuzick and Edwards test Eq. (67.9), $Q_t^{(k)}$ evaluates global clustering of cases at time t , such that the amount of case clustering observed when all of the participants are considered together is evaluated. For convenience, the summation is over the n_1 cases. This is a “global” test since it is comprised as the sum of the local statistic from Eq. (67.10).

$$Q^{(k)} = \sum_{i=1}^{n_1} Q_i^{(k)} \quad (67.13)$$

Equation (67.13) provides a global test that sums over all of the life course statistics from Eq. (67.11). It is used to evaluate whether there is significant life course clustering of cases when all of the participants are considered together.

Mobility histories have the advantage of relaxing the assumption of immobile individuals imposed by methods based on static spatial point distributions. Residential histories for health studies are available in the USA from commercial vendors and appear to have acceptable accuracy (Jacquez et al. 2011). Several European countries, such as Denmark, track place of residence information from birth, a valuable resource in spatial health analysis.

67.9 Conclusions

This chapter has focused on spatial autocorrelation and clustering of health events. It presented a cognitive framework for the spatial analysis of health events based on Strong inference, which systematically evaluates the hypotheses that might explain an observed spatial pattern. Operationally, each hypothesis may be incorporated into the null hypothesis of a statistical test for disease pattern using neutral models, and in this manner, the members of the set of plausible hypotheses can be systematically evaluated. The remaining hypothesis(es) then plausibly explains the observed geographic pattern in health events.

Sources of positional uncertainty need to be carefully evaluated when assessing disease clusters, as they are now known in some instances to be substantial, potentially leading to false negatives. Under Strong inference, this can lead one to incorrectly accept the neutral model, thereby retaining it as an explanation for the observed spatial patterns when it should, in fact, be excluded.

Philosophically, the spatial analysis of health events makes an implicit assumption regarding the importance of location for the health event in question. As noted earlier, place of residence at time of diagnosis can be misleading when disease latency is long, especially when one wishes to make inferences regarding disease onset and causative exposures. Aside from latency processes, there are other reasons why location may not be too informative, such as whether it is appropriate to use location as an exposure surrogate. Spatial analysis contrasts in some respects with the more traditional clinical approach that focuses on the individual as the nexus of health data. Ultimately, we hope to make inferences regarding the causes of disease and changes in health status at the individual level and to be able to extend those findings to put in place appropriate public health policies.

The research funding, technological, and data milieu are changing rapidly. In an era of constrained funding, large case-control, cohort, and other study designs will be increasingly difficult to undertake. At the same time, new data sources are becoming available, and the era of “Big data” is upon us, where streams from Web searches,

smart phones, houses with Web-enabled devices, and a broad range of location- and Web-enabled devices are fused and mined. Big data hold the possibility of replacing the expensive large epidemiological study with studies incorporating crowd sourcing, volunteered geographic information, and other sources. But this will require advances in spatial epidemiological study designs that put in place appropriate sampling frameworks for Big data that support sound scientific inference. This is one of the new frontiers at the forefront of spatial health analysis.

Abstract

Describing area-based differences in health outcomes has a long history (Kawachi and Berkman *Neighborhoods and health*. Oxford University Press, Oxford, 2003), and evidence of ecologic variations in health sparks interest from multiple perspectives. In particular, researchers investigate these ecologic variations for surveillance and monitoring of health disparities (Krieger et al. *Am J Public Health* 95:312–323, 2005) and to understand the impacts contexts have on individuals. In the latter category, causal questions motivated by evidence of area-based differences in health include the following: How much do contexts, such as neighborhoods, impact health? What is the impact of a specific contextual exposure on health? How do contexts mediate the effects of individual-level health risk factors? Ecologic factors may have tremendous importance for population health (Kawachi and Berkman *Neighborhoods and health*. Oxford University Press, Oxford, 2003), underscoring the value of recognizing opportunities and methodological challenges for causal inference when ecological variations in health are present. We address these issues as follows: we begin by identifying what constitutes a multilevel data analysis and present a discussion on how a range of data structures that are observed in the real world, or due to sampling design, can be accommodated within a multilevel framework. We discuss the types of research questions that typically motivate multilevel analyses and contrast the application of multilevel methods against other approaches for answering such questions with an emphasis on causal inference. After laying down the substantive motivation to utilize multilevel methods, key statistical models are specified with a description of the properties of each model. We close by presenting extensions to the basic multilevel model that allow us to incorporate realistic complexity in our analyses.

68.1 Introduction

Where you live makes a difference to your health over and above who you are (Berkman and Kawachi 2000; Jones and Moon 1993). People's lives are lived in different settings, including neighborhoods, worksites, and schools, as well as in larger scale political or economic contexts, including states, metropolitan regions, or countries. Notwithstanding individual influences on health, researchers are increasingly emphasizing the role that contexts play in shaping health and health inequities in the population. The term "multilevel" refers to the distinct levels or units of analysis, which usually, but not always, consist of individuals (at the lower level) who are nested within contextual/aggregate units (at the higher level). Viewing factors that affect health as simultaneously operating at the level of individuals and at the level of contexts is quintessentially a multilevel analytic perspective. **Multilevel methods**, vital for applying multilevel frameworks to empirical questions, consist of statistical procedures that are pertinent when:

- The observations that are being analyzed are correlated or clustered along spatial, geographic/political, and/or temporal dimensions.
- Causal processes are thought to operate simultaneously at more than one level.
- There is an intrinsic interest in describing the variability and heterogeneity in the population, over and above the focus on average relationships (Diez Roux 2002; Subramanian 2004a).

Multilevel methods are specifically geared toward the statistical analysis of data that have a *nested* structure. The nesting, typically, but not always, is hierarchical. For instance, a two-level structure would have many level 1 units nested within a smaller number of level 2 units. In educational research, the field that provided the impetus for multilevel methods, level 1 usually consists of pupils who are nested within schools at level 2. Such structures arise routinely in health and social sciences, such that level 1 and level 2 units could be workers in organizations, patients in hospitals, or individuals in neighborhoods, respectively. Third levels and higher may also be considered, for example, individuals at level 1 nested neighborhoods at level 2, which in turn are nested in cities at level 3.

The existence of **nested data structures** is neither random nor ignorable; neighborhoods and other contexts differ just as individuals do. Differences among these contexts could reflect differences among individuals nested in them, or they may arise for reasons less strongly associated with the characteristics of the individuals they encompass (e.g., children within a school may be arbitrarily assigned to classrooms). Regardless, once contexts are established, they tend to become differentiated and therefore meaningful, even if their establishment is random. This would compel analysts interested in causal questions to consider covariates at multiple levels. Researchers must a priori specify why they think that there will be variation in the outcome at the levels they include over and above variation at level 1. For example, do we expect variation in a given outcome at the level of small neighborhoods (e.g., census blocks) or larger neighborhoods (e.g., census tracts)? Will states additionally play a role?

Theory and subject matter knowledge must drive the decision of what levels to consider and omit, and a proper application of methods is needed to ensure valid causal inferences. This chapter is methodologically focused with an aim to help researchers identify multilevel data structures, causal questions that may be asked using a multilevel framework, substantive differences between multilevel and other approaches to handling nested data, and opportunities and challenges for causal inference at the ecological level using multilevel approaches.

68.2 Recognizing Multilevel Data Structures

Multilevel data structures dominate observational datasets and even some experimental designs. While multilevel methods are commonly employed to make inferences about how contexts affect people, it is important to note that multilevel methods are applicable in a range of other settings as well. One well-recognized source of nested data structures is sampling design. For instance, multistage

sampling designs are often employed during large-scale survey data collection for reasons of cost and efficiency. A national population survey, for example, might involve a three-stage design, with regions sampled first, then neighborhoods, and then individuals. A design of this kind generates a three-level hierarchically clustered structure of individuals at level 1 nested within neighborhoods at level 2, which in turn are nested in regions at level 3. Observations taken on individuals living in the same neighborhood can be expected to be more alike than they would be if the sample were truly random, meaning that data points are not truly independent. Similar dependence can be expected for data collected on neighborhoods within a region.

Much documentation exists on measuring this “**design effect**” and correcting for it. Indeed, clustered designs (e.g., individuals at level 1, nested in neighborhoods at level 2, and nested in regions at level 3) are often a nuisance in traditional analysis. This “nuisance perspective,” while often appropriate to handle clustering induced by sampling design, is in contrast with the idea that individuals, neighborhoods, and regions can be seen as distinct structures that exist in the population that should be measured and modeled. Despite these differences in motivations, multilevel methods are applicable in both types of settings.

The idea of multilevel structure can also be recast, with great advantage, to address a range of other circumstances where one may anticipate clustering. Outcomes as well as their causal mechanisms are rarely stable and invariant over time, producing data structures that involve repeated measures. **Repeated measures** over time taken on a higher-level unit such as an individual or context can be considered a special case of multilevel clustered data structures. Consider the “repeated cross-sectional design” that can be structured in multilevel terms with neighborhoods at level 3, year/time at level 2, and individuals at level 1. In this example, level 2 represents repeated measurements on the neighborhoods (level 3) over time. Such a structure can be used to investigate what sorts of individuals and what sorts of neighborhoods have changed with respect to the outcome. Alternatively, there is the classic “longitudinal or panel design” in which level 1 is the measurement occasion, level 2 is the individual, and level 3 is the neighborhood. This time, the individuals are repeatedly measured at different time intervals so that it becomes possible to model changing individual behaviors within a contextual setting of, say, neighborhoods.

“Multivariate” multilevel data structures occur when different responses or outcomes reported for a higher-level unit are correlated. For example, level 1 could be a set of response variables measured on individuals at level 2 nested in neighborhoods at level 3. The “**multivariate responses**” could be, for instance, different aspects of, say, health behavior (e.g., smoking and drinking). In addition, such responses could be a mixture of “quality” (do you smoke/do you drink) and “quantity” (how many/how much), producing “mixed multivariate responses.” The substantive benefit of this approach is that it is possible to assess whether different types of behavior and whether the qualitative and quantitative aspects of each behavior are related to individual characteristics in the same or different ways. This structure also lets us study whether neighborhoods suffer or enjoy similar

levels of related characteristics, such as whether neighborhoods with a high prevalence of smoking also suffer high rates of drinking and drug use.

While the previous examples are strictly hierarchical, meaning that each level 1 observation belongs to just one level 2 unit, data structures could alternatively be nonhierarchical. For example, a model of health behavior could be formulated such that behavioral information, such as exercise frequency, is collected on individuals (level 1) who are members of both residential neighborhoods *and* workplaces at level 2. In this example, individuals are not strictly nested but rather “cross-classified” in two different higher-level groupings. Individuals are then allowed to occupy more than one set of contexts, each of which may have an important influence. For instance, individuals in a single workplace may come from many different neighborhoods, and individuals in a given neighborhood may each work in a different worksite.

A related nonhierarchical structure may occur even when there is only one type of level 2 context. For example, level 1 observations, such as students, often belong to more than one level 2 unit, such as classrooms, even if information about additional *types* of contexts is not available. In contrast to the **cross-classified structures** described above, where information is available on two types of contexts (i.e., neighborhoods and workplaces), “**multiple membership designs**” accommodate level 1 units belonging to more than one level 2 unit of the same type. A college student taking several courses can simultaneously belong to several classrooms even if we know nothing about his/her neighborhood or worksite, for example, with the contribution of each classroom weighted in relation time spent by the student in that environment. Similar arrangements can be made for individuals within neighborhoods, where weights might be determined by spatial distance or time allocation, or any other metric that is meaningful for the research question at hand. In summary, between some combination of hierarchical structures, cross-classified nesting, and multiple membership, a great complexity that is imprinted either explicitly or implicitly in data can be incorporated via multilevel models.

68.3 Causal Research Questions That Motivate Multilevel Analyses

As evidenced by the previous section, multilevel data structures are more a rule than an exception in epidemiologic research and should be considered for both technical and substantive reasons. Particularly when trying to understand observed ecologic variations in health, a wide range of causal questions are best answered using multilevel methods, and a subset of these can *only* be answered using a multilevel approach. Among the questions that may be asked and answered using a multilevel framework are the following: What is the impact of a specific contextual exposure on an outcome? How much do contexts, generally speaking, matter for a given outcome? How do contexts mediate the effects of individual-level factors?

68.3.1 Specific Ecologic Effects

Beginning with the first of these questions, assessing the effect of a contextual-level exposure on individuals often calls for a multilevel approach. To put this in perspective, we consider an influential study of progress among primary school children from the 1970s. Bennett (1976) used a single-level multiple regression analysis to claim that children exposed to “formal” style of teaching exhibited more progress than those who were not. While recognizing individual children as units of analysis, the study ignored the grouping of children into classrooms. In what was the first important example of multilevel analysis using social science data, Aitkin (Aitkin et al. 1981) reanalyzed the data and demonstrated that when the analysis accounted properly for the grouping of children (level 1) into classrooms (level 2), the progress of formally taught children could not be shown to significantly differ from the others.

Why was the initial analysis flawed? Children within any one classroom tended to be similar in their performance simply because they were taught together, thereby providing much less information than would have been the case if the study relied on a sample of children that had been taught separately. More formally, the individual samples (in this case data collected on children) were *correlated* or *clustered*. Such clustered samples do not contain as much information as simple random samples of similar size. As was shown by Aitkin (Aitkin et al. 1981), ignoring this autocorrelation, or clustering, resulted in an increased risk of finding differences and relationships where none existed.

In his investigation of student progress in 1976, Bennett was attempting to understand a *specific ecologic effect*, specifically the role of formal teaching style on children’s progress. The term *specific ecologic effect* refers to the impact a particular characteristic of a context has on lower-level units. This can be contrasted with the concept of a *common ecologic effect*, or the overall impact a higher-level environment has on lower-level units. Examples of specific ecologic effects include the impact of neighborhood poverty on individual smoking behavior, the effect of workplace breastfeeding policies on individual breastfeeding behavior, or how school-level physical education policies impact student BMI. In each of these examples, the target of inference is a quantifiable aspect of a given context, not the impact of the context generally speaking. However, researchers may wish to focus on overall contextual effects without specifying what it is about contexts that are beneficial or harmful for a given outcome.

68.3.2 Common Ecologic Effects

In contrast to the illustrations above, examples of *common ecologic effects* include the degree to which school districts influence high school seniors’ chances of going to college above and beyond individual factors, or the extent to which physician practice networks rather than patient-level factors determine if sick individuals are

prescribed antibiotics. In these examples, there are no quantifiable characteristics of the school district or physician practices that are under review; rather, the focus is on whether membership in a context matters in general and to what extent. Generic neighborhood, or contextual, effects are useful for two reasons. First, recognizing that ecologies matter is often a first step toward identifying a specific influential contextual characteristic of interest for a given outcome. Second, contextual influences on health are likely to be mediated through multiple and synergistic interactions of several neighborhoods or other contextual elements, as opposed to a single exposure. As such, common ecologic effects may be important in an intrinsic sense (Sampson et al. 2002). As opposed to a *specific ecologic effect*, which describes the impact of changing an isolated aspect of a context, a *common ecologic effect* would include the consequences of being placed in a different environment with different opportunity structures as well as different neighbors, classmates, or residents, rather than just a different value for one specific contextual characteristic.

As applied to neighborhoods and health research, for example, the basic causal question asked when studying a specific ecologic effect therefore is this: If one were to change specific neighborhood characteristic(s) of the neighborhood setting but change nothing about the individual in question, what would be the impact on the individual's health, on average? The basic causal question asked when studying common ecologic effects is to what extent does membership in a neighborhood impact an individual's health above and beyond individual factors.

It is important to emphasize that these types of causal research questions (i.e., about common ecologic effects) asked under a multilevel framework focus on variability rather than means. Consequentially, researchers are not primarily interested in effect estimates associated with specific exposures at either level 1 or level 2. It is the norm in epidemiology to investigate causation as changes in group means, although many variables of interest may cause a change in the variance of the distribution of the dependent variable and not cause a change in the mean. In fact, there has been little interest to date in variance that underlies averages (Braumoeller 2006). This is because variance is often considered a measure of uncertainty or a troublesome entity, rather than a source of substantive information even in multilevel investigations (Roux 2008). To ignore information discernible by assessing measures of variance is certainly a missed opportunity (Kawachi and Berkman 2003; Larsen and Merlo 2005; Subramanian 2004b). Researchers should always remember that the goal of social medicine is not only to increase the (mean) health of the population, but also to decrease **inequities in health** (variance).

Rather than choose, researchers can also integrate studies of specific and common ecologic effects using a multilevel framework, estimating both the effect of a specific neighborhood characteristic on an outcome and whether the neighborhood predicts the outcome in a model conditional on that neighborhood characteristic. For example, we could estimate the effect of fast-food outlet density of a neighborhood on BMI and ask whether there are additional differences in BMI across neighborhoods of similar fast-food density.

68.3.3 Composition Versus Context

Whether focused on specific or common ecologic effects, a main goal for causal inference is disentangling different sources of variation in the outcome at different levels. Evidence of variation in poor health among different neighborhoods, for instance, could be due to factors that are intrinsic to the neighborhoods themselves and are measured at the neighborhood level. In other words, the variation may be due to what are called *contextual* or *neighborhood effects*. Alternatively, variations between neighborhoods may be *compositional* or simply reflective of the characteristics of residents. For example, if people who are likely to be in poor health due to their individual characteristics are clustered in neighborhoods, we will see ecologic variations in health due to the composition of neighborhoods rather than any causal effect neighborhood exerts on residents. If we were to find that average BMI tends to be higher in neighborhoods with a higher proportion of impoverished residents, such an observation does not, by itself, provide insight into the causal question of interest, that is, does living in high-poverty neighborhoods increase individual residents' BMI compared with living in low-poverty neighborhoods? The issue, therefore, is not whether variations between different neighborhoods exist (they usually do), but what is the primary source of these variations. Put simply, are there significant contextual differences in health between neighborhoods, after taking into account the individual compositional characteristic of the neighborhood? The notions of contextual and compositional sources of variation have general relevance, and they are applicable whether the context is administrative (e.g., political boundaries), temporal (e.g., different time periods), or institutional (e.g., schools or hospitals). Multilevel studies allow us to examine such questions by considering both individual and contextual characteristics. For causal inference, it is important that variables at these levels are not completely confounded.

68.3.4 Describing Contextual Heterogeneity

Yet another motivation to employ a multilevel approach is to understand how the effect of an individual-level exposure varies according to context or how contextual effects vary according to individual factors. As an example of the former, the effect of low personal income on health may be mitigated or exacerbated by neighborhood conditions generally or by specific contextual-level factors such as presence of affordable housing, transit access, or food environment. As for the latter, individual age or sex may affect the impact vulnerability to the negative effects of neighborhood-level violence.

Describing such *contextual heterogeneity* is an important aspect of multilevel analysis and can have two interpretative dimensions. First, there may be a *different amount* of neighborhood variation for a given outcome, such that, for example, for high-income individuals, it may not matter in which neighborhoods they live (thus a lower between-neighborhood variation in health outcomes), but it matters a great

deal for the low-income residents and as such shows a large between-neighborhood variation in health outcomes. Second, there may be a *differential ordering*: neighborhoods that are high on a value for one group are low on the same value for the other and vice versa. Stated simply, the multilevel analytical question is whether the contextual neighborhood differences in poor health, after taking into account the individual composition of the neighborhood, different for different types of population groups.

In one empirical demonstration of this approach, researchers involved in the MONICA project on blood pressure investigated contextual effects on the individual-level factors of BMI and antihypertensive medication use (Merlo et al. 2004). Researchers found that contextual effects were particularly strong in overweight women on antihypertensive medication. Approximately 20 % of the individual differences in blood pressure in this sample could be attributed to a contextual effect, while only about 8 % of variability could be attributed to context in the population overall. Such a large difference may reflect disparities in the effectiveness of individual antihypertensive treatment across different national health-care systems. These findings illustrate that contextual differences may be complex such that effects may not be the same for all types of people.

68.3.5 Characterizing and Explaining Contextual Variations

Contextual differences, in addition to people's characteristics, may also be influenced by the different characteristics of neighborhoods. In other words, individual differences may interact with context, and ascertaining the relative importance of individual and neighborhood covariates is another key aspect of a multilevel analysis. For example, over and above income (individual characteristic), health may depend upon the poverty levels of neighborhoods (neighborhood characteristic), as stated previously. We might consider that the **contextual effect** of poverty is the same for both the high- and low-income individuals, suggesting that while neighborhood poverty could explain the prevalence of poor health in a poor neighborhood, it does not influence the social class inequalities in health. On the other hand, the contextual effects of poverty may be different for different groups, such that neighborhood poverty adversely affects the low-income residents, but benefits the health of high-income residents. Thus, neighborhood-level poverty not only may be related to average health achievements but also shapes social inequalities in health. The analytical question of interest is whether the effect of neighborhood-level socioeconomic characteristics on health is different for different types of people.

In sum, **casual ecologic inferences** may concern changes in means or variance and direct influences of context on health or indirect influences wherein context mediates individual exposures. Below we map a variety of **study designs** against what types of questions they enable researchers to answer. We contrast multilevel against other approaches for these various types of reviews.

68.4 Multilevel Framework: A Necessity for Understanding Ecologic Effects

Figure 68.1 identifies a typology of designs for data collection and analyses (Blakely and Woodward 2000; Subramanian et al. 2007), where the rows indicate the level or unit at which the outcome variable is being measured (i.e., at the individual level (y) or the ecological level (Y)) and the columns indicate whether the exposure is being measured at the individual level (x) or the ecological level (X). The ecological level could be any context of interest such as a school, country, or city, but we will refer to it as the neighborhood level for simplicity here. Study-type (y,x) is most commonly encountered when the researcher aims to link exposure measured at the individual level to outcomes also measured at the individual level and is common in “risk factor epidemiology.” Study-type (y,x) typically ignores ecological effects (either implicitly or explicitly), essentially remaining agnostic about context.

Conversely, study-type (Y,X) – referred to as an “ecological study” – may seem intuitively appropriate for research where higher levels (for instance, neighborhoods, regions, states, schools, and so on) are the targets of interest. However, study-type (Y,X) also misses key information in that it fails to disentangle the genuinely ecological (i.e., “**contextual**”) and the aggregate (i.e., “**compositional**”) (Moon et al. 2005) and precludes the possibility of testing heterogeneous contextual effects on different types of individuals. Ecological, or contextual, effects reflect predictors and associated mechanisms that operate primarily at the contextual level. That is, context exerts a causal influence on individuals. The search for such measures and their scientific validation and assessment is an area of active research (Kawachi and Berkman 2003). Aggregate effects, or compositional effects, in contrast, equate the effect of a neighborhood with the sum of the individual effects associated with the people living within the neighborhood. In this situation, the interpretative question becomes particularly relevant. If common membership of a neighborhood by a set of individuals brings about an effect that is over and above those resulting from individual characteristics, then there may indeed be an ecological effect. Under a purely ecological study, it is impossible to differentiate between ecological, or contextual, and aggregate, or compositional effects.

Study-type (y,X) provides a multilevel approach under which an ecological exposure is linked to an individual outcome. A more complete representation would be (y,x,X) such that we have an individual outcome, individual confounders (x), and neighborhood exposure. Such data would reflect a multilevel structure of individuals nested within neighborhoods. A fundamental motivation for study-type (y,x,X) is to distinguish “neighborhood differences” from “the difference a neighborhood makes” (Moon et al. 2005). Stated differently, ecological effects on the individual outcome should be ascertained *after* individual factors that reflect the composition of the places (and may be potential confounders) have been controlled. Indeed, compositional explanations for ecological variations in health are common. It nonetheless makes intuitive sense to test for the possibility of ecological effects. Besides anticipating their impact on individual outcomes,

		Exposure	
		Individual (x) (measured at individual level)	Ecologic (X) (measured at ecological level)
Outcome	Individual (y)	(y,x) Traditional risk factor study	(y,X) Multilevel study
	Ecologic (Y)	(Y,x) ^(A)	(Y,X) Ecological study

Fig. 68.1 Typology of studies (Subramanian et al. 2007). Note: ^(A) This type of study is impossible to specify as it stands. Practically speaking, it will either take the form of (Y,X), that is, ecological study, where X will now simply be central tendency of x . Or, if dis-aggregation of Y is possible, so that we can observe y , then it will be equivalent to (y,x) (Source: Subramanian et al. 2009)

compositional factors may vary by context. Moreover, composition itself has an intrinsic ecologic dimension; the very fact that individual (compositional) factors may drive ecologic variations serves as a reminder that the real understanding of **ecologic effects** is likely to be complex.

The multilevel framework with its simultaneous examination of the characteristics of the individuals at one level and the context or ecologies in which they are located at another level accordingly offers a comprehensive framework for understanding the ways in which places can affect people (contextual) and/or people can affect places (composition). It likewise allows for a more precise distinction between **aggregative fallacy** versus ecologic effects (Subramanian et al. 2009).

68.5 Multilevel Statistical Analysis

In the presence of a multilevel data, as described in Sect. 68.2, and having motivations as discussed in Sect. 68.3, there are substantive as well as technical reasons to use **multilevel statistical models** to analyze such data (Goldstein 2003; Raudenbush and Bryk 2002). We shall not review the basic principles of multilevel modeling here as they have been described elsewhere in the context of health research (Blakely and Subramanian 2006; Kawachi and Berkman 2003; Moon et al. 2005), but rather provide a brief overview of the type of models invoked for identifying ecologic effects discussed in Sect. 68.3.

Multilevel models can broadly be expressed as follows: response = fixed/average parameters + (random/variance parameters). A multilevel model is distinguished from a conventional regression model by the random part of the model. Conventional models usually restrict the random portion of a model to a single term (called as “error terms” or “residuals”); in the multilevel regression model, the random part of the statistical model is expanded.

Suppose we are interested in studying the variation in health, represented by a “health score,” as a function of certain individual and **neighborhood predictors**. Let us assume that a researcher collected data on a sample of 50 neighborhoods and, within each of these neighborhoods, a random sample of individuals. This design produces a two-level structure where the outcome is a health score, y , for individual i in neighborhood j . Individual level, poverty, x_{1ij} , is collected and coded as 0 if not poor and 1 poor, for every individual i in neighborhood j . The researcher also collects data on one neighborhood predictor, w_{1j} , a socioeconomic deprivation index in neighborhood j .

68.5.1 Variance Component or Random Intercepts Model

We will now develop regression equations at the individual and neighborhood levels of analysis in order to understand how a multilevel model would accommodate the data structure above. In the illustration considered here, models would have to be specified at two levels, level 1 and level 2, though additional levels are possible if the research question calls for this. For example, a model at level 1 can be formally expressed as

$$y_{ij} = \beta_{0j} + \beta_1 x_{1ij} + e_{0ij} \quad (68.1)$$

In this level 1 model, β_{0j} (associated with a constant, x_{0ij} , a constant vector of 1s) is the mean health score for the j^{th} neighborhood for the nonpoor group; β_1 is the average differential in health score associated with individual poverty status (x_{1ij}) across all neighborhoods. Meanwhile, e_{0ij} is the individual, or the level 1, residual term. We create a two-level model by allowing β_{0j} to become a **random variable** as

$$\beta_{0j} = \beta_0 + u_{0j} \quad (68.2)$$

where u_{0j} is an error term that describes the random neighborhood-specific displacement associated with the overall mean health score (β_0) for the nonpoor group. Since we do not allow, at this stage, the average differential for the poor and nonpoor group (β_1) to vary across neighborhoods, u_{0j} is assumed to be same for both groups. We refer to Eq. (68.2) as the level 2, between-neighborhood model.

We can now integrate these two parts to form a multilevel model. We first substitute the level 2 model [Eq. (68.2)] into level 1 model [Eq. (68.1)] and then group the fixed and random part components of the model (bracketed). The result is the following combined, also referred to as **random intercepts** or *variance components*, model:

$$y_{ij} = \beta_0 + \beta_1 x_{1ij} + (u_{0j} + e_{0ij}) \quad (68.3)$$

Our response variable y_{ij} is the sum of fixed and random model components. Assuming a normal distribution with a 0 mean, we can estimate a variance at level 1

(σ_{e0}^2 : the between-individual within-neighborhood variation) and level 2 (σ_{u0}^2 : the between-neighborhood variation), both conditional on fixed poverty differences in health score. The structure of the random component of this model, specifically that it contains more than one residual term, distinguishes the multilevel model from the standard linear regression models or analysis of variance-type analysis. The underlying random structure (variance-covariance) of the model specified in Eq. (68.3) is

$$\text{Var}[u_{0j}] \sim N(0, \sigma_{u0}^2); \text{Var}[e_{0ij}] \sim N(0, \sigma_{e0}^2); \text{and } \text{Cov}[u_{0j}, e_{0ij}] = 0$$

This underlying **variance-covariance structure** requires special estimation procedures in order to obtain satisfactory parameter estimates (Goldstein 2003).

The model specified in Eq. (68.3) with the above random structure is typically used to partition variation according to the different levels, with the variance in y_{ij} being the sum of σ_{u0}^2 and σ_{e0}^2 . This partitioning allows us to calculate a statistic known as the **intra-class correlation**, or *intra-unit correlation*, or more generally *variance partitioning coefficient* (Goldstein et al. 2002), which represents the degree of similarity between two randomly chosen individuals within a neighborhood. When individuals within a neighborhood are nearly identical, this statistic approaches 1. When individuals are truly independent, meaning that the contextual level explains practically none of the variance among observations, the statistic approaches zero. The variance partitioning coefficient can be expressed as

$$\rho = \frac{\sigma_{u0}^2}{\sigma_{u0}^2 + \sigma_{e0}^2} \quad (68.4)$$

Note that Eq. (68.3) estimates a variance based on the observed sample of neighborhoods. While this is important to establish the overall importance of neighborhoods as a unit or level (i.e., the **common ecologic effect**), another quantity of interest may pertain to estimating whether living in neighborhood j_1 , as compared to neighborhood j_3 , for example, predicts a different health score conditional on compositional influences of covariates. Given Eq. (68.3), we can estimate for each level 2 unit:

$$\hat{u}_{0j} = E(u_{0j}|Y, \hat{\beta}, \hat{\Omega}) \quad (68.5)$$

The quantities \hat{u}_{0j} are referred to as “estimated” or “predicted” residuals, or using Bayesian terminology, as “posterior” residual estimates. To calculate these posterior residuals, we first calculate the raw residual for level 1 units from the random intercepts model:

$$r_{ij} = \hat{y}_{ij} - y_{ij} \quad (68.6)$$

The r_{ij} contains both level 1 and level 2 residuals, not separated out. We then calculate the mean of the raw residuals for each level 2 unit, giving us r_j .

Essentially, these are the estimates that we would get if we had specified neighborhoods as dummy variables in the fixed part of the model (with no intercept). These are also referred to as the unshrunk estimates of u_{0j} . We use the mean of the raw residuals for each level 2 unit, r_j , to calculate the **posterior residuals** as

$$\hat{u}_{0j} = r_j \times \frac{\sigma_{u0}^2}{\sigma_{u0}^2 + \sigma_{e0}^2/n_j} \quad (68.7)$$

where σ_{u0}^2 , σ_{e0}^2 , and r_j are defined above and n_j is the number of people within each neighborhood. This formula for \hat{u}_{0j} uses the level 1 and level 2 variances and the number of people observed in neighborhood j to scale the observed level 2 residual (r_j). As the level 1 variance declines or the sample size increases, the scale factor approaches 1, and thus, estimated \hat{u}_{0j} approaches r_j .

Neighborhood-level residuals are random variables assumed to originate from a distribution and whose parameter values quantify the variation among the higher-level or neighborhood units (Goldstein 2003). That is, observed neighborhoods are treated as a sample from a larger distribution of neighborhoods, of which the sample is representative. Another interpretation is that each \hat{u}_{0j} estimates neighborhood j 's departure from expected mean outcome. This interpretation is premised on the assumption that each neighborhood belongs to a population of neighborhoods, and the distribution of the population provides information about plausible values for neighborhood j (Goldstein 2003). For a neighborhood with only a few individuals, we can obtain more precise estimates by combining the population and neighborhood-specific observations than if we were to ignore the population membership assumption and use only the information from that neighborhood. When the estimated residuals at higher-level units are of interest in their own right, we need to provide standard errors, interval estimates, and significance tests as well as point estimates for them (Goldstein 2003).

68.5.2 Contrasting Multilevel and Other Approaches: Fixed Versus Random Effects

While this chapter has argued for the utility of multilevel methods for ecologic inference, we note that there are alternative approaches that can address nested data structures and may be appropriate under some circumstances, especially when measuring and modeling variance are not prime targets of analysis. For example, multilevel methods may not be *required* when clustering of data is viewed as a nuisance or when mean associations between a contextual variable and individual outcome are of prime interest, though multilevel models may still provide richer analytic options under these conditions. We return to examples addressed earlier to explore alternate specifications.

Multilevel methods help us understand the effects of contexts generally and/or the effects of specific contextual variables on a given outcome. However, this is not the only approach to understanding differences among contexts. Taking the

example of health variations across neighborhoods in Sect. 68.5.1, it is worth emphasizing that the “neighborhood effect,” u_{0j} , described in Eq. (68.2) can be treated in one of the two ways. Rather than treat the neighborhoods as a sample from a larger distribution of contexts, one can estimate each neighborhood separately as a fixed effect (i.e., treat them as a variable; with 50 neighborhoods, there will be 49 additional parameters to be estimated).

It is worth drawing this parallel between multilevel or a random-effects model (Eq. 68.3) and the conventional OLS or **fixed-effects regression model** because each has different strengths. Consider the fixed-effects model, whereby the neighborhood effect is estimated by including a dummy for each neighborhood, as shown below:

$$y_{ij} = \beta_0 + \beta_1 x_{1ij} + \beta N_j + (e_{0ij}) \quad (68.8)$$

where N_j is a vector of dummy variables for $N - 1$ neighborhoods. As stated above, the key conceptual difference between the fixed- and the random-effects approach to modeling neighborhoods is that while the fixed coefficients are estimated separately in multilevel modeling, the random differentials (u_{0j}) are conceptualized as coming from a distribution (Goldstein 2003). This multilevel conceptualization results in three practical benefits (Jones and Bullen 1994):

1. *Pooling information* between neighborhoods, with all the data contributing to the combined estimation of the fixed and random parts; in particular, the overall regression terms are based on the information for all neighborhoods.
2. *Borrowing strength*, whereby neighborhood-specific relations that are imprecisely estimated benefit from the information for other neighborhoods.
3. *Precision-weighted estimation*, whereby unreliable neighborhood-specific fixed estimates are differentially down weighted or shrunk toward the overall city-wide estimate. A reliably estimated within-neighborhood relation will be largely immune to this shrinkage.

The random-effects and the fixed-effects estimates for each neighborhood, meanwhile, are related (Jones and Bullen 1994). The neighborhood-specific random intercept (β_{0j}) in a multilevel model is a weighted combination of the specific neighborhood coefficient in a fixed-effects model (β_{0j}^*) and the overall multilevel intercept (β_0), in the following way:

$$\beta_{0j} = w_j \beta_{0j}^* + (1 - w_j) \beta_0 \quad (68.9)$$

with the overall multilevel intercept being a weighted average of all the fixed intercepts:

$$\beta_0 = \left(\sum w_j \beta_{0j}^* \right) / \left(\sum w_j \right) \quad (68.10)$$

Each neighborhood weight is the ratio of the true between-neighborhood parameter variance to the total variance, which additionally includes sampling variance

resulting from observing a sample from the neighborhood. Consequently, the weights represent the reliability or precision of the fixed terms:

$$w_j = \frac{\sigma_{uo}^2}{v_j^2 + \sigma_{uo}^2} \quad (68.11)$$

where the random sampling variance of the fixed parameter is

$$v_j^2 = \frac{\sigma_{2e0}}{n_j} \quad (68.12)$$

with n_j being the number of observations within each neighborhood. This weighting structure means that when there are genuine differences among neighborhoods and sample sizes within neighborhoods are large, the sampling variance will be small in comparison to the total variance, and the random neighborhood effect estimate will be very close to the fixed neighborhood effect. As the sampling variance increases, however, the weight will be less than 1, and the multilevel estimate will increasingly be influenced by the overall intercept based on pooling across neighborhoods. “**Shrinkage estimates**” allow the data to determine an appropriate compromise between specific estimates for different neighborhoods and the overall fixed estimate that pools information across places over the entire sample (Jones and Bullen 1994).

Importantly, the fixed-effects approach to modeling neighborhood differences using cross-sectional data is *not* a choice for a typical multilevel research question, where there is an intrinsic interest in an exposure measured at the level of neighborhood such as the one specified in Eq. (68.3); in such instances, a multilevel modeling approach is a necessity. This is because the dummy variables associated with the neighborhoods (measuring the fixed effects of each neighborhood) and the neighborhood exposure of interest are perfectly confounded and, as such, the effect of the neighborhood-level exposure cannot be estimated. Thus, the fixed-effects specification to understand neighborhood differences is unsuitable for the sort of complex questions which multilevel modeling can address.

Assuming that multilevel, or random, rather than fixed-effects approach is chosen, we return to our original example of health scores across neighborhoods. Building on our basic multilevel model, we can also expand the *random structure* in Eq. (68.3) by allowing the fixed effect of individual poverty (β_1) to randomly vary across neighborhoods in the following manner:

$$y_{ij} = \beta_{0j} + \beta_{1j}x_{1ij} + e_{0ij} \quad (68.13)$$

At level 2, there will now be two models:

$$\beta_{0j} = \beta_0 + u_{0j} \quad (68.14)$$

$$\beta_{1j} = \beta_1 + u_{1j} \quad (68.15)$$

Substituting the level 2 models in Eqs. (68.14) and (68.15) into the level 1 model in Eq. (68.13) gives

$$y_{ij} = \beta_0 + \beta_1 x_{1ij} + (u_{0j} + u_{1j} x_{1ij} + e_{0ij}) \quad (68.16)$$

Equation (68.13) allows us to ask whether individual poverty has different consequences for health in different neighborhoods. This is one example of a research question focused on the indirect effect contexts can have on health, specifically as mediators of individual-level risk factors.

Across neighborhoods, the mean health score for nonpoor is β_0 , and $\beta_0 + \beta_1$ is the mean health score for the poor, and the mean “poverty differential” is β_1 . The poverty differential is no longer constant across neighborhoods, but varies by the amount u_{1j} around the mean, β_1 . Such models are also referred to as *random-slopes* or *random-coefficient models*. These models have a more complex variance-covariance structure than before:

$$\text{Var} \begin{bmatrix} u_{0j} \\ u_{1j} \end{bmatrix} \sim N \left(0, \begin{bmatrix} \sigma_{u0}^2 & \\ \sigma_{u0u1} & \sigma_{u1}^2 \end{bmatrix} \right) \quad (68.17)$$

and

$$\text{Var}[e_{0ij}] \sim N(0, \sigma_{e0}^2) \quad (68.18)$$

With this formulation, it is no longer straightforward to think in terms of a summary **intraclass correlation** statistic ρ as the level 2 variation is now a function of a individual predictor variable, x_{1ij} . In our exemplification when x_{1ij} is a dummy variable, we will have two variances estimated at level 2: one for nonpoor which is

$$\sigma_{u0}^2 \quad (68.19)$$

and one for poor which is

$$\sigma_{u0}^2 + 2\sigma_{u0u1}x_{1ij} + \sigma_{u1}^2x_{1ij}^2 \quad (68.20)$$

That is, level 2 variation will be a “quadratic” function of the individual predictor variable when x_{1ij} is a continuous predictor. Thus, the notion of “random intercepts and slopes,” while intuitive, is not entirely appropriate. Rather, what these models are really doing is modeling variance as some function (constant, quadratic, or linear) of a predictor variable (Kawachi and Berkman 2003).

Building on the above perspective of modeling the variance-covariance function (as opposed to “random intercepts and slopes”), we can extend the concept to modeling variance function at level 1. It is extremely common to assume that the

variance is “homoskedastic” in the random part at level 1 (σ_{e0}^2); Eq. (68.16), and indeed researchers seldom report whether this assumption was tested or not. One strategy would be to model the different variances for poor and nonpoor of the following form:

$$y_{ij} = \beta_0 + \beta_1 x_{1ij} + (u_{0j} + u_{1j} x_{1ij} + e_{1ij} x_{1ij} + e_{2ij} x_{2ij}) \quad (68.21)$$

where $x_{1ij} = 0$ for nonpoor, 1 for poor; the new variable $x_{2ij} = 1$ for nonpoor, 0 for poor, with $Var[e_{1ij}] = \sigma_{e1}^2$ giving the variance for poor and $Var[e_{2ij}] = \sigma_{e2}^2$ giving the variance for nonpoor; and $Cov[e_{1ij}, e_{2ij}] = 0$. There are other parsimonious ways to model level 1 variation in the presence of a number of predictor variables (Kawachi and Berkman 2003). With this specification, we do not have an interpretation of the random level 1 coefficients as “**random slopes**” as we did at level 2. The level 1 parameters σ_{e1}^2 and σ_{e2}^2 describe the complexity of level 1 variation, which is no longer homoskedastic (Goldstein 2003). Anticipating and modeling heteroskedasticity or heterogeneity at the individual level may be important in multilevel analysis as there may be **cross-level confounding** – what may appear to be neighborhood heterogeneity (level 2) to be explained by some ecological variable could be due to a failure to take account of the between-individual (within neighborhood) heterogeneity (level 1).

Such exploration of variance is not possible using a fixed-effects approach, though fixed-effects models have their own merits. A fixed-effects approach may be appropriate if researchers are interested in making inferences about specific neighborhoods in a dataset, though much is lost in terms of flexibility and exploiting the richness of heterogeneity that underlies a dataset. A single-level model is used to control stringently for confounding by shared neighborhood environment such that main effects apart from neighborhood environment can be estimated. A fixed-effects approach also allows for direct comparisons among places, as an effect on the outcome of interest will be estimated for each neighborhood. On the other hand, if neighborhoods are treated as a (random) sample from a population of neighborhoods (which might include neighborhoods in future studies if one has complete population data), the target of inference is the variation between neighborhoods in general. Adopting this multilevel statistical approach makes u_{0j} a random variable at level 2 in a two-level statistical model.

The degree to which stringent control for potential confounding by neighborhood is needed and the value of directly comparing specific neighborhoods to answer the research question at hand should drive the choice of a fixed-effects versus random-effects approach. When **specific ecologic effects** are of interest, an attractive feature of multilevel models – one that is perhaps most commonly used in social science research – is their utility in modeling neighborhood *and* individual characteristics, and any interaction between them, simultaneously. We will consider the underlying level 2 model related to Eq. (68.20), which is exactly the same

as specified in Eqs. (68.14)–(68.15), but now including a level 2 predictor, w_{1j} , the deprivation index for neighborhood j :

$$\beta_{0j} = \beta_0 + \alpha_1 w_{1j} + u_{0j} \quad (68.22)$$

$$\beta_{1j} = \beta_1 + \alpha_2 w_{1j} + u_{1j} \quad (68.23)$$

Note that the separate specification of micro- and macro-models correctly recognizes that the contextual variables (w_{1j}) are predictors of between-neighborhood differences. The extension of Eq. (68.21) will now be

$$y_{ij} = \beta_0 + \beta_1 x_{1ij} + \alpha_1 w_{1j} + \alpha_2 w_{1j} x_{1ij} + (u_{0j} + u_{1j} x_{1ij} + e_{1ij} x_{1ij} + e_{2ij} x_{2ij}) \quad (68.24)$$

The combined formulation in Eq. (68.24) highlights an important feature, the presence of an interaction between a level 2 and level 1 predictor ($w_{1j} \cdot x_{1ij}$), represented by the fixed parameter, α_2 . Now, α_1 estimates the marginal change in health score for a unit change in the neighborhood deprivation index for the nonpoor, and α_2 estimates the extent to which the marginal change in health score for unit change in the neighborhood deprivation index is *different* for the poor. This multilevel statistical formulation allows **cross-level effect modification** or *interaction* between individual and neighborhood characteristics to be robustly specified and estimated.

Multilevel models are concerned with modeling both the average and the variation around the average, at different levels. To accomplish this, they consist of two sets of parameters: those summarizing the average relationships(s) and those summarizing the variation around the average at both the level of individuals and neighborhoods. Models presented in preceding section can be easily adapted to other structures with nesting of level 1 units within level 2 units. Additionally, these models can be extended to three or more levels. While the preceding discussion considered a single normally distributed response variable for illustration, multilevel models are capable of handling a wide range of responses. These include binary outcomes, proportions (as logit, log-log, and probit models), multiple categories (as ordered and unordered multinomial models), and counts (as Poisson and negative binomial distribution models). In essence, these models work by assuming a specific, “non-Gaussian” distribution for the random part at level 1 while maintaining the normality assumptions for random parts at higher levels. Consequently, the discussion presented in this entry focusing at the neighborhood level would continue to hold regardless of the nature of the response variable, with some exceptions. For instance, determining intraclass correlation or partitioning variances across individual and neighborhood levels in complex nonlinear multilevel logistic models is not straightforward (see elsewhere for details (Goldstein et al. 2002; Browne et al. 2005)). **Fixed-effects models**, by contrast, are not suited for such analyses, though they are appropriate for some research questions.

68.5.3 Contrasting Multilevel and Other Approaches: Marginal Versus Mixed Approaches

Aside from a purposeful focus on variability within a dataset, a primary motivation for applying multilevel methods to nested data is to correct for the nonindependence of level 1 observations within level 2 units. To explore this motivation, we return to the example of Aitkin's work in assessing the effect of teaching style on student progress given in Sect. 68.3.1. To answer the question of whether formal teaching style was associated with student progress on average across the population, a marginal (also known as a "population average" or **generalized estimation equation** [GEE]) model could account for clustering of students within classes and provide a "correct" answer. In fact, a marginal model specification would be less sensitive to the assumptions of random effect as compared to mixed or multilevel models (Raudenbush and Bryk 2002). However, under a marginal approach, valuable information would be lost. **Marginal models**, which do not attempt to model data structure in terms of correlations and variances, are only able to provide information about whether, on average, there is an association between two variables. Marginal models are not designed to answer other questions, such as whether the effect of an individual factor varies across contexts, or the extent to which contexts matter for an outcome. Yet, showing the average association between a contextual attribute and individual outcome is only one of several ways to consider ecologic effects. Complex heterogeneity can underlie marginal associations and may also be of interest to researchers. Multilevel approaches both account for the effect of clustering on population average estimates and can capture additional and valuable information on variance. Semi-parametric specifications of random-effects distributions let the data determine the distribution for random effects, thereby reducing the reliance of the model on parametric assumptions and making inferences based on the **mixed model** more robust (Subramanian and O'Malley 2010).

68.6 Sources of Bias in Ecologic Inference

Although multilevel studies have much to offer in terms of understanding ecologic effects and heterogeneity, it is important to keep in mind several sources of **bias** that may arise in studies of contextual effects. The problem of bias is not unique to **multilevel approaches**, but rather to observational data in general, which are most often the subjects of analysis by multilevel methods. It is therefore worth noting common pitfalls of trying to identify average treatment effects using multilevel models to analyze observational data. To ground this discussion, we consider various ways in which health might vary across neighborhoods, though these concerns are applicable to other contexts and units of observation as well.

68.6.1 Reverse Causation

“**Reverse causation**” is at play if our outcome of interest has actually preceded and caused our exposure of interest rather than the other way around. Imagine a research study aimed at uncovering whether the presence of parks in a neighborhood makes residents healthier finds that neighborhood park density and fitness are indeed related. If this relationship were the result of healthy people moving to park-filled neighborhoods, perhaps because they are fit enough to take advantage of jogging trails, we would not want to attribute resident health to a contextual effect of park exposure. Rather, the relationship would imply reverse causation, whereby the outcome status drives the extent to which an exposure is experienced. In such a situation, an effect estimate describing how neighborhood-level park availability impacts fitness would be biased.

68.6.2 Uncontrolled Confounding

When neighborhood-level exposures and individual outcomes are driven by the same factors and these factors cannot be controlled, confounding will bias average treatment effect estimates. For example, if resident preferences in food drive both individual food choices, and therefore BMI, and neighborhood-level fast-food density measures, confounding limits our ability to understand the causal effect of fast-food density in a neighborhood on BMI.

68.6.3 Covariate Balance

A lesser known source of bias in contextual studies is the misspecification of covariates. This can occur when distributions of covariates in different neighborhoods do not overlap or do overlap very little. For example, consider a study of individual smoking predicted by neighborhood violence. Imagine that individual income is associated with living in a neighborhood that experiences a lot of violence and income also affects the risk of smoking. If the distribution of income in violent versus safer neighborhoods is such that no rich people lived in high-violence communities and no poor people lived in safe neighborhoods, then it is impossible to control for income when estimating the effect of neighborhood violence on smoking. This is because only extrapolated data exist that would allow us to estimate the effect of violence conditional on income.

68.6.4 Treatment Heterogeneity

Finally, average treatment effect estimates may be biased when treatment effects are heterogeneous. That is, an exposure may have one effect in a certain population

and an opposite, or at least meaningfully different, effect in another. Imagine trying to estimate the effect of a sun exposure on skin cancer if the only people willing to live in sunny environments were those who were minimally susceptible sun burn. Anyone who felt they were susceptible to sunburn would choose to live in areas without much sun exposure under this scenario. Were residents organized in this way, a study of sun exposure and skin cancer would conclude that the two variables were not related. In this scenario, while the average treatment effect would be biased, the effect of “treatment” (i.e., sun exposure) on the “treated” (i.e., those living in sunny areas) would be a valid estimate. The plausibility of heterogeneous treatment effects is specific to the social and biological background for each research question. Furthermore, such “**treatment heterogeneity**” can be of substantive importance in its own right.

68.6.5 Alternatives to Observational Data

While these sources of bias are not unique to multilevel data structures, they are common pitfalls to be aware of when making ecologic inference via multilevel methods. Concerns that observational data collected on people in contexts can never be completely free of endogeneity, or confounding by preference, have led some researchers to call for randomized community trails as the only valid way of estimating neighborhood effects (Oakes 2004).

While there are multiple flaws in this thinking (Subramanian 2004b), two types of experiments can be conceptualized for identifying ecologic effects. One approach randomly assigns individuals to neighborhoods under experiments called “mobility programs.” The Gautreaux (Rosenbaum 1995) and Moving to Opportunity (MTO) (Katz et al. 2000) studies provide the only experimental investigation of **neighborhood effects** of socioeconomic and health outcomes (although Gautreaux was technically quasi-experimental) under this type of scheme. As background, MTO randomized families in public housing to receive housing vouchers for use on the private market with different stipulations attached or to receive no new assistance. Some families received vouchers that had to be used in low-poverty neighborhoods, while others were able to use their vouchers without geographic restrictions. Follow-up on the families, who were moved between 1994 and 1997, shows that randomization to low-poverty neighborhoods decreased rates of obesity and diabetes and mental health problems in adults (Katz et al. 2000; Ludwig et al. 2011).

This study provides strong evidence that neighborhoods matter for health, though it is unclear whether MTO results can be interpreted as specific or **common ecologic effects**. While the study was designed to review the effects of neighborhood poverty on various aspects of well-being (a specific ecologic effect), the impact of poverty cannot be isolated if individuals have ties to their neighborhoods that influence well-being through means other than contextual percent poverty. Such interventions are sometimes called “fat hand” because the clumsy intervening hand has altered more than the specific causal agent of interest. Similarly, it is

difficult to impossible to intervene on one neighborhood characteristic without affecting others. For example, interventions that seek to lower levels of community violence would almost always also impact levels of community trust, aspects of the built environment, and other factors. However, if it is impossible to change one neighborhood characteristic without changing others, the causal effect of isolated interventions may not be of much interest.

A second type of experiment for identifying ecologic effects involves randomly assigning neighborhoods various characteristics, by, for example, randomly choosing areas in which bike lanes will be striped or parks enhanced. There are two challenges with these types of interventions, which rely on pre- and post-intervention data points to assess impacts. First, secular trends must be accounted, meaning “control” neighborhoods that do not receive an intervention are also followed. Secondly, required sample sizes are quite high. This is because the number of level 2 units, in this case neighborhood, rather than level 1 units, in this case residents, drives the **effective sample size**. Random assignment of potentially meaningful treatments to hundreds, if not thousands of neighborhoods, depending on the anticipated magnitude of the effect, would be a political and fiscal challenge, to say the least. To this end, those interested in estimating ecologic effects should be trained to analyze experimental, quasi-experimental, and observation data collected on multiple levels of analysis.

68.7 Extensions to the Basic Multilevel Models

68.7.1 Multiple Membership Models

While multilevel methods are powerful and flexible tools for studying ecologic effects, current implementations of multilevel models have generally failed to exploit the full capabilities of the analytical framework (Moon et al. 2005; Subramanian 2004a). Much, if not all, of the current research linking neighborhoods and health is cross-sectional and assumes a hierarchical structure of individuals nested within neighborhoods. This simplistic scenario ignores the possible data structures discussed in this chapter, including that an individual might move several times and as such reflect neighborhood effects drawn from several contexts or that other competing contexts (e.g., schools, workplaces, hospital settings) may simultaneously contribute to contextual effects. Figure 68.2 provides a visual illustration of one complex, but realistic multilevel structure for neighborhoods and health research, where time measurements (level 1) are nested within individuals (level 2) who are in turn nested within neighborhoods (level 3). Importantly, individuals are assigned different weights for the time spent in each neighborhood. For example, individual 25 moved from neighborhood 1 to neighborhood 25 during the time period t_1 – t_2 , spending 20 % of his/her time in neighborhood 1 and 80 % in his/her new neighborhood. This **multiple membership design** would allow control of changing context as well as changing composition. Such designs could be extended to incorporate memberships to additional contexts, such as workplaces or schools.

Fig. 68.2 Multilevel structure of **repeated measurements** of individuals over time across neighborhoods with individuals having multiple membership to different neighborhoods across the time span (Source: Subramanian 2004a)

It can also be extended to consider the effects of proximate contexts, weighted according to distance or other spatial measures. So, for example, the geographic distribution of disease can be seen not only as a matter of composition and the immediate context in which an outcome occurs but also a consequence of the impact of nearby contexts with nearer areas being more influential than more distant ones. This is also called **spatial** autocorrelation and forms an important area of spatial statistical research. While such analyses require high-quality longitudinal and context-referenced data, models that incorporate such “realistic complexity” (Best et al. 1996) are likely to improve our understanding of true neighborhood effects. While the foregoing discussion provides a sound rationale to adopt a multilevel analytic approach for modeling ecologic effects, they obviously do not overcome the limitations intrinsic to any observational study design, single level or multilevel.

68.7.2 Spatial Models

As noted above, the geographic distribution of disease can be seen as a consequence of the impact of nearby contexts with nearer areas being more influential than more distant ones. This idea that proximate observations and contexts are correlated by virtue of their locations in space drives the application of multilevel methods for the analysis of spatial data. Just as we can nest observations in more than one context, such as people in multiple workplaces or neighborhoods through **cross-classified** and multiple membership models, we can also nest observations within geographically defined “spatial patches” rather than within administrative boundaries. That is, rather than assign some observation higher-level groupings based on membership, we can base assignment in higher levels on space. To do this, a list of neighbors must be constructed for each observation. To know who is a neighbor, information about space is needed.

We can construct a **weights matrix** that defines the spatial relationships among all observations in a dataset to identify their spatial relationship. For observations considered “neighbors” estimates are allowed to be correlated, just as observations

that share a context are allowed to be correlated in traditional hierarchical models. That is, the assumption that level 2 residuals, u_{0j} , are spatially unstructured can be varied, for example, such that u_{0j} is allowed to follow a conditional autoregressive prior based on neighborhood contiguity. Non-neighbors are assumed to be independent, unless otherwise specified at other levels. A common neighborhood structure is “queen-based contiguity.” The term “queen-based contiguity” derives from chess where the queen can move in any direction from her starting location and implies that all shared borders constitute first-order neighbors (Fischer and Getis 2010). To illustrate this scheme, imagine a given map of nine areas a, \dots, i shown in Fig. 68.3.

Using a first-order regional structure using queen-based contiguity, this map translates into a 9×9 adjacency matrix, as shown in Fig. 68.4.

Pairs of adjacent observations receive a value of 1, and all other pairs are assigned 0. To look up the relationship between subjects a and b , we find observation a in the first row and observation b in the second column. Reading across the matrix’s first row, the second cell contains 1 because a is adjacent to b on the map. By contrast, the cell indicating the relationship between a and c is a 0 (first row, third column) because the two areas are not adjacent on the map.

Of course, first-order adjacency matters for only some research questions, while different conceptualizations are more appropriate in other settings. Testing for and understanding spatial clustering require hypotheses of how relevant processes function over space. Contagion and/or influence by spatially patterned variables may be structured by distance, adjacency, shared access to transportation networks,

or other factors, and each of these constructs can be translated into a **spatial** weights matrix. Researchers should choose a spatial weights matrix based on expert knowledge of the topic under study. Below are other commonly employed specifications.

Distance. Distance should be considered for processes that literally operate through space. For example, studying a disease spread by insect vectors that can only travel up to 800 m from their nests, researchers might create a spatial weights matrix where all pairs of points within 800 m of each other are neighbors and all others are not.

Spatial relationships could alternatively be described by the distance between the two points where cell values would simply be the number of meters between point pairs. To provide further flexibility, these distances could be calculated either in Euclidian terms, along a road network, or by another scheme (Apparicio et al. 2008). **Geographic information systems** will also allow users to calculate “cost distances” between points that can account for the slope of a walking route, cost of tolls on a road, or even total trip time so that distances could be conceptualized in terms of minutes commuting or gasoline costs.

Adjacency. Where shared borders or regionalism matters (e.g., immigration or trade), adjacency may be a more useful concept. Adjacency can be conceptualized flexibly (Fischer and Getis 2010), where the presence, amount, or even spatial orientation of a shared border is used to construct a spatial weights matrix. Further, second-order and higher neighbors (i.e., a neighbor’s neighbor) can be ignored or included.

Nearest Neighbors. A hybrid approach between the distance and adjacency approaches is to select k nearest neighbors, with proximity based on centroid distances, from a pool of adjacent areas for each subject.

Regardless of neighborhood specification, **conditional autoregressive (CAR) models** can be fit to spatial data using multilevel methods. This is because CAR models are simply extensions of traditional original random-effects models. Instead of nesting a given observation completely within one higher-level unit, CAR models allow observations to be “cross-classified,” or influenced by a *group* of neighbors, according to any spatial weights matrix such as those described above.

Bayesian estimation of CAR models, which accounts for uncertainty in the data, also helps smooth estimates over space so that areas with few neighbors are borrowing information from other regions (LeSage and Pace 2004).

68.8 Conclusion

The multilevel statistical approach – an approach that explicitly models the correlated nature of the data arising either due to sampling design or because populations are clustered – is a powerful tool for ecologic inference.

From a substantive perspective, these multilevel methods circumvent the problems associated with **ecological fallacy** (the invalid transfer of results observed at the ecological level to the individual level), individualistic fallacy (occurs by failing to take into account the ecology or context within which individual relationships happen),

and atomistic fallacy (arises when associations between individual variables are used to make inferences on the association between the analogous variables at the group/ecological level). The issue common to the above fallacies is the failure to recognize the existence of unique relationships being observable at multiple levels and each being important in its own right. Specifically, one can think of an individual relationship (e.g., individuals who are poor are more likely to have poor health), an ecological/contextual relationship (e.g., places with a high proportion of poor individuals are more likely to have higher rates of poor health), and an individual-contextual relationship (e.g., the greatest likelihood of being in poor health is found for poor individuals in places with a high proportion of poor people). Multilevel models explicitly recognize the level-contingent nature of relationships.

Multilevel approaches also enable researchers to obtain statistically efficient estimates of fixed regression coefficients. Multilevel models provide correct standard errors and thereby robust confidence intervals and significance tests. These generally will be more conservative than the traditional ones that are obtained simply by ignoring the presence of clustering. More broadly, multilevel models allow a more appropriate and realistic specification of complex variance structures at each level. Multilevel models are also precision weighted and capitalize on the advantages that accrue as a result of “pooling” information from all the neighborhoods to make inferences about specific neighborhoods.

Developing and interpreting multilevel applications for inferences at the ecologic level entail several considerations. First, subject matter expertise and theory should drive choice of higher levels in a multilevel analysis. Second, establishing the relative importance of context and composition is probably more apparent than real, and necessary caution must be exercised while conceptualizing and interpreting the compositional and contextual sources of variation. Disentangling context from composition requires exposure and covariate data be collected at multiple levels, and that higher-level variables are not completely confounded with lower-level attributes. Third, it is important that the sample of neighborhoods belong to well-defined population of neighborhoods such that the sample shares exchangeable properties that are essential for robust inferences. In other words, units that are treated in statistical models as though they come from the same distribution should actually share commonalities that justify this treatment. Fourth, it is important to ensure adequate sample size at all levels of analysis. In general, if the research focus is essentially on neighborhoods, then clearly the analysis requires more neighborhoods (as compared to more individuals within a neighborhood). Lastly, like all quantitative procedures, the ability of multilevel models to make **causal inferences** is limited, and innovative strategies including randomized neighborhood-level research designs (via trials or natural experiments) in combination with multilevel analytical strategy may be required to convincingly demonstrate causal effects of social contexts such as neighborhoods. However, to the extent that experimental studies of contextual effects are few and far between, applying multilevel frameworks to observational data is a key aspect of neighborhood research.

Abstract

This chapter provides an overview of spatial dynamics in the field of regional science. After defining the context of spatial dynamics and the alternative conceptualizations of space and time, the chapter surveys the various areas of substantive interest where spatial dynamics come to the fore. A second focus is on the methodological and technical issues surrounding the methods of space-time data analysis. Here the emphasis is on exploratory methods for space-time data focusing on the evolution of spatial patterns as well as the identification of temporal dynamics that cluster in space.

69.1 Introduction

All human activity happens somewhere in space and time. As a consequence, spatial dynamics and space-time data analysis are of interest across a wide array of cognizant fields. Regional science is no exception as the consideration of the spatial and temporal domains in the theoretical and empirical analysis of socioeconomic phenomena is now a central theme in the discipline.

There are a number of forces that have given rise to this prominence. The first is technological in nature and reflects the increasing availability of longitudinal spatial data sets which have been made possible by the rise in geospatial technologies such as Global Positioning Services (GPS), network sensors, and areal photography.

The second development is theoretical in nature and reflects a shift in the focus of substantive theory from an initial view of independent agents operating in a spaceless world to one where geographical space becomes a key dimension of the underlying theory. The rise of spatial economics and the new economic geography are emblematic of this phase, which perhaps was prematurely labeled as “space: the final frontier” (Krugman 1998).

More recently, however, the frontier has been expanded by the recognition that in order to posit causal relationships, both the “where” question and the “when” question need to be addressed (Cressie and Wikle 2011). In this sense space-time is seen as the next frontier. Similarly, Goodchild (2008) sees spatiotemporal concerns as one of the key challenges facing the development of future GIS research. As regional science has increasingly adopted methods from geographical information science, it too faces these newly emerging challenges.

This chapter provides an overview of spatial dynamics in the field of regional science. After defining the context of spatial dynamics and the alternative conceptualizations of space and time, the chapter surveys the various areas of substantive interest where spatial dynamics come to the fore. A second focus is on the methodological and technical issues surrounding the methods of space-time data analysis. Here the emphasis is on exploratory methods for space-time data focusing on the evolution of spatial patterns as well as the identification of temporal dynamics that cluster in space.

69.2 Spatial Dynamics in Regional Science

To situate the discussion, it is important to first consider the different ways that space and time, as well as spatial dynamics, have been conceptualized in practice. Both space and time have been viewed in a variety of ways, which makes the consideration of space-time even more complex.

From a geographical perspective, two different conceptualizations of space have been used: the object and field views. In the former, the world is seen as populated by discrete homogeneous units such as factories, homes, roads, lakes, and rivers that are located using some form of geographical coordinate system. Often these are represented using a vector data model that relies on points, lines, and polygons.

Alternatively, in a field-based ontology, the focus is on the spatial variation in some phenomenon (such as temperature, risk exposure, or elevation) across space that can conceptually be observed at any location and is thus spatially continuous. For fields, a raster data model is adopted where pixels, grid cells, or voxels are used to exhaust space. Conventionally, the object view has been dominant in regional science given the focus on macro-spatial economic, demographic, and social phenomena.

In a similar way time has been treated as both discrete and continuous in regional science. By and large the former perspective is more commonly encountered, and this is in large part due to practical considerations related to the way data series are recorded. At the same time, work on continuous-time models has remained largely theoretical with emphases on understanding the dynamic trajectories following from various forms of growth and interaction specifications.

Consideration of the discrete versus continuous categorization of space and time gives rise to a four-way classification. By far the most commonly employed classification in regional science is the discrete-space, discrete-time classification, where, for example, space is organized as areal units (states, provinces, counties) and time is measured on an monthly, quarterly, annual, or decadal frequency. Although this is the dominant approach, exceptions can be found. The work by Arbia and Paelinck (2003) on regional convergence is an example of a discrete-space, continuous-time approach. Conversely, in Duranton and Overman (2008) the focus is on the distribution of individual firms over a continuous space but in discrete time. Finally, the theoretical work of Fujita et al. (2001) specifies models for optimizing agents in continuous time and continuous space.

The intersection of space-time provides a mechanism to move beyond the traditional cross-sectional focus that has long dominated empirical work in regional science. The estimation of econometric relationships using cross-sectional data rests on the assumption that the underlying process has reached a state of equilibrium. At the same time, however, many of the phenomena of interest to regional science are often viewed from an adjustment or disequilibrium perspective. Methodologically, the latter requires space-time data in order for empirical investigation to be possible.

Along with the discrete versus continuous view of space and time, existing work in regional science can also be characterized according to the relative dominance of one of these dimensions. For example, work in spatial econometrics and exploratory spatial data analysis has been predominately concerned with the analysis of spatially referenced data at one point in time. Here the spatial dimension is central, while the temporal dimension is ignored or radically reduced to $t = 1$. These could be referred to as large n , extremely small t type studies. In contrast, there are studies of single regions where the emphasis is on the dynamic behavior of the individual regional economic or demographic system as in the case of early work on single-region macroeconomic models (Bolton 1985). These are extremely small $n = 1$, large t -type studies where the time series dimension is exploited to parameterize models for a small number of regions.

More data rich studies arise when multiple regions and time periods are analyzed. Prominent examples of large n small t type studies would include most β -convergence studies where the growth rate over two points of time is analyzed for a large set of n regions (Rey and Le Gallo 2009). Further distinctions must be drawn between studies that involve multiregional versus interregional analysis. In the former multiple regions (i.e., $n > 1$) provide an increased sample size for model parameterization, but the regions themselves may not interact. By contrast, interregional models explicitly incorporate interactions between the regions. This provides for further differentiation between dynamic processes and spatial processes. A dynamic process is one that transitions over time, for example, in the study of regional business cycles, a focus on the characteristic of a particular region's cycle behavior. A spatial process is distinct from a temporal process in that the former does not act on a single location but involves interaction across different locations that transpire over time.

Spatial dynamics pertains to a dynamic process that is spatially dependent (Irwin 2010). Spatial dynamics are relevant to many areas of applied and theoretical regional science. A prominent substantive motivation for spatial dynamics is in the study of optimal currency areas (OCA). One of the key criteria for a group of economies to be a candidate for an OCA is that their business cycles display a high degree of co-movement or synchronization so that a single monetary policy could be effectively employed (Partridge and Rickman 2005). An additional example is the related literature that attempts to identify the leading-lagging relationships between pairs of regional economies using various Granger causality and vector autoregressive models (LeSage and Reed 1990).

A further distinction arises from a consideration of two related, but distinct, concepts: comparative statics versus spatial difference. In comparative statics, a system is compared at two, or more, points in time to identify shifts or changes in the state of the system in discrete time, such as movements of, or along, a supply or demand curve. In a geographical context, the analogy is one of spatial difference – that is, comparing the articulation of a process at two or more different locations, but at the same moment in time.

In practice the researcher is faced with the similar challenge of trying to make inferences about the process that may be responsible for the temporal change or spatial differences observed. Two broad strategies have been adopted here. The first relies on so-called pattern models which can be viewed as analogous to a reduced form model in that they focus on describing the evolution of patterns which reflect the operation of some underlying process. Alternatively process-based models are akin to a structural form in that model parameters are tied directly to behavioral units in the underlying substantive theory for the process under study. A key challenge to linking substantive theory to space-time patterns is that substantive theories are often not detailed enough to make this linkage.

Not only do the different conceptualizations result in different representations of phenomena in space and time, but they tend to be more prevalent in certain types of space-time domains and can also require different analytical and statistical methods as is explored below.

In addition to these different conceptual frameworks for understanding space-time data analysis, one can also approach the topic from the different space-time domains that appear in substantive studies. Goodchild (2008) has offered a taxonomy of space-time domains that considers five different areas of inquiry.

Tracking the movement of individuals within a city using GPS devices provides a new way to understand human activity patterns within an urban context. These can be seen as modern extensions of foundational work of Hägerstrand (1970) formalization of tracking individual activity spaces as space-time prisms. In the current implementation, the masses of data generated from real-time network sensors, RFID, GPS, and social media postings (i.e., Twitter) have generated an active literature developing interesting new ways to analyze such data, and these methods are driving new innovations in transportation planning.

The second domain for space-time analysis concerns change detection or so-called snapshots. Time series of remotely sensed images of urban areas (Yang et al. 2003) can be used to analyze changes in urban morphology as well as trends in rural–urban land-use conversion that are becoming increasingly important to the understanding of coupled human and natural systems. Formal modeling of the evolution of such spatial patterns has been a central concern in health and environmental applications (Abellan et al. 2008; Wikle and Cressie 2000).

Polygon coverage, the third space-time domain, focuses on changes in attribute values for areal units over time. As we return to below in Sect. 69.3, a rich set of methods has been suggested to characterize these space-time dynamics. An important challenge in the polygon coverage domain arises when the reporting units and boundaries as well as the attribute values change over time. We return to this challenge below.

The fourth space-time domain shifts the focus to the raster data model and employs cellular automata (CA) models in which a set of states for each raster cell are specified together with a set of rules that determine the state transitions through time. Emblematic of this line of inquiry is the work on urban development (Clarke et al. 2007). Closely related to CA models are agent-based models in which space is viewed as populated with discrete agents, which could be either geographical features or actors, that are embodied with rules governing their behavior.

The final space-time domain concerns events and transitions. The classic example is Minard's map in Fig. 69.1 depicting Napoleon's march and retreat on Russia. This visualization combines spatial and temporal dimensions along with the depiction of temperature and information on the size of Napoleon's army in a highly complex representation. Although to date it has not been done, there is no reason why such methods could not be applied to events in regional science, such as business cycles or interstate migration patterns. Currently the business cycles are studied at two spatial scales, with attention at one level on the individual business cycles of states and how those cycles may be correlated or synchronized with the cycles of other states, or how they may be related to the cycle at a higher

spatial scale, say nation. The event framework provides the potential for integrating these seemingly distinct cycles into a unified cycle that may be articulated across space at different points and time.

The empirical analysis of each of these space-time domains relies on data that is organized in some space-time framework. Spatial data has conventionally been organized along the following taxonomy. Point data are used to represent the locations of individual events and the interest rests on the resulting spatial pattern of those locations together with any additional attribute data about the events – as is the case for marked point patterns used in the study of firm location and retail competition.

Geostatistical data arises when observations at fixed locations are obtained on some spatial phenomena that conceptually varies continuously over some spatial domain. Unlike point patterns, where the interest is on the pattern of the locations, in geostatistical data the focus is on the variation in the attribute across the fixed observation (or sample points), and models of this variation are used to develop predictions of the phenomena at target sites.

Arguably the most commonly encountered type of spatial data in regional science is lattice or areal unit data. Here space is viewed as partitioned into discrete areal units, and variables are measured for each of the units. The focus is on understanding the variation in the attribute across spatial units; however, unlike the case of geostatistical data, interpolation or spatial prediction is meaningless since the areal units exhaust the spatial domain.

Although these three types of spatial data form the core of the taxonomy in most spatial statistics texts, there are other types of spatial data that are commonly encountered in regional science research. Chief among these is network data which is prominent in many transportation studies. Network data are also encountered in various optimization models, and network concepts play a central role in defining spatial relationships between areal units in the analysis of lattice data. Networks are increasingly being used to model social interactions as in the growing literature on social networks with interest in embedding these social networks in geographic space.

Space-time data opens up a number of important ways to address fundamental problems that confront researchers working in either a cross-sectional or time series framework. In spatial analysis there has long been tension between so-called complete spatial heterogeneity where each location can be seen as unique, and more general lawlike constructions that apply in all locations. From a data analysis perspective, the former is a nonstarter since insufficient degrees of freedom are available – in a sense the number of parameters grows with the number of areas under consideration since each place is unique and requires its own parameter values. Enforcing spatial homogeneity is one way to reduce the parameter space and make inference tractable. This comes at a cost of course of imposing uniformity on the processes over space.

With space-time data there is more flexibility in the types of specifications that could be considered. In cases where a long enough time series is available, the formally intractable problem of allowing each place to have its own model

as it were can now be relaxed. Indeed, certain models adopted in practice actually require long time series for their use, as in the case of the Hildreth Prescott filter used to study regional business cycle behavior. Use of the HP filter with shorter series is known to introduce distortions (Partridge and Rickman 2005).

While the temporal dimension allows for a relaxation of the spatial homogeneity assumption, treatment of spatial dependence in a dynamic context must also be considered. Rather curiously, most approaches that consider spatial dynamics assume that the form of the interaction process is stable over time. In other words the strength of the spatial dependence is often held constant. For example, work on the identification of leading and lagging regions employs Granger causality type frameworks that exhaust the temporal dimensions to estimate the nature of the dynamic relationships between each pair of economies. The identified temporal lags are then assumed to hold over the entire time series.

While this approach does allow for spatial variation in the degree of spatial dependence (since each pair of economies can have distinct lead-lag relationships), it comes at a cost of assuming the spatial dynamics are temporally invariant. Such an assumption may be overly restrictive, since research in the area of regional income convergence (Rey and Le Gallo 2009) and business cycles (Partridge and Rickman 2005) is suggesting that the strength of spatial interaction in regional macro-series is often not constant over time.

Research that is extending these different types of spatial data supports and the associated analytical methods to include a temporal dimension is only at very embryonic stage of development. Most of the work on developing analytical methods for space-time data in regional science has focused on areal unit or polygon data and has adopted exploratory focus. An overview of the key directions in this regard is provided in the remainder of the chapter.

69.3 Exploratory Space-Time Data Analysis

Methods for exploratory space-time data analysis for lattice data can be organized in a number of ways. The first is to make a distinction between those that have their origins as cross-sectional methods that have been extended to incorporate a temporal dimension. Alongside of these are methods that were originally temporal exploratory data analysis (EDA) methods that were modified to incorporate space. The former group of methods can be viewed as studying the evolution of spatial patterns in time, while the latter switches the perspective to put temporal dynamics into space. In other words, the first group of methods views the spatial dimension from a temporal perspective, while in the latter the spatial signature of dynamic patterns becomes the focus.

To distinguish between these two sets of methods in what follows the acronym, ETSDA is used for the approaches that have their origins in the temporal domain but have been extended to incorporate space, while ESTDA is used for the originally spatial methods that have been extended to incorporate time. Although the perspectives are distinct across these two groups, in both cases there are

methods that are numerical and sometimes coupled with novel visualization methods which are also discussed.

69.3.1 ETSDA Methods

A main branch of the ETSDA literature begins with discrete Markov chains. A Markov chain is a particular type of dynamic stochastic process $\{X(t)|t \in T\}$ that satisfies the following condition. For any $t_0 < t_1 < \dots < t_n$,

$$\begin{aligned} P[X(t_n) = x_n | X(t_{n-1}) = x_{n-1}, X(t_{n-2}) = x_{n-2}, \dots, X(t_0) = x_0] \\ = P[X(t) = x_n | X(t_{n-1}) = x_{n-1}] \end{aligned} \quad (69.1)$$

This condition implies that the conditional distribution function of $X(t_n)$ only depends on $X(t_{n-1})$. In other words, given the present state of the process, the future state of the process is independent of the past.

A discrete-state Markov process is one in which the random variable X takes on one of n unique values. Such a Markov process is known as a Markov chain in which case Eq. (69.1) takes the following form:

$$P[X_k = j | X_{k-1} = i, X_{k-2} = n, \dots, X_0 = m] = P[X_k = j | X_{k-1} = i] = p_{i,j,k} \quad (69.2)$$

where $p_{i,j,k}$ is the state transition probability reflecting the conditional probability that the process will be in state j at time k given that it is in state i at time $k - 1$. For a time homogeneous Markov chain, the transition probabilities are time invariant, which implies the following:

$$P[X_k = j | X_{k-1} = i, X_{k-2} = n, \dots, X_0 = m] = P[X_k = j | X_{k-1} = i] = p_{i,j} \quad (69.3)$$

These transition probabilities satisfy the following conditions:

1. $0 \leq p_{i,j} \leq 1$
2. $\sum_j p_{i,j} = 1, \forall i, i = 1, 2, \dots, n$.

Given the n states, the transition probability matrix is

$$P = \begin{bmatrix} p_{1,1} & p_{1,2} & \dots & p_{1,n} \\ p_{2,1} & p_{2,2} & \dots & p_{2,n} \\ \vdots & \vdots & \vdots & \vdots \\ p_{n,1} & p_{n,2} & \dots & p_{n,n} \end{bmatrix} \quad (69.4)$$

Estimation of the transition probabilities can be based on maximum likelihood assuming time homogeneity:

$$\hat{p}_{i,j} = \frac{v_{i,j}}{\sum_j v_{i,j}} \quad (69.5)$$

where $v_{i,j}$ is the number of observed chain transitions from state i to state j .

Markov chains have played a central role in the literature on regional income convergence, following the pioneering work by Quah (1993). The typical approach is to discretize the distribution of per capita incomes or gross regional product measured over n regions into k classes in each time period, giving the discrete distribution π_t . Next, transition probabilities across each of these k classes of this distribution are formalized in a $k \times k$ matrix of transition probabilities:

$$P = \begin{bmatrix} p_{1,1} & p_{1,2} & \cdots & p_{1,k} \\ p_{2,1} & p_{2,2} & \cdots & p_{2,k} \\ \vdots & \vdots & \vdots & \vdots \\ p_{k,1} & p_{k,2} & \cdots & p_{k,k} \end{bmatrix} \quad (69.6)$$

where $p_{i,j}$ is the probability of an economy moving from class i of the distribution at time t into class j in period $t + 1$. Two key assumptions are often relied upon in regional convergence applications of Markov chains. The first is that temporal homogeneity holds

$$P_t = P_{t+1} = \dots = P_{T-1} = P_T \quad (69.7)$$

The second assumption is that the chain is first order:

$$P(X_t = j | X_{n-1} = k, \dots, X_0 = l) = P(X_t = j | X_{n-1} = k) \quad (69.8)$$

This means that the only relevant information is the state of the chain in the preceding period – the state of the chain from more distant periods has no effect on future dynamics.

These two assumptions allow a mapping of the distribution between any pair of periods:

$$\pi'_{t+1} = \pi'_t P \quad (69.9)$$

or, more generally,

$$\pi'_{t+b} = \pi'_t P^b \quad (69.10)$$

A final assumption that is also sometimes made is that the chain is irreducible. Formally, for each pair of states there is some length of time $v_{i,j}$ where

$$\pi_{i,j}^{v_{i,j}} > 0 \quad \forall i, j \quad (69.11)$$

meaning that movements between any pair (i, j) of states in the distribution are possible over some time horizon.

Homogeneity and irreducibility combined implies that the chain will have a steady-state distribution π_* where

$$\pi'_* = \pi'_* P \quad (69.12)$$

with

$$\Pi_* = P^v_{v \rightarrow \infty} \quad (69.13)$$

The rows of the matrix Π_* will be identical and represent the long-run or ergodic income distribution π_* .

In the convergence literature this framework has been used to study a number of issues, including the time required to achieve convergence, the extent of polarization, and the degree of intradistributional mobility (Rey and Le Gallo 2009). In addition to regional convergence, Markov chains have seen application in the area of city-size distributions (Black and Henderson 2003). It should also be noted that approaches such as the stochastic kernel which is the continuous equivalent of the transition probability matrix that overcomes some of the inherent shortcomings of a discrete-space setup have been suggested (Fischer and Stumpner 2008).

The classic Markov framework applied above has been extended to incorporate a spatial dimension in a number of ways. The first is through regional conditioning (Quah 1993) in which the distribution of neighbor-relative incomes is mapped into the distribution of nation-relative incomes, with the former obtained by normalizing incomes relative to the average of those of a region's geographical neighbors:

$$yr_{i,t} = \frac{y_{i,t}}{\sum_j^n w_{i,j} y_{j,t}} \quad (69.14)$$

where $y_{i,t}$ is income in region i in time period t and $w_{i,j}$ is an element of a row-standardized spatial weights matrix expressing the neighbor relation between each pair of economies. The national-relative distribution is defined using

$$yn_{i,t} = \frac{y_{i,t}}{1/n \sum_j^n y_{j,t}} \quad (69.15)$$

The regional conditioning allows for an analysis of the degree of spatial clustering in the regional income distribution since the two discrete relative distributions (69.14) and (69.15) should be independent if incomes were randomly distributed in space. This would be reflected in a diagonally dominant transition matrix that maps Eq. (69.14) into Eq. (69.15).

Spatial Markov: Regional conditioning, however, considers spatial autocorrelation at one point in time, so in a sense it is not a dynamic Markov chain. Rey (2001) extended the classic dynamic Markov chain to include a spatial component through the concept of a *spatial Markov chain*. Defining Markov chains conditioned on

different classes of the spatial lag (defined using the denominator of Eq. (69.14)) allows for an assessment of the role of spatial context in shaping the transitional dynamics. A growing body of research reveals contextual effects of a spatial nature as transition probabilities show clear dependence on the relative incomes of neighboring economies (Bosker 2009; Hammond 2004; Le Gallo 2004).

Spatial Rank Dynamics: A second subclass of ETSDA methods departs from the use of various bivariate correlation methods to explore dynamics. Borrowing from work on map comparisons where different types of correlation methods are applied to two contemporaneous map patterns (Lloyd and Steinke 1977), it was a short step to apply the same framework for maps from two different time periods (rather than for different variables at the same point in time).

Interestingly the methods used are classical, or spatial, correlation methods. More specifically, a traditional rank correlation statistic is applied:

$$\tau_{t,t-1} = \frac{C_{t,t-1} - D_{t,t-1}}{n(n-1)/2} \quad (69.16)$$

where $C_{t,t-1}$ is the number of concordant pairs of observations and $D_{t,t-1}$ is the number of discordant pairs between time periods $t-1$ and t . A pair of regions i, j is concordant if

$$(r_{i,t} - r_{j,t})(r_{i,t-1} - r_{j,t-1}) > 0 \quad (69.17)$$

where $r_{i,t}$ is the rank of region i in period t . If the sign of the rank difference product is negative, the pair of regions is discordant. A close inspection of this statistic reveals that the only position that matters here is the relative location of each area in the rank distribution. The geographical location of the observation is ignored.

Rey (2004) has suggested an extension of this traditional rank correlation measure to incorporate a spatial dimension. Using a spatial concordance decomposition,

$$\tau_{t,t-1} = \frac{CG_{t,t-1} + CN_{t,t-1} - DG_{t,t-1} - DN_{t,t-1}}{n(n-1)/2} \quad (69.18)$$

where the number of contiguous pairs is separated into those involving geographical neighbors (G) and those that are not neighbors (N):

$$C_{t,t-1} = CG_{t,t-1} + CN_{t,t-1} \quad (69.19)$$

and the same decomposition is used for the discordant pairs. This can be viewed in a number of ways. First, the contributions of the two types of pairs to the spatial level of concordance or discordance can be evaluated. Alternatively, the degree of rank concordance for the two sets of pairs of regions can be contrasted, by noting:

$$\tau_{t,t-1} = \omega_G \tau_{G,t,t-1} + \omega_N \tau_{N,t,t-1} \quad (69.20)$$

where ω_G is the share of all pairs that involve geographic neighbors and

$$\tau_{G,t,t-1} = \frac{CG_{t,t-1} - DG_{t,t-1}}{\omega_G n(n-1)/2} \quad (69.21)$$

This provides insight as to the role of spatial dependence in the overall degree of temporal rank concordance. By contrasting the degree of rank correlation for neighboring pairs of regions with that of geographically separated pairs, the degree to which distributional mixing is spatially clustered can now be estimated.

69.3.2 ESTDA Methods

For ESTDA methods the point of departure is a method that was originally developed for cross-sectional analysis. Typically this takes the form of a method designed to detect spatial autocorrelation, either as a global or local form. From here, a dynamic component is added to enable the analysis of spatial dynamics. A common strategy is the repeated application of Moran's I to a temporal sequence of measurements on a variable for regions. Moran's I in period t is given as

$$I_t = \frac{n}{S_0} \frac{\sum_{i=1}^n \sum_{j=1}^n z_{i,t} w_{ij} z_{j,t}}{\sum_{i=1}^n z_{i,t}^2} \quad (69.22)$$

where $S_0 = \sum_{i=1}^n \sum_{j=1}^n w_{ij}$ and $z_{i,t} = y_{i,t} - \bar{y}_{i,t}$, and w_{ij} is as defined in Eq. (69.14). Examples of this approach can be found in the convergence literature where a common finding has been that time series of global Moran's I values for per capita income/product display significant positive spatial autocorrelation over time but also the strength of that spatial clustering exhibited substantial temporal variation (Rey and Le Gallo 2009).

The same comparative static design has also been used to explore how local measures of spatial autocorrelation change over time. In a cross-sectional setting, local measures provide indications of departures of the overall pattern of global spatial dependence or allow for the detection of spatial outliers, hot spots and/or cold spots (Anselin 1995). In a similar vein, when extended to a space-time setting, this provides a useful complement to the comparative static analysis of global spatial autocorrelation dynamics. The focus remains on the relative stability of local spatial association patterns through time which is enabled through a comparison of a series of snapshots. The situation is more complex in the local case as now there are n values in each snapshot and their evolution over time increases the analytical demands relative to the global case in which only a single indicator is studied from a dynamic perspective.

Space-Time LISA: Closely related to the comparative static analysis of the LISA statistics is the bivariate LISA. The bivariate LISA modifies the original indicator

by shifting the time period for either the variable or the spatial lag of the variable. Two possibilities exist. The first consists of a temporal lag of the spatial lag:

$$L_{i,t} = z_{i,t} \sum_{j=1}^n w_{i,j} z_{j,t-k} \quad (69.23)$$

which relates the value at focal unit i in period t to that observed in its geographical neighborhood k periods previously. In the second form the shift is applied to the variate:

$$L_{i,t} = z_{i,t-k} \sum_{j=1}^n w_{i,j} z_{j,t} \quad (69.24)$$

The two forms lend themselves to different types of questions about local spatial dynamics that relate to the form and direction of the space-time spillover or diffusion. In the first form, if positive local space-time association was indicated, this would be consistent with inward diffusion from the surrounding units into the core focal unit. By contrast, the temporal lag of the focal unit in the second form means that any positive association revealed would be consistent with diffusion originating from that unit and spreading outward to the neighbors.

The bivariate LISA moves the ESTDA methods from a comparative static view toward an explicit consideration of spatial dynamics in the sense that the dependence between a measurement at one location and point in time is being related to a different location at a different point in time. This is an important shift because it reduces the gap between the patterns being observed and the underlying dynamic process that may be responsible for that pattern.

Nowhere is this more apparent than in the distinction between apparent and true contagions. The former arises from a spatial pattern that could be consistent with a dynamic process such as the spread of an infectious disease through contact of individuals in close proximity to one another. A single map displaying spatial autocorrelation of disease incidence would be consistent with the operation of such a process. However, there are other processes that could also give rise to the same pattern – such as when the disease incidence may be driven by environmental factors (i.e., contaminated water supplies). Based on the single map, it is impossible to identify which is the operative process.

With maps from multiple time periods, however, the possibility to differentiate between true and apparent contagions now exists. The key signature difference would be for the map pattern to change over time in the case of true contagion reflecting the transmission over space, while the area of high incidence would remain spatially fixed in the case of apparent contagion – assuming the focal source was spatially immobile.

In the bivariate LISA, outward diffusion can be represented on a scatterplot where the x-axis has the rate in an initial period and the y-axis measures the spatial lag of the rate in the future period. For inward diffusion, the x-axis has the rate in the

future period, while the y-axis depicts the spatial lag in the previous period. In other words, the spatial lag is shifted either backward (inward diffusion) or forward (outward diffusion) in time to depict different forms of spatial dynamics.

There are several complications in association with this interpretation of the bivariate LISA as an indicator of spatial dynamics. One difficulty is that these patterns are also consistent with spatial dependence that is not changing over time. For example, if there was positive spatial autocorrelation that was constant over time, then a bivariate correlation of a variable at time t and its spatial lag at time $t \pm k$ are likely to be positive. Because the correlation is positive for both the forward and backward time-shift of the spatial lag, the approach would yield indications of both false inward and outward contagions, when in fact the underlying spatial dependence has been constant over time.

Directional LISA: A number of extensions to the LISA in a dynamic context have recently been suggested as ways to address these issues. The first is directional LISA that explicitly considers the movement of the LISA statistic between a pair of periods (Rey et al. 2011). More specifically, two Moran scatterplots are compared: one for the initial period (Fig. 69.2a) and one for the end time period (Fig. 69.2b). Based on these, the movement vectors are extracted to form the directional Moran scatterplot (Fig. 69.2c). The movement vectors can be either origin or destination standardized, which then permits a visualization of the direction, magnitude, and any biases in the spatial dynamics between the two periods (Fig. 69.2d).

The characteristics of these movement vectors can be summarized using several new visualization or inferential tools. For the former, a rose diagram depicts the relative frequency of movement vectors providing insights as to the concentration and potential biases of movements observed over a period (Fig. 69.2e). Coupled with this is a computationally based approach to inference in which the extent of spatial dependence in the movement vectors is tested against a null hypothesis that an observation and its spatial lag move independently over the time period.

LISA Markov: Closely related to both the directional LISA and the original space-time bivariate LISA is the LISA Markov (Rey 2001). This extends the focus to consider a sequence of moves by the local statistics, not just one period as is the case for the directional LISA. This relies on the quadrants of the Moran scatterplot which are now used to define the states for a discrete Markov chain. The four quadrants are I (H,H), II (L,H), III (L,L), and IV (H,L) with the first position indicating whether the observations are above or below the mean, while the second does the same but for the spatial lag. These four states give rise to 16 types of transitions.

The 16 transition types offer a rich taxonomy for characterizing spatial dynamics. For example, the issue of outward and inward diffusion that was encountered in the discussion of the bivariate space-time LISA can now be associated with particular moves in this taxonomy. Outward diffusion would be reflected in transitions where the spatial lag increases in value over time and the core either declines or remains high: (H,L)–(H,H) or (H,L)–(L, H). The two cases allow for a differentiation between saturation diffusion, in the former, and displacement diffusion in the latter. For inward diffusion the relevant moves

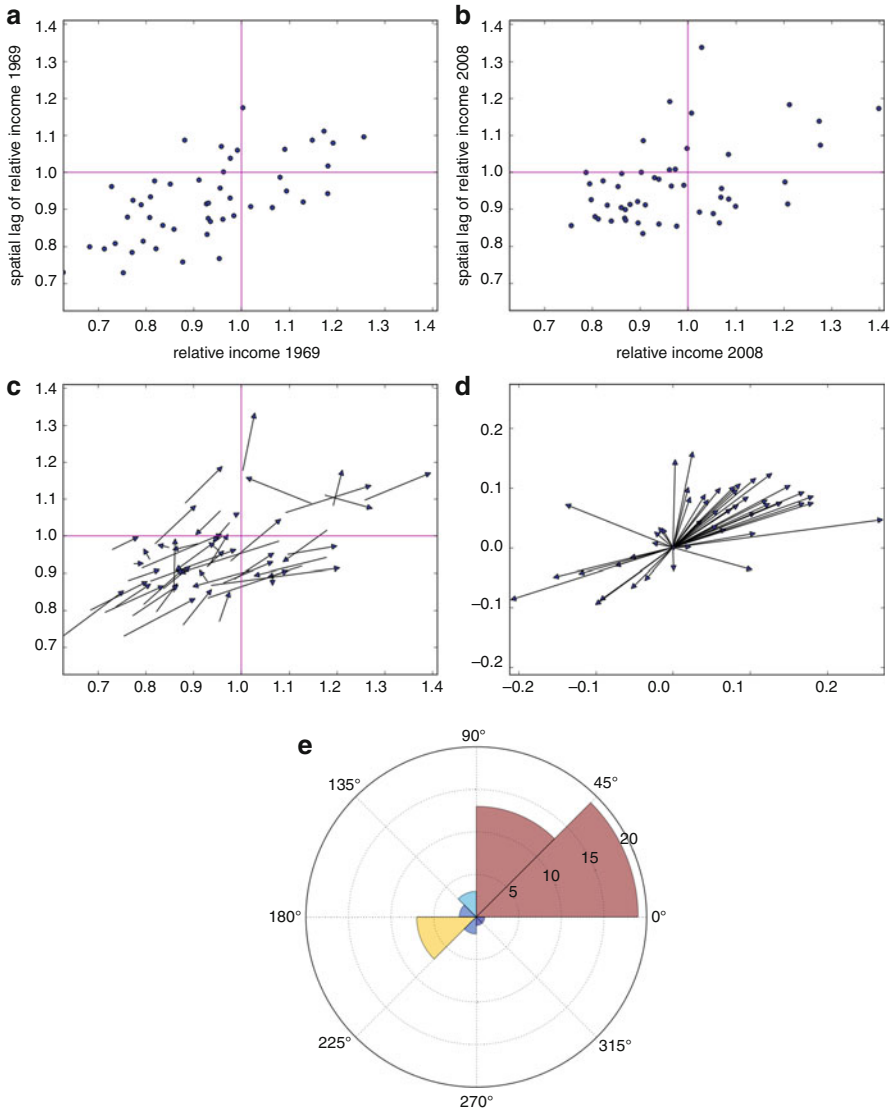

Fig. 69.2 Directional Moran scatter plots. (a) Moran scatter 1969. (b) Moran scatter 2008. (c) Unstandardized movement vectors. (d) Origin standardized movement vectors. (e) Rose diagram

would be (L,H)–(H,H) or (L,H)–(H,L); in either case the core increases over time, while the lag declines (displacement) or remains high (saturation).

Formal inference on these spatial dynamics has been suggested by Rey et al. (2012). The notion of a joint spatial Markov chain decomposes the spatial dynamics into two separate discrete chains, one for the original attribute and one for the spatial lag of this attribute. Each of these individual chains can occupy one of two

states in a given period, either (H) or (L). Letting $P(Y)$ represent the transition probability matrix for the original attribute chain and $P(WY)$ the transition probability matrix for the spatial lag of this attribute, under a null of independence (or lack of spatial dynamics), we have

$$P(\widetilde{Y}, \widetilde{WY}) = P(\widetilde{Y}) \otimes P(\widetilde{WY}) \quad (69.25)$$

where \otimes is the Kronecker product operator.

The estimated joint transition probability matrix from Eq. (69.25) is then compared to the observed joint transition probability matrix, $P(\widetilde{Y}, \widetilde{WY})$, and a formal test of the equality of these two transition matrices can be based on large sample theory for discrete Markov chains. Rejection of the equality hypothesis means that the two chains are non-separable. In other words, the dynamic transitions of the attribute lag values at a given location are not independent of the transitions of the spatial lag of these values.

In addition to providing a global test of spatial dynamics, comparison of the two estimated joint transition probability matrices allows for an identification of what types of moves are over, or under, represented in the observed spatial transitions, relative to the case where the dynamics displayed spatial randomness.

69.4 Conclusion

Regional science has long considered spatial dynamics as an organizing framework from which to view different regional phenomena. Regional growth theory by definition would not exist without a space-time framing. The inverted-U pattern proposed by Williamson (1965) of regional inequality provides a specific example where the level of regional inequality is viewed through a dynamic lens. While regional growth is a process that operates over space and time, the inverted-U framework is largely a-spatial as the regions are simply observational units used to measure dispersion in incomes. The actual location of these regions and issues of spatial interactions have not given explicit empirical treatment in this framework. As Miller (2006) has argued in the context of other areas of regional science, the spatial and temporal dimensions underlying human activity cannot be meaningfully separated. By the same token, regional science cannot be separated from a space-time framework or a consideration of spatial dynamics.

With recent technical and methodological developments in the areas of space-time data analysis, the possibility now exists to extend the traditional framework to include a richer spatial dynamics component, one that allows for a tighter linkage between abstract theoretical constructs and their empirical implementation. There are also gains to be had from applying some of these new measures of space-time dynamics to summarize outcomes of other types of modeling frameworks. For example, more comprehensive summaries of the predictions from land-use change models become possible. Similarly, the growing

use of agent-based models and cellular automata creates a need for efficient methods that can capture and summarize the spatial dynamics of these complex patterns generated from these frameworks.

Abstract

Spatial sampling is the process of collecting observations in a two-dimensional framework. Careful attention is paid to (1) the quantity of the samples, dictated by the budget at hand, and (2) the location of the samples. A sampling scheme is generally designed to maximize the probability of capturing the spatial variation of the variable under study. Once initial samples have been collected and its variation documented, additional measurements can be taken at other locations. This approach is known as second-phase sampling, and various optimization criteria have recently been proposed to determine the optimal location of these

new observations. In this chapter, we review fundamentals of spatial sampling and second-phase designs. Their characteristics and merits under different situations are discussed, while a numerical example illustrates a modeling strategy to use covariate information in guiding the location of new samples. The chapter ends with a discussion on heuristic methods to accelerate the search procedure.

70.1 Introduction

70.1.1 Context

According to Haining (2003), spatial or two-dimensional sampling has been applied to many disciplines such as mining, soil studies, telecommunications, ecology, geology, and geography, to cite a few (Akella et al. 2011). Scientists may be constrained by available budget and time to acquire a certain number of samples instead of trying to obtain information everywhere (Müller 1998; Thompson 2002; Delmelle 2009). It is generally desirable to find samples that are as representative as possible from the real data. Not only the cost of a complete census is prohibitive, it is time-consuming (Haining 1990) and it may result in redundant data when those are spatially autocorrelated (Griffith 2005). The autocorrelation function is defined as the similarity of the values of the variable of interest as a function of their separating distance (Gatrell 1979). This similarity decreases as the distance among sample points increases. Positive autocorrelation occurs when nearby observations are more alike than samples collected further away. Sparse sampling is less costly, but the variability of the variable of interest may go unnoticed. Consequently, not only the quantity of the samples is important but also their locations.

70.1.2 One-Dimensional Sampling

Pioneering research on sampling was devoted to one-dimensional problems (see, e.g., Cochran 1946; Madow 1946, 1953; Madow and Madow 1949). Cochran documented the efficiency associated with random sampling, systematic sampling, and stratified sampling. A *random sampling* scheme (Fig. 70.1a) allocates n sample points randomly within a population of interest. Each location is equally likely selected. In a *systematic random sampling* (Fig. 70.1b), the population is partitioned into a prespecified number of intervals. For each interval, a number of samples are collected, and the total of all samples is of size n . In a *systematic sampling* scheme (Fig. 70.1c), the population of interest is divided into n intervals of similar size. The first element is chosen within the first interval, starting at the origin, and the remaining $n - 1$ elements are aligned according to the same, fixed interval. A discussion of these configurations to the field of natural resources can be found in Stevens and Olsen (2004).

Fig. 70.1 One-dimensional sampling schemes for $n = 10$. The x -axis is partitioned in 10 intervals for cases (b) and (c). The random sampling locations have been generated using MATLAB rand function

70.1.3 Two-Dimensional Sampling

Necessary and common to both spatial and nonspatial sampling strategies are (i) the size of the sampling set, which is dictated by the budget (or time) at hand; (ii) the configuration of the sampling design; (iii) an estimator to characterize the population; and (iv) an estimation of the sampling variance to compute confidence intervals. Das (1950) has documented the variation of the sampling variance of two-dimensional designs. A *simple random sampling* design (Fig. 70.2a) randomly selects m sample points in a study region, generally denoted \mathcal{D} , where each location has an equal opportunity to be sampled. In a *systematic sampling* design, (illustrations given in Fig. 70.2b–d), the study region is discretized into m intervals of equal size Δ . The first element is randomly or purposively chosen within the first interval, and so are other points in the remaining regions. If the first sample is chosen at random, the resulting scheme is called *systematic random sampling*. When the first sample point is not chosen at random, the resulting configuration is called *regular systematic sampling*. A *centric systematic sampling* occurs when the first point is chosen in the center of the first interval, resulting in a checkerboard configuration. The most common regular geometric configurations are the equilateral triangular grid, the rectangular (square) grid, and the hexagonal one (Cressie 1991). The benefits of a systematic approach reside in a good spreading of observations across \mathcal{D} , guaranteeing a maximized sampling coverage, and preventing sampling clustering and redundancy. This design however presents two inconveniences:

- The distribution of separating distances in \mathcal{D} is not represented well because many pairs of points are separated by the same distances,
- If the spatial process shows evidence of recurrence, periodicities, there is a risk that the variation of the variable will remain uncaptured, because the systematic design coincides in frequency with a regular pattern in the landscape (Overton and Stehman 1993).

A *systematic random method* addresses the second concern since it combines both systematic and random procedures (Dalton et al. 1975). One observation is

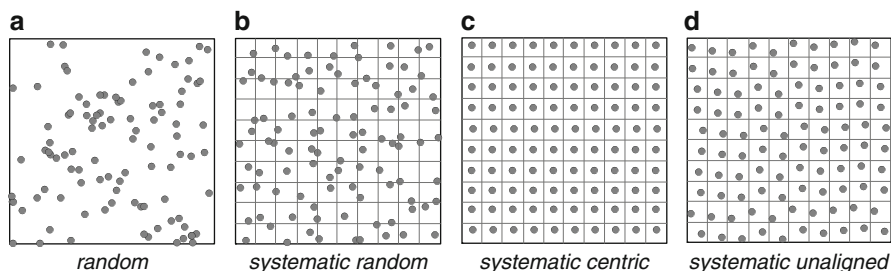

Fig. 70.2 Two-dimensional sampling schemes for $n = 100$. In figures (b), (c), and (d), both x - and y -axis have been divided into 10 intervals. Points were randomly generated using MATLAB rand function

randomly selected within each cell. However, sample density needs to be high enough in order to document the strength of the spatial relationship (e.g., variogram) among observations. From Fig. 70.2b, some patches of \mathcal{D} remain undersampled, while others regions show evidence of clustered observations. A *systematic unaligned* scheme prevents this problem from occurring by imposing a stronger restriction on the random allocation of observations (King 1969).

In *stratified sampling* (Delmelle 2009), the population (or \mathcal{D}) is partitioned into nonoverlapping strata. A set of samples is collected for each stratum, where the sum of the samples over all strata must equal m (strata may be of different size, for instance, a census tract). The knowledge of the underlying process is a determining factor in defining the shape and size of each stratum. Smaller strata are preferred in nonhomogeneous subregions.

Evaluation of Sampling Strategies. Following Quenouille's approach of a linear autocorrelation model, stratified random sampling is generally considered to yield a smaller variance than a systematic design. However, if the autocorrelation function is not linear (for instance, exponential), systematic sampling is the most efficient technique, followed by stratified random sampling and random sampling. Overton and Stehman (1993) presented some numerical results illustrating the magnitude of the differences of the three aforementioned designs under various population models. When sampling a phenomenon characterized by a regular pattern in the landscape, a systematic unaligned configuration is generally preferred (Delmelle 2009).

70.2 Geostatistical Sampling

An essential commonality of many natural phenomena is its spatial continuity in the geographical space. The field of geostatistics (Matheron 1963) provides a set of regression techniques to mathematically summarize the spatial variation of the phenomenon and use this information to predict the phenomenon under study at unsampled locations. Central to geostatistics is kriging, an interpolation technique that uses the semivariogram, a function which reflects the dissimilarity of pairs of points at different distance lags. The strength of this correlation determines the

weighting scheme used to create a prediction surface at unsampled locations, while minimizing the estimation error. As the distance separating two sample points increases, their similarity decreases and the influence on the weighting scheme diminishes. Beyond a specific distance called the range where autocorrelation is very small, the semivariogram flattens out (see, e.g., Ripley (1981) and Cressie (1991) for various summaries).

Mathematical Expression for Kriging. A variable of interest Y is collected at m supports within a study region \mathcal{D} . Using data values of the primary variable, an empirical semivariogram $\hat{\gamma}(h)$ summarizes the variance of values separated by a particular distance lag (h) :

$$\hat{\gamma}(h) = \frac{1}{2d(h)} \sum_{|s_i - s_j|=h} (y(s_i) - y(s_j))^2 \quad (70.1)$$

where $d(h)$ is the number of pairs of points for a given lag value, and $y(s_i)$ the observation value at location s_i . The semivariogram is characterized by a nugget effect a and a sill σ^2 where $\hat{\gamma}(h)$ levels out. The nugget effect reflects the spatial dependence at microscales, caused by measurement errors at distances smaller than sampling distances (Cressie 1991). Once the lag distance exceeds the range r , there is no spatial dependence between the sample sites anymore. The semivariogram function $\hat{\gamma}(h)$ becomes constant at a value called the sill σ^2 . A model $\gamma(h)$ is fitted to the experimental variogram, for instance, an exponential model:

$$\gamma(h) = \sigma^2 \left(1 - e^{-\frac{3h}{r}}\right) \quad (70.2)$$

In the presence of a nugget effect a , Eq. (70.2) becomes

$$\gamma(h) = a + (\sigma^2 - a) \left(1 - e^{-\frac{3h}{r}}\right) \quad (70.3)$$

Equation (70.4) denotes the corresponding covariogram $C(h)$ that summarizes the covariance between any two points:

$$C(h) = C(0) - \gamma(h) = \sigma^2 - \gamma(h) \quad (70.4)$$

The interpolated, kriged value at a location \mathbf{s} in space is given as a weighted mean of surrounding values, where each value is weighted according to the variogram model:

$$\hat{y}(\mathbf{s}) = \sum_{i=1}^W w_i(\mathbf{s})y(s_i) \quad (70.5)$$

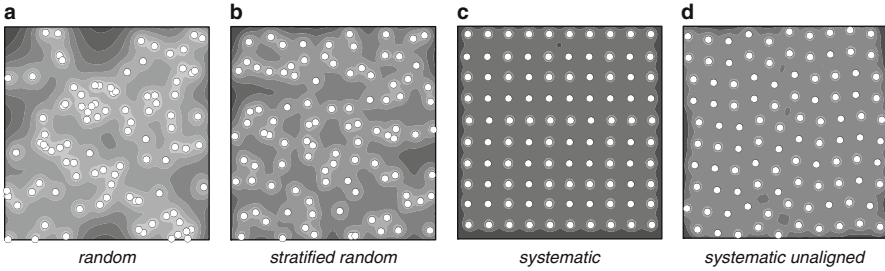

Fig. 70.3 Kriging variance associated with the two-dimensional sampling schemes of Fig. 70.3

where W is the set of neighboring points that are used to estimate the interpolated value at location \mathbf{s} , and $w_i(\mathbf{s})$ is the weight associated with each surrounding point, which is a function of the semivariogram function. The weight of each sample can be determined by an exponential function (Eq. (70.2)). For computational purposes, kriging is performed on a set of grid nodes \mathbf{s}_g ($g = 1, 2, \dots, G$). Kriging yields an associated variance that measures the prediction uncertainty. The kriging variance at a location \mathbf{s} is given by

$$\sigma_k^2(\mathbf{s}) = \sigma^2 - \mathbf{c}^T(\mathbf{s})\mathbf{C}^{-1}\mathbf{c}(\mathbf{s}) \tag{70.6}$$

where \mathbf{c}^T is the transpose of the covariance matrix \mathbf{C} based on the covariogram function and \mathbf{C}^{-1} its inverse. The overall kriging variance (σ_k^2) is obtained by integrating Eq. (70.6) over the region \mathfrak{D} . Computationally, it is easier to perform a spatial of \mathfrak{D} and sum the kriging variance over all grid points \mathbf{s}_g :

$$\int_{\mathfrak{D}} \sigma_k^2(\mathbf{s}_g) \approx \frac{1}{G} \sum_{g \in G} \sigma_k^2(\mathbf{s}_g) \tag{70.7}$$

The kriging variance can be calculated with an estimated variogram and the known location of existing sampling points. The kriging variance solely depends on the spatial dependence and configuration of the observations (Cressie 1991). Figure 70.3 summarizes the variation in the kriging variance estimate for the four designs of Fig. 70.2.

Van Groenigen et al. (1998, 1999) suggest that initial sampling schemes should be optimized for a reliable estimation of the variogram function, which can either be used for the prediction of the variable under study or to help designing additional sampling phase(s). For the former, two strategies have been suggested in the literature:

- (a) A geometric coverage of sample points over the study region is generally desirable to guarantee enough pairs of points at different distances.
- (b) Points need to be distributed in the multivariate field to capture as much variation as possible.

Moreover, optimal sampling strategies exist to reduce the kriging variance associated with the interpolation process. The next paragraphs illustrate three common objectives in spatial sampling: variogram estimation, minimization of the kriging variance, and sampling in a multivariate field.

70.2.1 Designs for Variogram Estimation

Traditional ways to evaluate the goodness of a sampling scheme do not incorporate the spatial structure of the variable. The increasing use of geostatistics as a least-squares interpolation technique, however, has fostered research on optimizing sampling configurations to maximize the amount of information obtained during a first sampling phase. Matérn (1960) and Yfantis et al. (1987) have suggested that the use of an equilateral triangular sampling grid (Fig. 70.4) can yield to a very reliable estimation of the variogram and predict the mean over a study region, assuming radially symmetric, decreasing covariances.

Systematic designs (Fig. 70.2c, d) offer the advantage of good coverage of observations, capturing the main features of the variogram (Van Groenigen et al. 1999). It may be necessary to strategically design a scheme where a subset of the observations are evenly spread across the study area and the remaining points clustered together to capture the autocorrelation function at very small distances (Delmelle 2009).

The reliability of the variogram function depends on the number of pairs of points within each distance band. Russo (1984) and Warrick and Myers (1987) have proposed some strategies to reproduce an a priori defined ideal distribution of pairs of points, based on a given variogram function. The procedure allows to account for the variation in distance and direction (anisotropy¹). Corsten and Stein (1994) use a nested sampling design for a better estimation of the nugget effect. A nested sampling design consists of taking observations according to a hierarchical scheme, with decreasing distances between observations. This type of sampling scheme distributes a high number of observations in some parts of the area and a low observation density in other regions. This in turn generates only a few distances for which variogram values are available. Taking into account a prior information of the spatial structure of the variable and assuming a stationary variable, Van Groenigen and Stein (1998) have combined two different objectives to allocate samples during an initial phase. The first objective called the Warrick/Myers criterion ensures optimal estimation of the covariogram and aims at redistributing pairs of points over the distance and direction lags according to a prespecified distribution. The second criterion, called *minimization of the mean of the shortest distances* (MMSD), requires all sampling points spread evenly to ensure that

¹Anisotropy is a property of a natural process, where the autocorrelation among points changes with the distance and direction between two locations. We talk about an isotropic process however when there is no effect of direction in the spatial autocorrelation of the primary variable.

Fig. 70.4 Three common geometric sampling schemes

unsampled locations are never far from a sampling point. The second criterion suggested by the authors is of deterministic nature, resulting an even spreading pairs of points across the study area, which is similar in nature to a systematic pattern.

70.2.2 Optimal Designs to Minimize the Kriging Variance

The kriging procedure generates a minimum-error estimate of the variable of interest. This uncertainty is minimal – or zero when there is no nugget effect – at existing sampling points and increases with the distance to the nearest samples. One approach suggested in the literature is to design a sampling configuration to minimize this uncertainty. Since continuous sampling is not feasible, seeking the best sampling procedure must be carried out on a discretized grid. Using an a priori variogram model (Eq. (70.4)), it is possible to design an initial sampling scheme S to minimize the overall kriging variance (Eq. (70.8)) or the maximum kriging variance (Eq. (70.9)).

$$\underbrace{\text{MINIMIZE}}_{\{s_1, \dots, s_m\}} J(S) = \frac{1}{G} \sum_{g \in G} \sigma_k^2(s_g; S) \tag{70.8}$$

$$\underbrace{\text{MINIMIZE}}_{\{s_1, \dots, s_m\}} J(S) = \frac{1}{G} \sup_{g \in G} \{ \sigma_k^2(s_g; S) \} \tag{70.9}$$

Burgess et al. (1981) estimate kriging variances for different scenarios of sampling densities, nugget effects, and size of study regions. The strategy attempts to identify the minimum number of samples necessary to reach a certain level of kriging variance. General findings are the increase of the prediction error as the nugget effect increases or when the sampling density is reduced. An equilateral

triangular configuration of sampling points (Fig. 70.4c) is best under isotropic conditions, but a square grid at the same density is nearly as good, and is preferred for data collection convenience. An equilateral triangle design will keep the variance to a minimum, because it reduces the farthest distance from initial sample points to nonsample points. A square grid performs well, especially in case of isotropy (McBratney and Webster 1981; McBratney et al. 1981). When directional discontinuities are present, a square grid pattern is preferred (Olea 1984; Yfantis et al. 1987).

70.2.3 Sampling in a Multivariate Context

McBratney and Webster (1983) have discussed the importance of spatial sampling to multivariate fields. Sample data can be very difficult to collect, and very expensive, especially when monitoring air or soil pollution, for instance (Haining 1990). Secondary data can be a valuable asset if they are available continuously over a study area and combined within the primary variable (Hengl et al. 2003). Secondary spatial data sources can include maps, digital elevation models, and national, socioeconomic, and demographic census data. Cross-variograms express the spatial relationships among those variables. In turn, this information is capitalized to calibrate the parameters of the kriging equations. When the variogram of the primary variable and the cross-variograms are known a priori, an improved sampling configuration can be obtained. A rule of thumb consists of locating the observations of the main variable where covariates exhibit substantial spatial variation (Delmelle and Goovaerts 2009). Secondary variables should be used to reduce the sampling effort in areas where their local contribution in predicting the primary variable is maximum (Delmelle 2009). If a set of covariates predicts accurately the data value where no initial sample has been collected yet, there is little incentive to perform sampling at that location. On the other hand, when covariates perform poorly in estimating the primary variable, additional samples are necessary.

70.3 Second-Phase Sampling

Second-phase spatial sampling is defined as the addition of new observations to improve the overall prediction of the variable of interest. A set M of m initial measurements has been collected, and a variogram that summarizes the spatial structure of the variable of interest will help to determine the location and size for an additional set and location of their samples. It is generally agreed in the literature that the objective function aims to collect new samples to reduce the prediction error (kriging variance) by as much as possible.

Mathematical Expression for Minimizing of the Kriging Variance in a Second Phase. We add a set of n new sample points to the initial sample set of size m .

Using the variogram function from the first sample set, the change in kriging variance $\Delta\sigma_k^2$ is over all grid points \mathbf{s}_g :

$$\Delta\sigma_k^2 = \frac{1}{G} \left[\sum_{g \in G} \sigma_k^{\text{old}}(\mathbf{s}_g) - \sum_{g \in G} \sigma_k^{\text{new}}(\mathbf{s}_g) \right] \quad (70.10)$$

where σ_k^{old} is the mean kriging variance calculated with the set of $[m]$ initial sample points and σ_k^{new} is the mean kriging variance with the $[m+n]$ additional set of points. From Eq. (70.10)

$$\sigma_k^{\text{old}}(\mathbf{s}_g) = \sigma^2 - \underbrace{\mathbf{c}(\mathbf{s}_g)}_{[1,m]} \times \underbrace{\mathbf{C}^{-1}}_{[m]} \times \underbrace{\mathbf{c}^T(\mathbf{s}_g)}_{[m,1]} \quad (70.11)$$

$$\sigma_k^{\text{new}}(\mathbf{s}_g) = \sigma^2 - \underbrace{\mathbf{c}(\mathbf{s}_g)}_{[1,m+n]} \times \underbrace{\mathbf{C}^{-1}}_{[m+n]} \times \underbrace{\mathbf{c}^T(\mathbf{s}_g)}_{[m+n,1]} \quad (70.12)$$

The objective function helps to locate the set of additional n points that will maximize this change in kriging variance (Christakos and Olea 1992; Van Groenigen et al. 1999; Rogerson et al. 2004). The n additional points are to be chosen from a set of size $(N - m)$, that is, all possible sample sites in \mathcal{D} except the m ones selected during the first sampling phase. In that case, there are $\binom{N-m}{n}$ possible combinations and it is almost impossible to find the optimal using. The objective function is formulated as follows:

$$\underbrace{\text{MAXIMIZE}}_{\{s_{m+1}, \dots, s_{m+n}\}} J(S) = \frac{1}{G} \sum_{g \in G} \Delta\sigma_k^2(s_g; S) \quad (70.13)$$

Incorporating Secondary Information in a Second Sampling Phase. New samples can be collected in areas where secondary variables do not provide good estimates of the primary variable. Consider the situation where the primary data is supplemented by k additional secondary variables X_i ($\forall i = 1, \dots, k$) available at G grid nodes \mathbf{s}_g ($g = 1, 2, \dots, G$). Local regression techniques such as geographically weighted regression (Brunsdon et al. 1996) provide locally linear regression estimates at every point i , using distance weighted samples. Our goal is to sample in those areas characterized by low local r^2 , since it is in those areas that covariates are not performing well in predicting the outcome of the primary variable. A local r^2 can be conceived as how well covariates predict the main variable locally, for instance, from a GWR model.

Formulating the Second-Phase Sampling Problem. This approach is proposed by Cressie and has been applied by Rogerson et al. (2004) and Delmelle and

Goovaerts (2009) to weight the kriging variance, where the importance of a location to be sampled is represented by a weight $w(s)$, which is location specific.

$$\underbrace{\text{MAXIMIZE}}_{\{s_{m+1}, \dots, s_{m+n}\}} J(S) = \frac{1}{G} \sum_{g \in G} w(s_g) \Delta \sigma_k^2(s_g; S) \quad (70.14)$$

The weight should reflect the importance provided locally by covariates, but could also account for the rapid change in spatial structure of the primary variable at s_g (Delmelle and Goovaerts 2009).

70.4 Numerical Example

A numerical example is provided to gain insight into the structure of the sampling problem. The goal is to maximize the change in the weighted kriging variance. As a hypothetical example, we simulated a synthetic snowfall data in a 10×10 km bounding box.

Minimizing the Kriging Variance. Figure 70.5 displays the initial set of 50 measurements and the associated interpolated map, based on an exponential semivariogram with a range of 3,000 m, a nugget effect $C(0) = 0$, and sill $a = 0.025$. The amount of snowfall is simulated to be minimal in the upper northwestern corner and increases steadily southeastwards. Figure 70.6 on the left is an interpolated contour map of the prediction error. The variance increases away from existing data points, to reach maximum values in the corner of the study area. The right figure displays the discretized study area, generating a set $P = 51 \times 51$ potential points. If the goal is to maximize the change in kriging variance only (Eq. (70.13)), the location of the new points would be far away from existing ones.

Weights to Reflect Sampling Priorities. An example of sampling weights is given in Fig. 70.3 on the left and is multiplied by the kriging variance on the right. As a result of this multiplication, some locations exhibiting high weight for second-phase sampling (where we observe a stronger variation in the spatial structure of the primary variable) may not be recommended for further sampling since they are located in the close vicinity of an existing initial sampling point. For instance, on the left figure, the location $[6, 705, 000; 4, 718, 500]$ is characterized by a high sampling weight. However, the region has already been sampled and consequently the likelihood for second-phase sampling decreases. Consider that we have the intention to add one sample point that would optimize Eq. (70.14). To find the point that would maximize the change in kriging variance, summed over all grid points, an iterative procedure is necessary which evaluates the score of each candidate sample points to the objective function. Such an enumeration can be very time-consuming, and for computational purposes, it is less demanding to select a point where the weighted kriging variance value is maximum. From Fig. 70.7, the location of the point exhibiting the maximum weighted kriging variance was

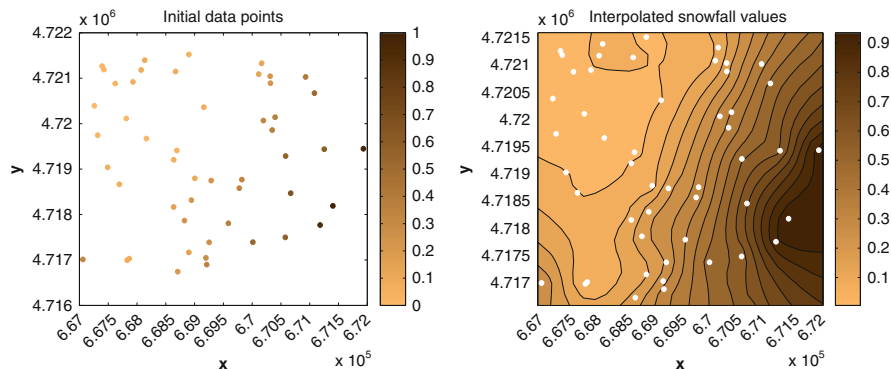

Fig. 70.5 Dark colors denote regions characterized by heavier amounts of snow. Units are in feet

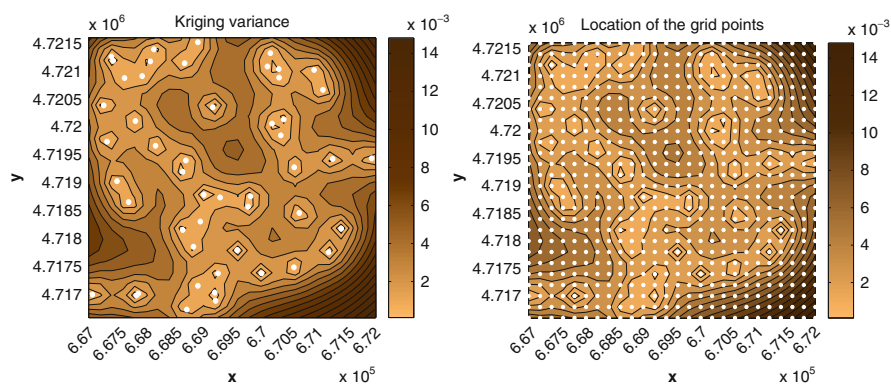

Fig. 70.6 The prediction error on the left and the location of grid nodes s_g

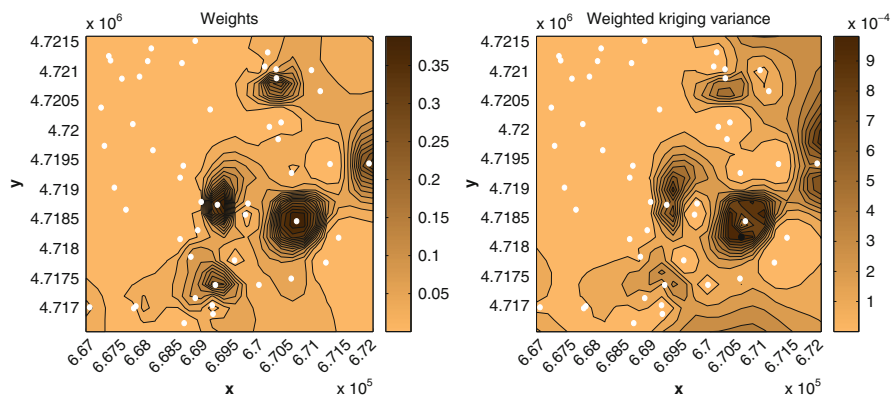

Fig. 70.7 Combined objectives 2 and 3 (on the left), multiplied with the kriging variance (on the right)

[6, 70, 600; 4, 718, 200]. Once an optimal (or near optimal) point has been added, it is possible to recompute the objective function. It is also desirable to adapt the constraints as the iteration continues.

70.5 Search Strategies

The set of candidate sampling locations may be large, and it is desirable to rely on heuristic techniques to return an acceptable solution in a limited time frame. A heuristic guides the search towards a sample set S that is optimal (or near optimal) to a predefined objective function, for instance, the set S^* is optimal to the objective function J defined in Eq. (70.14). The efficiency of a heuristic depends on its capacity to give as often as possible a solution close to S^* . In second-phase sampling, a heuristic that would select m points at random would not return a very good value for J . Examples of search techniques include the *greedy* algorithm, *simulated annealing*, *tabu search*, and *genetic algorithms*, among others (Christakos and Olea 1992; Delmelle and Goovaerts 2009). The *greedy* algorithm builds a solution sequentially only accepting improving moves, while the other methods improve the value of the objective function by iterations starting from an initial solution s_0 , but also accepting non-improving moves. Specifically, the three first methods usually remain stuck in a local optimum while the last three – also called *metaheuristics* – may find the optimal solution s^* . Greedy leads to a unique solution S_0^+ and does not explore the entire set of candidate samples. *Simulated annealing* authorizes to occasionally decrease the objective function (in our case to be maximized) in order to continue exploring for better solutions. Note that the simulated annealing algorithm does not always converge. Both *tabu search* and *genetic algorithm* techniques have not been applied to sampling optimization. They both lead to an optimal solution, yet the tabu search algorithm tends to cycle.

70.6 Conclusion

Accurate and effective spatial sampling strategies are very important when researchers are limited by their available budget (or time). A careful design is crucial to identify the main features of the phenomenon under study and avoid that its spatial characteristics remain unnoticed. For instance, incorporating some randomness in a systematic sampling design may be useful to document patterns with periodicities. Once initial samplings have been collected, a variogram can be built, which ultimately helps designing a second-phase sampling survey (away from existing samples and where the variation is maximum). When the set of candidate locations is large and the objective nonlinear, heuristic methods may be necessary to find a set optimal to some sampling criteria. The methods illustrated in this chapter may easily be extended to areal data (for instance, census tracts or socio-economic strata). Some areas may be deemed more important for sampling, and the proposed objectives are flexible to reflect sampling priorities.

Abstract

Bayesian inference has been at the center of the development of spatial statistics in recent years. In particular, Bayesian hierarchical models including several fixed and random effects have become very popular in many different fields. Given that inference on these models is seldom available in closed form, model fitting is usually based on simulation methods such as Markov chain Monte Carlo.

However, these methods are often very computationally expensive and a number of approximations have been developed. The integrated nested Laplace approximation (INLA) provides a general approach to computing the posterior marginals of the parameters in the model. INLA focuses on latent Gaussian models, but this is a class of methods wide enough to tackle a large number of problems in spatial statistics.

In this chapter, we describe the main advantages of the integrated nested Laplace approximation. Applications to many different problems in spatial statistics will be discussed as well.

71.1 Introduction

Spatial models provide a suitable way of analyzing data when observations are thought to be correlated because of their locations in space. Bayesian inference has proven useful when dealing with spatial models and modeling local dependence. In Bayesian analysis (see, e.g., Gelman et al. 2003), inference about the vector of model parameters \mathbf{x} is based on computing their joint posterior distribution given the vector of observed data \mathbf{y} . This is done by means of Bayes' rule:

$$\pi(\mathbf{x}|\mathbf{y}) \propto \pi(\mathbf{y}|\mathbf{x})\pi(\mathbf{x})$$

Here $\pi(\mathbf{y}|\mathbf{x})$ represents the likelihood of the model given its parameters and $\pi(\mathbf{x})$ is the prior distribution of the parameters of the model. Hence, the posterior distribution depends on the mechanism which generates the data (i.e., the likelihood) and the previous information about the model parameters (i.e., the prior distribution). Note that $\pi(\mathbf{x})$ is often supposed to depend on some hyperparameters which in turn have their own prior distributions.

$\pi(\mathbf{x}|\mathbf{y})$ is a multivariate distribution of the ensemble of model parameters which is often hard to obtain. In many applications it is sufficient with obtaining a separate posterior distribution for some of the parameters in the model because no joint inference is needed (e.g., the estimates of the relative risk in different areas). These distributions are called posterior marginals and can be denoted $\pi(x_i|\mathbf{y})$.

As these are univariate distributions, they are often easier to compute or approximate than the joint posterior distribution.

Given that in most cases there is no closed form for the posterior distributions of most parameters in the model, Markov chain Monte Carlo

(MCMC, see Gelman et al. 2003) techniques have been employed to estimate the joint posterior. Furthermore, a number of sound techniques for model criticism, comparison, and selection make Bayesian inference appealing.

For models with complex spatial dependence or large datasets, MCMC may not be a convenient solution due to computational time. For this reason, Rue et al. (2009) propose the use of approximate inference based on what they have called the integrated nested Laplace approximation (INLA). This approximation will focus on the posterior marginals which are easier to compute than obtaining an approximation to the joint posterior distribution. Also, INLA will only consider approximations for hierarchical models whose latent effects can be expressed as a Gaussian Markov random field (GMRF).

Successful applications of INLA include disease mapping (Schroedle et al. 2011), geostatistics (Eidsvik et al. 2009), point patterns (Illian et al. 2012), and others (Martino and Rue 2010).

71.2 Integrated Nested Laplace Approximation

The integrated nested Laplace approximation (INLA) focuses on providing a good approximation to the posterior marginal distributions of the parameters in the model. In particular, this approximation has been developed for latent Gaussian models. These cover a general class of models which appear in many areas of interest. Spatial statistics is one of them, as spatial correlation can be introduced by means of correlated random effects.

First of all, let us assume that we have n observed variables $y_i, i = 1, \dots, n$ with a distribution (usually from the exponential family) with a mean μ_i which is related to a linear predictor η_i through a convenient link function. In turn, η_i is modeled additively on different effects:

$$\eta_i = \alpha + \sum_{j=1}^{n_f} f^{(j)}(u_{ji}) + \sum_{k=1}^{n_\beta} \beta_k z_{ki} + \varepsilon_i$$

Here, $f^{(j)}$ represents some nonlinear function or random effects (of which there are n_f) on a set of covariates \mathbf{u} , β_k are coefficients for linear effects on a vector of covariates \mathbf{z} , and ε_i are unstructured terms. The latent effects $\mathbf{x} = \{\{\eta_i\}, \alpha, \{\beta_k\}, \dots\}$ are assumed to be Gaussian with zero mean and precision matrix $\mathbf{Q}(\theta_1)$, where θ_1 is a vector of hyperparameters. Hence, the observations will have a likelihood which will depend on the latent effects \mathbf{x} and a set of parameters θ_2 . Furthermore, the observations y_i are supposed to be independent given \mathbf{x} and θ_2 .

In the particular case of spatial statistics, the terms $f^{(j)}(u_{ji})$ can be taken as $f_i^{(j)}$ (or u_i abusing of notation) to represent a random effect at a spatial location i . Hence, covariate u_{ji} acts as the spatial index i of area i for the set of random effects j . For example, taking $n_f = 2$ we can define $u_i = f^1(u_{1i})$ and $v_i = f^2(u_{2i})$,

where $\mathbf{u} = \{u_1, \dots, u_n\}$ is a vector of independent random effects and $\mathbf{v} = \{v_1, \dots, v_n\}$ is a vector of spatially correlated random effects.

Rue et al. (2009) focus on the posterior distribution of \mathbf{x} and the vector of hyperparameters $\theta = (\theta_1, \theta_2)$:

$$\pi(\mathbf{x}, \theta | \mathbf{y}) \propto \pi(\theta) \pi(\mathbf{x} | \theta) \prod_{i \in \mathcal{I}} \pi(y_i | x_i, \theta) \propto \pi(\theta) |\mathbf{Q}(\theta)|^{n/2} \exp \left\{ -\frac{1}{2} \mathbf{x}^T \mathbf{Q}(\theta) \mathbf{x} + \sum_{i \in \mathcal{I}} \log(\pi(y_i | x_i, \theta)) \right\}$$

Here \mathcal{I} is the subset of indices (from 1 to length of \mathbf{x} , the number of latent effects) that are observed with observations \mathbf{y} and their respective linear predictors $\{\eta_i\}$. Note that η_i is the only observed latent effect (through y_i) and that all the other latent effects are not observed directly and need to be estimated. In addition, the latent effects may be subject to some linear constraints of the form $\mathbf{A}\mathbf{x} = \mathbf{e}$. Finally, the latent field is supposed to have conditional independence properties, so that \mathbf{x} becomes a Gaussian Markov random field (GMRF). As we will show later, these Markov properties play an important role when modeling spatial data.

The likelihood of the data $\pi(\mathbf{y} | \mathbf{x}, \theta)$ is not constrained to be Gaussian. At the moment, INLA can deal with several likelihoods from the exponential family as well as with mixtures, such as zero-inflated distributions. Furthermore, INLA is flexible enough to allow different observations to have different likelihoods. Hence, INLA can deal with a myriad of models.

Instead of aiming at the full posterior distribution of the model parameters \mathbf{x} and θ , Rue et al. (2009) focus on obtaining an approximation to the posterior marginal distributions $\pi(x_i | \mathbf{y})$ and $\pi(\theta_j | \mathbf{y})$. These marginals can be written down as

$$\pi(x_i | \mathbf{y}) \propto \int \pi(x_i | \theta, \mathbf{y}) \pi(\theta | \mathbf{y}) d\theta$$

and

$$\pi(\theta_j | \mathbf{y}) \propto \int \pi(\theta | \mathbf{y}) d\theta_{-j}$$

Here θ_{-j} denotes θ minus component θ_j .

The approximations will be for the conditional distributions in the right-hand sides of the previous expressions. Note that an approximation to $\pi(\theta | \mathbf{y})$ is also required and that numerical integrations will be feasible only if the dimension of θ is small (as it often happens in practice).

A first approximation to $\pi(\theta | \mathbf{y})$ using Gaussian distributions can be constructed as follows:

$$\tilde{\pi}(\theta | \mathbf{y}) \propto \frac{\pi(\mathbf{x}, \theta, \mathbf{y})}{\tilde{\pi}_G(\mathbf{x} | \theta, \mathbf{y})} \Big|_{\mathbf{x}=\mathbf{x}^*(\theta)}$$

$\tilde{\pi}_G(\mathbf{x}|\theta, \mathbf{y})$ is the Gaussian approximation to the full conditional of \mathbf{x} and $x^*(\theta)$ is the mode of the full conditional for a given value of θ .

Hence, the marginals of interest can be computed using numerical integration over a multidimensional grid of values of θ . For example,

$$\tilde{\pi}(x_i|\mathbf{y}) = \sum_k \tilde{\pi}(x_i|\theta_k, \mathbf{y}) \times \pi(\theta_k|\mathbf{y}) \times \Delta_k$$

where Δ_k represents the weights for each vector of values θ_k in the grid.

Rue and Martino (2007) and Rue et al. (2009) stress the importance of having a good approximation to $\pi(x_i|\theta, \mathbf{y})$. A Gaussian approximation $\tilde{\pi}_G(x_i|\theta, \mathbf{y})$ is based on using a normal distribution with mean $\mu_i(\theta)$ and marginal variance $\sigma_i^2(\theta)$. The approximation provided by INLA (and in particular the Gaussian approximation for $\pi(\mathbf{x}|\theta, \mathbf{y})$) is exact for Gaussian data and the approximation is only due to integration (with respect to θ) error. This may be a good starting point, but it may not suffice because of possible inaccuracy if it is not centered at the correct point and because of its lack of skewness.

For this reason, they also propose other alternatives such as the Laplace approximation and the *integrated nested Laplace approximation (INLA)*. Firstly, an improved approximation may be obtained by using a Laplace approximation:

$$\tilde{\pi}_{LA}(x_i|\theta, \mathbf{y}) \propto \frac{\pi(\mathbf{x}, \theta, \mathbf{y})}{\tilde{\pi}_{GG}(\mathbf{x}_{-i}|x_i, \theta, \mathbf{y})} \Big|_{\mathbf{x}_{-i}=\mathbf{x}_{-i}^*(x_i, \theta)}$$

Here $\tilde{\pi}_{GG}(\mathbf{x}_{-i}|x_i, \theta, \mathbf{y})$ is a Gaussian approximation to $\mathbf{x}_{-i}|x_i, \theta, \mathbf{y}$ which is centered around the mode $\mathbf{x}_{-i}^*(x_i, \theta)$. As this approximation must be computed for every x_i , some numerical techniques are required to speed up computation.

Finally, Rue et al. (2009) derive a simplified Laplace approximation to improve the approximation given by $\tilde{\pi}_{LA}(x_i|\theta, \mathbf{y})$ by means of a series expansion of the Laplace approximation around $x_i = \mu_i(\theta)$. This provides a better approximation and it corrects for location and skewness. As $\tilde{\pi}_{LA}(x_i|\theta, \mathbf{y})$ is very expensive to compute, the simplified Laplace approximation seems the best trade-off between speed and accuracy.

It should be noted that while these approximations will center on the posterior marginal of a single latent effect x_i or hyperparameter θ_i , the methodology behind them could be applied to obtain an approximation of the joint posterior of any subset S of latent effects \mathbf{x}_S (see Sect. 6.1, Rue et al. 2009). However, in that case, the approximations become more complex and the numerical integration needed is more demanding.

71.2.1 Gaussian Markov Random Fields

Approximate inference using INLA is based on the assumption that the latent field \mathbf{x} is Gaussian and fulfills some conditional independence properties. In particular,

any two latent effects x_i and x_j in \mathbf{x} should be independent given the remaining latent effects \mathbf{x}_{-ij} . Furthermore, the number of hyperparameters appearing in the distribution of \mathbf{x} is assumed to be small.

Rue and Held (2005) provide a description of methods for efficient computation of Gaussian Markov random fields (GMRF) which can be used to speed up computations and provide fast approximations. GMRF are the key to providing good Gaussian approximations for the posterior marginals. INLA is based on providing Gaussian approximations to densities like

$$\pi(\mathbf{x}|\theta, y) \propto \exp\left\{-\frac{1}{2}\mathbf{x}^T\mathbf{Q}\mathbf{x} + \sum_{i \in \mathcal{I}} \log(y_i|x_i, \theta)\right\}$$

where \mathbf{Q} is the precision matrix of the GMRF. Note that if \mathbf{Q} is a known matrix, its determinant (sometimes termed Jacobian) can be ignored at this stage as the posterior distribution can be rescaled later. This distribution may be subject to a set of linear constraints $\mathbf{A}\mathbf{x} = \mathbf{e}$. In any case, the approximation will result in a Gaussian distribution with mean \mathbf{x}^* and precision matrix $\mathbf{Q}^* = \mathbf{Q} + \text{diag}(\mathbf{c}^*)$ (see Rue et al. 2009, Sect. 2 for details). If linear constraints are present, the mean and precision matrices of the Gaussian approximation are conveniently corrected.

These constrained models are useful for fitting geostatistical models and adjacency-based spatial correlation effects for areal data (e.g., using an intrinsic conditional autoregressive model). Other spatial and temporal random effects can be modeled by using intrinsic GMRFs with linear constraints (see Rue and Held 2005, Chap. 3). Linear constraints are often employed to impose a sum-to-zero constraint on intrinsic GMRFs in order to make these effects identifiable. This is particularly important when dealing with complex spatiotemporal effects (Knorr-Held 2000).

71.2.2 Priors

So far, we have dealt with how the likelihood and the latent Gaussian Markov random fields are defined. As in all Bayesian approaches, a set of priors needs to be assigned to the parameters.

First of all, covariate coefficients in the linear predictor will be assigned a normal distribution with zero mean and precision τ . A similar distribution will be used for the random errors ε_i .

In principle, the latent random effects will be all Gaussian with zero mean. Hence, only the parameters in the precision matrix will need a prior. For the case in which the precision matrix is of the form $\tau\mathbf{Q}$, where \mathbf{Q} is a known matrix, τ can be assigned either a gamma, truncated normal, or improper flat (in the log-scale) prior. If the whole precision matrix is to be assigned a prior, then a Wishart distribution is available for correlated random effects of small dimension (up to 5). Finally, the INLA software provides other prior distributions. For example, correlation parameters, such as the ones used to model spatial autocorrelation, can be assigned a beta prior.

Note that, for simple models, these choices are equivalent to setting a conjugate prior distribution and that in all cases the prior parameters are supposed to be known (i.e., these cannot be assigned a prior in turn). It should be mentioned that these priors are the ones implemented in the INLA software (available from <http://www.r-inla.org>), but user-defined priors can be used as well by providing the mathematical expression for them.

Other priors can be built on upon simpler prior specifications. For example, spatially varying coefficients on a covariate can be implemented by using a prior which is the sum of independent and spatially correlated random effects. More information about how priors can be specified are available at <http://www.r-inla.org/models/priors>.

71.2.3 Model Criticism and Selection

INLA provides a number of ways of comparing and assessing models. First of all, an approximation to the marginal likelihood $\pi(\mathbf{y})$ is provided. This approximation is based on

$$\tilde{\pi}(\mathbf{y}) = \int \frac{\pi(\mathbf{x}, \theta, \mathbf{y})}{\pi_G(\mathbf{x}|\theta, \mathbf{y})} \Big|_{\mathbf{x}=\mathbf{x}^*(\theta)} d\theta$$

where $\pi(\mathbf{x}, \theta, \mathbf{y}) = \pi(\theta)\pi(\mathbf{x}|\theta)\pi(\mathbf{y}|\mathbf{x}, \theta)$. Models with a larger value of the marginal likelihood will be preferred. Also, marginal likelihood can be used to compute Bayes factors in order to compare models.

Predictive measures can also be computed very easily. In particular, INLA can compute the predictive distribution of y_i given all the other observations, that is, $\pi(y_i|\mathbf{y}_{-i})$. Following Pettit (1990), INLA reports the probability integral transform (PIT):

$$PIT_i = Prob(y_i^{new} \leq y_i|\mathbf{y}_{-i})$$

This criterion has been used to assess the validity of spatial models in disease mapping and it avoids the use of other sampling-based methods which may be less accurate (Marshall and Spiegelhalter 2003).

Roos and Held (2011) discuss sensitivity to priors for binary data using the conditional predictive ordinate (CPO, Geisser 1993), which is defined as $\pi(y_i|\mathbf{y}_{-i})$. They use the mean logarithmic CPO to build the following statistic as a measure of the predictive quality of the model:

$$\overline{CPO} = -\frac{1}{n} \sum_i^n \log(\pi(y_i|\mathbf{y}_{-i}))$$

Lower values of \overline{CPO} indicate a better model. As the authors state, this criterion can easily be extended to other hierarchical models. Held et al. (2010) compare the

CPO and PIT between “exact” Bayesian inference (using MCMC) and approximate inference (with INLA) showing that the approximated values are very close in general to the exact ones.

Finally, INLA can also compute the deviance information criterion (DIC, Spiegelhalter et al. 2002) which is a popular way of comparing Bayesian hierarchical models. The DIC also computes a measure of the effective number of parameters which is a measure of the complexity of the model.

71.2.4 Implementation

Besides the original paper, the authors have released a software (called INLA) which implements all the techniques mentioned here. In addition, an interface for the R programming language (R Development Core Team 2011) can be downloaded (from <http://www.r-inla.org>) which makes the use of the software easier and is able to produce summary statistics and plots of the results.

71.2.5 Other Features

In addition to an easy to use interface, the INLA software provides some other features. The joint posterior distribution of the hyperparameters can be computed. In addition, it is possible to define several linear combinations of the latent effects so that their posterior marginals are computed. Furthermore, if several of these linear combinations are computed, the joint correlation matrix can be computed as well, and this can be used to approximate the joint posterior distribution.

71.3 Spatial Models

Spatial dependence can be modeled in different ways in Bayesian hierarchical models (Banerjee et al. 2004). Given that INLA focuses on latent Gaussian models and given that the latent effects are Gaussian, spatial correlation can be embedded in the precision matrix. Furthermore, because of the Markov properties of the latent field, these variance-covariance matrices are often very sparse. How these methods can be applied to the different areas of spatial statistics is discussed below.

71.3.1 Geoadditive Mixed-Effects Models

Geoadditive models appear when regression models on a set of covariates are combined with other types of random effects (Kammann and Wand 2003). A geoadditive model will be based on modeling the mean μ_i at each location i on the sum of a set of fixed and random effects:

$$\mu_i = \mu + \mathbf{z}_i\boldsymbol{\beta} + u_i + v_i$$

where \mathbf{z}_i is a vector of covariates and $\boldsymbol{\beta}$ the associated coefficients. \mathbf{u} is a vector of spatially correlated random effects, while \mathbf{v} is a vector of independent random effects.

Note that this modeling can be done regardless of the likelihood employed for the data. In the case of a generalized linear model, a convenient link function will be used to transform the linear predictor accordingly.

Other nonparametric approaches can be implemented taking advantage of this approach. Kammann and Wand (2003) and Ruppert et al. (2003) show how penalized splines (P-splines) can be expressed as a mixed-effects model. Lee and Durbán (2009) describe how P-splines and a CAR model can be used to model spatial data. They develop an expression of these models as mixed-effects models. Although this is not a fully Bayesian approach, these models could be fitted with INLA using the following representation:

$$\mu = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}$$

Here \mathbf{X} and \mathbf{Z} represent design matrices for the fixed and random effects which have a particular structure derived from the fact that this mixed model represents a P-spline (see Sect. 4.9 in Ruppert et al. 2003, for details). A fully Bayesian approach to P-splines can be found in Lang and Brezger (2004), and it is based on imposing a prior on the coefficients $\boldsymbol{\gamma}$ of a design matrix \mathbf{B} (based on the basis functions):

$$\mu = \mathbf{B}\boldsymbol{\gamma}$$

Different priors on $\boldsymbol{\gamma}$ lead to different types of splines (Fahrmeir and Kneib 2011). For producing smoothed values of an observed covariate using P-splines, the prior should be a random walk. To achieve spatial smoothing, the prior on $\boldsymbol{\gamma}$ should be a GMRF with spatial structure. See Lang and Brezger (2004) for details on how to define \mathbf{B} and the prior of $\boldsymbol{\gamma}$ for spatial smoothing.

71.3.2 Disease Mapping

The analysis of public health data has played an important role in the development of spatial statistics in the last two decades. Besag et al. (1991) provided a suitable model in which spatial correlation and unstructured variation are combined in a geoaddivitive way which is also computationally appealing. Other authors have extended this model later, some of them for spatiotemporal disease mapping.

It should not be forgotten that disease mapping is a particular example of the analysis of lattice data. In this case, observations are aggregated over some region (counties, states, health districts, etc.) and spatial models assume that neighboring areas will have similar behavior. Here, dependence is between neighbors and a popular criterion is that two areas are neighbors if they share a common boundary.

Besag et al. (1991) proposed the use of two latent random effects: a spatially correlated one \mathbf{u} and an independent one \mathbf{v} . The first will account for any spatial correlation and the second will account for any other unstructured difference between the regions. While the nonstructured random effects are Gaussian with zero mean and precision τI_n (where I_n is the identity matrix of size $n \times n$), the spatially correlated random effects are defined using conditional distributions given the values at the neighbors. This is equivalent to using an intrinsic GMRF (Rue and Held 2005, Chap. 3), which is known as intrinsic conditionally autoregressive (CAR) model.

In order to encode this spatial information into a GMRF with zero mean and precision \mathbf{Q} , we will make use of the Markov property to note that if areas i and j are independent given the remaining areas, then $Q_{ij} = Q_{ji} = 0$. Hence, the precision matrix \mathbf{Q} will be very sparse, and the algorithms described in Rue and Held (2005) can be used for fast sampling from this GMRF.

In particular, the intrinsic CAR precision matrix is defined as

$$Q_{ij} = \kappa \begin{cases} n_i & i = j \\ -1 & i \sim j \\ 0 & \text{otherwise} \end{cases}$$

Here $i \sim j$ means that areas i and j are neighbors, κ is a conditional precision, and n_i is the number of neighbors of area i . This makes the conditional distribution of $u_i | \mathbf{u}_{-i}$, κ Gaussian with mean $\frac{1}{n_i} \sum_{j \sim i} u_j$ and variance $\frac{1}{\kappa n_i}$.

Note that the intrinsic CAR is an improper GMRF of rank $n - 1$. For this reason the constraint $\sum_i u_i = 0$ is added so that these effects can be identified. This is a common assumption for random effects based on intrinsic GMRF (Martino and Rue 2010).

A proper version of the intrinsic CAR model is available and it has a precision matrix similar to the previous one but adding a term $d > 0$ to the diagonal elements, so that they become $Q_{ii} = n_i + d$. $\log(d)$ is assigned a log-gamma prior distribution by default. Note that the main point of this model is to make the precision matrix strictly diagonally dominant so that it becomes invertible and the prior distribution is a proper one.

A more general approach is obtained when the precision matrix is defined as

$$\mathbf{Q} = \left(I - \frac{\rho}{\lambda_{max}} \mathbf{C} \right)$$

This can be used to define a general CAR spatial effect by taking \mathbf{C} as a matrix of spatial weights (see Chap. 9 in Bivand et al. 2008, to see how different spatial weights can be defined). ρ represents the spatial correlation (and it can be assigned a prior) and takes values between 0 and 1 because the weight matrix is \mathbf{C} divided by λ_{max} , its maximum eigenvalue, and by default a Gaussian prior is on $\text{logit}(\rho)$. Note that this will produce a proper distribution for the spatially correlated random effects. Negative spatial autocorrelation is often ignored in disease mapping.

In this general case, the conditional distribution of u_i is

$$u_i | \mathbf{u}_{-i}, \kappa \sim N\left(\rho \frac{\sum_{j \neq i} w_{ij} u_j}{w_{i+}}, \frac{1}{\kappa w_{i+}}\right)$$

where $w_{ij} = c_{ij} / \lambda_{\max}$ and $w_{i+} = \sum_{j=1}^n w_{ij}$. Note that if \mathbf{C} is row standardized, then $\lambda_{\max} = 1$ and $w_{i+} = 1$ and the marginal distribution has a simpler form.

71.3.3 Geostatistical Models

In addition to fitting a model to the data, geostatistics focuses on predicting a continuous surface (often approximated by a discrete grid of points) so these models are often computationally very expensive. Spatially correlated random effects are built for the set of sampling locations, which may lead to trouble if the number of locations is large. Geostatistical models are not restricted to Gaussian likelihoods, as described in Banerjee et al. (2004) and Diggle and Ribeiro (2007), and they can be used to model other types of data using a geostatistical latent effect.

Spatial correlation in geostatistical models is built upon the distances between the sampling points, usually using a decaying function on the distance. For example, a simple covariance function is defined such as $\Sigma_{ij} = \sigma^2 \exp(-d_{ij}/\varphi)$. Here d_{ij} is the distance between points i and j , and φ is a parameter to control for the spatial scale. Once the model is fitted, prediction relies on the posterior distributions of the parameters and the covariances for the points in the grid.

A more general class of spatial covariance is provided by the Matérn correlation function, of which the exponential decaying function is a particular example. The Matérn covariance is defined as

$$\Sigma_{ij} = \sigma^2 \frac{\tau^\kappa K(\tau, \kappa)}{2^{\kappa-1} \Gamma(\kappa)}; \tau = \alpha_\kappa d_{ij} / \varphi$$

$K(\cdot, \kappa)$ is the modified Bessel function of order κ and $\Gamma(\cdot)$ the gamma function. α_κ and φ can be used to control the scale of the spatial variation. Setting κ to 0.5 leads to an exponential covariance. Other values of κ will lead to other known spatial covariance functions (Eidsvik et al. 2009).

When it comes to provide a prediction on the grid, INLA treats the observation at each point on the grid as a missing value. This makes INLA compute the marginal posterior distribution at that point so that summary statistics can be obtained later.

In this approach, modeling and prediction occur on a regular grid, and observations need to match to some location in the grid. Lindgren et al. (2011) aim at modeling the geostatistical model by using a mesh based on a triangulation of the sampling points (instead of a regular grid) and stochastic partial differential equations (SPDE). In this approach, the spatially distributed effect \mathbf{u} is

$$u(s) = \sum_{k=1}^n \psi_k(s) w_k, s \in \mathbb{R}^2$$

where $\{\psi_k\}$ are some basis functions, $\{w_k\}$ are Gaussian distributed weights, and n is the number of points in the triangulation used to split the study area. As this is a more complex approach, the reader is referred to the original paper (Lindgren et al. 2011) and the gentle introduction by Cameletti et al. (2011) for details on how the basis functions and weights are taken.

Finally, INLA can be used for geostatistical design. Methods and results discussed in Diggle et al. (2010) for preferential sampling can be reproduced with INLA (see the Case Studies section in <http://www.r-inla.org>). Anisotropic models could also be employed, as discussed in Fuglstad (2011), and use of these models is being integrated into the software package.

71.3.4 Point Process Models

Rue et al. (2009) show an example of the analysis of a point pattern with INLA using a Poisson process. Rather than modeling the continuous intensity of the point process, they divide the study area in N disjoint cells (not necessarily of equal size) and model the data as coming from a counting process. Hence, the response variable y_i represents the number of occurrences of the process in square w_i ; $i = 1, \dots, N$. For simplicity a square lattice may be employed. In a square lattice all the squares have the same area, and spatially correlated random effects can be defined similarly as in lattice data (i.e., two squares are neighbors if they have a common boundary).

In their example, Rue et al. (2009) use a hierarchical Poisson process to model the number of trees in each square using a log-Gaussian Cox process (LGP). In this case, the intensity function is $\lambda(s) = \exp\{Z(s)\}$; $s \in \mathbb{R}^2$, where $Z(s)$ is a Gaussian field at $s \in \mathbb{R}^2$.

Hence, y_i is the observed number of occurrences in cell w_i . If η_i is the realization of $Z(s_i)$, then $\pi(\mathbf{y}|\eta) = \prod_i \pi(y_i|\eta_i)$, where $\pi(y_i|\eta_i)$ represents a Poisson distribution with mean $|w_i| \exp(\eta_i)$. $|w_i|$ is the area of cell w_i .

In turn, η_i is modeled according to a number of covariates plus some random effects:

$$\eta_i = X_i\beta + u_i + v_i$$

\mathbf{u} and \mathbf{v} are modeled in a similar way as with the lattice data case. v_i are independent Gaussian with zero mean and variance σ_v^2 so that they represent independent variation between the squares. On the other hand, u_i are modeled using a second-order polynomial intrinsic GMRF. In this way, first-, second-, and third-order neighbors

are taken into account, each one with a different weight, to mimic thin plate splines. See Rue and Held (2005) for details.

Simpson et al. (2011) extend the ideas in Lindgren et al. (2011) to model the latent LGP in a continuous way using a mesh on the study area. They show that this is a better approach that reduces the computational burden as a mesh is used instead of a regular grid and there is no need to aggregate cases into small cells.

More complex models cannot be fully addressed using INLA, in particular, those for which a closed likelihood does not exist as, for example, Gibbs processes. In a Gibbs process, future observations depend on present observations and, hence, producing a likelihood in closed form is not feasible.

71.4 Examples

As it happens, INLA is one of many alternatives for fitting Bayesian hierarchical models. In this section we provide a comparison to other software available for the R programming language, including computing times. Our aim here is not to provide a full comparison of computation times but to indicate how different approaches compare in terms of time and accuracy of results when used to fit a similar model to the same data set.

71.4.1 Geostatistics

For geostatistical models, we will use the Rongelap data set analyzed in several works on model-based geostatistics (Diggle and Ribeiro 2007). This data set records radionuclide concentration at 157 different locations, and the interest is on providing an estimate of the concentration over the whole Rongelap island.

As INLA makes computation on a regular grid, we have considered a 5×5 regular grid on one of the clusters in the northeast part of the island to make a fair comparison between computing times. We have used the INLA software (using the Laplace approximation) and the R package `geoRglm`, which provides model fitting using MCMC. The different computation times are shown in Table 71.1, while a map comparing the different estimates is shown in Fig. 71.1.

71.4.2 Lattice Data

For the case of lattice data, we have used the number of total malignant neoplasms mortalities in Georgia in 1999. We have fitted the model proposed in Besag et al. (1991) with population density as a covariate. In this case, we have used the INLA software as well as WinBUGS. Times are available in Table 71.1 and a graphical comparison of the estimates is available in Fig. 71.2.

Table 71.1 Summary of computation times for different problems, softwares, and fitting methods

Software	Method	Geostatistics		Lattice data		Point patterns	
		# Iter.	Time (s)	# Iter.	Time (s)	# Iter.	Time (s)
R-INLA	INLA	–	0.251	–	0.422	–	0.758
geoRglm	MCMC	22,000	0.409	–	–	–	–
WinBUGS	MCMC	–	–	22,000	11.420	22,000	35.336

Fig. 71.1 Estimates of the radionuclide concentration using different methods: Integrated nested Laplace approximation (INLA) and MCMC (using geoRglm)

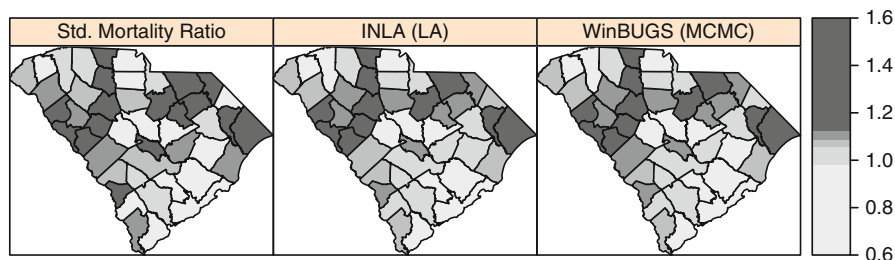

Fig. 71.2 Estimates of the relative risk using different methods: Standardized mortality ratio (SMR), integrated nested Laplace approximation (INLA), and MCMC (using WinBUGS)

71.4.3 Point Patterns

Finally, a point pattern has been included; we have performed an analysis of the Japanese pines data set available in R package Spatstat. This data set provides the location of Japanese pine saplings in a square region in a natural forest. Again, model fitting with INLA requires the use of a regular square grid so that the data are the number of saplings in each grid square. A 10×10 square grid has been used in this case, and the model to account for spatial dependence is the same as in the

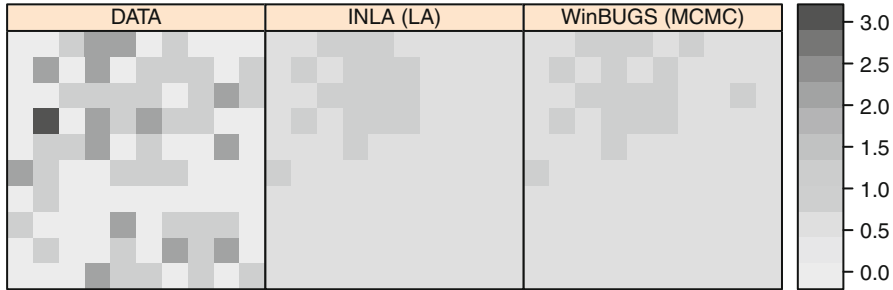

Fig. 71.3 Estimates of the number of saplings per square using two different methods: Integrated nested Laplace approximation (INLA) and MCMC (using WinBUGS)

previous example (Besag et al. 1991). This will also give us an idea of how INLA behaves as the grid size increases.

Figure 71.3 summarizes the fitted number of saplings and computing times are available in Table 71.1. It is worth noting how the differences between INLA and WinBUGS have increased now.

71.5 Conclusions

The integrated nested Laplace approximation developed in Rue et al. (2009) provides a series of approximations for the posterior marginals of the parameters of a Bayesian hierarchical model in which the latent effects are a Gaussian Markov random field. This family of models covers a good number of Bayesian hierarchical models, including several of those most used in spatial statistics. In addition, Markov properties are very convenient in dealing with spatial data and they can be used to model local dependence. Besides an approximation to the posterior marginals of the parameters in the model, INLA can compute several criteria for model criticism and selection, such as PIT and the DIC.

Regarding spatial models, INLA has been used to tackle problems in the analysis of lattice data, geostatistics, and point processes. In all cases, spatial dependence is modeled via the precision matrix of Gaussian random effects. The recent developments by Lindgren et al. (2011) allow for continuous modeling of latent spatial effects, which avoids the use of a grid and provides a good computational approach as well.

The availability of associated software that implements all these methods provides a suitable framework for their wider use. Other external software may be required to display the results in maps or create adjacency matrices for the analysis of lattice data. For this reason, the authors of the INLA software have provided an interface to the R programming language. The R-INLA web site (<http://www.r-inla.org>) provides the latest version of the software and its documentation as well as an updated list of published and working papers.

Abstract

Spatial statistics has in the last decade or two emerged as a major sub-specialism within statistics. Applications areas are diverse, and there is cross-fertilization with methodologies in other disciplines (econometrics, epidemiology, geography, geology, climatology, ecology, etc). This chapter reviews three major settings and techniques that have attracted attention from statisticians: spatial econometrics and simultaneous autoregressive models, spatial epidemiology and conditional autoregressive models, and geostatistical methods for point pattern data. The review is oriented to Bayesian inferences for such models, including discussion of choice of prior densities, questions of identification, outcomes of interest, and methods of estimation (using Markov chain Monte Carlo).

72.1 Introduction

Bayesian applications in spatial statistics have multiplied considerably in the last two decades, facilitated by improved estimation using Markov chain Monte Carlo (MCMC) methods and by advances in relevant statistical theory. Application areas where Bayesian ideas have impacted include spatial epidemiology, spatial ecology, spatial econometrics and political science, and geostatistics. In spatial epidemiology, Bayesian studies include spatial smoothing of rare health outcomes, modelling spatial clustering in disease risks (e.g., Richardson et al. 2004), and models for health impacts of environmental point sources (Wakefield and Morris 2001), while in spatial ecology, applications include habitat and remote sensing models (Carroll et al. 2010). Applications in spatial econometrics concentrate on models for behavior by economic actors (house purchasers, firms, etc) involved in spatially defined behaviors (e.g., LeSage and Pace 2009), while spatial applications in political science (Beck et al. 2006) focus on spatially defined electoral and legislative processes. Another major application context is the continuous spatial framework of geostatistics with diverse applications including geology, infectious epidemiology, and meteorology (e.g., Ecker and Gelfand 1997; Diggle and Ribeiro 2007; Schur et al. 2011).

Bayesian analysis in such applications is distinct from frequentist approaches in the need to consider the specification of prior densities for parameters θ . Such densities can potentially summarize existing evidence (e.g., from previous studies) where available or may express subject matter based constraints, such as confining a spatial correlation parameter to positive values. Prior densities may vary in their informativeness, meaning essentially the degree of concentration in the mass: a diffuse or flat prior will spread the prior density over a wide range of values (e.g., as in a uniform prior for a probability or rate), whereas an informative prior will concentrate potential values within a narrower range. The prior density $\pi(\theta)$ for a parameter is updated by the likelihood of the data $L(\theta|y) = p(y|\theta)$, and posterior inferences are based on the updated parameter density $\pi(\theta|y) = kp(y|\theta)\pi(\theta)$. Typically modern spatial data analysis using Bayesian principles will also use Markov chain Monte Carlo (MCMC) sampling methods in the updating stage, and there may be advantages in being able to use particular MCMC sampling methods such as Gibbs sampling (Casella and George 1992), which involves repeated sampling from the full conditional density of a parameter. Choice of prior density may be important in facilitating MCMC sampling, as illustrated in some of the techniques described below. As well as facilitating estimation of complex spatial models, MCMC techniques aid in related inferences: examples include posterior probabilities of elevated disease risk, also called exceedance probabilities (Richardson et al. 2004; Hossain and Lawson 2006).

72.2 Spatially Autoregressive Regression in Spatial Econometrics

Consider the normal linear regression with continuous outcomes y_i , predictor vector X_i , and errors ε_i , $i = 1, \dots, n$. In applications to observations for discrete spatial

units (also called lattice data), an *iid* assumption regarding the errors is likely to be invalid, and instead there will often be covariation in errors for closely co-located areas i and j . For example, if the model is for crime rates, then positive regression residuals may tend to be spatially clustered because crime rates themselves are spatially clustered (e.g., Ratcliffe 2010). In spatial econometrics, an adaptation of linear regression tackles potential spatial correlation in terms of spatially lagged dependence in errors or observations. This is analogous to similar forms of lagged dependence often applied in time series regression, such as first- and possibly higher-order lags in the dependent variable, and serially correlated errors in time.

Thus, consider an $n \times n$ matrix C of contiguity dummies, with $c_{ij} = 1$ if areas i and j are adjacent, and $c_{ij} = 0$ otherwise (with $c_{ii} = 0$). Alternatively distance-based interactions might be specified, for instance, $c_{ij} = \exp(-\gamma d_{ij})$, where $\gamma > 0$ reflects distance decay. From C may be obtained the row-standardized matrix $W = [w_{ij}] = [c_{ij} / \sum c_{ij}]$. The most general model, known as a spatial autoregressive regression,⁴ includes a spatial lag in both errors and observations, namely (for y of dimension $n \times 1$, predictors X of dimension $n \times p$, and β of dimension $p \times 1$),

$$\begin{aligned} y &= \lambda W_1 y + X\beta + \varepsilon \\ \varepsilon &= \rho W_2 \varepsilon + u \\ u &\sim N(0, \sigma^2 I) \end{aligned}$$

where λ and ρ are unknown correlation parameters. The coefficients λ and ρ have bounds $\left\{ \frac{1}{\omega_{1,\min}}, \frac{1}{\omega_{1,\max}} \right\}$ and $\left\{ \frac{1}{\omega_{2,\min}}, \frac{1}{\omega_{2,\max}} \right\}$, respectively, where $\omega_{j,\min}$ and $\omega_{j,\max}$ are the minimum and maximum eigenvalues of W_j . For W standardized within rows, ω_{\max} is 1, and since spatial correlation is usually positive, a prior on λ or ρ constrained to $[0, 1]$ is often used, for example, a beta prior, $\pi(\lambda) = \text{Beta}(a_\lambda, b_\lambda)$ (LeSage and Pace 2009, p. 142).

A widely used scheme for error dependence is a reduced version of the above model, known commonly as the spatial error model, with $W_1 = 0$. This model expresses spatial covariation in errors caused by omitted predictor variables, measurement errors, and possible mismatch between the spatial units used, and the scale at which the process occurs (Anselin and Bera 1998). The corresponding likelihood is

$$L(\beta, \sigma^2, \rho | y) = (2\pi)^{-n/2} \sigma^{-n} |I - \rho W| \exp\left(-\frac{1}{2\sigma^2} \varepsilon' \varepsilon\right)$$

where $\varepsilon = (I - \rho W)(y - X\beta)$. Spatially lagged effects in the dependent variable rather than errors (i.e., $W_2 = 0$ in the general model above) lead to the spatial autoregressive model

$$y = \lambda W y + X\beta + u$$

where u is an *iid* error. This model is often used to represent neighborhood diffusion or spillover effects, as in applications to technical innovation and house prices, respectively. The corresponding likelihood is

$$L(\beta, \sigma^2, \lambda|y) = (2\pi)^{-n/2} \sigma^{-n} |I - \lambda W| \exp\left(-\frac{1}{2\sigma^2} u'u\right)$$

where $u = (I - \lambda W)(y - X\beta)$.

To demonstrate the derivation of conditional posterior densities and appropriate forms of MCMC sampling, consider the spatial autoregressive model (without spatially correlated errors). One may assume prior independence between λ and the other parameters, but assume a normal prior for β that conditions on the sampled value of σ^2 . Thus, with $IG(a, b)$ denoting the inverse Gaussian density, one has

$$\begin{aligned} \pi(\sigma^2) &= IG(\sigma^2|a_0, b_0) = \frac{b_0^{a_0}}{\Gamma(a_0)} (\sigma^2)^{-(a_0+1)} \exp(-b_0/\sigma^2) \\ \pi(\beta|\sigma^2, c_0, d_0) &= N(c_0, d_0\sigma^2) \end{aligned}$$

where c_0 is a vector and d_0 is a matrix. The prior on λ is uniform between bounds determined by the eigenvalues ω of W :

$$\pi(\lambda|\omega, W) = U\left(\frac{1}{\omega_{\min}}, \frac{1}{\omega_{\max}}\right)$$

The combination of priors and likelihood assumptions determines the form of conditional density for each parameter θ_r , namely, that part of $L(\theta|y)\pi(\theta)$ varying in θ_r . Choice of MCMC sampling depends on the form of density $p(\theta_r|\theta_{[r]}, y)$ for a particular parameter θ_r conditional on all other parameters $\theta_{[r]}$. To implement Gibbs sampling usually requires that these full conditional densities have a known form that permits direct sampling. Letting $A = I - \lambda W$, the full conditional density for β has a normal form, permitting Gibbs sampling, namely,

$$\begin{aligned} p(\beta|\sigma^2, \rho, y) &= N(c_1, d_1\sigma^2) \\ c_1 &= d_1(X'Ay + d_0^{-1}c_0) \\ d_1 &= (X'X + d_0^{-1})^{-1} \end{aligned}$$

The full conditional density for σ^2 is also inverse Gaussian (again allowing Gibbs sampling) with form

$$\begin{aligned} p(\sigma^2|\beta, \rho, y) &= IG(a_1, b_1) \\ a_1 &= a_0 + 0.5n, \quad b_1 = b_0 + 0.5(Ay - X\beta)'(Ay - X\beta) \end{aligned}$$

However, the full conditional density for λ has the form

$$p(\lambda|\sigma^2, \beta, y) = k|I - \lambda W| \exp\left(-\frac{1}{2\sigma^2} u'u\right) U\left(\frac{1}{\omega_{\min}}, \frac{1}{\omega_{\max}}\right)$$

where k is an unknown constant. This is not a standard density, and so more general Metropolis or Metropolis-Hastings sampling is needed. Let $p(\lambda^{(t)})$ denote the value of $p(\lambda|\sigma^2, \beta, y)$ at the current value $\lambda^{(t)}$ in an MCMC sampling sequence $t = 1, \dots, T$. Let $p(\lambda_{new})$ be the value of the same conditional density at a candidate value generated by a proposal density. Let h be a random number between 0 and 1. Then, in Metropolis sampling, the candidate value replaces the current value either if $p(\lambda_{new}) > p(\lambda^{(t)})$ or if $p(\lambda_{new}) < p(\lambda^{(t)})$ but $h < p(\lambda_{new})/p(\lambda^{(t)})$. An alternative to a uniform or beta prior on λ (or ρ) mentioned by LeSage and Pace (2009, p. 139) is a prior defined over a grid of feasible values $\{\lambda_1, \dots, \lambda_L\}$, usually with an equal prior probability on each value λ_i . This allows pre-calculation of the log determinants of $I - \lambda_i W$, so lessening the computational burden during MCMC sampling.

While developed for continuous data, these techniques can be adapted to binary, multinomial, or ordinal outcomes using latent outcome representations. For binary data defined over areas $i = 1, \dots, n$

$$y_i \sim \text{Bern}(\pi_i)$$

the spatial autoregressive and spatial error models can be applied using a latent variable model, sometimes denoted the spatial probit model, whereby

$$\begin{aligned} y_i &= 1 && \text{if} && z_i > 0 \\ y_i &= 0 && \text{if} && z_i \leq 0 \end{aligned}$$

where z_i can be interpreted as the utility difference $U_{1i} - U_{0i}$ between binary options, with $Pr(y_i = 1) = Pr(U_{1i} > U_{0i}) = Pr(z_i > 0)$ (Smith and LeSage 2004). For example, the spatial autoregressive model for dichotomous outcomes based on the latent variable representation is

$$z = \lambda Wz + X\beta + u, \quad u \sim N(0, I)$$

so that

$$\begin{aligned} z &= (I - \lambda W)^{-1} X\beta + v \\ v &= (I - \lambda W)^{-1} u \sim N_n(0, [(I - \lambda W)'(I - \lambda W)]^{-1}) \end{aligned}$$

The variance of the residuals is preset for identifiability, while priors on λ and β follow schemes such as those discussed above.

72.3 Discrete Outcomes: Conditional Priors in Spatial Epidemiology

Simultaneous autoregressive schemes are primarily designed for continuous univariate responses, whereas count variables (usually leading to Poisson or binomial likelihoods) are common in health and ecological applications. Although transformations of count variables may be applied, leading to approximate normality (e.g., the Anscombe transform), inverse transformation is sometimes subject to bias, and direct analysis of untransformed counts may be easier for multivariate outcomes. Also while simplifications using grid priors and pre-calculated determinants can be used, Bayesian estimation of simultaneous regression models may be burdensome in large datasets, requiring sampling from a high-dimension multivariate normal density, and inverse or determinant calculations for large matrices.

By contrast, conditional autoregressive priors are an alternative, especially for discrete data outcomes, provided they are consistent with valid joint priors. Instead of focusing on the joint multivariate distribution of the entire vector ε , conditional priors involve the univariate density of each area's error, ε_i , conditioning on errors in all other areas $\varepsilon_{[i]} = \{\varepsilon_j, j \neq i\}$. Certain restrictions on the form of the spatial weight matrix C and the conditional precision of the ε_i need to be followed to ensure a valid joint density is obtained from the collection of conditional priors (Besag and Kooperberg 1995).

Conditional priors can be used in all forms of generalized linear model, including linear regression with $y = X\beta + \varepsilon$. Under the conditional autoregressive or $CAR(\rho)$ prior (Bell and Broemeling 2000), one has

$$\varepsilon_i | \varepsilon_{[i]} \sim N \left(\rho \sum_{j \neq i} c_{ij} \varepsilon_j, \sigma^2 \right)$$

where the conditional mean is a weighted average of errors in other areas and ρ is bounded by the inverses of the minimum and maximum eigenvalues of C . Using a standardized weight matrix leads to what are often termed intrinsic conditional autoregressive or $ICAR(\rho)$ priors (Stern and Cressie 2000), with

$$\varepsilon_i | \varepsilon_{[i]} \sim N \left(\rho \frac{\sum_{j \neq i} c_{ij} \varepsilon_j}{\sum_{j \neq i} c_{ij}}, \sigma^2 / \sum_{j \neq i} c_{ij} \right)$$

The upper bound for ρ is now 1, and a uniform prior on ρ with values between 0 and 1 is often reasonable. If ρ is an unknown, then a common practice is to discretize the prior to equally spaced points (e.g., from 0.001 in spaces of 0.001 up to 0.999) to facilitate MCMC sampling.

A popular scheme, analogous to random walk priors in time series, in fact assumes $\rho = 1$. Additionally estimation of distance-decay parameters can be avoided by taking $c_{ij} = 1$ for adjacent areas, and $c_{ij} = 0$ otherwise. Define

$M_i = \sum_{j \neq i} c_{ij}$ as the number of areas adjacent to area i , and let L_i denote this collection of areas. Then, the *ICAR*(1) prior is

$$\varepsilon_i | \varepsilon_{[i]} \sim N \left(\sum_{j \in L_i} \varepsilon_j / M_i, \sigma^2 / M_i \right)$$

The joint prior version of this scheme is technically improper (Sun et al. 1999), but propriety is achieved in practice by recentering the sampled ε_i to sum to zero under MCMC sampling (Rodrigues and Assuncao 2008).

For example, suppose y_i denotes small-area disease counts, with expected events E_i obtained using region-wide incidence rates. The outcomes may be taken as Poisson, $y_i \sim Po(E_i \theta_i)$, where θ_i denotes relative risk of disease in area i . A classical approach (widely applied in area profiles of health outcomes) takes the θ_i as fixed effects, with (implicit) flat priors, and produces relative risk estimates $\hat{\theta}_i = y_i / E_i$. These may be misleading as indicators of varying disease patterns, since the resulting maps may be distorted by imprecisely estimated rates derived from low event counts or populations, and small changes in event totals may produce major shifts in estimates $\hat{\theta}_i$. Instead one possible plausible scheme for spatial borrowing of strength suggests two forms of underlying random variation: a smooth spatial signal ε_i following an *ICAR*(1) prior with variance σ_ε^2 and a *iid* term u_i for representing idiosyncratic local effects (Mollie 1996), leading to the so-called convolution prior with

$$\log(\theta_i) = X_i \beta + u_i + \varepsilon_i$$

where the *iid* errors are normal, $u_i \sim N(0, \sigma_u^2)$. Only the total error $t_i = u_i + \varepsilon_i$ is identified by the data, and estimates of variances σ_ε^2 and σ_u^2 may be sensitive to priors adopted (e.g., Yan 2006). Lee (2011) shows limitations of the convolution prior in both weak and strong spatial correlation situations.

To demonstrate the MCMC sampling involved in this model, define $\bar{\varepsilon}_i = \sum_{j \in L_i} \varepsilon_j / M_i$, and respécify the model for the log-relative risk as

$$\begin{aligned} \log(\theta_i) &= u_i + \varepsilon_i \\ u_i &\sim N(X_i \beta, \sigma_u^2) \end{aligned}$$

Then, the full conditional for each spatial error is

$$p(\varepsilon_i | \varepsilon_{[i]}, \sigma_\varepsilon^2, \beta, u_i) = k_1 \exp\{y_i \varepsilon_i - E_i \theta_i - 0.5 M_i (\varepsilon_i - \bar{\varepsilon}_i) / \sigma_\varepsilon^2\}$$

while the full conditional for each *iid* error is

$$p(u_i | \beta, \sigma_u^2, \beta, \varepsilon_i) = k_2 \exp\{y_i u_i - E_i \theta_i - 0.5 (u_i - X_i \beta) / \sigma_u^2\}$$

These conditionals can be sampled one at a time, or via block updating, using Metropolis-Hastings algorithms (Lee 2011).

Conventional spatial priors may not adequately model spatial discontinuities. Among ways to better represent discontinuities, and also avoid distorting the smooth spatial signal, the convolution prior may use a Student's t-distribution for the *iid* effect. This may be implemented using scale mixing, namely,

$$u_i \sim N(0, \sigma_u^2 / \kappa_i)$$

$$\kappa_i \sim G\left(\frac{\nu}{2}, \frac{\nu}{2}\right)$$

where ν is a degrees of freedom parameter. Areas with significantly lower κ_i are potential spatial outliers. The spatial prior itself may be adapted to be heavier-tailed: more robust alternatives including the double exponential prior

$$p(\varepsilon) \propto \chi \exp[-0.5\chi|\varepsilon_i - \varepsilon_j|^2]$$

where χ is a scaling parameter. Another option is mixture priors, such as

$$\log(\theta_i) = \gamma + u_i + \eta_i \varepsilon_{1i} + (1 - \eta_i) \varepsilon_{2i}$$

where ε_{1i} is *ICAR*(1), ε_{2i} follows the double exponential form, and η_i has a beta distribution (Lawson and Clark 2002).

Extending conditional autoregressive schemes to model multivariate spatial effects is relatively straightforward. Suppose there are J sets of spatial effects ε_{ji} for each area i . These might be relevant when there are J outcome variables, each with a spatially distributed regression residual, but can also be used in other ways: for example, in discrete mixtures over spatial effects or when regression coefficients show a spatial patterning. The latter scenario is sometimes denoted as spatially varying coefficient or SVC modelling and has the same intention in terms of representing spatial heterogeneity as techniques such as geographically weighted regression (Wheeler and Waller 2009). Multivariate CAR priors can also be applied in multilevel models; for example, a random intercept-random slope model with areas at level 2 would lead to a bivariate CAR prior.

Under the intrinsic multivariate conditional autoregressive or *IMCAR*(ρ, J) prior (Mardia 1988), the conditional prior for the *ith* area effect vector $\varepsilon_i = (\varepsilon_{1i}, \varepsilon_{2i}, \dots, \varepsilon_{ji})$, given such effects for other areas, $\varepsilon_{[i]} = (\varepsilon_1, \dots, \varepsilon_{i-1}, \varepsilon_{i+1}, \dots, \varepsilon_n)$, is multivariate normal of dimension J with conditional outcome-specific means

$$\mu_{ji} = E(\varepsilon_{ji} | \varepsilon_{[i]}) = \rho \sum_{k \neq i} c_{ik} \varepsilon_{jk} / \sum_{k \neq i} c_{ik}$$

where ρ applies across all outcomes. When the c_{ik} are binary and based on contiguity, the outcome-specific conditional means are

$$\mu_{ji} = \rho \sum_{k \in L_i} \varepsilon_{jk} / M_i$$

namely, locality averages of spatial effects for outcome j , with corresponding within area conditional precision matrices

$$\text{Prec}(\varepsilon_i | \varepsilon_{[i]}) = M_i \Phi$$

where Φ is $J \times J$. Taking $\rho = 1$ in the $IMCAR(\rho, J)$ prior leads to the multivariate version of the $ICAR(1)$ prior.

72.4 Spatial Covariation in Continuous Space

The preceding discussion and examples consider continuous and discrete outcomes for zones (also called “lattice” data). Alternatively spatial data may consist of point data (e.g., geolocations for mineral deposits or for disease cases), sometimes denoted point pattern data, or aggregate data identified by grid-referenced location (Goovaerts and Gebreab 2008). For such data, the influence of interpoint or inter-location proximity on covariation in the outcome or regression errors needs to be explicitly considered or estimated.

Consider point or locational observations y_i at sites s_i in two-dimensional space, $s_i = (s_{1i}, s_{2i})$, with s_{1i} denoting longitude and s_{2i} denoting latitude. A starting point for estimating the effect of proximity is provided by a distance metric such as Euclidean interpoint distances, $d_{ij} = |s_i - s_j|$. A baseline assumption is that the spatial covariance matrix is isotropic, namely, independent of location and a function only of distance: so for points s and s' , separated by distance $d = |s - s'|$, one has $\Sigma(s, s') = \Sigma(d)$. Let $Y(s)$ and $\varepsilon(s)$ be $n \times 1$, with a predictor matrix $X(s)$ of dimension $n \times P$. Then,

$$\begin{aligned} Y(s) &= X(s)\beta + \varepsilon(s) \\ \varepsilon(s) &\sim N(0, \Sigma(d)) \end{aligned}$$

with $n \times n$ covariance matrix $\Sigma(d)$. Techniques such as variogram analysis can be used to explore covariation in regression residuals or investigate relevant assumptions such as isotropy (Irvine et al. 2007). Parametric functions can then be applied to represent $\Sigma(d)$.

Thus, consider $\Sigma(d) = \sigma^2 R(d)$ in terms of an overall variance σ^2 (defined along the diagonal when $i = j$ and $d_{ii} = 0$), and $R(d) = [r_{ij}(d_{ij})]$ reflecting correlations between the errors $\varepsilon(s_i)$ and $\varepsilon(s_j)$, usually such that $r_{ii}(0) = 1$ and $R(d)$ is positive definite (Diggle and Ribeiro 2007). Commonly used schemes include the exponential model

$$r_{ij} = \exp(-d_{ij}/\phi)$$

where ϕ is the range (distance at which spatial correlation ceases to be important) or the Gaussian function

$$r_{ij} = \exp(-d_{ij}^2/\phi^2)$$

In some cases there will be further *iid* variability (e.g., due to measurement error), leading to

$$\begin{aligned} Y(s) &= X(s)\beta + \varepsilon(s) + u \\ \Sigma(d) &= \sigma^2 R(d) + \tau^2 I \end{aligned}$$

where τ^2 is commonly known as the nugget variance, with the limiting variance as d_{ij} tends to zero being $\tau^2 + \sigma^2$ instead of σ^2 . Writing $V = \Sigma(d) = \sigma^2 R(d) + \tau^2$, $y = y(s)$, $X = X(s)$, the log-likelihood kernel is

$$-0.5 \log |V| - 0.5(y - X\beta)' V^{-1}(y - X\beta)$$

Prediction of y_{new} at a new site s_{new} under the linear model involves a vector of covariances $\lambda_i = Cov(s_{new}, s_i)$ between the new point and the sampled sites $s_i, i = 1, \dots, n$, and the prediction is then a weighted combination of the existing point values with weights w_i determined by

$$w = \lambda V^{-1}$$

Bayesian inference and estimation for such models may provide additional scope for inferences not possible under classical estimation approaches (e.g., ML or REML). An example is provided by Irvine et al. (2007), regarding the “effective range” or distance beyond which the correlation between observations, $\rho(d) = \Sigma(d)/\Sigma(0)$, is less than or equal to 0.05. On the other hand, computation may be slowed by MCMC calculations for high-dimension covariance matrices. An alternative is lower dimension spatial kernel methods such as discrete convolution priors (Higdon 2007). Precise estimation in such models may be facilitated by informative priors, for example, on distance-decay parameters such as ϕ or on the nugget-to-sill ratio $v^2 = \tau^2/\sigma^2$ in a reparameterized covariance matrix $\Sigma = \sigma^2(R + v^2 I)$ (Diggle and Ribeiro 2007, Chap. 7). Univariate or bivariate grid priors at selected points within a feasible range for ϕ and/or v^2 allow prior calculation of Σ or Σ^{-1} at the grid points and thus reduced computation.

Spatial covariance models can be defined for Poisson or binomial data (Diggle et al. 1998). Consider counts $y_i(s)$ assumed Poisson, with means $v(s_i)$. For equidispersed data a log link regression would then include a spatial error

$$\log(v(s_i)) = X(s_i)\beta + \varepsilon(s_i)$$

with $\varepsilon(s) \sim N_n(0, \sigma^2 R(d))$. However, for overdispersed data, both spatial and *iid* errors may be relevant, namely,

$$\log(v(s_i)) = X(s_i)\beta + \varepsilon(s_i) + u_i$$

with $u_i \sim N(0, \tau^2)$

72.5 Space-Time Models

Longitudinal spatial observations raise similar issues to those for panel data generally, such as the modelling of temporal autocorrelation and permanent area effects. The main strands in spatial modelling (spatial econometrics, spatial epidemiology, and geostatistics) all have space-time representations, though Bayesian modelling in some applications has been relatively limited. Thus spatio-temporal variations on spatial lag and spatial error models have only recently been considered in Bayesian terms. For example, Debarsy et al. (2012) generalize the spatial autoregressive model to incorporate time-lags in own area and neighboring areas, as in

$$y_{it} = \phi y_{i,t-1} + \lambda \sum_j w_{ij} y_{jt} + \theta \sum_j w_{ij} y_{j,t-1} + X_{it} \beta + \gamma \sum_j w_{ij} X_{jt} + \alpha + \varepsilon_{it}$$

This model does not include permanent area effects, whereas Kakamu and Wago (2008) propose

$$y_{it} = \lambda \sum_j w_{ij} y_{jt} + X_{it} \beta + \alpha_i + u_{it}$$

where u_{it} is iid, $u_{it} \sim N(0, \sigma^2)$. Assuming α_i is random, for example $\alpha_i \sim N(0, \sigma_\alpha^2)$, the stage 1 likelihood for period t is

$$p(y_t | \lambda, \beta, \alpha, \sigma^2) = (2\pi\sigma^2)^{-n/2} |I - \lambda W| \exp(-0.5 u'_t u_t / \sigma^2)$$

where $u_t = y_t - \lambda W y_t - X_t \beta - \alpha$, and α is the vector of area permanent effects. As for cross-sectional spatial lag or error models, computational savings are achieved by taking uniform grid priors on λ , allowing pre-calculation of the log determinants, $\log|I - \lambda W|$, at each grid point.

Conditional hierarchical space-time priors may have benefits in MCMC applications and are applicable straightforwardly in area-time analysis involving binomial or Poisson count data. For example, in Poisson modelling of area health risks ρ_{it} , one may, by analogy to the random intercept-random slope model of conventional panel models, assume spatially structured area-specific random variation for both the level and the growth effect, so that neighboring areas have similar trends in relative risk (Bernardinelli et al. 1995). For equally spaced time points and expected events E_{it} , one has

$$y_{it} \sim Po(E_{it} \rho_{it})$$

$$\log(\rho_{it}) = \alpha + \delta_t + \lambda_{1i} + \lambda_{2i} t$$

where the level effects λ_{1i} describe the stable relative risk pattern, while trend parameters λ_{2i} describe incremental changes in relative risk. The broad scale trend is represented by parameters δ_t , which for T small may be modelled as fixed effects

with a corner constraint (e.g., $\delta_1 = 0$). The two sets of spatial effects $\{\lambda_{1i}, \lambda_{2i}\}$ can be assigned a bivariate conditional autoregressive prior, $IMCAR(\rho, 2)$, as discussed above.

To allow for local heterogeneity, space-time priors can incorporate the convolution principle, combining a pure spatial signal with an *iid* term, as in

$$\log(\rho_{it}) = \alpha + \delta_t + \omega_{1i} + u_{1i} + (\omega_{2i} + u_{2i})t$$

where u_{1i} and u_{2i} are *iid*, and $(\omega_{1i}, \omega_{2i})$ are separate *ICAR*, or jointly *IMCAR* with $\rho = 1$. Setting $c_{ji} = \omega_{ji} + u_{ji}$ one has

$$\log(\rho_{it}) = \alpha + \delta_t + c_{1i} + c_{2i}t$$

While some realignment of spatial risks is likely over time, one may, however, seek to model persistent differentials. Let $c_{it} = \omega_{it} + u_{it}$ denote a convolution scheme, combining area-time specific spatial effects ω_{it} and *iid* effects, u_{it} . Then, correlation through time can be represented by an AR1 process, with

$$\log(v_{it}) = \alpha + \delta_t + c_{it} + \lambda c_{i,t-1}, \quad \lambda \in (-1, 1), \quad t > 1$$

with initial time model (at $t = 1$) being

$$\log(v_{i1}) = \alpha + \delta_1 + \frac{c_{i1}}{(1 - \lambda^2)^{0.5}}$$

Space and time dependence in area-time interactions c_{it} can also be represented using a Kronecker product of the relevant structure matrices defining the inverse covariance matrices in the joint prior (Lagazio et al. 2001). Thus, an *ICAR*(1) scheme for spatial errors, with interaction matrix C based on adjacency, has a joint multivariate normal prior with inverse covariance $\tau_s K_s$, where τ_s is a precision parameter and the off-diagonal terms $K_{s[ij]}$ are -1 for neighboring areas i and j , and $K_{s[ij]} = 0$ otherwise. Diagonal terms in K_s are given by M_i , the number of neighbors of area i . For time, one may assume a low-order random walk (RW) prior. If a first-order RW prior in time is assumed with K_t as the structure matrix in the joint prior, then the off-diagonal elements are $K_{t[ab]} = -1$ for adjacent times a and b , and $K_{t[ab]} = 0$ otherwise. Diagonal terms equal 1 when $a = b = 1$ or $a = b = T$, and equal 2 for other diagonal terms. Then, an area-time interaction effect c_{it} formed by crossing an *RW1* time prior with a *ICAR*(1) spatial effect has a joint prior with precision specified by the Kronecker product

$$\tau_c K_s \otimes K_t$$

The corresponding conditional priors (for c_{it} conditioning on all other interactions) have precisions $\tau_c M_i$ when $t = 1$ or $t = T$, and $2\tau_c M_i$ otherwise. With L_i denoting the neighborhood of area i , the prior conditional means \bar{c}_{it} for c_{it} are

$$\begin{aligned}\bar{c}_{i1} &= c_{i2} + \sum_{j \in L_i} \frac{c_{j1}}{M_i} - \sum_{j \in L_i} \frac{c_{j2}}{M_i} \\ \bar{c}_{it} &= 0.5(c_{i,t-1} + c_{i,t+1}) + \sum_{j \in L_i} \frac{c_{jt}}{M_i} - \sum_{j \in L_i} \frac{(c_{j,t+1} + c_{j,t-1})}{(2M_i)}, \quad 1 < t < T \\ \bar{c}_{iT} &= c_{i,T-1} + \sum_{j \in L_i} \frac{c_{jT}}{M_i} - \sum_{j \in L_i} \frac{c_{j,T-1}}{M_i}\end{aligned}$$

For identification, the c_{it} should be doubly centered at each iteration (over areas for a given t and over times for a given area i).

72.6 Focused Clustering Models

In environmental epidemiology, disease risk may be related to proximity to one or more known or unknown hazard sites (e.g., Ismaila et al. 2007; Maule et al. 2007). A benchmark scheme in such situations includes background risk and focused risk (Diggle 1990), with relative risk for subjects at location s in relation to a point source at s_0 represented as

$$\lambda(s, s_0) = \rho g_0(s) g_1(s, s_0)$$

where ρ is the regional incidence rate, $g_0(s)$ is the population at risk at location s (or more broadly the background risk), and $g_1(s, s_0)$ expresses disease exposure postulated to reflect location in relation to the source. For example, one may take $g_1(s, s_0)$ to be a function of distance $d = |s - s_0|$ from the source (so that direction has no impact), namely,

$$g_1(s, s_0) = g_1(d) = 1 + \eta f(d, \phi)$$

where $f(d, \phi)$ is a distance-decay function expressing lessened risk at greater distance, such as an exponential function, $f(d) = \exp(-\phi d)$, and where $1 + \eta$ defines relative risk at or near the source (where $d \simeq 0$ and $f(d) \simeq 1$). Provided $\phi > 0$, $g_1(d)$ tends to 1 as d tends to infinity (and $f(d)$ tends to zero). Probabilities of excess risk for particular subjects (at distance d_i from the source) may be obtained by monitoring

$$I(g_1^{(t)}(d_i) > g_E)$$

over MCMC iterations t , where g_E is judged to represent excess risk depending on the context (e.g., $g_E = 1.25$ or $g_E = 1.5$). The posterior probability estimate is then

$\sum_{t=1}^T I(g_1^{(t)}(d_i) > g_E) / T$ where T is the total number of iterations. A simpler ‘‘hot spot’’

clustering model specifies uniformly elevated risk $1 + \eta$ in a neighborhood (defined by distances $d < \delta$ around the focus, but background risk elsewhere. If there are multiple foci, one may generalize to

$$\lambda(s, s_0) = \rho g_0(s) \left[1 + \sum_k \eta_k f(d, \phi_k) \right]$$

Observed data for focused clustering models may involve individual-level disease status or small-area disease totals. For the former type of outcome, the population density may be modelled via kernel methods, for example, using small-area population estimates. An alternative is to proxy the background population distribution using a control disease unrelated to exposure from the point source. Cases and controls have binary outcomes $y_i = 1$ and $y_i = 0$, respectively, and if there are individual risk factors X_i , the odds of being a case may be represented as

$$\pi_i / (1 - \pi_i) = \rho^* [1 + \eta f(d)] \exp(X_i \beta)$$

where $\rho^* = (a/b)\rho$, a and b are sampling proportions of cases and of controls, respectively, and ρ is the population odds of disease.

Focused clustering may be relevant to small-area studies, for example, in modelling area counts of cancer incidence according to distance from a source or in modelling human flow behaviors (to hospitals or supermarkets). For observations consisting of disease counts y_i in areas i , the background risk in an area might be approximated by the expected disease total E_i based on population totals or age structure. To account for spatial correlation effects distinct from the effect of distance from the focus (or foci), the Poisson mean μ_i might include conditionally autoregressive spatial effects ϵ_i as discussed above, area predictors (e.g., deprivation), and *iid* effects u_i also, as in

$$\mu_i = \rho E_i \exp(X_i \beta) [1 + f(d_i)] \exp(u_i + \epsilon_i)$$

For example, setting $\alpha = \log(\rho)$, an exponential decay model would lead (Ma et al. 2007) to

$$\log(\mu_i) = \alpha + \log(E_i) + X_i \beta + \log(1 + e^{-\phi d}) + u_i + \epsilon_i$$

72.7 Conclusions

The chapter has reviewed some themes relevant to Bayesian applications and inferences to spatial data. There are many further issues to consider such as the development of efficient MCMC sampling for certain types of spatial model or in large datasets (e.g., Murray et al. 2010) and also the development of approximate Bayesian estimation methods (Rue et al. 2009). Among areas offering potential for

methodological development and benefitting from a Bayesian inferential perspective are space-time models used in econometric, health and climate applications (Tingley and Huybers 2010), nonparametric models for spatial data (e.g., Reich and Fuentes 2012), models for spatial cluster detection, and more general models for the spatial interaction matrix beyond simple assumptions such as contiguity. Routine application of Bayesian techniques to spatial and space-time models also depends on the availability of suitable software, and this is exemplified by packages developed for the freeware R package, such as Ramps and spBayes.

Abstract

Geographically weighted regression (GWR) was proposed in the geography literature to allow relationships in a regression model to vary over space. In contrast to traditional linear regression models, which have constant regression coefficients over space, regression coefficients are estimated locally at spatially referenced data points with GWR. The motivation for the introduction of GWR is the idea that a set of constant regression coefficients cannot adequately capture spatially varying relationships between covariates and an outcome variable. GWR is based on the appealing idea from locally weighted regression of estimating local models for curve fitting using subsets of observations centered on a focal point. GWR has been applied widely in diverse fields, such as ecology,

forestry, geography, and regional science. At the same time, published work from several researchers has identified methodological issues and concerns with GWR and has questioned the application of the method for inferential analysis. One of the concerns with GWR is with strong correlation in estimated coefficients for multivariate regression terms, which makes interpretation of map patterns for individual terms problematic. The evidence in the literature suggests that GWR is a relatively simple and effective tool for spatial interpolation of an outcome variable and a more problematic tool for inferring spatial processes in regression coefficients. The more complex approach of Bayesian spatially varying coefficient models has been demonstrated to better capture spatial nonstationarity in regression coefficients than GWR and is recommended as an alternative for inferential analysis.

73.1 Introduction

Geographically weighted regression (GWR) was proposed in the geography literature by Brunson et al. (1996) to allow relationships in a regression model to vary over space. In contrast to traditional linear regression models, where the regression coefficients are constant over space, regression coefficients are estimated locally at spatially referenced data points with GWR. The movement of local regression coefficients away from their global values, where the global values come from a traditional linear regression model, is termed parametric nonstationarity and spatial nonstationarity in the case of spatial processes (Brunson et al. 1996). The motivation for the introduction of GWR is the idea that it is unreasonable to assume that a set of constant regression coefficients can adequately capture spatially varying relationships between covariates and an outcome variable.

GWR is based on the simple idea of estimating local models using subsets of observations located around a focal point. GWR has as its methodological foundation the nonparametric technique of locally weighted regression, developed in statistics for curve-fitting and smoothing applications. In locally weighted regression, parameters are estimated using subsets of data proximate to a model estimation point in variable space, where observations in the subset are applied weights that decrease with increasing distance in variable space. The modification proposed with GWR is to use a subset of data proximate to the model estimation location in geographic space in place of variable space.

Though the emphasis with traditional locally weighted regression in statistics has been on curve fitting, i.e., predicting or estimating the outcome variable (Cleveland and Devlin 1988), GWR has been presented as a method for conducting statistical inference on spatially varying relationships, in an attempt to extend the original emphasis on prediction to confirmatory analysis. The use of GWR for inferential analysis has been questioned and criticized, however, and it has been suggested that the method is more appropriately used for interpolation of an outcome variable, which is more in harmony with its origins. This chapter reviews the details of specifying and estimating a geographically weighted regression

model, summarizes a few important concerns with GWR, presents some diagnostic tools and alternative approaches, and concludes with an illustrative analysis of estimating concentrations of the pesticide chlordane with GWR.

73.2 Model Specification

In notation, the foundation for GWR is the traditional linear regression model

$$y_i = \beta_0 + \sum_{k=1}^{p-1} \beta_k x_{ki} + \varepsilon_i \quad (73.1)$$

where y_i is the normally distributed outcome variable and x_{ki} is the value for the k th covariate for observation i , β_0 is the intercept, β_k is the regression coefficient for the k th covariate, and ε_i is the random error for observation i . There are p regression coefficients to estimate with the linear regression model. GWR specifies that the regression coefficients vary over observations as

$$y_i = \beta_{0i} + \sum_{k=1}^{p-1} \beta_{ki} x_{ki} + \varepsilon_i \quad (73.2)$$

where there is now an intercept and covariate regression coefficient for each data point. For $i = 1, \dots, n$ observations in the dataset, there are np regression coefficients to estimate because p coefficients are estimated at each of the n observations. It is required that the observations are spatially referenced, i.e., spatial coordinates are known to represent each data point. The observations may be areal units or individual-level data, such as residences. In the case of area data, the centroid of each areal unit is typically used as the basis for the spatial coordinates.

As with the linear regression model, it is convenient to express the GWR model in matrix notation

$$y_i = \mathbf{X}_i \boldsymbol{\beta}_i + \varepsilon_i \quad (73.3)$$

where \mathbf{X}_i is a row vector of explanatory variables and $\boldsymbol{\beta}_i$ is a column vector of regression coefficients at location i . In GWR, spatial structure is specified in the model through applying weights to the data. The weights are applied to the outcome variable and the covariates. The weights are calculated from a kernel function that typically assigns more weight to observations that are spatially closer to the data point (i th location) where the model is estimated. The introduction of the weights into the model follows from the assumption of spatial autocorrelation, where observations more proximate in space are thought to be more similar. Spatial autocorrelation ignored in the linear regression model results in spatially correlated errors, a violation of the model assumption of independent and identically

distributed errors. One can choose to model spatial autocorrelation either through the error term or through the regression coefficients, which is the GWR approach.

The kernel function used to calculate the weights in the GWR setting takes as input distances between all locations, conveniently in the form of a distance matrix. The kernel function has a bandwidth parameter that determines the spatial range of the kernel. The bandwidth parameter must be selected a priori or estimated from the data. The function returns a weight between locations that is inversely related to distance. A number of different kernel functions can be used in GWR. There are two general types of kernel functions, adaptive and fixed. Adaptive kernel functions inherently adjust for the density of data points by using a bandwidth expressed in number of observations. This results in a spatially larger kernel in data-sparse areas and a smaller kernel in data-dense areas. Fixed kernel functions have a bandwidth expressed as a constant distance; hence, the kernel is the same spatial size regardless of the density of data points. This could result in a varying number of observations weighted in kernels across the study area if the kernel function has weights that are zero beyond a certain distance.

Some of the most popular fixed kernel functions applied within GWR are continuous functions that produce weights that monotonically decrease with distance, such as the Gaussian or exponential kernel functions. The Gaussian kernel function is

$$w_{ij} = \exp\left(-\frac{1}{2}\left(\frac{d_{ij}}{\gamma}\right)^2\right) \quad (73.4)$$

where w_{ij} is the weight for data at location j in the model estimated for location i ; d_{ij} is the distance between locations i and j ; γ is the kernel bandwidth, a distance, that controls the decay and range of spatial correlation; and $\exp()$ is the exponential function. For matrix multiplications in the calculations of the model parameter estimates in GWR, the n weights for each model calibration location i , in row vector \mathbf{w}_i , are placed in an $n \times n$ weights matrix \mathbf{W} . The simpler exponential kernel function is

$$w_{ij} = \exp\left(-\frac{d_{ij}}{\gamma}\right) \quad (73.5)$$

which removes the scaling and powering of the Gaussian function. Another fixed kernel function is the bi-square kernel function

$$w_{ij} = \begin{cases} \left[1 - \left(\frac{d_{ij}^2}{\gamma^2}\right)\right]^2 & \text{if } d_{ij} \leq \gamma \\ 0 & \text{if } d_{ij} > \gamma \end{cases} \quad (73.6)$$

where the weight $w_{ij} = 0$ if the interpoint distance exceeds the kernel bandwidth γ . Hence, this function is continuous until a distance threshold is reached and then

is constant (zero) beyond the threshold. A similar kernel function is the tricube function

$$w_{ij} = \begin{cases} \left[1 - \left(d_{ij}^3/\gamma^3\right)\right]^3 & \text{if } d_{ij} \leq \gamma \\ 0 & \text{if } d_{ij} > \gamma \end{cases} \quad (73.7)$$

One of the more popular adaptive kernel functions is the bi-square nearest neighbor kernel. The function is

$$w_{ij} = \begin{cases} \left[1 - (d_{ij}/d_{iN})^2\right]^2 & \text{if } j \text{ is one of the } N\text{th nearest neighbors of } i \\ 0 & \text{otherwise} \end{cases} \quad (73.8)$$

where d_{iN} is the distance to the N th nearest neighbor of location i and the number N of spatially nearest neighbors to use in the kernel function is estimated from the data. This function assigns a nonzero weight that decays with distance to points within the threshold number of neighbors and a weight of zero to points that are beyond the distance to the N th nearest neighbor.

Given the several options for a kernel function, one must first select the form of the kernel function before estimating the GWR model parameters, including the kernel bandwidth. Conventional thinking from the statistical nonparametric literature holds that the selection of the functional form for the kernel is less important than the selection of the kernel bandwidth for the model estimation results (Berk 2008). While this thinking is likely appropriate for GWR, a systematic assessment of the relative performance of different kernel functions in GWR has not been reported. Instead, most research has assumed a kernel function and focused on a criterion to select the kernel bandwidth.

73.3 Model Estimation

There are two methods for estimating the kernel bandwidth in GWR, cross-validation or minimizing the modified Akaike Information Criterion (AIC, Akaike 1973). Of the two approaches, cross-validation appears more commonly used, likely due to its heavy use in other related areas of statistics, such as local regression and statistical learning, and its conceptual simplicity.

Cross-validation is an iterative process that searches for the kernel bandwidth that minimizes the prediction error of all the observed outcome values using a subset of the data for prediction. The kernel bandwidth, denoted here generally as γ , is estimated in cross-validation by finding the γ that minimizes the cross-validation (CV) score. The sum of CV errors and the root mean squared prediction error (RMSPE) have been used as the CV score. The kernel bandwidth that minimizes the sum of CV errors, denoted $\hat{\gamma}$, is defined as

$$\hat{\gamma} = \arg \min_{\gamma} \sum_{i=1}^n [y_i - \hat{y}_{(i)}(\gamma)]^2 \quad (73.9)$$

where $\hat{y}_{(i)}$ is the predicted value of observation i with calibration location i left out of the estimation dataset. The kernel bandwidth minimizing the RMSPE is

$$\hat{\gamma} = \arg \min_{\gamma} \sqrt{\frac{1}{n} \sum_{i=1}^n [y_i - \hat{y}_{(i)}(\gamma)]^2} \quad (73.10)$$

This form of cross-validation is known as leave-one-out because only one observation is removed from the dataset for each local model when estimating the kernel bandwidth. The data point i is removed when estimating y_i to avoid estimating it perfectly. There are several search routines available for finding the optimal kernel bandwidth, including the golden search and the bisection search. Alternatively, one may systematically evaluate the CV score over a range of reasonable possible kernel bandwidths. In the kernel functions described above, the kernel bandwidth is a global parameter and is applied to all local models individually.

In contrast to cross-validation, the corrected AIC approach to estimating the kernel bandwidth is based on minimizing the estimation error of the outcome variable, not on the prediction of the outcome variable. The corrected AIC in GWR is adopted from locally weighted regression. The AIC is a compromise between model complexity and goodness of fit of the model, as there is a penalty for the effective number of parameters in the model. The corrected AIC for GWR is

$$\text{AIC}_c = 2n \log(\hat{\sigma}) + n \log(2\pi) + n \left(\frac{n + \text{trace}(\mathbf{H})}{n - 2 - \text{trace}(\mathbf{H})} \right) \quad (73.11)$$

where $\hat{\sigma}$ is the estimated standard deviation of the error, \mathbf{H} is the hat matrix, and the trace of a matrix is the sum of the matrix diagonal elements. The kernel bandwidth is used in the calculation of \mathbf{H} and $\hat{\sigma}$. Row i of the hat matrix is defined as

$$\mathbf{H}_i = \mathbf{X}_i (\mathbf{X}^T \mathbf{W}_i \mathbf{X})^{-1} \mathbf{X}^T \mathbf{W}_i \quad (73.12)$$

which can also be expressed as

$$\mathbf{H}_i = \mathbf{X}_i \mathbf{A}_i \quad (73.13)$$

The estimated error variance is

$$\hat{\sigma}^2 = \sum_{i=1}^n (y_i - \hat{y}_i)^2 / (n - (2\text{trace}(\mathbf{H}) - \text{trace}(\mathbf{H}^T \mathbf{H}))) \quad (73.14)$$

To estimate the kernel bandwidth using the AIC, one can either use a search algorithm or evaluate the AIC over a range of possible bandwidth values to find the bandwidth that minimizes the AIC. The second approach is commonly used to show the relationship between the AIC and the kernel bandwidth.

The GWR estimates for the outcome variable values, \hat{y}_i , are calculated by

$$\hat{y}_i = \mathbf{X}_i \hat{\boldsymbol{\beta}}_i \quad (73.15)$$

where $\hat{\boldsymbol{\beta}}_i$ is a column of estimated regression coefficients at location i . The vector of estimated regression coefficients at one location is

$$\hat{\boldsymbol{\beta}}_i = [\mathbf{X}^T \mathbf{W}_i \mathbf{X}]^{-1} \mathbf{X}^T \mathbf{W}_i \mathbf{Y} \quad (73.16)$$

where $\mathbf{X} = [\mathbf{X}_1^T; \mathbf{X}_2^T; \dots; \mathbf{X}_n^T]^T$ is the design matrix of covariates and leading column of ones for the intercept, $\mathbf{W}_i = \text{diag}[w_{i1}, \dots, w_{in}]$ is the $n \times n$ diagonal weights matrix calculated for each location i , \mathbf{Y} is the $n \times 1$ vector of outcome variables, and $\hat{\boldsymbol{\beta}}_i = (\hat{\beta}_{0i}, \hat{\beta}_{1i}, \dots, \hat{\beta}_{p-1i})^T$ is the vector of p local regression coefficients at location i for $p - 1$ explanatory variables and the intercept. The weight matrix \mathbf{W}_i must be calculated at each location using the kernel function and bandwidth before the local regression coefficients can be estimated. The predictions of the outcome variable values $\hat{y}_{(i)}$ in cross-validation are calculated similarly, but with the element $w_{ii} \equiv 0$ to effectively remove the i th observation from consideration in the model to predict y_i . Given the definition of the estimated regression coefficients, GWR can be viewed as a locally weighted least squares regression model where the weights associate pairs of data points.

In previous studies using GWR, researchers have mapped estimated regression coefficients in attempts to interpret the spatial pattern of the coefficients in the context of the research problem (Brunsdon et al. 1996; Wheeler and Tiefelsdorf 2005). Researchers have typically been interested in where the estimated regression coefficients are statistically significant, according to some prespecified significance level. In the frequentist setting of traditional GWR, statistical significance tests of the coefficients use the variance of the estimated regression coefficients. According to Fotheringham et al. (2002, p. 55), the variance of the regression coefficients is

$$\text{Var}[\hat{\boldsymbol{\beta}}_i] = \mathbf{A}_i \mathbf{A}_i^T \hat{\sigma}^2 \quad (73.17)$$

Technically, this equation is incorrect because the Fotheringham et al. (2002) version of GWR is not a formal statistical model with kernel weights that are specified as part of the errors. The equation used for the local coefficient covariance is only approximate when using cross-validation because the kernel weights are calculated from the data first, before the regression coefficients are estimated from the data. The kernel weights are inherently a function of the outcome variable, as are the regression coefficients, and the correct expression for the coefficient covariance would be nonlinear.

73.4 Implementation

Implementations of GWR are freely available for the software R in the packages `spgwr`, written by Roger Bivand and Danlin Yu, and `gwrr`, written by the author. The package `spgwr` contains functions for estimating GWR model parameters by minimizing the AIC or using cross-validation with several possible kernel functions, including a Gaussian kernel, a bi-square kernel, and a tricube kernel. The `gwrr` package has functions for estimating GWR model parameters by cross-validation with exponential and Gaussian kernel functions and a bisection search routine. The `gwrr` package also has a function to diagnose collinearity with GWR models, and functions to estimate a penalized version of GWR, known as geographically weighted ridge regression, to dampen collinearity effects.

73.5 Issues

73.5.1 Statistical Inference

Though the introduction of GWR has provided an approach to investigate regression relationships that may vary over space, there are several critiques of the method. A central issue is a lack of formal statistical inference. GWR lacks a unified statistical framework, as it is effectively an ensemble of local spatial regressions, where the dependence between regression coefficients at different data locations is not specified in the model. This is a fixed effects model with no pooling across estimates. A consequence of a lack of a formal statistical model is that the standard error calculations in GWR are only approximate. This fact is due to reusing data for parameter estimation at multiple locations (Congdon 2003; Lesage 2004) and to using the data to estimate first the kernel bandwidth through cross-validation and then the regression coefficients (Wheeler and Calder 2007). The implication of the approximate standard errors is that the confidence intervals for estimated GWR coefficients are only approximate and should not be considered exactly reliable for detecting statistically significant covariate effects.

Another issue for inference on regression relationships with GWR is with the nature and amount of spatial variation in the estimated coefficients, i.e., nonstationarity. Tests for significant spatial variation in the estimated coefficients for one term in a GWR model have been proposed by Fotheringham et al. (2002) and Leung et al. (2000a). However, the tests do not consider the source of the spatial variation observed in the coefficients. There is concern that variation in the pattern of estimated coefficients may be artificially introduced by the smoothing methodology in GWR and may not represent true nonstationarity in the regression effects (Wheeler and Tiefelsdorf 2005). In other words, nonstationary regression effects could be an artifact of the methodology. Additionally, regression coefficient variability in GWR could result from collinearity effects.

In this light of uncertain statistical inference, GWR is more appropriately viewed as an exploratory approach and not a formal model to infer parameter nonstationarity. This view conflicts with the broad application of GWR as an inferential method. Instead of formal statistical inference on spatially varying regression effects, GWR is perhaps better suited to estimation and prediction of an outcome variable. This use would be more congruous with the theoretical origins of GWR in local linear regression, which was developed to estimate a response variable locally. GWR has produced favorable results in estimating a dependent variable compared with other interpolation techniques (Páez et al. 2008). Another argument for using GWR as a local estimator of a response variable is that when interpolation of an outcome variable over space is the main interest, regression coefficient estimation issues in GWR, such as collinearity, are no longer a major concern.

73.5.2 Collinearity

An issue that can interfere with statistical inference in linear regression models generally is collinearity. Collinearity is the presence of linear dependencies in the design matrix of a regression model, resulting in redundant information in the design matrix and an ill-conditioned variance matrix. Some of the negative consequences of collinearity are overestimates of covariate effect magnitudes, coefficient sign reversals, inflated variances for regression coefficients, and strong correlation in two or more estimated regression coefficients, all of which are likely to lead to incorrect interpretations of relationships in the regression model (Neter et al. 1996). These symptoms of collinearity have all been observed with GWR models for either simulated or actual datasets (Wheeler and Tiefelsdorf 2005; Waller et al. 2007; Griffith 2008; Finley 2011). The most conspicuous result of estimated GWR models pointing to collinearity effects in many studies has been strongly correlated regression coefficients for pairs of regression terms, including the intercept, evident in maps or scatter plots of estimated coefficients. Particular concern about collinearity symptoms is warranted with GWR, as collinearity has been found in empirical work to be an issue in local GWR models when it is not present in the traditional linear regression model with the same data (Wheeler 2007). Wheeler and Tiefelsdorf (2005) show through a simulation study that although GWR coefficients can be correlated when there is no correlation in explanatory variables, the coefficient correlation increases systematically with increasingly stronger collinearity.

73.6 Diagnostic Tools

There are several established diagnostic tools that have become an essential part of the practice of model fitting for traditional linear regression models, including methods to check for collinearity, influential observations, and autocorrelation. Use of a more complex regression model, such as GWR, should also be

complemented with diagnostic tools. Methods to identify spatial residual autocorrelation in GWR models have been developed by Leung et al. (2000b) and by Páez et al. (2002). A limitation of these approaches is that they are not model-based, remembering that the GWR method is a collection of local models that are not part of a unified framework. As a result, it is not clear that the source of autocorrelation can be identified. Farber and Páez (2007) proposed a method to adjust for influential observations in the cross-validation of GWR.

The need for diagnostic tools for collinearity in GWR models is motivated by several examples in the literature of the presence of redundant information in sets of estimated GWR coefficients from models built for different datasets (Wheeler and Tiefelsdorf 2005; Waller et al. 2007; Griffith 2008). Local collinearity in the GWR model can cause strong correlation in pairs of estimated regression coefficients, as is a consequence of collinearity in the traditional linear regression model. Based on existing published findings, researchers should strongly consider using diagnostic tools for collinearity when estimating GWR coefficients. Conveniently, there are diagnostic tools available to determine if there are substantial collinearity effects present in a GWR model. Simple tools to detect collinearity effects in GWR models include scatter plots of regression coefficients for pairs of regression terms, maps of approximate local regression coefficient correlations (Wheeler and Tiefelsdorf 2005), and local variance inflation factors (VIFs) (Wheeler 2007). The VIF measures how much the estimated variance of a regression coefficient is increased by collinearity. A limitation of the VIF as a diagnostic tool is that it does not consider collinearity with the intercept. More advanced and recommended tools are the variance-decomposition proportions and the associated condition indexes (Belsley 1991; Wheeler 2007). An advantage of the variance-decomposition approach over the VIF is that it measures and conveys the nature of the collinearity among all regression terms at the same time, including the intercept. As motivation for using these tools, applying them to a GWR model to explain crime rates in Columbus, OH, clearly linked local collinearity to strong GWR coefficient correlation and increased coefficient variation for two economic status covariates at numerous data locations with counterintuitive positive regression coefficient signs (Wheeler 2007).

The variance-decomposition proportion and condition index diagnostic tools introduced by Belsley (1991) and modified for GWR by Wheeler (2007) use singular value decomposition of the GWR kernel-weighted design matrix to calculate variance-decomposition proportions and condition indexes of the coefficient covariance matrix. The variance-decomposition proportion is the percentage of the variance of a regression coefficient that is explained with any one component of the variance matrix decomposition. The condition index is the ratio of the largest singular value and a smaller singular value of the decomposition. Each variance-decomposition proportion has an associated condition index. The singular value decomposition of the design matrix in the GWR model is

$$\mathbf{W}_i^{1/2}\mathbf{X} = \mathbf{UDV}^T \quad (73.18)$$

where \mathbf{U} and \mathbf{V} are orthogonal $n \times p$ and $p \times p$ matrices, respectively, and \mathbf{D} is a $p \times p$ diagonal matrix of singular values of $\mathbf{W}_i^{1/2}\mathbf{X}$, starting at matrix element (1,1) and decreasing in value down the diagonal. The matrix $\mathbf{W}_i^{1/2}$ is the square root of the diagonal weight matrix for calibration location i using a kernel function with the estimated kernel bandwidth from the GWR model. By way of the decomposition, the local variance-covariance matrix of the regression coefficients is

$$\text{Var}(\hat{\boldsymbol{\beta}}_i) = \sigma^2 \mathbf{V} \mathbf{D}^{-2} \mathbf{V}^T \quad (73.19)$$

The variance of the local k th regression coefficient is

$$\text{Var}(\hat{\beta}_{ik}) = \sigma^2 \sum_{j=1}^p \frac{v_{kj}^2}{e_j^2} \quad (73.20)$$

where the v_{kj} 's are the elements of the \mathbf{V} matrix and the e_j 's are the singular values. The variance-decomposition proportion for the local k th regression term and the j th component of the decomposition is

$$\pi_{jk} = \frac{\phi_{kj}}{\phi_k} \quad (73.21)$$

where

$$\phi_{kj} = \frac{v_{kj}^2}{e_j^2} \quad (73.22)$$

and

$$\phi_k = \sum_{j=1}^p \phi_{kj} \quad (73.23)$$

The condition index for variance component $j = 1, \dots, p$ is

$$\eta_j = \frac{e_{\max}}{e_j} \quad (73.24)$$

where e_{\max} is the largest singular value.

Belsley (1991) introduced guidelines for using the variance-decomposition proportions and condition indexes in the traditional linear regression setting. Through experimentation results, Belsley (1991) suggests a conservative value of 30 as a threshold for a condition index which indicates collinearity, although the threshold could be as low as 10 if there are large variance-decomposition proportions for two or more regression terms for the same variance component. In general, larger condition

indexes suggest stronger collinearity. A guideline for the variance-decomposition proportions is that the presence of two or more variance-decomposition proportions greater than 0.5 for the same variance component indicates that collinearity exists between those regression terms. It appears reasonable to apply these guidelines for diagnosing collinearity in a GWR model; however, the guidelines have not been systematically studied in the GWR setting.

The condition index and variance-decomposition proportion diagnostic tools reveal collinearity locally for the individual GWR models and consequently enable researchers to construct plots of the diagnostic values and link them directly to estimated GWR coefficients for visual analysis of any collinearity problems present in the model. Estimated GWR coefficients from local models that are diagnosed as problematic should be interpreted with severe caution, and additional analysis should be carried out in these areas to better understand the nature of the relationships being modeled. The variance-decomposition proportions and condition index tools are implemented in the freely available R package `gwr`.

73.7 Extensions

Several different models have been introduced to extend the concept of geographically weighted regression. The focus here is on extensions that address the issue of collinearity. Collinearity effects in linear regression models have been dampened by constraining the amount of variation in regression coefficients. Two extended versions of GWR have been proposed that are based on the coefficient shrinkage models of ridge regression and the lasso: geographically weighted ridge regression (GWRR; Wheeler 2007) and the geographically weighted lasso (GWL; Wheeler 2009). The methods limit the amount of variation in the coefficients through the addition of a constraint, or penalty, on the size of the regression coefficients. Ridge regression coefficients minimize the sum of a penalty on the residual sum of squares and the size of the squared coefficients,

$$\hat{\boldsymbol{\beta}}^R = \arg \min_{\boldsymbol{\beta}} \left\{ \sum_{i=1}^n \left(y_i - \beta_0 - \sum_{k=1}^p x_{ki} \beta_k \right)^2 + \lambda \sum_{k=1}^p \beta_k^2 \right\} \quad (73.25)$$

where λ is the shrinkage parameter controlling the magnitude of the regression coefficients. The lasso coefficients minimize the sum of the residual sum of squares and the absolute value of the coefficients,

$$\hat{\boldsymbol{\beta}}^L = \arg \min_{\boldsymbol{\beta}} \left\{ \sum_{i=1}^n \left(y_i - \beta_0 - \sum_{k=1}^p x_{ki} \beta_k \right)^2 + \lambda \sum_{k=1}^p |\beta_k| \right\} \quad (73.26)$$

The nature of the constraint in the lasso results in more shrinkage in the regression coefficients than with ridge regression, potentially shrinking some of

the coefficients to zero. The lasso solution coefficients are a transformation of the least squares solution by a constant factor, truncated at zero. As such, the lasso may be viewed as a model-selection method, in that it can remove a term from the model by zeroing its effect. Because the methods are scale dependent, it is common practice when using the lasso or ridge regression to center the response variable and center and scale the explanatory variables to have unit variances. The estimates of the GWRR coefficients using centering of the variables are

$$\hat{\boldsymbol{\beta}}_i = (\mathbf{X}^{*T} \mathbf{W}_i \mathbf{X}^* + \lambda \mathbf{I})^{-1} \mathbf{X}^{*T} \mathbf{W}_i \mathbf{y}^* \quad (73.27)$$

where \mathbf{X}^* is the matrix of standardized explanatory variables, \mathbf{I} is the identity matrix, and \mathbf{y}^* is the standardized response variable. There are different options for the type of scaling and centering (see Wheeler 2007). The absolute value constraint on the regression coefficients in GWL makes the problem nonlinear, but computationally efficient algorithms exist for estimating the parameters (Wheeler 2009). GWRR is implemented in the R package `gwrr`.

73.8 Alternatives

Bayesian hierarchical models are an alternative to GWR for estimating spatially varying coefficients in regression models. The Bayesian hierarchical modeling framework is flexible and provides formal statistical inference for model parameters in a unified statistical model. In the Bayesian setting, the distribution of the outcome variable is specified conditional on unknown parameters, whose distribution is in turn conditional on other parameters. All parameters are considered random in a Bayesian model. As an alternative to GWR, one can use a Bayesian hierarchical model with random effects for the intercept and covariate effects and specify the random effects as either independent in the prior and borrow strength across observations globally or as spatially correlated and borrow strength locally. The second specification is closer in spirit to GWR, and Bayesian models of this type are called spatially varying coefficient (SVC) models. There are two different approaches for specifying the spatial structure in spatially varying coefficients (Banerjee et al. 2004). One is a prior conditional specification of the coefficients that uses only neighboring observations, and the other is a prior joint specification of the coefficients that models correlation in the coefficients as a continuous spatial process. The second specification is more similar in form to the fixed kernel functions described earlier for modeling spatial correlation in GWR.

The Bayesian SVC model with the continuous spatial process prior for the regression coefficients may be specified conveniently with matrix notation as

$$[\mathbf{Y} | \boldsymbol{\beta}_p, \tau^2] \tilde{N}(\mathbf{X}_p^T \boldsymbol{\beta}_p, \tau^2 \mathbf{I}) \quad (73.28)$$

where \mathbf{Y} is assumed to be Gaussian conditional on the parameters τ^2 and $\boldsymbol{\beta}_p$. $\boldsymbol{\beta}_p$ is an $np \times 1$ vector of regression coefficient parameters, and \mathbf{X}_p^T is the $n \times np$ block

diagonal matrix of covariates, where each row contains a row from the $n \times p$ design matrix \mathbf{X} along with zeros in the appropriate places (the covariates from \mathbf{X} are shifted p places in each subsequent row in \mathbf{X}_p^T). The subscript P denotes the different sizes of the design matrix and the regression coefficient matrix associated with the process model. τ^2 is the error variance and \mathbf{I} is the $n \times n$ identity matrix.

The prior distribution for the regression coefficient parameters is

$$[\boldsymbol{\beta}_p | \boldsymbol{\mu}_\beta, \Sigma_\beta] = N(\mathbf{1}_{n \times 1} \otimes \boldsymbol{\mu}_\beta, \Sigma_\beta) \quad (73.29)$$

where the vector $\boldsymbol{\mu}_\beta = (\mu_{\beta_0}, \dots, \mu_{\beta_p})^T$ contains the means of the regression terms. The Kronecker product operator (\otimes) multiplies every element in $\mathbf{1}_{n \times 1}$ by $\boldsymbol{\mu}_\beta$. The prior on the regression coefficients takes into account possible spatial dependence in the coefficients through the covariance, Σ_β , which has a separable form with two components, one for the within-site dependence between coefficients and one for the spatial dependence in the regression coefficients. The separable form of the covariance matrix for $\boldsymbol{\beta}_p$ is

$$\Sigma_\beta = \mathbf{R}(\phi) \otimes \mathbf{T} \quad (73.30)$$

where $\mathbf{R}(\phi)$ is the $n \times n$ correlation matrix that models the spatial association between the n locations using interpoint distances, ϕ is an unknown spatial dependence parameter, and \mathbf{T} is a positive-definite $p \times p$ matrix for the covariance of the regression coefficients at any spatial location. In contrast to the repeated application of spatial kernel functions in GWR, this $np \times np$ covariance matrix simultaneously captures the covariation between all the regression coefficients. In the separable covariance matrix, each of the p coefficients represented in the covariance is assumed to have the same spatial dependence structure. This matches the assumption in GWR of equivalent spatial ranges for each regression term.

The specification of the Bayesian SVC process model is completed with the specification of prior distributions for the other parameters. Conjugate priors are Gaussian for the coefficient means, inverse gamma for the error variance, and inverse Wishart for the within-site covariance matrix. The spatial dependence parameter can be specified with a uniform or gamma prior distribution. Inference on the model parameters is realized through Markov chain Monte Carlo (MCMC) by sampling from the joint posterior distribution of the parameters and then summarizing the distribution with posterior means, medians, and credible intervals. Details for the MCMC simulation are provided in Wheeler and Calder (2007) and Finley (2011). A variety of Bayesian spatial process models are implemented in the R package `spBayes`, written by Andrew Finley, Sudipto Banerjee, and Brad Carlin. Bayesian SVC models with spatial dependence specified through neighborhood adjacency may be fitted with GeoBUGS (Thomas et al. 2004) and WinBUGS software (Spiegelhalter et al. 2003).

Researchers can choose to model spatial autocorrelation in a regression model through the regression coefficients, as in GWR and the Bayesian SVC model, or through the error term. As such, assuming nonstationarity in the regression

coefficients is a choice made about the source and form of the spatial dependence in the data. GWR was designed to address spatial autocorrelation through nonstationary regression coefficients. If one is not confident about the presence of spatially varying effects but wants to adjust for spatial autocorrelation, one can always specify a regression model with spatially structured residuals (see Congdon 2010 for examples in the Bayesian framework).

73.9 Application: Residential Chlordane Exposure in Los Angeles County

Insecticides are biologically active chemicals that have been used for agricultural and household applications for decades in the United States. Epidemiologic studies have linked residential exposure to insecticides with elevated risk of cancer, including non-Hodgkin lymphoma (NHL) (Colt et al. 2005, 2006). Specifically, positive associations were found between NHL risk and dust residues of dichlorodiphenyldichloroethylene (DDE), a metabolite of DDT (dichlorodiphenyltrichloroethylene) (Colt et al. 2005) and chlordane, which was used in the United States for subterranean termite control from 1978 to 1988 (Colt et al. 2006). Chlordane was banned in 1988 because of concerns over cancer risk and danger to wildlife. Risk of NHL was elevated among subjects who had home termite treatments before 1988, but not after 1988 (Colt et al. 2006). As with other organochlorine chemicals such as polychlorinated biphenyl (PCB), chlordane is persistent in the environment, and it has been detected in the indoor air of homes 15 years after termite treatment (Livingston and Jones 1981). Given the health concerns and the persistence of these organochlorine chemicals, it is important to describe their spatial distribution in the environment and determine factors that explain the distribution.

The National Cancer Institute Surveillance, Epidemiology, and End Results (NCI-SEER) NHL study was a multicenter, population-based case–control study that was conducted to investigate potential risk factors for NHL. Details of the study design have been reported previously (Colt et al. 2005; Wheeler et al. 2011). NHL cases 20–74 years of age were identified between July 1, 1998, and June 30, 2000, from the SEER registries covering Iowa and the metropolitan areas of Detroit, Seattle, and Los Angeles County. Controls were selected by random digit dialing or from Medicare files. Computer-assisted personal interviews (1,321 cases and 1,057 controls) were conducted in 1998–2000 to elicit data on medical history, demographic variables, and various risk factors for NHL, including home insecticide use. Participants were also asked to provide lifetime residential histories that were address matched to geographic address databases to yield spatial coordinates. For study subjects who had used a vacuum in the home in the past year and owned most of their carpets for 5 years or more (682 cases and 513 controls), carpet dust samples from used vacuum cleaner bags were collected to measure residential exposure to certain chemicals, including the insecticide chlordane. Some insecticides applied indoors or tracked in from the outdoors persist in carpet dust for months or years, where they are protected from degradation by rain, sunlight,

Fig. 73.1 Log chlordane concentration in Los Angeles County

temperature extremes, and microbial action. Pesticides and other chemicals in dust were analyzed using gas chromatography/mass spectrometry (ng per gram of fine dust [$<100\ \mu\text{m}$ diameter]).

For this analysis, I used linear regression and geographically weighted regression models to explain chlordane levels in house dust in the NCI-SEER NHL study Los Angeles center, where chlordane levels were highest in the study. This example analysis could be read as a cautionary example in using GWR models; however, no data analysis or manipulation was performed to create an unfavorable situation in which to apply these models. Data on gender, race, education, home age, presence of Oriental rugs, housing type, and pest treatments of sampled homes were available from interviews. US Census 2000 tract variables for median income, median year homes were built, and percent of the tract that was urban were used to characterize the neighborhood socioeconomic status and urbanicity. The 1992 National Land Cover Dataset (NLCD) was used to determine land use around residences. Percent of land cover within specified distance buffers (500, 1,000, 2,000, 3,000, 5,000, 10,000, 15,000, 20,000 m) of each residence was calculated for classifications of use (agricultural, residential, urban/recreational, orchards/vineyards). All statistical analyses were performed using the software R.

Observed chlordane concentration was approximately lognormally distributed (Fig. 73.1); therefore, it was modeled as natural lognormal in the models. Chlordane concentrations below the minimum detection limit of 20.8 ng/g were imputed with a regression model (Colt et al. 2005). Concentrations of the insecticides α -chlordane and γ -chlordane were summed to compose the total chlordane

Table 73.1 Estimated parameters for the first traditional linear regression model and geographically weighted regression model for chlordane concentration in Los Angeles County

Coefficient	LM estimate	Standard error	p value	VIF	Mean GWR estimate
Intercept	119.40	25.93	<0.001		116.48
Race	0.90	0.38	0.019	1.21	0.85
Year built	-0.06	0.01	<0.001	1.07	-0.06
Termite treatment	1.10	0.30	<0.001	1.01	1.09
Median income	-4.3E-06	4.9E-06	0.378	1.19	-4.2E-06
F-statistic	10.02		<0.001		
R-squared	0.25				0.28 ^a
RMSE	1.64				1.60

^aR-squared is only approximate for GWR

concentration. The first step in the analysis was to use a traditional linear regression model of the form

$$y_i = \mathbf{X}_i\boldsymbol{\beta} + \varepsilon_i \quad (73.31)$$

where y_i is log chlordane concentration (ng/g) in the home at time of the study interview for subject i , \mathbf{X}_i is a row vector of explanatory variables for subject i , $\boldsymbol{\beta}$ is a column vector of regression coefficients, and ε_i is the random error for subject i . The first element of \mathbf{X}_i is 1 for the intercept. The initial model considered the relationship of log chlordane concentration with the variables gender, race (whites and Asians vs. other races), education (<12 years, 12–15 years, ≥ 16 years), median year home built (tract level), median income (tract level), percent urban, presence of Oriental rug, home type, home termite treatment before 1988, lawn treatment, percent land used for agriculture within 15 km of residence, percent land used for orchards within 15 km, and percent residential land within 10 km. Lawn treatment was included as another potential source of organochlorine compounds. Of the covariates, only race, home termite treatment, and median year home built were statistically significant in the model at the 0.05 level. All other variables except median income were excluded from the model to reach a parsimonious model. Median income was retained in the model because it was suspected a priori to potentially have a significant relationship with chlordane concentration that could also vary over space. Lower income communities and poorly maintained housing are positively associated with pest infestation and consequently treatments for pests.

The estimated linear regression model parameters are listed in [Table 73.1](#). Median year home built and home termite treatment were highly statistically significant with intuitive coefficient signs: newer homes were associated with lower concentrations of chlordane, and termite treatments before 1988 was associated with increased chlordane concentrations. Whites and Asians had lower

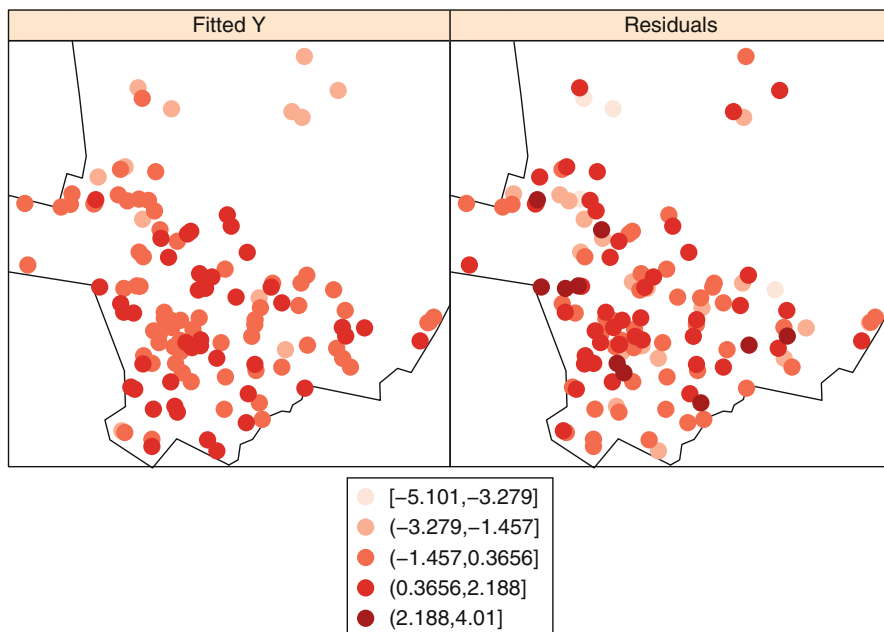

Fig. 73.2 Fitted log chlordane concentration and model residuals from the traditional linear regression model

residential chlordane concentrations than other races. Increasing median income was associated with lowered chlordane concentration, although not significantly. The coefficient of determination (R^2) was 0.25, and the root mean squared error (RMSE) was 1.64. The variance inflation factors did not suggest a problem of collinearity for any covariate term with the other covariate terms. The standard error for the intercept appears large, and generally this could suggest a collinearity issue; however, the standard error is not large relative to the intercept. The residuals of the model do not suggest lack of normality or heteroscedasticity (not shown). There does appear to be some local spatial pattern in the model residuals (Fig. 73.2). A Moran's I test using inverse distance weighting and 75 % of the data closest to each point yielded a p value of 0.01, suggesting that the null hypothesis of no spatial autocorrelation can be rejected.

Given the apparent spatial correlation in the residuals, I next used a generalized additive model (GAM) (Wood 2006) to model the residual spatial variation in chlordane concentration. The GAM specification is

$$y_i = \mathbf{X}_i\boldsymbol{\beta} + z(s) \quad (73.32)$$

where $z(s)$ is a smooth function of the spatial coordinates at location s , and the other terms are as previously defined. The smoothing function models spatial pattern in

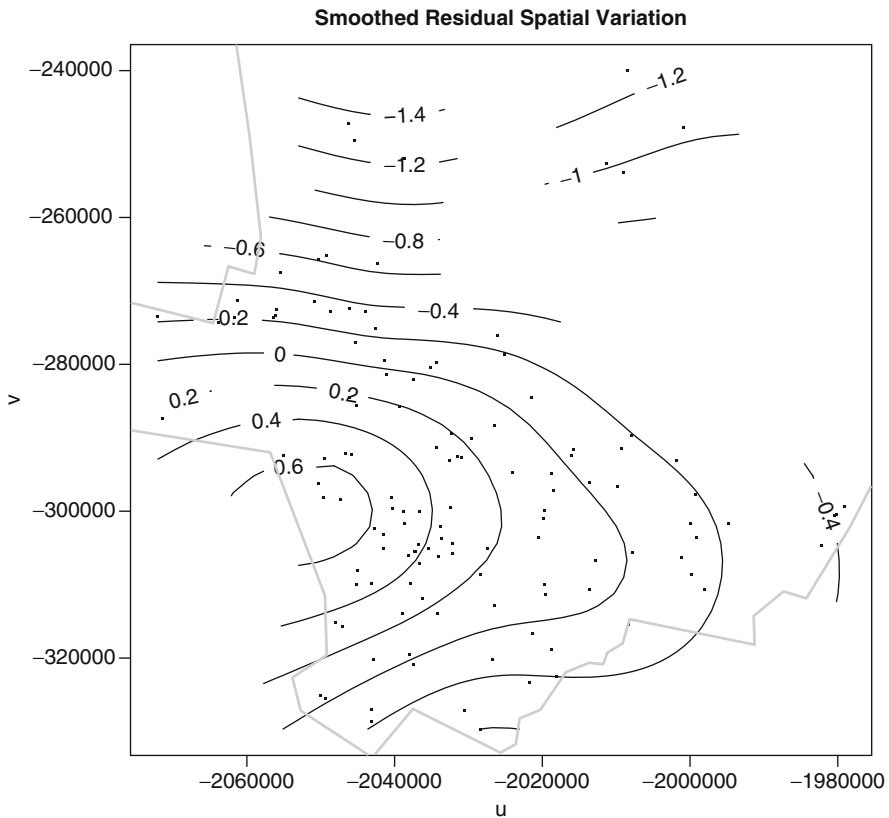

Fig. 73.3 Smoothed residual spatial variation from a generalized additive model for log chlordane concentration

what is not described by the covariates in the model. I used thin plate regression splines for the smoothing function (Wood 2006) with the R package *mgcv*. There is a clear pattern in the estimated residual spatial variation (Fig. 73.3), where residual chlordane concentration increases generally from southwest to northeast across the county. It is unknown whether the pattern observed in the residuals is due to spatial nonstationarity in the regression model relationships or from a misspecified model, where important covariates have been omitted.

To explore nonstationarity processes, I expanded on the basic linear regression model by estimating the GWR model specified in Eq. (73.3) for chlordane concentration using the R package *gwr*. Though the GWR model improves slightly on the fit of the linear regression model (Table 73.1), the GWR coefficients are immediately suspicious. The scatter plot matrix of estimated regression coefficients shows that the coefficients for the intercept (β_0) and year home built (β_2) are nearly

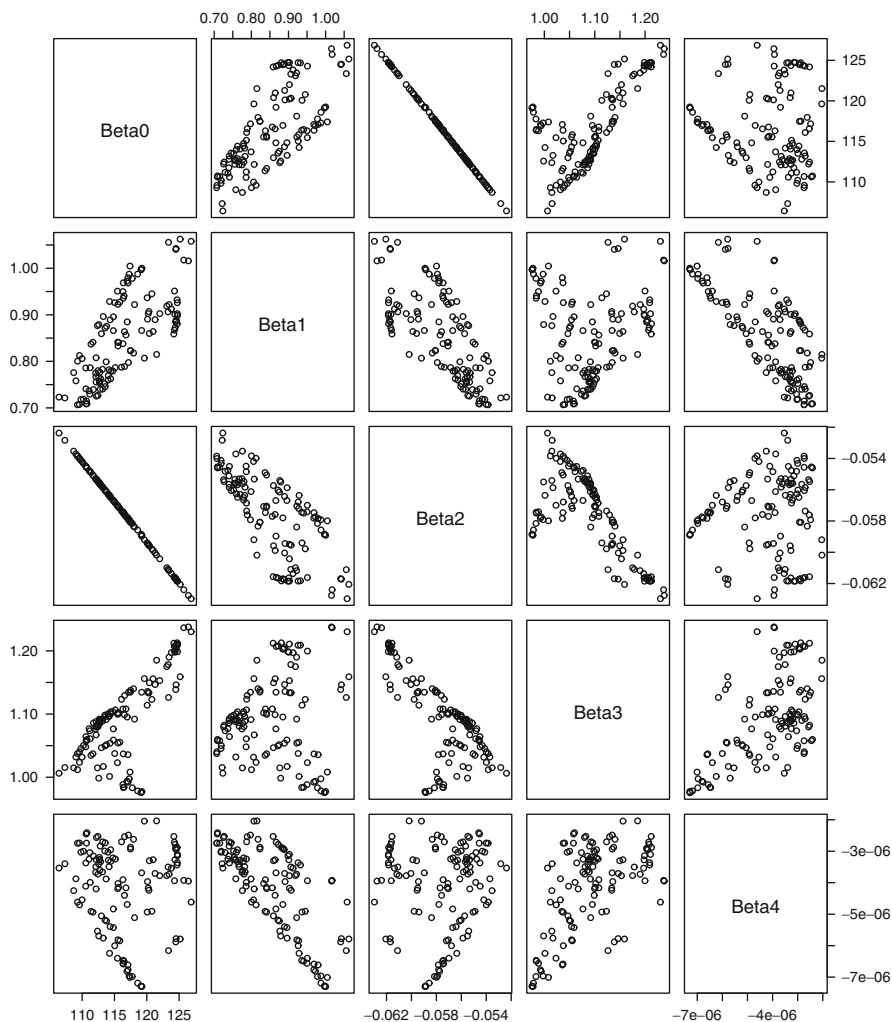

Fig. 73.4 Scatter plot matrix of estimated coefficients from the first GWR model

perfectly correlated (Fig. 73.4). The strong correlation in this pair of regression terms is evident in maps of the estimated coefficients (Fig. 73.5), where the maps are clearly complementary; β_0 is high where β_2 is low, and vice versa. The collinearity diagnostics for the GWR model indicate a major problem of collinearity with the intercept and year home built term. The condition index and variance-decomposition proportions calculated using the R package `gwrr` are extremely large, with the largest condition index for every local model exceeding 400 and the variance-decomposition proportions for the intercept and year home built each exceeding 0.99 for all local models. The strong collinearity results in

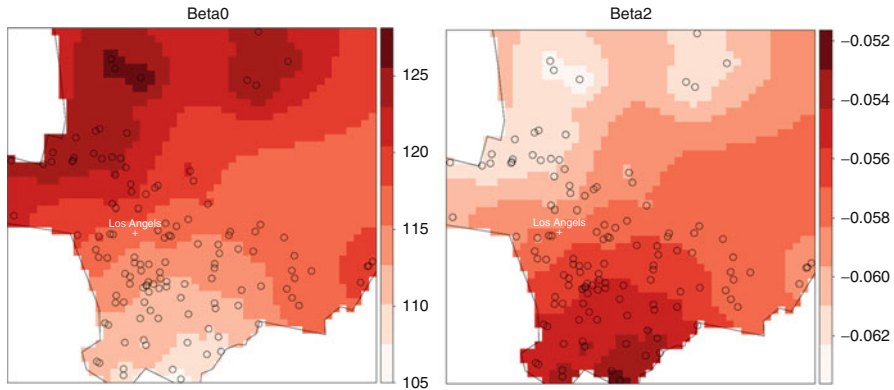

Fig. 73.5 Interpolated estimated regression coefficients for the intercept (Beta0) and year home built (Beta2) from the first GWR model with points indicating the sample locations

coefficients for year home built that are not meaningful, as they are perfectly correlated with the intercept, and knowing the local intercept effectively determines the year home built coefficient. Instead of having five regression terms, there are actually only four terms.

Reflecting back on the linear model, it would not be unexpected for practitioners to fail to detect an issue of collinearity in the model between the intercept and year home built, as some level of correlation with the intercept is expected with the linear model, researchers are not often encouraged to check for collinearity with the intercept, and the commonly used diagnostic of the variance inflation factor does not address collinearity with the intercept. Applying the collinearity diagnostics of the condition index and variance-decomposition proportions to the design matrix for the linear regression model revealed the collinearity issue, as the largest condition index was 504 and the corresponding variance-decomposition proportions for the intercept and year home built exceeded 0.99. Collinearity was present in the linear model, but it only became glaringly obvious with the GWR model. It would only have been detected using the appropriate, but infrequently applied, tools of the variance-decomposition proportions and condition index.

Potential solutions to the collinearity issue are to attempt a penalized regression or to remove the year home built variable from the model. I removed the year home built variable for both the linear regression model and the GWR model in this example. Removing this variable overcomes the collinearity issue in both models according to the collinearity diagnostics, as the condition indexes were on the order of 5 and there were no pairs of variance-decomposition proportions exceeding 0.5 for different regression terms. The fit of this second GWR model improved slightly by removing year home built, but the linear regression model fit decreased substantially (Table 73.2). In this case, when avoiding serious collinearity, GWR provided a substantially better fit than the linear regression model. Fitted values for chlordane concentration from the reduced GWR model convey the overall

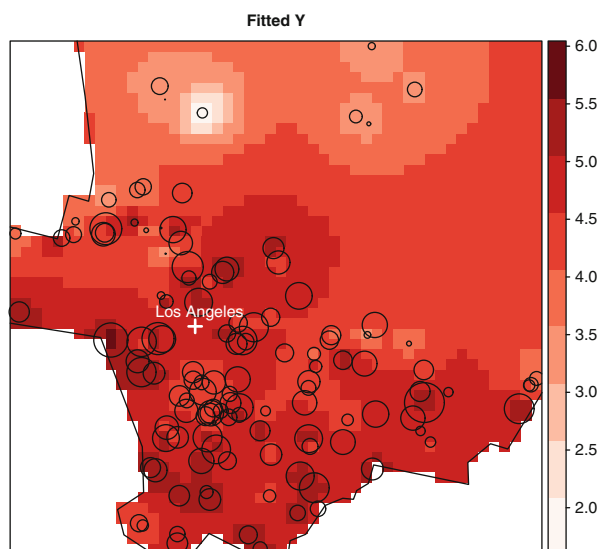

Table 73.2 Estimated parameters for the reduced traditional linear regression model and geographically weighted regression model for chlordane concentration in Los Angeles County

Coefficient	LM estimate	Standard error	p value	VIF	Mean GWR estimate

pattern in the observed values, but are less granular (Fig. 73.6). There is noticeable spatial heterogeneity in the observed values, and the smoothing approach of GWR does not capture some of the local heterogeneity. Overall, the fitted and observed values are larger south of Los Angeles, although there is a line of higher concentration stretching northwest from Los Angeles into the San Fernando Valley. The estimated regression coefficients for the reduced GWR model still appear somewhat complimentary for pairs of regression terms, specifically for the intercept and home termite treatment, and for race and median income (Fig. 73.7). Even though the diagnostic tools do not indicate a problem with serious collinearity in the model, caution should still be used when interpreting the estimated regression coefficients.

The regression coefficients are for the terms intercept (Beta0), race (Beta1), home termite treatment (Beta2), and median income (Beta3)

73.10 Conclusions

The main proposed application of geographically weighted regression for the spatial sciences was to investigate spatially varying relationships between variables in a regression model. GWR has been presented as a statistical model to be used for inference on spatially varying relationships. Based on a review of the literature, it has been adopted as such by researchers in several disciplines, including geography, regional science, ecology, and forestry. There is sufficient published evidence, however, to seriously question the uncritical application of GWR for studying multivariate spatially varying relationships. Evidence suggests that substantial spatial variation in estimated regression coefficients and correlation between estimated coefficients for pairs of regression terms is inherent to the method. Given the evidence, researchers should be extremely cautious about interpreting GWR coefficients and especially on making policy decisions based on GWR output. Instead, researchers should use diagnostic tools when building GWR models to detect

suspicious behavior of the model, including collinearity effects. When diagnostics reveal problems with the stability of the GWR model, alternative methods for making inferences about spatially varying processes should be considered. Alternatives include penalized versions of GWR and Bayesian spatially varying coefficient models, where Bayesian models provide formal statistical inference. Though the use of GWR for inference on spatially varying relationships has been questioned, it can be considered an accessible exploratory tool that is effective for estimating and predicting a spatially referenced outcome variable.

Abstract

Characterizing the spatial structure of variables in the regional sciences is important for several reasons. Firstly, the spatial structure may itself be of interest. The structure of a population variable tells us something about how the population is configured spatially. For example, is the population clustered by some properties, but not others? Secondly, mapping variables from sparse

sample observations or transferring values between areal units requires knowledge of how the property of interest varies spatially. Thirdly, we require knowledge of spatial variation in order to design sampling strategies which make the most of the effort, time, and money expended in sampling. Geostatistics comprises a set of principles and tools which can be applied to characterize or model spatial variation and use that model to optimize the mapping, simulation, and sampling of spatial properties. This chapter provides an introduction to some key ideas in geostatistics, with a particular focus on the kinds of applications which may be of interest for regional scientists.

74.1 Introduction

Geostatistics provides a body of techniques which can be used to characterize spatial variation, interpolate and simulate spatial variables, and design optimal spatial sampling strategies (Journel and Huijbregts 1978; Goovaerts 1997; Haining et al. 2010). To date, most applications of geostatistics have been in the physical sciences. However, there is an increasing diversity of research in the social sciences which makes use of geostatistical methods. This chapter reviews some of the key principles underlying geostatistics and considers the contributions these approaches may make in a regional science context.

Underlying classical geostatistics is the random function (RF) model (Journel and Huijbregts 1978; Chilès and Delfiner 1999). A RF is a set of random variables (RVs) which vary as a function of location \mathbf{x} . A RV is a stochastic process, a simple discrete example of which is the rolling of a die with the outcome being a value between one and six. Each outcome of this process is termed a *realization*. In most practical applications of geostatistics, variables are continuous. As an example, in a geostatistical framework, population density z at location \mathbf{x} is considered a RV, and the set of RVs at locations $z(\mathbf{x}_i) i = 1, \dots, n$ is a RF, or more precisely, since n is finite, a random *vector*. Observations of population densities are termed regionalized variables (ReVs), and they are treated as stochastic realizations of an underlying RF.

In geostatistics, it is common to fit a stationary RF model (Journel and Huijbregts 1978; Chilès and Delfiner 1999). First, a spatially stationary (i.e., constant) mean parameter is usually defined. However, various alternatives are common in which the mean is allowed to vary across space (Goovaerts 1997) including those RF models that include a spatially varying “trend” (e.g., a two-dimensional polynomial or some spatially varying function of covariates; Hudson and Wackernagel 1994). A second parameter (more strictly a model comprising several parameters) that is usually defined is the stationary spatial covariance function (which implies second-order stationarity; see Journel and Huijbregts 1978) or variogram (defined further below, which implies intrinsic stationarity), either of which can be used to represent the “character” of spatial variation. Since the variogram function is more widely applicable than the spatial covariance function, we will refer to it here and in the remainder of the text. The mean and

variogram are, thus, the parameters that define the RF, and, thus, it is these parameters that need to be estimated to provide a useful model for geostatistical inference (e.g., prediction of the value of the property of interest at some unobserved location).

One might be wondering what utility the variogram brings and why stationarity is required as a modeling decision. We offer the following lay person explanation. In geostatistics, the central modeling decision is that the character of spatial variation can be treated as “stationary” (i.e., independent of location). This decision to fit a RF model that is parameterized by a stationary function representing the character of spatial variation is crucial to geostatistical inference. It means that it is possible to (i) lump together the observed spatial variation from different pairs of locations separated by specific distances, and possibly directions (this is essentially what the variogram does); (ii) use that information to infer the character of spatial variation at new pairs of locations; and (iii) crucially, given an observation representing one of a new pair of locations, predict at the other unobserved location based on the imputed character of spatial variation and, thus, how related we expect the two locations to be.

We now show (i) how the RF model can be estimated through calculation of the empirical or experimental variogram and the fitting of mathematical models with parameters and (ii) how the parameterized RF model can be used for spatial prediction through a technique known as Kriging and in other geostatistical operations.

74.2 Characterizing Spatial Variation

Most geostatistical analyses proceed with a summary of the properties of the data, and this is generally regarded as good practice. As in any statistical analysis, summary statistics and the histogram may suggest that the data should be transformed in some way (e.g., taking a logarithm so that the transformed distribution is approximately normal).

The spatial structure of a variable can be characterized with several structure functions, most commonly the variogram (outlined below).

74.2.1 The Experimental Variogram

The variogram cloud relates (half the) the squared differences (i.e., the semivariances) between paired data values to the distance (and possibly direction) by which they are separated, and it, thus, provides a summary of how different observations are as a function of distance.

The variogram (or, more properly, semivariogram) collapses the information contained in the variogram cloud; the semivariances within distance bands are averaged, and so, for example, there is an average semivariance for data pairs separated by 0–10 m, 10–20 m, and so on. The plot of average semivariance against

distance band indicates how spatially dependent the variable is. In practice, many properties tend to become more dissimilar as the separation distance increases.

The experimental variogram, $\hat{\gamma}(\mathbf{h})$, is estimated from $p(\mathbf{h})$ paired observations, $z(\mathbf{x}_\alpha), z(\mathbf{x}_\alpha + \mathbf{h})$, $\alpha = 1, 2, \dots, p(\mathbf{h})$ with:

$$\hat{\gamma}(\mathbf{h}) = \frac{1}{2p(\mathbf{h})} \sum_{\alpha=1}^{p(\mathbf{h})} \{z(\mathbf{x}_\alpha) - z(\mathbf{x}_\alpha + \mathbf{h})\}^2 \quad (74.1)$$

Semivariances can be computed within particular directional tolerances. For example, only data pairs which are aligned approximately north–south could be included in Eq. (74.1). In this way, it is possible to assess how spatial variation differs as a function of direction.

Where the variable of interest is a rate calculated from a numerator and a population-based denominator (e.g., as for disease rate), the standard experimental variogram can be modified easily to account for spatially varying underlying populations. That is, greater weight can be given to zones with large populations, and thus, it is possible to account for spatially varying uncertainties in rates (see Goovaerts 2005; Goovaerts et al. 2005).

74.2.2 Variogram Model Fitting

The variogram may be used as a means in itself to analyze the spatial structure of a variable (e.g., Berberoglu et al. 2000; Lloyd et al. 2004). More commonly, it is the first stage in Kriging-based spatial interpolation, as described below. A model can be fitted to the variogram, for example, by weighted least squares (Cressie 1985; McBratney and Webster 1986). Then the coefficients of the fitted model can be used as an input to the Kriging process. In principle, the variogram model provides information on how much weight is given to observations as a function of their distance from prediction locations. This use of information on spatial structure makes Kriging distinct from other commonly applied methods of interpolation such as inverse distance weighting, whereby weights are a simple function of distance and no account is taken of the specific spatial structure of the data being analyzed. The most commonly used models are taken from a set of “permissible” or “authorized” models.

Some of the most commonly used authorized models are detailed below. The nugget effect model, which indicates measurement error and microscale variation (variation at a distance smaller than the sample spacing), is given by:

$$\gamma(h) = \begin{cases} 0 & \text{for } h = 0 \\ c_0 & \text{for } |h| > 0 \end{cases} \quad (74.2)$$

Three of the most frequently used bounded models are the spherical model, the exponential model, and the Gaussian model, and these are each defined below. Each

Fig. 74.1 Bounded variogram model: nugget effect and spherical model

of these models is “bounded” in that each has a maximum value of semivariance defined by a “sill” parameter. The exponential model is given by:

$$\gamma(h) = c \left[1 - \exp\left(-\frac{h}{d}\right) \right] \tag{74.3}$$

where c is the sill of the exponential model and d is the non-linear distance parameter. The exponential model reaches the sill asymptotically, and the practical range is $3d$ (i.e., the separation at which approximately 95 % of the sill is reached).

The spherical model is a very widely used variogram model, and its form corresponds well with what is often observed in real-world studies, with an almost linear growth in semivariance to a particular separation and then stabilization (Armstrong 1998). It is given by:

$$\gamma(h) = \begin{cases} c \left[1.5 \frac{h}{a} - 0.5 \left(\frac{h}{a}\right)^3 \right] & \text{if } h \leq a \\ c & \text{if } h > a \end{cases} \tag{74.4}$$

where a is the non-linear parameter, known as the range.

The Gaussian model is given by:

$$\gamma(h) = c \left[1 - \exp\left(-\frac{h^2}{d^2}\right) \right] \tag{74.5}$$

As for the exponential model, the Gaussian model does not reach a sill at a finite distance, but rather approaches a defined sill asymptotically. The practical range is $a \times \sqrt{3}$ (Journel and Huijbregts 1978). Variograms with parabolic behavior at the origin, as represented by the Gaussian model here, are indicative of very regular spatial variation (Journel and Huijbregts 1978). Authorized models can be used in positive linear combination where a single model is insufficient to represent well the form of the variogram (Webster and McBratney 1989). Figure 74.1 depicts a variogram model comprising the combination of a nugget effect and a spherical component. In practice, the combination of the nugget effect and one or more permissible models is common.

Where the experimental variogram does not reach a maximum, it may be desirable to fit a trend model to the data and model the residuals with a bounded model. In some circumstances, it may be desirable to select an unbounded variogram model. The most widely used unbounded model is the power model:

$$\gamma(h) = mh^\omega \quad (74.6)$$

where ω is a power $0 < \omega < 2$ with a positive slope, m (Deutsch and Journel 1998); the linear model is a special case of the power model.

74.2.3 Example

The variogram characterizes the spatial structure in a variable. Where the variable represents some characteristic of a population, the variogram captures information on the dominant spatial scales of variation in that population property. Figure 74.3 shows variograms estimated from log-ratio transformed data on the percentage of Catholics in Northern Ireland in 1971, 1991, and 2001 for 1-km-square cells. The data are from the Census of Population, and the log ratios are computed with $1/\sqrt{2} \times \ln(\text{Catholics by religion (\%)/non-Catholics by religion (\%)})$. The percentages were computed with $n_1 + 1$ and $n_2 + 1$, where n_1 is the number of Catholics and n_2 is the number of non-Catholics for each 1-km cell; this avoids logging zeros and reflects uncertainties in small counts. The data and transformation rationale are described in Lloyd (2010). Briefly, where the variables used sum to a constant (e.g., percentages sum to 100), use of raw values may be problematic, and Aitchison (1986) suggests that use of log ratios is a suitable approach; most applications of such approaches are with respect to analysis of compositions with multiple parts. The present analysis is based on only one variable (religion or community background) with only two groups (Catholic or non-Catholic), which can, thus, be expressed as a single ratio. However, Filzmoser et al. (2009) show that univariate statistical methods should not be applied directly to (raw) compositional data. Furthermore, Pawlowsky and Burger (1992) argue that structural analysis should not be conducted using raw proportions or percentages as the constant-sum constraint may lead to a distorted picture of the spatial covariance structure and possibly erroneous interpretations.

The variograms in Fig. 74.2 were fitted with a nugget effect and two spherical components. This combination of models reflects nested spatial structures. That is, the variogram models exhibit two breaks corresponding to distances of approximately 5 and 30 km, and these spatial scales are represented by the two model ranges. The ranges and the nugget effects are similar for each of the 3 census years, while the total sill, which represents the magnitude of variation, for 1971 is much smaller than the sills for 1991 and 2001. These results suggest that the major scales of variation did not change between 1971 and 2001 – the areas which were dominated by Catholics or Protestants were broadly similar. What did change was the magnitude of differences between places. In support of previous studies

Fig. 74.2 Variogram of religion log ratios for 1971, 1991, and 2001 in Northern Ireland

Fig. 74.3 Variogram of deaths/1,000 persons for SOAs with fitted model and deconvolved model

of residential segregation in Northern Ireland, the variograms suggest that the concentrations of Catholics and Protestants increased between 1971 and 1991, but there was little change (at the Northern Ireland (NI) scale at least) between 1991 and 2001. In other words, in 1991 Catholic areas were more Catholic than they had been in 1971, while Protestant areas had also become more Protestant. Lloyd (2012) discussed these results in more depth and also estimates variograms locally to enable assessment of how population spatial structures vary across NI. The derivation of local variograms is discussed by Lloyd (2011).

74.3 Spatial Interpolation with Kriging

74.3.1 Simple and Ordinary Kriging

Ordinary Kriging (OK) predictions are weighted averages of the n locally available data. The OK weights define the best linear unbiased predictor (BLUP). The OK prediction, $\hat{z}_{OK}(\mathbf{x}_0)$, is defined as:

$$\hat{z}_{OK}(\mathbf{x}_0) = \sum_{\alpha=1}^n \lambda_{\alpha}^{OK} z(\mathbf{x}_{\alpha}) \quad (74.7)$$

with the constraint that the weights, λ_{α}^{OK} , sum to one to ensure an unbiased prediction:

$$\sum_{\alpha=1}^n \lambda_{\alpha}^{OK} = 1 \quad (74.8)$$

Using the Kriging system, appropriate weights can be determined, and these are multiplied by the available observations before summing the products to obtain the predicted value. These weights are derived given the coefficients of a model fitted to the variogram (or another function such as the covariance function) (Oliver 2010).

The Kriging prediction error must have an expected value of zero:

$$E\{\hat{Z}_{OK}(\mathbf{x}_0) - Z(\mathbf{x}_0)\} = 0 \quad (74.9)$$

The Kriging (or prediction) variance, σ_{OK}^2 , is expressed as:

$$\begin{aligned} \hat{\sigma}_{OK}^2(\mathbf{x}_0) &= E\{[\hat{Z}_{OK}(\mathbf{x}_0) - Z(\mathbf{x}_0)]^2\} \\ &= 2 \sum_{\alpha=1}^n \lambda_{\alpha}^{OK} \gamma(\mathbf{x}_{\alpha} - \mathbf{x}_0) - \sum_{\alpha=1}^n \sum_{\beta=1}^n \lambda_{\alpha}^{OK} \lambda_{\beta}^{OK} \gamma(\mathbf{x}_{\alpha} - \mathbf{x}_{\beta}) \end{aligned} \quad (74.10)$$

That is, we seek the values of $\lambda_1, \dots, \lambda_n$ (the weights) that minimize this expression with the constraint that the weights sum to one [Eq. (74.8)].

This minimization is achieved through Lagrange multipliers. The conditions for the minimization are given by the OK system comprising $n + 1$ equations and $n + 1$ unknowns:

$$\begin{cases} \sum_{\beta=1}^n \lambda_{\beta}^{\text{OK}} \gamma(\mathbf{x}_{\alpha} - \mathbf{x}_{\beta}) + \psi_{\text{OK}} = \gamma(\mathbf{x}_{\alpha} - \mathbf{x}_0) \alpha = 1, \dots, n \\ \sum_{\beta=1}^n \lambda_{\beta}^{\text{OK}} = 1 \end{cases} \quad (74.11)$$

where ψ_{OK} is a Lagrange multiplier. Given ψ_{OK} , the prediction variance of OK can be derived with:

$$\hat{\sigma}_{\text{OK}}^2 = \sum_{\alpha=1}^n \lambda_{\alpha}^{\text{OK}} \gamma(\mathbf{x}_{\alpha} - \mathbf{x}_0) + \psi_{\text{OK}} \quad (74.12)$$

The Kriging variance estimates the prediction variance (i.e., the square of the prediction error) based on the linear algebra given above. It is, thus, a measure of confidence in predictions and is a function of the form of the variogram, the sample configuration, and the sample support (Journel and Huijbregts 1978). The Kriging variance is, however, not conditional on the data values locally, and this has led some researchers to use alternative approaches such as conditional simulation (discussed in the next section) to build models of “spatial” uncertainty (Goovaerts 1997).

There are two standard varieties of OK: punctual OK and block OK. With punctual OK the predictions cover the same area or volume (the support, \mathbf{v} ; see Atkinson and Tate 2000) as the observations. For example, if observations of some property of a population are made through a grid-based census with a grid cell size of 1 km, as in NI, then predictions made from those data will also have a support of (i.e., represent) 1-km cells. In block OK, the predictions are made to a larger support than the observations. With punctual OK the original observation data are honored. That is, they are retained in the output map. Block OK predictions are averages over areas (i.e., the support has increased). Thus, at \mathbf{x}_0 the prediction is not the same as an observation and does not need to honor it. In regional science contexts, data are rarely available on point supports, and often a concern may be how to predict from areas to points, a topic discussed below.

The choice of variogram model affects the Kriging weights and, therefore, the predictions. However, if the form of two models is similar at the origin of the variogram, then the two sets of results may be similar (Armstrong 1998). The choice of nugget effect may have marked implications for both the predictions and the Kriging variance. As the nugget effect is increased, the predictions become closer to the global average (Isaaks and Srivastava 1989).

Poisson Kriging provides an appropriate means to interpolate rare events such as mortality. The Poisson Kriging system incorporates the population-weighted mean of the rates (Goovaerts 2005) which accounts for the variability due to population

size, with larger weights where the population size is larger and, therefore, where the data may be considered more reliable.

Other forms of Kriging include Kriging with a trend model (where large-scale trends in the data are explicitly taken into account), cokriging (where information on secondary variables is used in the prediction process) (Wackernagel 2003), and indicator Kriging (where the data are transformed into a set of thresholds and the probability of exceeding thresholds is estimated) (Goovaerts, 1997).

74.3.2 Simulation

Kriging predictions are weighted moving averages, and thus, Kriging is a smoothing interpolator. In block Kriging, some amount of smoothing happens naturally through averaging over the larger support, but some occur due to the interpolation process itself, which effectively extends the support out to include the observations. The latter smoothing is an unwanted artifact of the interpolation process. A means of overcoming this unwanted smoothing is conditional simulation (Journel 1996; Goovaerts 1997; Dungan 1999). With conditional simulation, predictions are drawn from equally probable joint realizations of the RVs which comprise a RF model (Deutsch and Journel 1998). The simulated values are not the expected values (as in Kriging), but rather they are drawn from the conditional cumulative distribution function (ccdf), as a function of the available data, including both the observations and previously simulated data, and the (modeled) spatial variation. Since the approach is stochastic, multiple simulated realizations can be obtained. The range of values obtained represents the “spatial” uncertainty.

74.4 The Change of Support Problem

In regional science contexts, data are often available for zones rather than points. While individual or household level data are available in some contexts, these are usually provided without detailed spatial information, and spatially aggregated data usually offer the only means of exploring detailed spatial patterns. The data support, v , is defined as the geometrical size, shape, and orientation of the units associated with the measurements (Atkinson and Tate 2000). Thus, making predictions from areas to points corresponds to a change of support. Geostatistics offers the means to (i) explore how the spatial structure of a variable changes with change of support and (ii) change the support by interpolation to an alternative zonal system or to a quasi-point support (Schabenberger and Gotway 2005).

74.4.1 Regularization

For many applications, the variogram defined on a point support is not available. Indeed, it is physically impossible to measure on a point support given that all

measurements are integrals over a positive finite support. Thus, only values over a positive support (area) may be available. The variogram of such aggregated data is termed the regularized or areal variogram (Goovaerts 2008).

74.4.2 Variogram Deconvolution

Theoretically, given the point support variogram, it is possible to estimate the variogram for any support. Through variogram deconvolution, the point support variogram can be estimated from the variogram estimated from areal data. Atkinson and Curran (1995) derived the point support variogram from the areal support variogram, with the areas defined as regular grids, following an iterative procedure. Of greater relevance for many regional science applications is variogram deconvolution for irregular supports, that is, those cases where the data are available on irregular zones (such as census or administrative zones) rather than regular cells. Goovaerts (2008) presents a procedure for variogram deconvolution given irregular zones, and this method is implemented in the STIS software (see <http://www.biomedware.com/>).

The above deconvolution method is illustrated here through an example. The case study makes use of data on deaths per 1,000 of the population in Northern Ireland (NI). The death data are counts for 2008, and the denominator is given as the midyear estimates of total population in 2008 for super output areas (SOAs). Figure 74.3 gives the variogram estimated from deaths/1,000 persons over SOAs. The deconvolved model, derived using the method of Goovaerts (2008), is also given. The application of the deconvolved model for Kriging is illustrated below.

74.4.3 Area-to-Point Kriging

Given the deconvolution procedures outlined above, it is possible to make predictions at point locations given data defined on areal supports. Kyriakidis (2004) and Goovaerts (2008) show how the Kriging system is adapted in the case of areal data supports and point prediction locations.

Area-to-point Kriging is illustrated given the death rate data and the deconvolved variogram detailed in the previous section. Ordinary Kriging with Poisson population (2008 midyear estimates for each SOA) adjustment was applied with a population denominator of 1,000 (i.e., the deaths are rates per 1,000 of the population). The discretization geography was 1-km cells populated in 2001 (from 2001 Census of Population), with numbers of persons per cell (2001 Census counts) as weights. The destination geography (locations where estimates are required) was 1-km cells (as for the discretization geography). Figure 74.4 shows deaths/1,000 persons (A) for SOAs and (B) derived using area-to-point Kriging at 1-km cells. In areas covered by large SOAs (with lower density populations), the increased detail is particularly apparent.

74.5 Geostatistics and Regional Science

Geostatistics originated in the mining industry through the work of Danie Krige in the 1950s and particularly through Georges Matheron who developed the Theory of Regionalized Variables in the 1960s and 1970s. From the original mining geology application, domain geostatistics found further application in the dominant field of petroleum geology, particularly through the Stanford Center for Reservoir Forecasting (SCRF) led by Andre Journel, but also in hydrogeology led by researchers such as Jaime Gómez-Hernández, in soil science led by the work of Richard Webster (see Webster and Oliver 2000) and Alex McBratney and subsequently Pierre Goovaerts, and in remote sensing and environmental science more generally. Thus, most applications of geostatistics can be divided into mining, petroleum, and “environmental”, and indeed, many conferences such as GeoENV organized themselves in this way for many years. However, the potential of geostatistics in the social sciences has been highlighted in recent research.

Much interest has been generated in the use of geostatistics to study a range of population-based properties, including rates based on census attributes as exemplified in this chapter and disease outcomes. This has been enabled by two key developments: (i) the pioneering work of Pascal Monestiez and Pierre Goovaerts on Poisson Kriging (Goovaerts 2005; Monestiez 2006), which enables the prediction of counts (e.g., mortality or morbidity) given an underlying population (e.g., at-risk population), and (ii) the parallel development in statistics of what has become known as model-based geostatistics. For example, in relation to the former, population-weighted variograms enable robust estimation in cases where the population underlying the observations is variable in magnitude. Moreover, Poisson Kriging allows the spatial interpolation of variables representing “rare” events, such as mortality.

Model-based geostatistics deserves special mention here as it represents an alternative Bayesian approach to geostatistics that has been made popular by statisticians such as Peter Diggle and is favored by the epidemiological community. Model-based geostatistics differs from the classical approach presented in this chapter in that the parameters of the RF model are regarded as uncertain, whereas in the classical approach these parameters are estimated through variogram model fitting and then regarded as “fixed” for the purposes of Kriging. As a result, model-based geostatistics conveys naturally the uncertainty in parameter estimation through to the prediction, resulting in a more complete description of prediction uncertainty. The general approach advocated by Diggle and others is two staged: (i) regression is used to predict the variable of interest from covariates, and (ii) geostatistics is used to predict the residuals at unobserved locations based on spatial dependence in those residuals. Since model-based geostatistics naturally allows for the adoption of a range of regression link functions (including the Poisson and logistic functions), the framework is general and can be applied readily to the population-based prediction problems described above. Thus, the development of new approaches, or adaptations of existing methods, has made the potential range of applications of geostatistical methods in regional science much wider.

The utility of area-to-point Kriging is much greater than may at first seem the case. Censuses are the primary means of enumerating the populations of the world's nations. However, the majority of them use arbitrary areal units to convey the original data, which were measured at the individual level, to the public (e.g., for reasons of preventing disclosure of personal information). Consequently, key variables relating to the world's population are obscured by (i) the aggregation effect which is effectively the convolution discussed above and (ii) the zonation effect which means that alternative realizations of the set of arbitrary boundaries may lead to very different realizations. This is the well-known modifiable areal unit problem (MAUP) which has dogged census analysis for decades. Area-to-point Kriging tackles the MAUP head on allowing researchers to bypass the sampling frame imposed by a particular set of areal units and re-present the census data on any support. While there are obvious limits to what can be achieved (it is not possible to generate more information than one started with), the results are visually stunning and do represent an optimal linear solution to the problem (Kyriakidis 2004; Goovaerts 2008). Additionally, applications that require common supports for multiple time periods (e.g., for which zonal systems may differ) may also benefit from recent developments in variogram deconvolution and area-to-point Kriging.

74.6 Conclusions

This chapter has introduced classical geostatistics and emphasized the advances that have been made in recent years that have opened up the possibility of applying geostatistics in social science and regional science. The ease of access to software which implements modern geostatistical methods means that researchers are increasingly likely to be held back only by their knowledge, rather than appropriate tools. It is hoped that this chapter will provide a useful starting point for those who wish to explore geostatistical methods in the context of regional science.

Abstract

This chapter provides an introductory discussion of spatial autocorrelation (SA), which refers to correlation existing and observed in geospatial data, and which characterizes data values that are not independent, but rather are tied together in overlapping subsets within a given geographic landscape. This chapter summarizes the various interpretations of SA, one being map pattern. SA can be quantified in a number of different ways, too, one being with the Moran Coefficient. Spatial filtering is a statistical method whose goal is to obtain

enhanced and robust results in a spatial data analysis by decomposing a spatial variable into trend, a spatially structured random component (i.e., spatial stochastic signal), and random noise. Its aim is to separate spatially structured random components from both trend and random noise, and, consequently, leads statistical modeling to sounder statistical inference and useful visualization. This separation procedure can involve eigenfunctions of the matrix version of the numerator of the Moran Coefficient. This chapter summarizes the eigenvector spatial filtering (ESF) conceptual material, and presents the computer code for implementing ESF in R, Matlab, MINITAB, FORTRAN, and SAS. Next, it demonstrates that eigenvector spatial filter estimators are unbiased, efficient, and consistent. Finally, it summarizes an ESF empirical example application, and the extension of ESF to spatial interaction modeling.

75.1 Introduction

Spatial autocorrelation (SA) refers to correlation existing and observed in geospatial data – data collected together with their locational position tags on a two-dimensional (2-D) surface. This concept describes data values that are not independent but rather are tied together in overlapping subsets within a given geographic landscape. Relative location, commonly expressed in terms of geographic closeness, partly determines SA. Tobler's (1969, p. 7) first law of geography provides a generalized view of how phenomena occur across space within this context: "Everything is related to everything else, but near things are more related than distant things." This description indicates that a data value at a given location tends to be (dis)similar to those values for the same variable at nearby locations. For example, house price and house value comparisons among effectively equivalent neighboring houses partly govern a real estate market. That is, real-world phenomena are not likely to occur in a random fashion but rather in a spatially structured manner, over space.

Griffith (1992) points out that, in practice, spatial scientists essentially interpret SA in one of nine different ways: self-correlation, map pattern, a diagnostic tool, a missing variables surrogate, a spatial process mechanism, a spatial spillover effect, an outcome of areal unit demarcation (re. the MAUP), redundant information, and a nuisance parameter. Discussion in this chapter exploits the map pattern interpretation of SA.

75.1.1 Spatial Autocorrelation: A Conceptual Overview

SA (Getis 2010) can be interpreted in different ways. First, it can be interpreted literally as self-correlation which arises in 2-D space. Unlike the conventional Pearson's product moment correlation coefficient that measures co-variability of paired values in two variables, SA measures correlation among paired values in

Table 75.1 The 1981 Cliff-Ord example, with an extension

Model specification	(Pseudo-)R ²	Residual spatial autocorrelation z-score
$Y = \alpha + \beta X + \varepsilon$	0.404	1.87
$Y = \alpha X^\beta e^{\varepsilon}$	0.517	1.41
$Y = \alpha + \beta \text{LN}(X - \delta) + \varepsilon$	0.735	0.76

a single variable based on relative spatial locations. Because it focuses on a tendency among values of a variable based on their spatial closeness, SA is measured within the combinatorial context of all possible pairs of observed values for a given variable where corresponding weights that are determined by spatial closeness identify the pairings of interest. Second, SA can be interpreted as map pattern. In regional science, an analysis often involves datasets of individual observations post-stratified by geographical units such as census blocks/block groups/tracts, county boundaries, and country borders. The choropleth mapping of a variable using such areal units portrays a pattern over space. A tendency for similarity or dissimilarity for neighboring values on such a map can be directly interpreted as SA. While large clusters of similar values on a map indicate positive SA, an alternating map pattern, in which the tendency is for values to be dissimilar to those of their neighbors, constitutes negative SA. Third, SA can be interpreted as a diagnostic tool for misspecification in statistical modeling such as linear regression analysis. For example, detected SA among residuals in such a regression analysis can suggest that the linear relationship specified between a response variable and a covariate needs to be replaced with a nonlinear functional description of the relationship. Cliff and Ord (1981, pp. 209) furnish a useful illustration of this situation by employing an empirical example in which the 1961 population as a percentage of the 1926 population (Y) by Eire county ($n = 26$) is cast as a function of arterial road network accessibility (X). Table 75.1 summarizes selected results from their analysis, supplemented with an extension. As the nonlinear relationship between Y and X is better articulated, SA displayed by the corresponding regression residuals decreases to a clearly statistically nonsignificant level. Finally, SA also can imply that variables are missing from a regression model specification, in which case it serves as a surrogate for unexplained variation in the response variable in question. When a variable is missing from a model specification that, indeed, accounts for a substantial amount of variation in a dependent variable, then the unexplained variation may occur in the form of SA among residuals. If a missing variable forms an underlying map pattern – that is, significant SA exists – then residuals are very likely to exhibit a conspicuous level of SA.

Research in the spatial sciences in general, and in geography and regional science in particular, has addressed the numerical quantification of SA. The Moran coefficient (MC) is the most commonly used quantitative measure of SA; it is analogous to the Pearson's correlation coefficient. The MC may be written as

$$\frac{\sum_{i=1}^n \sum_{j=1}^n c_{ij} (y_i - \bar{y})(y_j - \bar{y}) / \sum_{i=1}^n \sum_{j=1}^n c_{ij}}{\sqrt{\sum_{i=1}^n (y_i - \bar{y})^2 / n} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2 / n}} = \frac{n}{\sum_{i=1}^n \sum_{j=1}^n c_{ij}} \frac{\sum_{i=1}^n (y_i - \bar{y}) \left[\sum_{j=1}^n c_{ij} (y_j - \bar{y}) \right]}{\sum_{i=1}^n (y_i - \bar{y})^2}$$

where c_{ij} is a non-negative nonzero spatial weight tying together the pair of areal units i and j , n is the number of areal units, and \bar{y} is the arithmetic mean of response variable Y . The value of c_{ij} reflects spatial closeness between areal units i and j . The numerator of the MC contains the pairs of values $(y_i - \bar{y})$ and $\sum_{j=1}^n c_{ij}(y_j - \bar{y})$, whose graphic portrayal is the Moran scatterplot. In most cases, the MC utilizes spatial connectivity information for a set of areal units. That is, in binary form, $c_{ij} = 1$ when areal units i and j have a common boundary, and 0 otherwise; the rook's case definition of spatial closeness is when all common boundaries have nonzero length (i.e., they are lines), whereas the queen's case definition is when some also have zero length boundaries (i.e., they are points). The range of the MC is slightly different from that of Pearson's correlation coefficient, which covers the interval $[-1, 1]$. Mathematical quantities of the n -by- n matrix of c_{ij} values, C , called eigenvalues determine the exact range of a MC (de Jong et al. 1984). Often, the largest value is slightly larger than 1, and the smallest value is between -1 and -0.5 .

Statistical hypothesis testing involving the MC can be based upon a normal distribution assumption; Cliff and Ord (1981) derive its sampling distribution theory as such. The expected value for the MC is $-1/(n-1)$ under the null hypothesis of zero SA. This expected value is the threshold value separating positive and negative SA. That is, while an MC value that is greater than this expected value indicates positive SA, one that is less than this expected value indicates negative SA. Although equations for the standard deviation of the MC are rather complicated (see Cliff and Ord 1981 for details), it can be well approximated by $\sqrt{\frac{2}{\sum_{i=1}^n \sum_{j=1}^n c_{ij}}}$ when $n \geq 20$ (Griffith 2010); the summation term, $\sum_{i=1}^n \sum_{j=1}^n c_{ij}$,

counts the number of 1s in matrix C , which equals twice the number of neighbors in a surface partition (i.e., a link from areal unit i to areal unit j plus a link from areal unit j to areal unit i). A z-score calculated for the MC with the foregoing expected value and standard deviation furnishes a basis for statistical inference that asymptotically is the standard normal distribution.

75.1.2 Spatial Filtering: A Conceptual Overview

Spatial filtering (Tiefelsdorf and Griffith 2007) is a statistical method whose goal is to obtain enhanced and robust results in a spatial data analysis. The fundamental idea is based upon a decomposition of a spatial variable into the

following three components: trend, spatially structured random component (i.e., spatial stochastic signal), and random noise. Its aim is to separate spatially structured random components from both trend and random noise, and, consequently, leads statistical modeling to sounder statistical inference and useful visualization. This separation procedure involves sophisticated mathematical operators and produces the aforementioned eigenvalues as well as their accompanying eigenvectors (the couplings are called eigenfunctions).

A limited number of spatial filtering methods currently exist, including autoregressive linear operators, Getis's G_i -based specification, interpoint distance matrix eigenfunctions, and spatial weight matrix eigenfunctions. These methods utilize different constructed mathematical operators to decompose a spatial variable into the three components. First, following the Cochrane-Orcutt procedure for time series analysis, autoregressive linear operators can be used to prewhiten dependent variable to render independent and identically distributed (i.i.d.) random errors (Tobler 1975; Haining 1991). This spatial filtering method takes the matrix form $(\mathbf{I} - \rho\mathbf{C})$, where ρ is a SA parameter, and \mathbf{I} is an n -by- n identity matrix. With the parameter ρ estimated solely from a variable Y , a prewhiten dependent variable is generated by $(\mathbf{I} - \rho\mathbf{C})\mathbf{Y}$. Second, Getis's G_i -based method converts each spatially correlated variable into two variates, one capturing SA and the other containing nonspatial systematic and random effects (Getis 1990). Regression with spatial and nonspatial variates enables a separation of SA components from trend and white noise components. Third, Borcard and Legendre (2002) propose a procedure called principal coordinates of neighbor matrices (PCNM) that exploits eigenfunctions of the n -by- n matrix of truncated geographic distances among locations [truncation can be at the (effective) range of SA as identified by, say, a semivariogram]. They use eigenvectors corresponding to positive eigenvalues as spatial descriptors in regression or canonical analysis. They argue that this method can be applied to any set of locations providing a good coverage of a given geographic landscape. Fourth, eigenvector spatial filtering (ESF) methodology utilizes eigenvectors extracted from spatial weight matrix \mathbf{C} (Griffith 2003). Details of this latter methodology are discussed in the next sections because this chapter focuses on the ESF method.

Spatial filtering methods are increasingly utilized in regression settings, although they can be applied to individual variables, too. Especially, the ESF methodology has been utilized in different model specifications, including linear regression (Getis and Griffith 2002), generalized linear models (Chun 2008; Griffith 2004), and space-time panel models (Chun and Griffith 2011; Patuelli et al. 2011).

75.2 Eigenvector Spatial Filtering

ESF uses a set of synthetic proxy variables, which are extracted as eigenvectors from a spatial weight matrix \mathbf{C} that ties geographic objects together in space and then adds these vectors as control variables to a model specification. These control variables identify and isolate the stochastic spatial dependencies among the georeferenced observations, thus allowing model building to proceed as if the observations are independent.

75.2.1 Eigenvectors of a Spatial Weight Matrix

The ESF method utilizes a mathematical decomposition, whose results are called eigenfunctions, of the following transformed spatial weight matrix:

$$(\mathbf{I} - \mathbf{1}\mathbf{1}^T/n)\mathbf{C}(\mathbf{I} - \mathbf{1}\mathbf{1}^T/n)$$

where $\mathbf{1}$ is an n -by-1 vector of ones, and T denotes the matrix transpose operator. The decomposition generates n eigenvectors and their associated n eigenvalues. In descending order, the n eigenvalues can be denoted as $\boldsymbol{\lambda} = (\lambda_1, \lambda_2, \lambda_3, \dots, \lambda_n)$. That is, the eigenvalues range between the largest eigenvalue that is positive, λ_1 , and the smallest eigenvalue that is negative, λ_n . The corresponding n eigenvectors can be denoted as $\mathbf{E} = (\mathbf{E}_1, \mathbf{E}_2, \mathbf{E}_3, \dots, \mathbf{E}_n)$, where each eigenvector, \mathbf{E}_j , is an n -by-1 vector. In matrix notation, the decomposition can be expressed as

$$\mathbf{MCM} = \mathbf{E} \boldsymbol{\Lambda} \mathbf{E}^T \quad (75.1)$$

where $\mathbf{M} = (\mathbf{I} - \mathbf{1}\mathbf{1}^T/n)$, the projection matrix that centers a variable and that commonly appears in standard multivariate statistical theory, and $\boldsymbol{\Lambda}$ is an n -by- n diagonal matrix whose diagonal elements are the set of n eigenvalues $(\lambda_1, \lambda_2, \lambda_3, \dots, \lambda_n)$.

The eigenfunctions have some important properties. First, the eigenvectors are mutually orthogonal and uncorrelated (Griffith 2000): the symmetry of matrix \mathbf{C} ensures orthogonality, and the projection matrix \mathbf{M} ensures eigenvectors with zero means, guaranteeing uncorrelatedness. That is, $\mathbf{E}\mathbf{E}^T = \mathbf{I}$ and $\mathbf{E}^T\mathbf{1} = \mathbf{0}$, and the correlation between any pair of eigenvectors, say \mathbf{E}_i and \mathbf{E}_j , is zero when $i \neq j$. Second, the eigenvectors portray distinct, selected map patterns. Tiefelsdorf and Boots (1995) show that each eigenvector portrays a different map pattern exhibiting a specified level of SA when it is mapped onto the n areal units associated with the corresponding spatial weight matrix \mathbf{C} . They also show that the MC value for a mapped eigenvector is equal to a function of its corresponding eigenvalue (i.e., $\text{MC}_j = \frac{n}{\mathbf{1}^T\mathbf{C}\mathbf{1}} \cdot \lambda_j$, for \mathbf{E}_j). Third, given a spatial weight matrix, the feasible range of MC values is determined by the largest and smallest eigenvalues; that is, by λ_1 and λ_n (de Jong et al. 1984). Based upon these properties, the eigenvectors can be interpreted as follows (Griffith 2003):

The first eigenvector, \mathbf{E}_1 , is the set of real numbers that has the largest MC value achievable by any set of real numbers for the spatial arrangement defined by the spatial weight matrix \mathbf{C} ; the second eigenvector, \mathbf{E}_2 , is the set of real numbers that has the largest achievable MC value by any set that is uncorrelated with \mathbf{E}_1 ; the third eigenvector, \mathbf{E}_3 , is the set of real numbers that has the largest achievable MC value by any set that is uncorrelated with both \mathbf{E}_1 and \mathbf{E}_2 ; the fourth eigenvector is the fourth such set of values; and so on through \mathbf{E}_n , the set of real numbers that has the largest negative MC value achievable by any set that is uncorrelated with the preceding $(n-1)$ eigenvectors. As such, these eigenvectors furnish distinct map

pattern descriptions of latent SA in spatial variables, because they are mutually both orthogonal and uncorrelated.

Figure 75.1 presents selected eigenvectors generated with the rook's definition of adjacency used to construct a 0–1 binary spatial weight matrix for the 73 municipalities of Puerto Rico. Figure 75.1a portrays the boundaries of the 73 municipalities together with their neighboring structure: the red lines indicate that c_{ij} for a pair of connected municipalities equals 1; otherwise, it equals 0. Figure 75.1b is a map of the first eigenvector, \mathbf{E}_1 , which portrays the maximum positive SA possible for the established matrix \mathbf{C} . Its MC value is 1.0938. This map pattern shows two large clusters of areal units, one of positive numbers and one of negative numbers. Figure 75.1c portrays the map pattern of \mathbf{E}_{18} , whose MC value is 0.2832. It still indicates positive SA but with a degree much weaker than that for eigenvector \mathbf{E}_1 . It depicts smaller-sized areal unit clusters of similar values. In contrast, Fig. 75.1d is the map of eigenvector \mathbf{E}_{73} , which portrays the extreme negative SA possible with this spatial tessellation. Its pattern is alternating positive and negative values, and its MC is -0.5657 .

Puerto Rico's east–west elongation coupled with its irregular municipality surface partitioning somewhat obscures the conspicuousness of map patterns portrayed by the eigenvectors of matrix \mathbf{C} . This notion is more clearly depicted by the eigenvectors of a regular square tessellation. Consider a landscape comprising 900 pixels forming a 30-by-30 square tessellation (Fig. 75.2). Figure 75.2a portrays the boundaries of the 900 pixels together with their neighboring structure. Figure 75.2b portrays a global SA pattern: it contains a northwest-southeast swath crossing a northeast-southwest swath of similar values – with a relative MC value of 0.9922. Figure 75.2c portrays a regional SA pattern: it contains 36 moderate-sized clusters of similar values – with a relative MC value of 0.8314. Figure 75.2d portrays a more local SA pattern: it contains 100 small clusters of similar values – with a relative MC value of 0.5358. In all three cases, appropriate spatial aggregation would yield negative SA (i.e., negative MC values).

75.2.2 An Eigenvector Spatial Filter Specification of the Linear Regression Model

ESF methodology utilizes the eigenvectors calculated in the previous section. In detail, it accounts for SA with a linear combination of the eigenvectors. In linear regression, the ESF model specification may be written as

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta}_X + \mathbf{E}_k\boldsymbol{\beta}_k + \boldsymbol{\varepsilon}$$

where \mathbf{X} is an n -by- $(p+1)$ matrix containing covariates, $\boldsymbol{\beta}_X$ is the corresponding $(p+1)$ -by-1 vector of regression parameters, \mathbf{E}_k is an n -by- k matrix containing k eigenvectors, $\boldsymbol{\beta}_k$ is the corresponding vector of regression parameters, and $\boldsymbol{\varepsilon} \sim N(\mathbf{0}, \mathbf{I}\sigma^2)$ is an n -by-1 error vector whose elements are i.i.d normal random variates. Because the linear combination of the eigenvectors, $\mathbf{E}_k\boldsymbol{\beta}_k$, accounts for

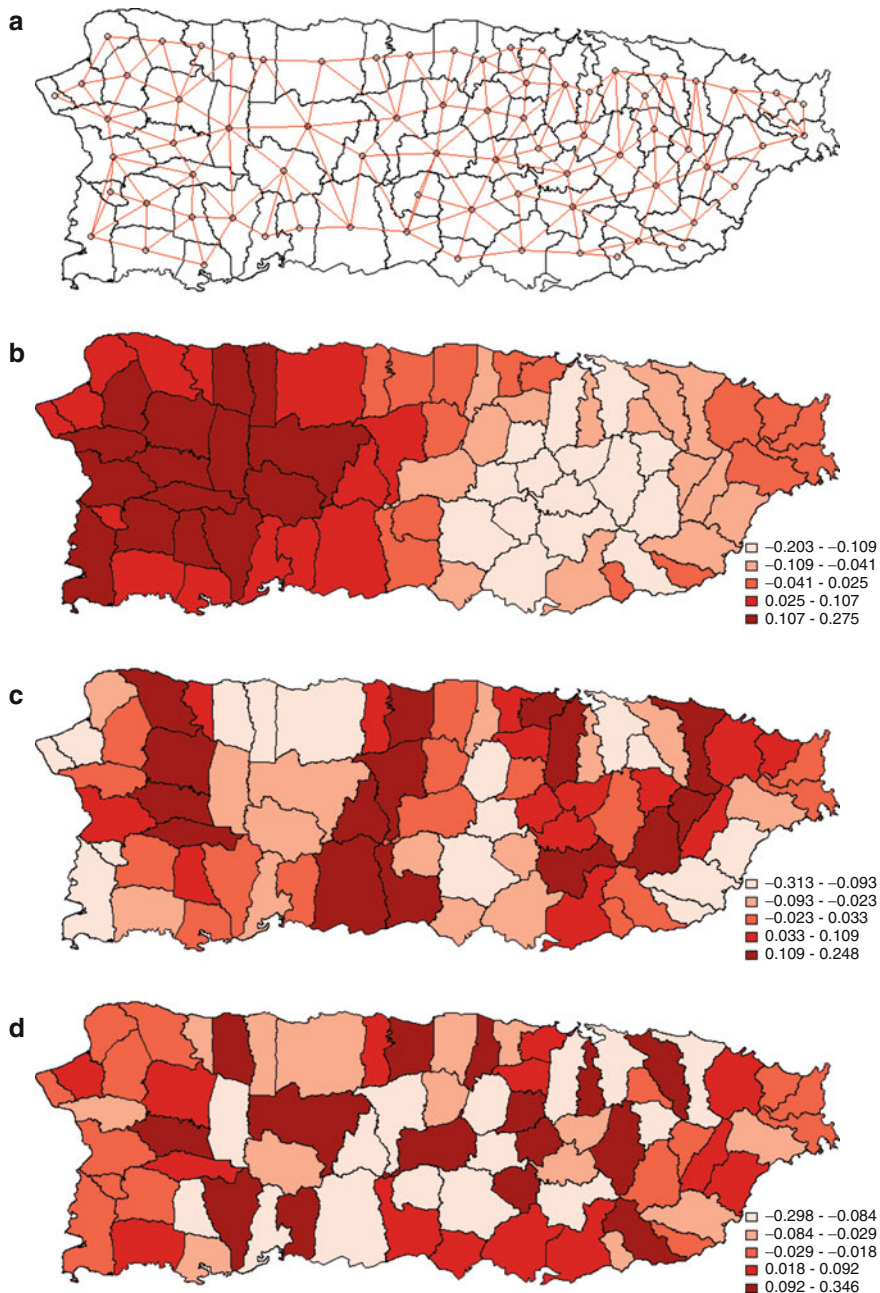

Fig. 75.1 The maps of selected eigenvectors based upon matrix **C** constructed for the municipalities of Puerto Rico: (a) the boundaries and links of the 73 municipalities, (b) the first eigenvector, E_1 , (c) the eighteenth eigenvector, E_{18} , and (d) the nth eigenvector, E_{73}

Fig. 75.2 The maps of selected eigenvectors based upon matrix \mathbf{C} constructed for the pixels of a 30-by-30 square tessellation: (a) the boundaries and links of the 900 pixels, (b) eigenvector $\mathbf{E}_{2,2}$, (c) eigenvector $\mathbf{E}_{6,6}$, and (d) eigenvector $\mathbf{E}_{10,10}$

SA, the ESF linear regression specification does not suffer from SA in its residuals. Addition of the eigenvectors in the regression equation does not change the expected conditional mean of Y because the mean of each eigenvector is zero.

Initializing ESF methodology requires the identification of a feasible set of eigenvectors. This procedure involves two steps. In the first step, a candidate set of eigenvectors, which is a noticeably smaller subset (i.e., $K \ll n$) of the entire set of eigenvectors, can be demarcated based upon several criteria. Eigenvectors whose MC values are close to the expected value of MC do not explain much spatial variation. These eigenvectors can be eliminated from a candidate set. Also, one of the eigenvalues of \mathbf{MCM} is zero due to the rank deficiency of matrix \mathbf{M} ; it can be eliminated, but the model specification actually already includes it through vector $\mathbf{1}$

attached to the mean response. The candidate set can be further restricted to only eigenvectors portraying positive SA, if the MC for a response variable displays positive SA, or to only eigenvectors portraying negative SA, if the MC for the response variable displays negative SA; most empirical datasets display positive SA. Considering these factors, one criterion for identifying this set is a minimum MC of 0.25, which relates to roughly 5% of the variance in a response variable being attributable to SA (see Appendix A).

In the second step, a smaller set of eigenvectors can be identified from its candidate set using a stepwise regression selection technique. One way to select an eigenvector is to maximize model fit at each step through statistical significance (e.g., invoking a 10%, 5%, or 1% level). This selection can be implemented easily with conventional stepwise regression procedures. Another way to select an eigenvector is to minimize residual SA in each stepwise regression iteration. This selection procedure can be repeated until a prespecified level of residual SA (e.g., $MC \approx 0$) is achieved.

75.2.3 The Numerical Calculation of Eigenvectors

Spatial science practitioners find eigenfunction calculation one of the most, if not the most, difficult tasks in implementing the ESF methodology. Most statistical software packages provide functions to calculate eigenvectors. Extracting eigenvectors from a spatial weight matrix can be executed with the following three steps: (1) loading (or creating) a spatial weight matrix C , (2) transforming the spatial weight matrix to its MCM version in Eq. (75.1), and (3) computing eigenvectors with software-specific functions or commands. This section outlines a wide array of computer codes for completing this task.

75.2.3.1 R Code for Generating MCM Eigenvectors

The *spdep* package of R provides functions to handle spatial datasets and to conduct spatial data analysis. The package can be loaded with the `library()` function:

```
> library(spdep)
```

For the first step, the spatial neighbor structure needs to be loaded from an existing file (e.g., `PuertoRico.gal`). A `.GAL` file can be created with GeoDa software. The function `read.gal()` reads a `.GAL` file and stores its neighbor structure in the `.nb` object format of *spdep*:

```
> pr.nb <- read.gal("PuertoRico.gal")
```

Although an `.nb` object contains lists of spatial neighbors, a `listw` object contains lists of actual weight values. A spatial weight matrix can be created directly from a `listw` object. The `nb2listw()` function requires an argument for a spatial weight matrix type. In the following code line, a spatial weight matrix is created from a `listw` object created as a binary type (`style="B"`), with the `listw2mat()` function:

```
> pr.listw <- nb2listw(pr.nb, style="B")
> B <- listw2mat(pr.listw)
```

In the second step, the matrix **MCM** can be created with matrix operations. The `length()` function returns the number of observations in the `pr.nb` object:

```
> n <- length(pr.nb)
> M <- diag(n) - matrix(1, n, n) / n
> MBM <- M %**% B %**% M
```

Finally, the function `eigen()` generates eigenvalues and eigenvectors. In the following code, `eig$vector`s contains n-by-n eigenvectors, and `eig$value`s contain n eigenvalues. The second line selects only eigenvectors with $MC_j/MC_1 > 0.25$. The third line changes the column names of the EV objects:

```
> eig <- eigen(MBM, symmetric=T)
> EV <- as.data.frame(eig$vector[, eig$value /
eig$value[1] > 0.25])
> colnames(EV) <- paste("EV", 1:NCOL(EV), sep="")
```

The EV objects can be further utilized in a regression analysis in R, or can be exported in a different file format, such as CSV, for other purposes.

75.2.3.2 Matlab Code for Generating MCM Eigenvectors

Matlab does not have a built-in function to read a .GAL file. But the spatial neighbor structure in a .GAL file can be imported with Matlab functions to open and read a file. The [Computer Code 1](#) window provides sample Matlab code to generate eigenvectors.

The first five lines of code (code block ①) open the `PuertoRico.gal` file in order to store all file contents in the `lines` variable and then close the file. The next four lines of code (code block ②) retrieve the number of observations, `n`, which is stored in the first line of a .GAL file, and then create an n-by-n matrix of all zeros for a binary spatial weight matrix, **B**. The `for` statement code block (code block ③) updates the matrix **B** by assigning 1s for spatial neighbors from the `PuertoRico.gal` file. The final six lines of code (code block ④) generate eigenvalues and eigenvectors from matrix **MCM** and then select only eigenvectors with $MC_j/MC_1 > 0.25$.

75.2.3.3 MINITAB Code for Generating MCM Eigenvectors

MINITAB supports matrix operations and works with the 0–1 binary spatial weight matrix. The [Computer Code 2](#) window provides sample MINITAB code for computing eigenvectors.

The first block of code reads in the spatial weight matrix. The next block of code constructs matrix **M**. The third block of code computes **MCM**. The fourth block of code calculates the eigenvalues and their associated eigenvectors. The fifth block of code converts the eigenvalues to MCs. The final block of code identifies for which eigenfunctions $MC_j/MC_1 > 0.25$.

75.2.3.4 FORTRAN Code for Generating MCM Eigenvectors

The IMSL subroutines package supports reliable matrix operations for FORTRAN. The [Computer Code 3](#) window provides sample FORTRAN code for computing eigenvectors.

```

filename = 'PuertoRico.gal';
fID = fopen(filename,'r');
gal = textscan(fID, '%s', 'delimiter', '\n', 'whitespace', '');
fclose(fID);
lines = gal{1};

header = lines{1};
headerNum = sscanf(header, '%f');
n = headerNum(2);
B = zeros(n);

for i = 1:n
    idline = sscanf(lines{i*2}, '%f');
    nbs = sscanf(lines{i*2+1}, '%f');

    nbloc = zeros(length(nbs),2);
    B(idline(1),nbs) = 1;
end

M = eye(n) - ones(n)/n;
MBM = M*B*M;
[vec, eval]=eig(MBM);
eval=diag(eval);
sel = eval/eval(1)>0.25;
EV = vec(:,sel);

```

The code is grouped into four sections:

- 1.1**: Reading the file and initializing variables.
- 1.2**: Parsing the header line to determine the number of neighbors (n) and initializing matrix B.
- 1.3**: Looping through the data lines to parse neighbor IDs and counts, and populating matrix B.
- 1.4**: Constructing matrix M, computing the eigenvalues and eigenvectors of MBM, and selecting the top 5% of eigenvectors based on their variance contribution.

Computer Code 1 Sample Matlab code for generating eigenvectors from a spatial weight matrix

The first part of the code reads in a spatial neighbors' file, similar to a .GAL file; its structure is id, number of neighbors, and list of neighbor ids. The first line of this file contains n. The next block of code constructs matrix **MCM**. Subroutine **DEVCSF** calculates the eigenvalues and their associated eigenvectors. The final block of code identifies for which eigenfunctions $MC_j/MC_1 > 0.25$.

75.2.3.5 SAS Code for Generating MCM Eigenvectors

The IML language facilitates eigenfunction calculations by SAS. The [Computer Code 4](#) window provides sample SAS code for computing eigenvectors.

As with the preceding FORTRAN code, SAS works with the spatial weight matrix as input. The first part of the code constructs matrix **M**. IML imports both matrix **C** and matrix **M**. It employs matrix operations to construction **MCM** and subroutine **EIGEN** to compute the eigenfunctions. Finally, it outputs a working file of eigenvalues (STEP3) and working file of eigenvectors (STEP4).

75.3 Statistical Features of ESF

Construction of an ESF begins with determination of a candidate set of eigenvectors, which is a substantially smaller subset of the total set of n eigenvectors. One criterion for identifying this set is a minimum MC of 0.25, which relates to roughly 5% of the variance in a response variable being attributable to SA (see Appendix A). Another

Computer Code 2 Sample MINITAB code for generating eigenvectors from a spatial weight matrix

criterion devised by Chun and Griffith (2009) builds on the level of SA detected in a response variable, Y , and may be summarized as follows:

$$MC_j \geq 2.9970 - \frac{2.8805}{1 + e^{-0.6606 - 0.2525 z_{MC}}} \quad (75.2)$$

where z_{MC} denotes the z -score of the MC for the response variable Y (or some transformed version of it, such as a Box-Cox power transformation, if used). Two weaknesses of ESF construction concern the selection of eigenvectors from a candidate set to include in the constructed variate and the increase in number of candidate and selected eigenvectors with increasing n .

To date, eigenvector selection has been undertaken with stepwise regression procedures, an approach plagued by the pretesting problem. One redeeming feature of the eigenvectors is that they are both orthogonal and uncorrelated.

Computer Code 3 Sample FORTRAN code for generating eigenvectors from a spatial weight matrix

Accordingly, a Bonferroni adjustment, for example, furnishes the appropriate significance level to use with a stepwise procedure. The number of eigenvectors in a candidate set determines this adjustment. A simulation experiment employing i.i.d. random normal data illustrates this contention: the selection probability used is $p = 0.01$; the estimated distribution of selected eigenvectors is exactly that for a binomial distribution with $p = 0.01$ (see [Tables 75.2](#) and [75.3](#)). The Bonferroni adjustment $- 0.01/(\# \text{ candidate eigenvectors})$ – more or less fully corrects for excess vector selection. In addition, for reasonably sized samples, essentially only 1 vector might be selected by chance, and its percentage of variance accounted for in the response variable tends to be trivial.

Using the Frisch-Waugh-Lovell theorem, Pace et al. (2011) confirm that ESF produces unbiased estimates of covariate regression parameters for data generated with a spatial error (i.e., SAR) model specification. They also find that for synthetic

data generated with a spatial lag model specification, an ESF specification tends to result in some bias. ESF yields unbiased covariate parameter estimates if SA is present in the covariates, but not in the response variable. If SA is present in the response variable, then a large number of eigenvectors may be needed to ensure unbiased parameter estimates. Nevertheless, they conclude that ESF reduces bias found in an ordinary least squares (OLS) solution, thus improving upon it.

To illustrate unbiasedness, consider the generalized least squares estimator (GLS) – which also is the maximum likelihood estimator – of the constant mean (i.e., no covariates are present in a model specification) SAR model specification, which is given by $\hat{\mu} = \mathbf{1}^T \mathbf{V} \mathbf{Y} / \mathbf{1}^T \mathbf{V} \mathbf{1}$. Its expected value is

$$E[\mathbf{1}^T \mathbf{V} \mathbf{Y} / \mathbf{1}^T \mathbf{V} \mathbf{1}] = \mathbf{1}^T \mathbf{V} E[\mathbf{Y}] / \mathbf{1}^T \mathbf{V} \mathbf{1} = \mathbf{1}^T \mathbf{V} E[\mu \mathbf{1} + \mathbf{V}^{-1/2} \boldsymbol{\varepsilon}] / \mathbf{1}^T \mathbf{V} \mathbf{1} = \mu$$

where $\boldsymbol{\varepsilon} \sim N(0, \sigma_\varepsilon^2)$, \mathbf{V} is the inverse covariance matrix [e.g., $(\mathbf{I} - \rho \mathbf{W})^T (\mathbf{I} - \rho \mathbf{W})$] for the SAR model, where \mathbf{W} is a row-standardized spatial weight matrix; $\mathbf{W} = \mathbf{D}^{-1} \mathbf{C}$, and where $d_{ii} = \sum_{j=1}^n c_{ij}$, and $d_{ij} = 0$ for $i \neq j$. Meanwhile, the ESF estimator of the constant mean model specification is given by $\mathbf{1}^T \mathbf{Y} / n$. Its expected value is as follows:

$$E[\mathbf{1}^T \mathbf{Y} / n] = \mathbf{1}^T E[\mathbf{Y}] / n = \mathbf{1}^T E[\mu \mathbf{1} + \mathbf{E}_k \mathbf{E}_k^T \mathbf{Y} + \mathbf{V}^{-1/2} \boldsymbol{\varepsilon}] / n = \mu$$

where \mathbf{E}_k are the K selected eigenvectors extracted from a binary 0–1 spatial weight matrix used to construct an eigenvector spatial filter and $\mathbf{1}^T \mathbf{E}_k = 0$ by construction. In other words, both estimators are unbiased.

The sampling variance of μ for the OLS estimator is $\sigma_\varepsilon^2 \mathbf{1}^T \mathbf{V}^{-1} \mathbf{1} / n^2$, and for the preceding GLS estimator is $\sigma_\varepsilon^2 / \mathbf{1}^T \mathbf{V} \mathbf{1}$. Meanwhile, the unbiased ESF estimator of σ_ε^2 is given by

$$\{(n - K) / [\text{TR}(\mathbf{V}^{-1}) - \mathbf{E}_k^T \mathbf{V}^{-1} \mathbf{E}_k]\} s_{\text{ESF}}^2$$

where s_{ESF}^2 is the MSE for ESF. In other words, s_{ESF}^2 underestimates σ_ε^2 . The sampling variance of μ for the OLS estimator is σ_ε^2 / n . The relative efficiencies of the OLS, GLS, and ESF estimators of a constant mean based upon unbiased variance estimators are given by

$$\text{GLS: OLS} = n^2 / [\mathbf{1}^T \mathbf{V} \mathbf{1} \mathbf{1}^T \mathbf{V}^{-1} \mathbf{1}] \tag{75.3a}$$

$$\text{ESF: GLS} = (1 - \rho)^2 \tag{75.3b}$$

$$\text{ESF: OLS} = n / \mathbf{1}^T \mathbf{V}^{-1} \mathbf{1} \tag{75.3c}$$

Eq. (75.3a)–(75.3c) equals 1 when no SA is present (i.e., $\mathbf{V} = \mathbf{I}$).

A numerical exercise was executed comparing efficiencies employing a 30-by-30 square lattice, and a simulation experiment was conducted employing a 10-by-10 square lattice, both utilizing the rook’s definition of geographic adjacency and a constant mean SAR model specification. The simulation employed normally distributed errors; all simulated pseudorandom numbers were converted to z-scores for each sample, the 31 eigenvectors for which $\text{MC}_j / \text{MC}_1 > 0.25$ and the 44 eigenvectors for which $\text{MC}_j / \text{MC}_1 > 0$, $\alpha = 0.01 / 31 \approx 0.00032$ or $0.10 / 44 \approx 0.00227$ or 0.10, and 10,000 replications.

Figure 75.3 portrays the efficiency results of the mean estimators [i.e., Eq. (75.3a)–(75.3c) values] for 11 selected values of ρ spanning the full range of positive SA. As reported by Cordy and Griffith (1993), the GLS estimator’s relative efficiency vis-à-vis the OLS estimator is very modest, and reaches only 0.82% when $\rho = 0.9999$. The ESF estimator increasingly is more efficient than either the GLS, SAR, or OLS estimators, with these latter estimators’ efficiencies decreasing quite precipitously with increasing ρ . As an aside, the tabulated simulation results in Fig. 75.3 almost perfectly align with their Eq. (75.3b) counterparts appearing in the Figure’s graph.

One implication suggested by the tabular part of Fig. 75.3 is that efficiency does not improve very much by increasing the number of eigenvectors available for constructing an ESF. In other words, once the prominent eigenvectors are selected

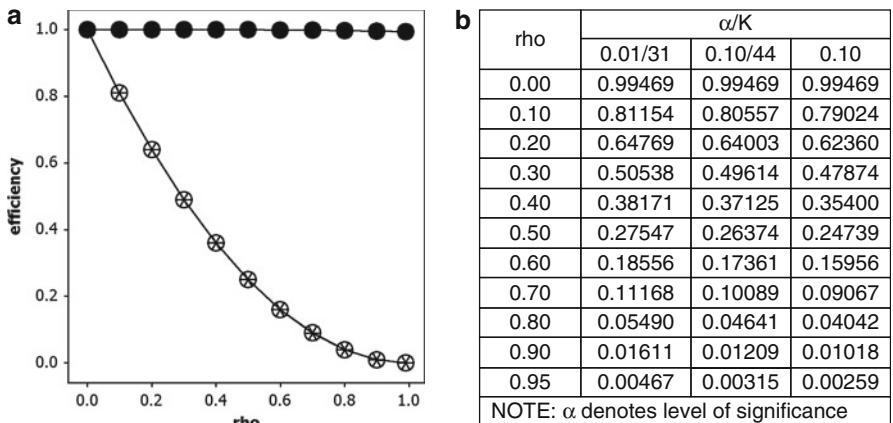

Fig. 75.3 Relative efficiency results for the mean. (a) the unbiased estimator efficiencies for a 30-by-30 regular square lattice: solid circle denotes s_{GLS}^2/s_{OLS}^2 , open circle denotes s_{ESF}^2/s_{GLS}^2 , and asterisk denotes s_{ESF}^2/s_{OLS}^2 . (b) the biased ESF versus SAR mean estimate for a 10-by-10 regular square lattice

in an ESF construction, marginal vectors add little to the efficiency of the ESF estimator. This result supports the use of the preceding Bonferroni adjustment during the construction of an ESF.

Linear regression parameter estimates are consistent when the covariates are orthogonal and uncorrelated with the error term in a model specification. But the context for this property to hold is that n increases while the number of covariates remains unchanged. ESF tends to have an increasing number of eigenvectors with increasing n (as well as with increasing SA). Based on a selected set of data analyses, where n ranges from 49 to 2,379 (see Table 75.4), the following logistic equation describes this increase:

$$n_{\text{selected}} \approx \frac{n_{\text{candidate}}}{1 + 3.16749 e^{-0.11409z_{MC} + 0.00255n}} \tag{75.4}$$

where n_{selected} is the number of selected eigenvectors for constructing a filter, $n_{\text{candidate}}$ is the number of candidate eigenvectors for a given surface partitioning (e.g., those with a $MC_j/MC_1 > 0.25$), and z_{MC} is the z-score for the response variable’s residual MC. Even when $n_{\text{candidate}} = n$ and for a completely connected planar graph, the limit of Eq. (75.4) divided by n (i.e., n_{selected}/n) is 0 as n goes to infinity. This result is in keeping with findings reported by Portnoy (1984). In other words, the covariate parameter estimates for an ESF model specification are consistent.

In summary, ESF estimators appear to be unbiased, efficient, and consistent. More comprehensive simulation experiments need to be completed to verify this generalization.

Table 75.4 Summary spatial autocorrelation and ESF results for selected geographic landscapes

Landscape	Attribute	MC	n	n _{selected}
Columbus, OH, census tracts	Crime	0.5206	49	6

75.4 Comparisons with the Spatial Lag Term

Conceptualization of the ESF model specification is based upon a spectral decomposition of a spatial weight matrix. The standard SAR specification furnishes the following approximation:

$$Y = \rho WY + (1 - \rho)\mu\mathbf{1} + \epsilon$$

$$Y = \rho D^{-1}CY + (1 - \rho)\mu\mathbf{1} + \epsilon$$

where **D** is a diagonal matrix whose cell (i,i) entry is the ith row sum of matrix **C**,

$$Y = \rho D^{-1}E\Lambda E^T Y + (1 - \rho)\mu\mathbf{1} + \epsilon$$

where **E** is the n-by-n matrix of eigenvectors and **Λ** is the corresponding diagonal matrix of eigenvalues

$$\Rightarrow Y = EE^T Y + \mu\mathbf{1} + \xi$$

This approximation requires the principal eigenfunction of matrix **C** to be removed from consideration; in theory, vector **1** attached to the mean parameter μ replaces it. Furthermore, the remaining n-1 eigenvectors are asymptotically uncorrelated (see Griffith 2000).

A more direct ESF model specification is based upon the spatial lag model specification:

$$Y = \mu\mathbf{1} + (\mathbf{I} - \rho C)^{-1}\epsilon$$

$$MY = \mu M\mathbf{1} + M(\mathbf{I} - \rho C)^{-1}\epsilon$$

where **M** = $(\mathbf{I} - \mathbf{1}\mathbf{1}^T/n)$ is the standard projection matrix used to center a vector of data values,

$$\begin{aligned} \mathbf{M}(\mathbf{I} - \rho \mathbf{C})\mathbf{M}\mathbf{Y} &= \mathbf{0} + \boldsymbol{\varepsilon} \\ \mathbf{M}\mathbf{Y} &= \rho \mathbf{M}\mathbf{C}\mathbf{M}\mathbf{Y} + \boldsymbol{\varepsilon} \end{aligned}$$

where matrix \mathbf{MCM} appears in the numerator of the MC,

$$\begin{aligned} \mathbf{Y} &= \rho \mathbf{M}\mathbf{C}\mathbf{M}\mathbf{Y} + \bar{y}\mathbf{1} + \boldsymbol{\varepsilon} \\ \Rightarrow \mathbf{Y} &= \mathbf{E}\mathbf{E}^T\mathbf{Y} + \mu\mathbf{1} + \boldsymbol{\xi} \end{aligned}$$

In other words, an ESF model specification approximates a spatial autoregressive model specification by approximating the included spatial lag variable. Removing those eigenvectors for which $\mathbf{E}_j^T\mathbf{Y} \approx 0$ reduces the covariate matrix \mathbf{E} used in a substitution for vector \mathbf{WY} from n-by-n to n-by-K, resulting in the general specification

$$\mathbf{Y} = \mathbf{E}_k\boldsymbol{\beta} + \mu\mathbf{1} + \boldsymbol{\xi}$$

where $\boldsymbol{\beta}$ is a K-by-1 vector of regression parameters. This particular general specification has the regression parameter estimates $\hat{\boldsymbol{\beta}} = (\mathbf{E}_k^T\mathbf{E}_k)^{-1}\mathbf{E}_k^T\mathbf{Y} = \mathbf{E}_k^T\mathbf{Y}$, yielding

$$\mathbf{Y} = \mathbf{E}_k\mathbf{E}_k^T\mathbf{Y} + \mu\mathbf{1} + \boldsymbol{\xi}$$

This reduction in matrix dimension can be achieved with stepwise regression techniques, which tremendously benefit from the mutual orthogonality and uncorrelatedness of the eigenvectors of modified matrix \mathbf{MCM} (two properties asymptotically achieved for matrix \mathbf{C} itself). From standard linear regression theory, the individual parameter estimate variances are given by the diagonal elements of matrix

$$\left[\begin{pmatrix} \mathbf{1}^T \\ \mathbf{E}_k^T \end{pmatrix} \begin{pmatrix} \mathbf{1} \\ \mathbf{E}_k \end{pmatrix} \right]^{-1} \sigma_\varepsilon^2 = \begin{pmatrix} \frac{1}{n} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_k \end{pmatrix} \sigma_\varepsilon^2$$

which furnishes the variance term used in the preceding estimator efficiency assessment.

The preceding discussion raises the question asking how well a set of selected eigenvectors approximates the spatial lag variate \mathbf{WY} . Figure 75.4 portrays the prediction of \mathbf{WY} by judiciously selected eigenvectors for the eight-specimen geospatial datasets used to assess consistency (see Table 75.4). An ESF description of vector \mathbf{Y} for these examples requires between 7% and 22% of the total number of eigenvectors. In contrast, an ESF description of vector \mathbf{WY} for these examples requires between 9% and 24% of the total number of eigenvectors, only a very slight increase in the number needed for describing variable \mathbf{Y} . In this context, Eq. (75.4) becomes

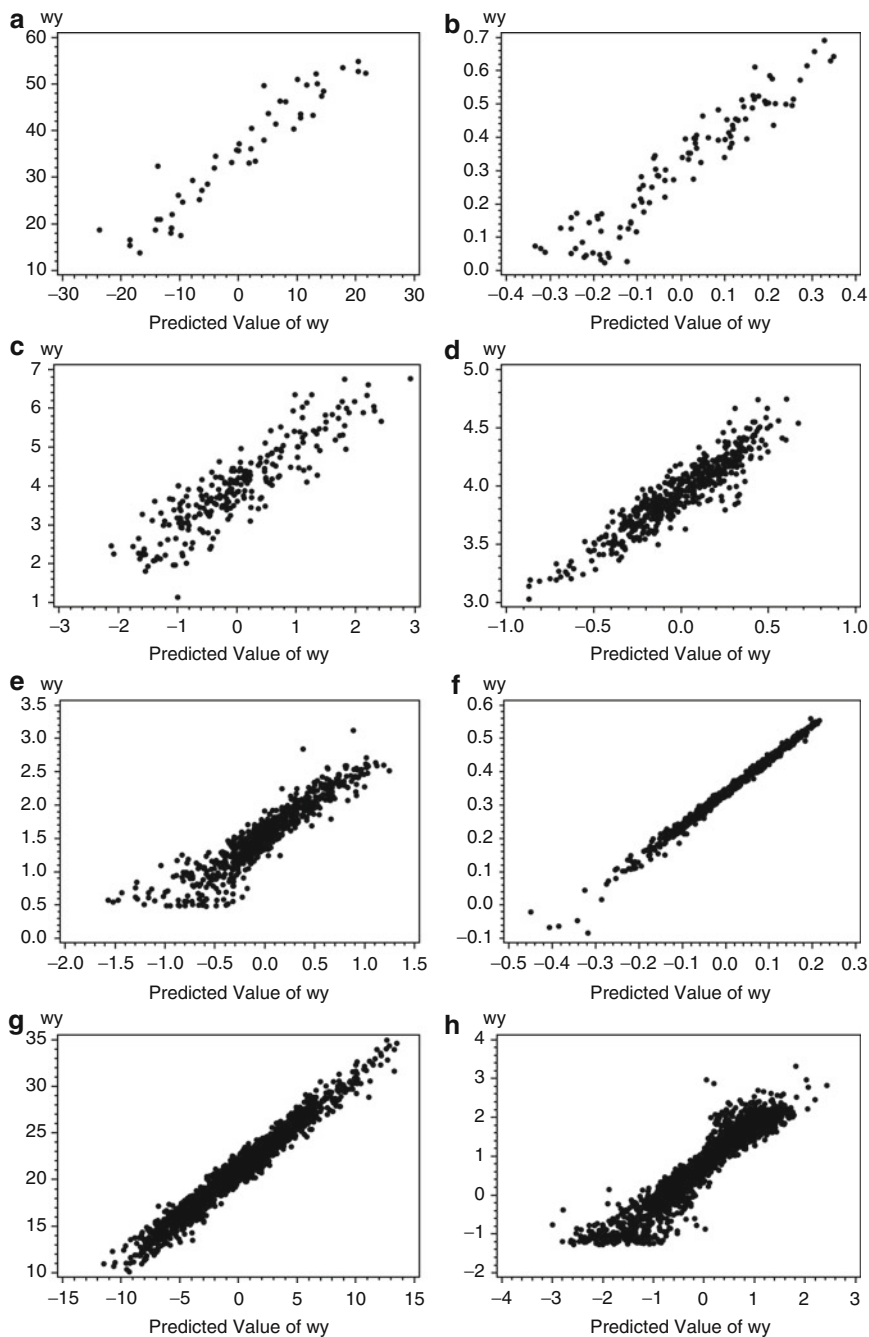

Fig. 75.4 Scatterplots of observed versus ESF-predicted WY vectors for the geographic landscapes listed in Table 75.4

$$n_{\text{selected}} \approx \frac{n_{\text{candidate}}}{1 + 0.85432 e^{-0.06967z_{\text{MC}} + 0.00189n}}$$

which still asymptotically goes to 0 when divided by n .

In summary, ESF furnishes a dimension reduction substitution for the spatial lag variate \mathbf{WY} in a spatial statistical model specification. Because the eigenvectors are fixed for a given matrix \mathbf{C} , this dimension reduction greatly simplifies accounting for SA in regression models.

75.5 An Empirical Example: An ESF Methodology Example

The 2007 farm densities in Puerto Rico (Y) were analyzed with conventional linear regression techniques. These densities are calculated by dividing the number of farms in by the area size of a municipality. Because the statistical distribution of these farm densities is highly skewed, they were subjected to a Box-Cox power transformation: $(Y - 0.12)^{0.38}$. The Shapiro-Wilk diagnostic test indicates that the transformed variable adequately mimics a normal distribution (p value = 0.5688). A benchmark bivariate linear regression model specification includes mean annual rainfall as a covariate variable. This allows a comparison between its parameter estimates and those for an ESF model.

Table 75.5 summarizes estimation results for the bivariate and ESF linear regression models. The residual MC tests indicate that the linear regression results contain significant spatial autocorrelation (the MC z -score is 6.2299), whereas the ESF model successfully accounts for all but trace spatial autocorrelation (the MC z -score is -0.8873). A change in both regression coefficient (i.e., intercept and slope) estimates and their standard errors accompanies the change in model specification. The ESF model produces a larger estimate (0.0210 vis-à-vis 0.0138) for the covariate regression slope coefficient. Its significance within the context of the ESF model also is higher. Finally, the percent of variance accounted for (R^2) increases considerably with inclusion of the eight eigenvectors, which partly is due to an increase in the number of covariates: the mean annual rainfall variable alone explains 13%, whereas spatial autocorrelation as captured by the ESF term explains an additional 60%, of the variation in Y .

Figure 75.5 portrays the decomposition of the 2007 farm densities based on the ESF model. Figure 75.5a is the map of the transformed farm densities. Figure 75.5b depicts the trend attributable to mean annual rainfall. This trend map illustrates that rainfall effectively explains the high values at the center of the island and in the eastern coast areas. Figure 75.5c portrays a spatially structured random component as captured by a linear combination of the eight selected eigenvectors. This map especially highlights the spatial clusters of low values in the northeast and of high values in the southwest parts of the island, indicating that they are well described by spatial autocorrelation map pattern components. Figure 75.5d visually confirms that the residuals of the ESF model lack a significant level of spatial autocorrelation.

Table 75.5 The results of linear regression for farm densities in Puerto Rico in 2007

Model features	Basic model		ESF model	
	Regression coefficient	Standard error	Regression coefficient	Standard error
Intercept	0.6622	0.3009*	0.1623	0.2235
Rainfall	0.0138	0.0042**	0.0210	0.0032***
# of selected eigenvectors	–		8	
R ²	0.1298		0.7283	
MC (z-score of MC)	0.4303 (6.2299)		–0.1644 (–0.8873)	

Significance codes: (*: 0.05, **: 0.01, ***: 0.001)

75.6 Extensions to Spatial Interaction Data Analysis

Spatial interaction can be conceptualized in a way that is analogous to gravity in Newtonian physics. The simple gravity model motivated its doubly constrained version containing origin and destination balancing factors (Wilson 1967). The balancing factors ensure that origin and destination totals are preserved. The factors may be interpreted as origin emissivity (i.e., a competitive accessibility measure vis-à-vis destinations with respect to origin i) and destination attractiveness (i.e., a competitive accessibility measure vis-à-vis origins with respect to destination j). This in turn motivated Poisson regression model estimation of its parameters (Flowerdew and Aitkin 1982). This Poisson probability model specification led to the use of origin and destination indicator variables [a separate indicator variable is included for each origin and each destination – that is, $2n-1$ binary variables, each having n 1s and $n(n-1)$ 0s], whose sets of coefficients are equivalent to the logarithm of the balancing factors when amalgamated. To avoid multicollinearity, coefficients for two of these indicator variables – one for the origin and one for the destination set – are set to 0, resulting in $2n-2$ binary variables. Contemporary research again is focusing on the role spatial autocorrelation plays in this model (Chun 2008; Griffith 2011; Fischer and Griffith 2008; LeSage and Pace 2008): correlation exists among flows originating near origin areal unit i and terminating at destination areal unit j .

Each of the n^2 geographic flows tends to be positively correlated with its origin and destination sizes and negatively correlated with the extent of the intervening distance. The following simple equation furnishes a very good description of this phenomenon (see Griffith 2011):

$$F_{ij} \approx \kappa e^{SF_{O_i \times D_j}} A_i O_i B_j D_j e^{-\gamma d_{ij}} \quad (75.5)$$

where F_{ij} denotes the flow (e.g., number of workers) between locations i and j , κ is a constant of proportionality,

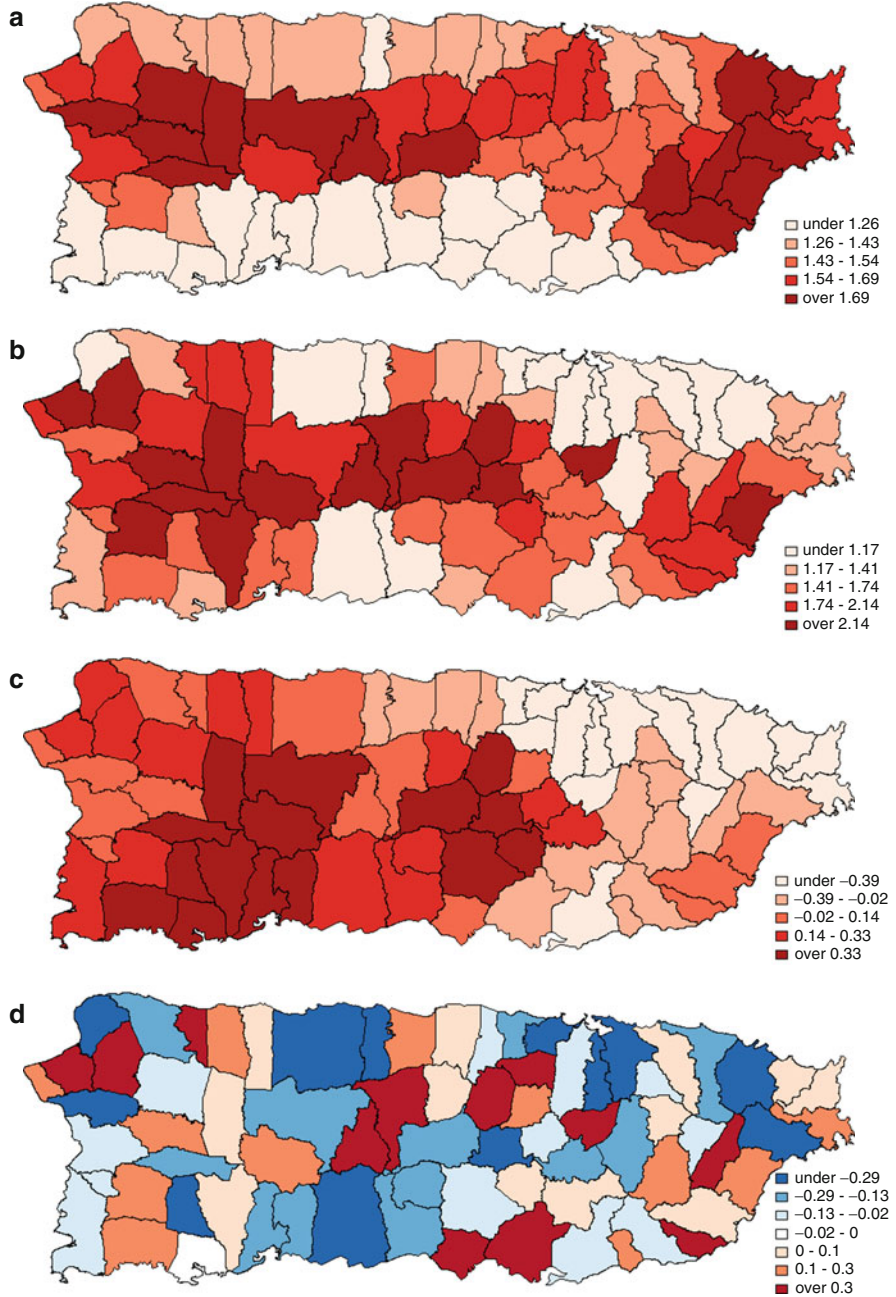

Fig. 75.5 Decomposed maps of 2007 farm densities in Puerto Rico: (a) dependent variable, (b) trend latent in the mean annual rainfall covariate, (c) spatially structured random component, and (d) random residuals

SF_{O_i} denotes the origin i spatial filter accounting for spatial autocorrelation in flows.

A_i denotes an origin balancing factor,

O_i denotes the total amount of flow leaving from origin i (e.g., number of workers residing in an origin),

SF_{D_j} denotes the destination j spatial filter accounting for spatial autocorrelation in flows,

B_j denotes a destination balancing factor,

D_j denotes the total amount of flow arriving to destination j (e.g., the number of jobs available in a destination),

d_{ij} denotes the distance separating origin i and destination j ,

γ denotes the global distance decay rate.

Selected results from the estimation of Eq. (75.5) for the Puerto Rican 2000 journey-to-work data (874,832 inter-municipality trips for 73^2 dyads) include the following:

Set values	$\hat{\kappa}$	$\hat{\gamma}$	Overdispersion	Pseudo- R^2
$SF_{O_i}=0, SF_{D_j}=0, A_i=1, B_j=1$	9.4×10^{-6}	0.1625	14.5227^2	0.8039
$SF_{O_i}=0, SF_{D_j}=0$	5.6×10^{-6}	0.2286	7.9801^2	0.9825
none	5.1×10^{-6}	0.2084	6.4750^2	0.9892

The spatial filter comprises 85 of 121 candidate eigenvectors (those with an MC of at least 0.25), from a total of 5,329 possible eigenvectors. The uncovered spatial autocorrelation in these flows contributes to excess Poisson variation. Adjusting for spatial autocorrelation in these flows yields a better alignment of the largest predicted and observed values (Fig. 75.6).

Figure 75.7 portrays the balancing factors and the spatial filters for the Puerto Rican journey-to-work example. Figures 75.7a and 75.7b, the A_i and B_j values, display conspicuous geographic patterns. Meanwhile, the origin spatial filter (Fig. 75.7c) contrasts the San Juan metropolitan region with the remainder of the island, whereas the destination spatial filter (Fig. 75.7d) highlights the four urban catchment areas (San Juan-Caguas, Arecibo, Mayaguez, and Ponce).

75.7 Conclusions

This chapter provides an introductory discussion about the concept of spatial autocorrelation together with ESF methodology. Spatial filtering furnishes a method to properly analyze a georeferenced variable by effectively separating a spatially structured random component from trend and random noise present in a georeferenced variable. Spatial filtering offers several advantages over other spatial data modeling methodologies, including spatial autoregression. First, it allows researchers to model spatially autocorrelated variables with conventional statistical tools, such as linear regression, which otherwise may well produce biased estimates with standard methodology, such as OLS. Second, it provides a way to

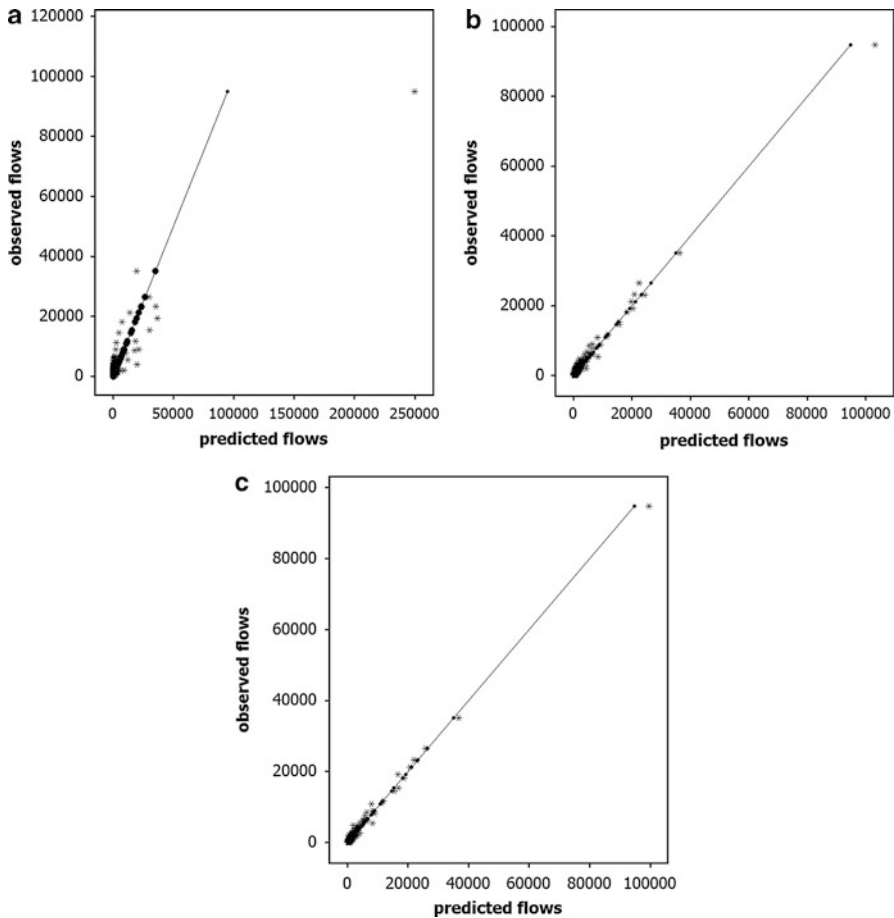

Fig. 75.6 Scatterplots of the Eq. (75.5)-predicted and observed journey-to-work trips. (a) $SF_{O_i} = 0$, $SF_{D_j} = 0$, $A_i = 1$, and $B_j = 1$. (b) $SF_{O_i} = 0$ and $SF_{D_j} = 0$. (c) all parameters estimated

analytically decompose a variable into underlying components, including a spatial component. Third, it provides a synthetic variate (the spatial filter) whose mapping visualizes spatial autocorrelation contained in a georeferenced variable. This visual representation can lead to a better understanding of geographical phenomenon, in part by furnishing a clue about possible variables missing from a linear regression model specification.

In addition, ESF methodology produces an enhanced and robust statistical result when compared with alternative model specifications, such as OLS linear regression and spatial autoregression: its parameters appear to be unbiased, relatively efficient, and consistent. Beyond the discussion in this chapter, the ESF methodology also offers the advantage of being able to accommodate positive spatial autocorrelation in a generalized linear model with discrete response variable,

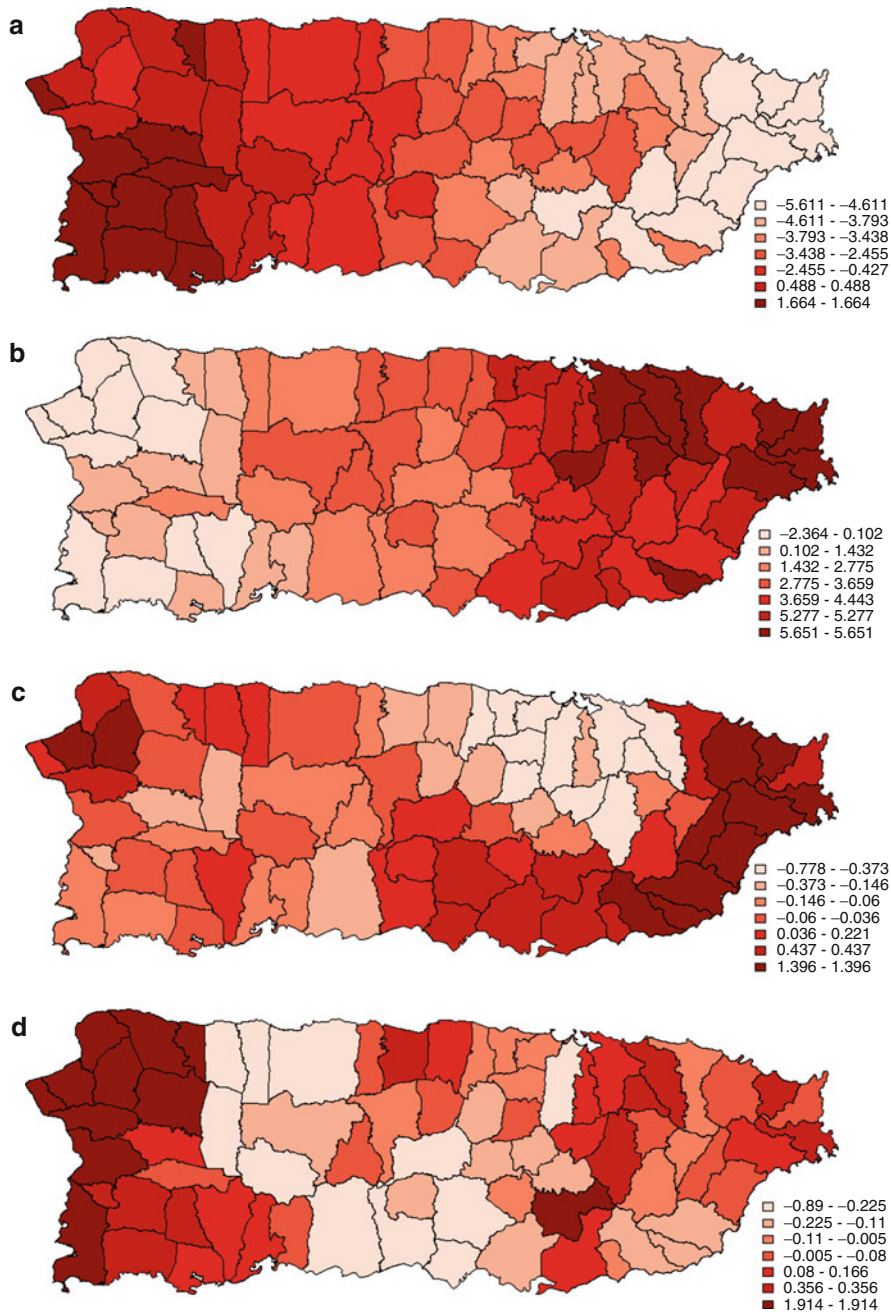

Fig. 75.7 Geographic distributions of Eq. (75.5) terms. (a) origin balancing factor (A_i). (b) destination balancing factor (B_j). (c) origin spatial filter. (d) destination spatial filter

such as Poisson and negative binomial, which cannot be modeled with the traditional auto specifications (Besag 1974). Further, the ESF methodology furnishes technology that can be utilized to account for spatial autocorrelation in geographical flows, such as population migration, journey-to-work flows, and interregional commodity flows. In other words, it offers a much wider array of tools, in more advanced spatial data analysis settings, than is addressed by the discussion in this chapter.

Finally, the ESF methodology can be extended to other spatial analysis problems. Spatial interaction modeling furnishes one such extension. Adjusting for spatial autocorrelation in geographic flow descriptions allows a better estimate of the global distance decay parameter, accounts for considerable excess variation characterizing flows, and better aligns the magnitudes of predicted and observed flows.

Appendix A

The relationship between the MC and a squared product moment correlation coefficient (r^2).

MC can be derived as a linear regression solution:

From OLS theory: $\mathbf{b} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{Y}$

- (i) Convert the attribute variable in question to z-scores
- (ii) Let $\mathbf{X} = \mathbf{z}_Y$ and $\mathbf{Y} = \mathbf{Cz}_Y$
- (iii) Regress \mathbf{Cz}_Y on \mathbf{z}_Y , with a no-intercept option
- (iv) Let $\mathbf{X} = \mathbf{1}$ and $\mathbf{Y} = \mathbf{C1}$
- (v) Regress $\mathbf{C1}$ on $\mathbf{1}$, with a no-intercept option
- (vi) $\text{MC} = b_{\text{numerator}}/b_{\text{denominator}}$

This relationship relates directly to the Moran scatterplot, conveying why it is a useful visualization of spatial autocorrelation.

Next, let $\text{MC} = (n / \mathbf{1}^T\mathbf{C1}) \mathbf{z}^T\mathbf{Cz}/(n-1)$ and rewrite vector \mathbf{z} as the following bivariate regression model specification: $\mathbf{z} = a\mathbf{1} + b\mathbf{CZ} + \mathbf{e}$, where \mathbf{e} is an n-by-1 vector of residuals. Then

$$b = \frac{\mathbf{z}^T\mathbf{Cz}}{\mathbf{z}^T\mathbf{C}^2\mathbf{z}} = \frac{s_z}{s_{Cz}}r = \frac{\sqrt{1}}{s_{Cz}}r$$

$$\frac{\text{MC}}{\text{MC}_1} \frac{n\lambda_1}{\mathbf{1}^T\mathbf{C1}} \frac{\mathbf{1}^T\mathbf{C1}}{n} \frac{n-1}{\mathbf{z}^T\mathbf{C}^2\mathbf{z}} = \frac{1}{\sqrt{\frac{\mathbf{z}^T\mathbf{C}(\mathbf{I}-\mathbf{11}^T/n)\mathbf{Cz}}{n-1}}}r$$

$$\left(\frac{\text{MC}}{\text{MC}_1}\right)^2 \lambda_1^2 \frac{(n-1)^2}{(\mathbf{z}^T\mathbf{C}^2\mathbf{z})^2} = \frac{n-1}{\mathbf{z}^T\mathbf{C}(\mathbf{I}-\mathbf{11}^T/n)\mathbf{Cz}}r^2$$

$$r^2 = \left(\frac{\text{MC}}{\text{MC}_1}\right)^2 \lambda_1^2 (n-1) \frac{\mathbf{z}^T\mathbf{C}(\mathbf{I}-\mathbf{11}^T/n)\mathbf{Cz}}{(\mathbf{z}^T\mathbf{C}^2\mathbf{z})^2}$$

where MC_1 denotes the maximum value of MC for a given spatial weight matrix C . For a large P -by- Q regular square lattice (i.e., $n = PQ$) and the rook's adjacency definition, for which $MC_1 \approx 1$, if $MC = 0.25$, then

$$\mathbf{1}^T C \mathbf{z} \approx 0$$

$$\mathbf{z}^T C^2 \mathbf{z} \approx 16 (PQ - 1)$$

$$\lambda_1 = 2[\cos(\frac{\pi}{P+1}) + \cos(\frac{\pi}{Q+1})] \approx 4$$

and, consequently, $r^2 \approx 0.05$. Therefore, roughly 5% of the variance in a spatially autocorrelation random variable with $MC = 0.25$ is attributable to spatial autocorrelation.

Abstract

This chapter provides a selective survey of specification issues in spatial econometrics. We first present the most commonly used spatial specifications in a cross-sectional setting in the form of linear regression models including a spatial lag and/or a spatial error term, heteroscedasticity or parameter instability. Second, we present a set of specification tests that allow checking

deviations from a standard, that is, nonspatial, regression model. An important space is devoted to unidirectional, multidirectional, and robust LM tests as they only require the estimation of the model under the null. Because of the complex links between spatial autocorrelation and spatial heterogeneity, we give some attention to the specifications incorporating both aspects and to the associated specification tests.

76.1 Introduction

In spatial regression models, the observations are collected from points or regions located in space. These models usually incorporate *spatial effects* that are commonly classified in two categories: *spatial autocorrelation* and *spatial heterogeneity*. On the one hand, spatial autocorrelation is a special case of cross-sectional dependence and refers to the coincidence of value similarity with locational similarity (Anselin and Bera 1998). Positive spatial autocorrelation means that observations from one location tend to exhibit values similar to those from nearby locations, while negative spatial autocorrelation points to the spatial clustering of dissimilar values. The typical characteristic of spatial autocorrelation is that it is two dimensional and multidirectional. On the other hand, spatial heterogeneity pertains to structural relations that vary over space, either in the form of nonconstant error variances in a regression model (heteroscedasticity) or in the form of spatially varying regression coefficients.

In recent years, the interest in *spatial econometrics*, that is, the subset of econometric methods that deals with the analysis of spatial effects in regression analysis, has seen an exponential growth in social sciences, leading to the creation of the *Spatial Econometrics Association* in 2006 (Arbia 2011). The upsurge in spatial econometrics has been driven by the recognition of the role of space and spatial/social interactions in economic theory, the availability of datasets with georeferenced observations, and the development of geographic information systems and spatial data analysis softwares. This field has even reached a stage of maturity through general acceptance as a mainstream methodology, according to Anselin (2010).

In this chapter, we provide a concise overview of the methodological issues related to the treatment of spatial effects in regression models. Attention here is given to specification issues, that is, how spatial correlation and spatial heterogeneity structures should be incorporated into a regression model and the implications for specification testing. We do not consider estimation issues, as this is the topic of other chapters in this volume (see Prucha and Jenish, ► Chap. 80, “Instrumental Variables/Method of Moments Estimation”; Mills and Parent, ► Chap. 79, “Bayesian MCMC Estimation” and Pace, ► Chap. 78, “Maximum Likelihood Estimation”). We have also limited the review to cross-sectional settings for linear regression models and do not consider spatial effects in space-time models (see Elhorst, ► Chap. 82, “Spatial Panel Models”) nor models for limited dependent variables (see Wang, ► Chap. 81, “Limited and Censored Dependent Variable Models”).

The chapter consists in two sections, starting with a presentation of the specification of spatial effects in cross-sectional linear regression models. Next, we consider specification tests that detect spatial autocorrelation and/or spatial heterogeneity. Most attention is devoted to spatial autocorrelation, the distinct nature of which requires a specialized set of techniques that are not a straightforward extension of time series methods to two dimensions. On the contrary, the treatment of spatial heterogeneity does not require specific econometric tools. However, we underline here the relationships between both effects. The chapter closes with some concluding remarks.

76.2 Spatial Effects in Cross-Sectional Models

Consider as a point of departure, the classical cross-sectional linear regression model:

$$y = X\beta + \varepsilon \quad (76.1)$$

where N is the total number of observations, here geographical areas; K is the total number of unknown parameters to estimate; y is the $(N,1)$ vector of observations on the dependent variable; X is the (N,K) matrix of observations on the K explanatory variables; β is the $(N,1)$ vector of unknown parameters to be estimated; and ε is the $(N,1)$ vector of error terms. We also assume that X is a non-stochastic matrix of full rank $K < N$.

If the error terms are $iid(0, \sigma^2 I_N)$, where I_N is the identity matrix of order N , then the Ordinary Least Squares (OLS) estimator defined by $\hat{\beta} = (X'X)^{-1}X'y$ is BLUE (Gauss-Markov theorem). However, the introduction of spatial effects in the linear regression model implies that some of these assumptions are not met. We first list the models incorporating some form of spatial autocorrelation and continue with models with spatial heterogeneity.

76.2.1 Forms of Spatial Autocorrelation in Regression Models

In the presence of spatial autocorrelation, the variance-covariance matrix in Eq. (76.1) $\Sigma = E(\varepsilon\varepsilon')$ contains N variances and $N(N-1)/2$ off-diagonal parameters following a spatial ordering. These cannot be estimated separately with a cross section of N observations. Hence, in order to incorporate spatial autocorrelation in regression models, several possibilities exist. Some aim at imposing some structure or constraints on the elements of Σ such that a finite number of parameters characterizing spatial autocorrelation can be estimated. Others remain nonparametric. We briefly review these options here.

First, a *stochastic process* may be specified that determines the form of the covariance structure. In doing this, spatial lags are incorporated in the regression model. Spatial lags are obtained as the product of a *spatial weights matrix* W with

the vector of observations on a random variable. This matrix is of dimension (N,N) and specifies the connectivity structure within the observations in the sample. It has nonzero elements w_{ij} in each row i for those columns j that are neighbors of location j . The elements on the diagonal are equal to 0. The notion of *neighbors* can be purely geographic, such as sharing a common border, or can be more general, such as neighbors in social network space. Spatial autocorrelation is then modeled by specifying various functional relationships between the vector of observations of the explained variable y and its spatial lag Wy , a spatially lagged error term $W\varepsilon$ and/or spatially lagged explanatory variables WX .

Second, the covariance between observations can be specified as a direct and continuous function of distance. Different specifications have been suggested.

Third, a nonparametric approach can be adopted where the functional form of the function of distance separating two equations is left unspecified. This can also accommodate heteroscedasticity of unknown form.

We detail these different possibilities below.

76.2.2 Spatial Lag Model

In this model, labeled SAR model, spatial autocorrelation is incorporated through a *spatial lag* of the *endogenous* variable. The *structural* model is written as

$$\begin{aligned} y &= \rho Wy + X\beta + \varepsilon \\ \varepsilon &\rightarrow iid(0, \sigma^2 I_N) \end{aligned} \tag{76.2}$$

Wy is the endogenous lag variable for the spatial weights matrix W ; ρ is the spatial autoregressive parameter that indicates the strength of interactions existing between the observations of y .

In the spatial lag model, observation y_i is, in part, explained by the values taken by y in neighboring observations: $(Wy)_i = \sum_{j \neq i} w_{ij} y_j$. Indeed, when W is standardized, each element $(Wy)_i$ is interpreted as a weighted average of the y values for i 's neighbors. The introduction of Wy allows evaluating the degree of spatial dependence when the impact of other variables is controlled for. When Eq. (76.2) is the result of a theoretical modeling implying some process of social and spatial interaction, this parameter measures substantive spatial dependence, that is, the extent of spatial externalities or spatial diffusion.

Symmetrically, it allows controlling spatial dependence when evaluating the impact of other explanatory variables. In this case, particular care should be given to the interpretation of the coefficient estimates (see below).

LeSage and Pace (2009) provide several motivations for regression models that include a spatial lag. One is a time-dependence motivation: cross-sectional model relations with a spatial lag may come from economic agents considering past period behavior of neighboring agents. The presence of a spatial lag has also been justified with theoretical models involving diffusion, copycatting,

or spatial externalities. These are the cases of substantive spatial dependence. It is then the formal representation of the equilibrium outcome of spatial interaction processes.

Note that ρ is not a conventional correlation coefficient between vector y and its spatial lag Wy . Indeed, this parameter is not restricted to the range -1 to 1 . From the DGP associated with the SAR model, the log-likelihood function involves a Jacobian term of the form $\ln|I_N - \rho W|$ that constrains the parameter ρ to be in the interval $[1/w_{\min}; 1/w_{\max}]$ where w_{\min} and w_{\max} are respectively the minimum and the maximum eigenvalues of W . If the latter is row standardized, then $w_{\max} = 1$.

When a spatial lag variable is ignored in the model specification, whereas it is present in the underlying data generating process, the OLS estimators in the spatial model Eq. (76.1) are biased and not consistent (omitted variable bias).

This specification has several properties:

76.2.2.1 Multiplier and Diffusion Effects

Assume that the matrix $(I_N - \rho W)$ is not singular. In this case, Eq. (76.2) can be rewritten in the following *reduced* form:

$$y = (I_N - \rho W)^{-1} X\beta + (I_N - \rho W)^{-1} \varepsilon \quad (76.3)$$

This model is nonlinear in ρ and β . It follows from Eq. (76.3) that $E(y) = (I_N - \rho W)^{-1} X\beta$. The matrix inverse $(I_N - \rho W)^{-1}$ is a full matrix and not triangular, as in the time series case where dependence is only one directional. When $|\rho| < 1$, this implies an infinite series, the *Leontief expansion*, involving the explanatory variables and the error term at all locations:

$$y = (I_N + \rho W + \rho^2 W^2 + \dots) X\beta + (I_N + \rho W + \rho^2 W^2 + \dots) \varepsilon \quad (76.4)$$

This expression allows defining two effects: a *multiplier* effect affecting the explanatory variables and a *spatial diffusion* effect affecting the error terms.

On the one hand, with respect to the explanatory variables, this expression means that in average, the value of y at one location i is not only explained by the values of the explanatory variables associated to this location but also by those associated to all the other locations (neighbors or not) *via* the inverse spatial transformation $(I_N - \rho W)^{-1}$. This spatial multiplier effect decreases with distance, that is, the powers of W in the series expansion of $(I_N - \rho W)^{-1}$.

On the other hand, with respect to the error process, this expression means that a random shock in a location i not only affects the value of y in this location but also has an impact on the values of y in all the other locations *via* the same spatial inverse transformation. This is the diffusion effect, which also declines with distance.

Both these effects are *global* in the sense that all locations in the system interact with each other (Anselin 2003).

From Eq. (76.3), it also follows that $E[(Wy)_i \varepsilon_i] = E\left[\left\{W(I_N - \rho W)^{-1} \varepsilon\right\}_i \varepsilon_i\right] \neq 0$. The spatial lag is therefore always endogenous, irrespective of the properties of ε , so that the estimation of model Eq. (76.2) cannot be based on OLS but should be performed using maximum likelihood (ML), instrumental variables (IV), or Bayesian methods.

76.2.2.2 Interpretation of Coefficient Estimates

A consequence of the multiplier effect in the spatial lag model is that particular care should be taken when interpreting the coefficient estimates (LeSage and Pace, ► Chap. 77, “Interpreting Spatial Econometric Models” for more details). Indeed, the impact of a marginal change in one variable X_k on $E(y)$ is not equivalent to the coefficient associated to X_k , noted β_k , as in the standard regression model. On the contrary, it follows from Eq. (76.3) that

$$\frac{\partial E(y_i)}{\partial X_{jk}} = S_k(W)_{ij} \quad (76.5)$$

where X_{jk} is the value of X_k at location j and $S_k(W)_{ij}$ is the ij^{th} element of the matrix $(I_N - \rho W)^{-1} \beta_k$. Hence, the impact of a change in an explanatory variable differs over all observations. Summary measures of these impacts are discussed in LeSage and Pace (2012).

76.2.2.3 Variance-Covariance Matrix

From Eq. (76.3), we derive the variance-covariance matrix of y :

$$E(yy') = (I_N - \rho W)^{-1} E(\varepsilon \varepsilon') (I_N - \rho W')^{-1} \quad (76.6a)$$

$$E(yy') = \sigma^2 (I_N - \rho W)^{-1} (I_N - \rho W')^{-1} \quad (76.6b)$$

This variance-covariance matrix is full, which implies that each location is correlated with every other location in the system. However, this correlation decreases with distance.

76.2.2.4 Endogenous Spatial Lag and Heteroscedasticity

Note $u = (I_N - \rho W)^{-1} \varepsilon$. Its variance-covariance is written as

$$E(uu') = \sigma^2 (I_N - \rho W)^{-1} (I_N - \rho W')^{-1} \quad (76.7)$$

Equation (76.7) shows that the covariance between each pair of error terms is not null and decreasing with the order of proximity. Moreover, the elements of the diagonal of $E(uu')$ are not constant. This implies error *heteroscedasticity* of u , whether or not ε is heteroscedastic.

76.2.3 Cross-Regressive Model: Lagged Exogenous Variable

Another possibility to incorporate spatial autocorrelation in a regression model is to include one or more *exogenous lagged variables* in Eq. (76.1):

$$\begin{aligned} y &= \rho W y + W Z \delta + \varepsilon \\ \varepsilon &\rightarrow iid(0, \sigma^2 I_N) \end{aligned} \quad (76.8)$$

Z is a matrix of dimension (N, L) containing L variables that may or not correspond to the variables included in X ; WZ is the matrix of observations for the exogenous lagged variables with weights matrix W , and δ is the $(L, 1)$ vector of spatial parameters indicating the intensity of spatial correlation existing between the observations in y and those of Z .

In this model, the observation y_i is explained by the values taken by the variables in X in location i and by the variables in Z in neighboring regions. The interactions in the system hence remain *local*.

Contrary to the spatial lag model and the models with a spatial error autocorrelation (below), the estimation of the cross-regressive model can be based on OLS.

76.2.4 Models with Spatial Error Autocorrelation

Finally, spatial autocorrelation can be incorporated in a regression model by specifying a spatial process in the error terms. It is therefore a special form of a nonspherical error variance-covariance matrix with $E[\varepsilon_i \varepsilon_j] \neq 0$ for two locations $i \neq j$. As such, these models should be estimated using ML, generalized method of moments (GMM), or Bayesian methods. The different possibilities lead to different error spatial covariances that differ with respect to the range and extent of spatial interaction in the model.

76.2.4.1 Spatial Autoregressive Process

The most commonly used specification is a spatial autoregressive process in the error terms. The structural model can be then written as

$$\begin{aligned} y &= X\beta + \varepsilon \\ \varepsilon &= \lambda W\varepsilon + u \end{aligned} \quad (76.9)$$

The parameter λ is the spatial autoregressive coefficient that reflects the interdependence between the regression residuals; u is the error term such as $u \rightarrow iid(0, \sigma^2 I_N)$. When spatial error autocorrelation is omitted, the OLS estimators are unbiased, but inefficient estimators and the statistical inference based on OLS are biased.

This specification has several properties:

Spatial Diffusion

First, if the matrix $(I_N - \lambda W)$ is not singular, then model Eq. (76.9) can be rewritten under the following reduced form:

$$y = X\beta + (I_N - \lambda W)^{-1}u \quad (76.10)$$

This expression leads to a global spatial diffusion effect as in model Eq. (76.3) but, as $E(y) = X\beta$, there is no spatial multiplier effect.

Variance-Covariance Matrix

From Eq. (76.10), we have

$$E(yy') = E(\varepsilon\varepsilon') = (I_N - \rho W)^{-1}E(\varepsilon\varepsilon')(I_N - \rho W')^{-1} \quad (76.11a)$$

$$E(yy') = E(\varepsilon\varepsilon') = \sigma^2(I_N - \rho W)^{-1}(I_N - \rho W')^{-1} \quad (76.11b)$$

Hence, we find, for ε and for y , a structure identical to that of the spatial lag model: this process leads to nonzero error covariance between each pair of observations, but these covariances decrease with distance. The spatial structure of the variance-covariance induced by the model with spatial error autocorrelation is therefore *global*, since it links all the locations of the system to all others.

Moreover, the error structure induces nonconstant elements of the diagonal of $E(\varepsilon\varepsilon')$, which implies heteroscedasticity of the errors ε , whether u is heteroscedastic or not.

Constrained Spatial Durbin Model

Model Eq. (76.9) can be rewritten in a form where both an endogenous spatial lag and all exogenous spatial lags appear. Indeed, by multiplying both sides of Eq. (76.10) by $(I_N - \lambda W)$ and moving the autoregressive term to the right, we obtain the constrained *spatial Durbin model*:

$$y = \lambda Wy + X\beta - \lambda WX\beta + u \quad (76.12)$$

This specification shows how the spatial error model is a special case of a spatial lag model, with additional nonlinear constraints on the parameters. This forms the basis of a specification test that will be presented below.

Several alternatives have been suggested in the literature even if their application is less frequent in the literature.

76.2.4.2 Spatial Moving-Average Process

The spatial *moving-average* process is specified as

$$\begin{aligned} y &= X\beta + \varepsilon \\ \varepsilon &= \gamma Wu + u \end{aligned} \quad (76.13)$$

where γ is the moving-average coefficient and u is the error term such as $u \rightarrow iid(0, \sigma^2 I_N)$. Contrary to the previous case, the reduced model does not contain any inverse matrices since Eq. (76.13) already corresponds to the reduced model. The variance-covariance matrix resulting from this process is

$$E(\varepsilon\varepsilon') = \sigma^2(I_N + \gamma W)(I_N + \gamma W') = \sigma^2[I_N + \gamma(W + W') + \gamma^2 WW'] \quad (76.14)$$

In contrast to the variance-covariance matrix associated with the autoregressive process, Eq. (76.14) is not a full matrix. The nonzero covariances only exist for first-order ($W + W'$) and second-order (WW') neighbors. This process therefore implies much less overall interaction than the autoregressive model, and the spatial structure of covariance induced by Eq. (76.14) is only *local* since it does link all the locations of system to each other.

Finally, as in the autoregressive case, the elements of the diagonal of Eq. (76.14) are not constant, implying, as in the previous model, heteroscedasticity in ε , irrespective of the nature of u .

76.2.4.3 Kelejian and Robinson Specification

Kelejian and Robinson (1995) suggest another specification in which the error term is the sum of two independent terms, one being a smoothing term of neighboring errors and the other being specific to the location:

$$\varepsilon = Wu + v \quad (76.15)$$

where u and v are supposed homoscedastic and independent. Then, the variance-covariance matrix of ε is

$$E(\varepsilon\varepsilon') = \sigma_u^2 I_N + \sigma_v^2 WW' = \sigma^2[I_N + \varphi WW'] \quad (76.16)$$

where σ_u^2 and σ_v^2 are the variance, respectively, associated with u and v , $\sigma^2 = \sigma_v^2 > 0$ and $\varphi = \sigma_u^2/\sigma_v^2$. The spatial interaction implied by Eq. (76.16) is more limited than in the moving-average model as it only concerns neighbors of the first and second order contained in the nonzero elements of WW' . Heteroscedasticity is also implied in this specification.

76.2.4.4 Direct Representation and Nonparametric Specifications

In this case, the covariance between each pair of error terms is directly specified as an inverse function of the distance between them: $\text{cov}(\varepsilon_i, \varepsilon_j) = \sigma^2 f(\theta, d_{ij})$ where d_{ij} is the distance between i and j , σ^2 is the error variance, and f is the distance function. This function is a distance decay function that should ensure definite-positive variance-covariance matrix. This imposes constraints on the functional form, the parameter space, the metric, and scale used for the distance measure. For instance, one might use a negative exponential distance decay function:

$$E(\varepsilon\varepsilon') = \sigma^2[I_N + \gamma\Psi] \quad (76.17)$$

where the off-diagonal elements of Ψ are given by $\Psi = e^{-\theta d_{ij}}$ where θ is a nonnegative scaling parameter. The diagonal elements of Ψ are set to zero.

Contrary to the previous specifications, the direct representation does not induce heteroscedasticity.

An alternative to parametric specifications is to leave the functional form unspecified: these are *nonparametric* models. We then have $\text{cov}(\varepsilon_i, \varepsilon_j) = f(d_{ij})$ where d_{ij} is a positive and symmetric distance metric. The regularity conditions on the distance metric have been derived by Conley (1999).

The presence of spatial error autocorrelation is often interpreted as a problem in the model specification, such as functional form problems or spatial autocorrelation resulting from a mismatch between the spatial scale of the phenomenon being studied and the spatial scale at which it is measured.

76.2.5 Spatial Durbin Model

An encompassing specification to the spatial lag model, the spatial cross-regressive model, and the spatial error model is the unconstrained spatial Durbin model. The latter contains a spatially lagged endogenous variable and all the spatially lagged exogenous variables. More specifically, it is written as

$$y = \lambda W y + X \beta + \lambda W X \delta + u \quad (76.18)$$

The spatial lag model, the spatial cross-regressive model, and the spatial error model are found with the appropriate constraints on the parameters, respectively, $H_0 : \delta = 0$, $H_0 : \rho = \delta = 0$, and $H_0 : \lambda \beta + \delta = 0$.

LeSage and Pace (2009) provide several motivations for a spatial Durbin model. One is an *omitted variable* motivation. Indeed, they show that if the linear regression model Eq. (76.1) is affected by an omitted variables problem and if these omitted variables are spatially correlated and correlated with the included explanatory variables, then unbiased estimates of the coefficients associated with the endogenous variables X can still be obtained by fitting a spatial Durbin model. Other motivations detailed in LeSage and Pace (2009) are based on spatial heterogeneity and model uncertainty.

76.2.6 Higher-Order Spatial Models

In these models, multiple spatially lagged dependent variables and/or multiple spatially lagged error terms are included.

For instance, the spatial autoregressive, moving-average SARMA(p, q) process is as follows:

$$\begin{aligned} y &= X \beta + \rho_1 W_1 y + \rho_2 W_2 y + \dots + \rho_p W_p y + \varepsilon \\ \varepsilon &= \lambda_1 W_1 u + \lambda_2 W_2 u + \dots + \lambda_p W_p u + u \end{aligned} \quad (76.19)$$

In general, the weights W_i are associated to the i^{th} order of contiguity. We could similarly consider a process where the errors follow a spatial autoregressive process of order q . However, in this case, identification issues may arise (Anselin 1988).

It may be that these *high-order processes* are the result of a poorly specified spatial weights matrix rather than a realistic data generating process (Anselin and Bera 1998). For instance, if the weights matrix of the model underestimates the real spatial interaction in the data, there will be residual spatial error autocorrelation. This can lead to the estimation of higher-order processes while only a well-specified weights matrix should be necessary. These higher-order models are in fact usually used as alternatives in diagnostic tests. Rejection of the null may then indicate that a different specification of the weights is necessary.

76.2.7 Heteroscedasticity

Until now, all specifications have assumed *iid* innovations. However, as we have seen, the sole presence of spatial autocorrelation induces *heteroscedasticity* in the models. In cross-sectional regression, additional heteroscedasticity is also frequently present. For instance, in the spatial autoregressive error model, we can have

$$\begin{aligned} y &= X\beta + \varepsilon \\ \varepsilon &= \lambda W\varepsilon + u \\ u &\rightarrow \text{iii}(0, \Omega) \end{aligned} \tag{76.20}$$

In this case, the variance-covariance matrix of ε is

$$E(\varepsilon\varepsilon') = (I_N - \rho W)^{-1} \Omega (I_N - \rho W')^{-1} \tag{76.21}$$

Several specifications have been used for Ω . In a spatial context, a useful one is that of *groupwise heteroscedasticity*. When the data are organized into spatial regimes, one variance is estimated for each regime so that Ω has a block-diagonal structure:

$$\Omega = \begin{bmatrix} \sigma_1^2 I_{N_1} & 0 & \cdots & 0 \\ 0 & \sigma_2^2 I_{N_2} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & \sigma_L^2 I_{N_L} \end{bmatrix} \tag{76.22}$$

where L is the number of regimes, N_l , $l = 1 \dots L$ is the number of observations in regime l , and I_{N_l} , $l = 1 \dots L$ is the identity matrix of dimension N_l .

The variance can also be specified as a function of variables:

$$\sigma_i^2 = \sigma^2 f(z_i' \alpha) \tag{76.23}$$

where σ^2 is a scale parameter, f is some functional form, and z_i is a $(P, 1)$ vector of variables and α_i , $i = 1 \dots P$ are unknown parameters to estimate. For instance, in a spatial context, Casetti and Can (1999) suggest the DARP (Drift Analysis of Regression Parameters) model: the variance of the error terms is expanded into a monotonic function of the observations' distance from a reference point in an expansion space:

$$\sigma_i^2 = e^{\gamma_0 + \gamma_1 h_i} \quad (76.24)$$

where h_i is the square of the distance between the i^{th} observation and one reference point (such as the Central Business District in a city).

The variance-covariance matrix can also be left unspecified as in the nonparametric approach. For instance, Kelejian and Prucha (2007) suggest a nonparametric heteroscedasticity- and autocorrelation-consistent (HAC) estimator of the variance-covariance matrix in a spatial context, that is, a SHAC procedure. They assume that the $(N, 1)$ disturbance vectors ε of model Eq. (76.1) are generated as follows: $\varepsilon = R\xi$ where R is a (N, N) non-stochastic matrix whose elements are not known. This disturbance process allows for general patterns of correlation and heteroscedasticity. The asymptotic distribution of the corresponding OLS or instrumental variable (IV) estimators implies the variance-covariance matrix $\psi = N^{-1}Z'\Sigma Z$, where $\Sigma = (\sigma_{ij})$ denotes the variance-covariance matrix of ε . Kelejian and Prucha (2007) show that the SHAC estimator for its $(r, s)^{\text{th}}$ element is

$$\hat{\psi}_{rs} = N^{-1} \sum_{i=1}^N \sum_{j=1}^N x_{ir} x_{js} \hat{\varepsilon}_i \hat{\varepsilon}_j K(d_{ij}/d_n) \quad (76.25)$$

where x_{ir} is the i^{th} element of the r^{th} explanatory variable, $\hat{\varepsilon}_i$ is the i^{th} element of the OLS or IV residual vector, d_{ij} is the distance between unit i and unit j , d_n is the bandwidth, and $K(\cdot)$ is the kernel function with the usual properties.

76.2.8 Parameter Instability

Spatial heterogeneity can also manifest by *parameter instability*, that is, the lack of constancy in some, or all, of the parameters in the regression model. This instability has a spatial dimension: the regression coefficients correspond to a number of distinct spatial regimes. The spatial variability of the coefficients can be discrete, if systematic differences between regimes are observed. In this case, model coefficients are allowed to vary between regimes. It can also be continuous over space.

In the absence of spatial autocorrelation, the case of discrete spatial heterogeneity can be readily treated with standard tools such as dummy variables, ANOVA, or spline functions. Recently, some authors have investigated the possibility of spatial heterogeneity affecting the spatial lag or spatial error coefficients. In this

case, the methodology consists in estimating higher-order models where the spatial matrices pertain to different spatial regimes rather than different order of contiguities.

Heterogeneity can also be continuous. In this case, rather than partitioning the cross-sectional sample into regimes, we assume that parameter heterogeneity is location specific. One possibility is to use *geographically weighted regression*, labeled GWR (Fotheringham et al. 2004), which is a locally linear, nonparametric estimation method. The base model for one location i is

$$y_i = \sum_{k=1}^K \beta_{ki} X_{ki} + \varepsilon_i \quad (76.26)$$

A different set of parameters is estimated for each observation by using the values of the characteristics taken by neighboring observations. With respect to spatial autocorrelation, Pace and LeSage (2004) have pointed out that if spatial autocorrelation only arises due to inadequately modeled spatial heterogeneity, GWR can potentially eliminate the problem. However, this is not necessarily the case when substantive interactions coexist with parameter heterogeneity. Therefore, Pace and LeSage (2004) have generalized GWR to allow simultaneously for spatial parameter heterogeneity and spatial autocorrelation: the *spatial autoregressive local estimation* (SALE):

$$U(i)y = \rho_i U(i)Wy + U(i)X\beta_i + U(i)\varepsilon \quad (76.27)$$

where $U(i)$ represents a (N,N) diagonal matrix containing distance-based weights for observation i that assigns the weights of one to the m nearest neighbors to observation i and weights of zero to all the other observations. The product $U(i)y$ then represents a $(m,1)$ subsample of observations on the explained variables associated with the m observations nearest in location to observation i . The other products are interpreted in a similar fashion. As $m \rightarrow N$, $U(i) \rightarrow I_N$, the local estimates approach the global estimates from the SAR model as the subsample increases.

76.3 Specification Tests in Spatial Cross-Sectional Models

Ignoring spatial effects when it is present have various effects on the estimates' properties. It may lead to biased and inconsistent estimates of the model parameters for an omitted spatial lag or inefficient estimated and biased inference for omitted spatial error autocorrelation and/or omitted heteroscedasticity. Hence, specification testing is therefore relevant in applied work and constitutes the topic of this section.

We first present Moran's I test, where the alternative is an unspecified form of spatial autocorrelation. Second, we detail the most commonly used tests of spatial autocorrelation based on *maximum likelihood*: tests of a single alternative,

conditional tests, and robust tests. Indeed, as featured in ► Chap. 80, “Instrumental Variables/Method of Moments Estimation” and ► Chap. 78, “Maximum Likelihood Estimation”, there might be some complexities involved in the estimation of spatial processes, based on nonlinear optimization (maximum likelihood or generalized methods of moments). Consequently, tests based on the *Lagrange multiplier* (LM) principle (or score test) have been extensively used in specification testing. Contrary to *Wald* (W) or *likelihood ratio* (LR) tests, they only necessitate the estimation of the model under the null hypothesis, typically the simple regression model as in Eq. (76.1). We also briefly present tests based on alternative principles. Third, some strategies aimed at finding the best specification have been devised, when the researcher does not have an a priori of the form taken by spatial autocorrelation. Finally, we outline the complex interactions between spatial autocorrelation and spatial heterogeneity and present how spatial heterogeneity can be tested.

76.3.1 Moran’s I Test

Moran’s I test is a *diffuse test* as the alternative is not a specified form of spatial autocorrelation. It is the two-dimensional analog of the test of temporal correlation in univariate time series for regression residuals (Moran 1950). In matrix notations, it is formally written as

$$I = \frac{N}{S_0} \left(\frac{e'We}{e'e} \right) \quad (76.28)$$

where $e = y - X\tilde{\beta}$ is the vector of OLS regression residuals, W is the spatial weights matrix, and S_0 is a standardization factor equal to the sum of all elements of W . For a row-standardized weights matrix W , this element simplifies to 1. The first two moments under the null were derived by Cliff and Ord (1972):

$$E(I) = \frac{tr(MW)}{N - K} \quad (76.29)$$

$$V(I) = \frac{tr(MWMMW') + tr(MW)^2 + \left\{ tr(MW)^2 \right\}}{(N - K)(N - K + 2)} - [E(I)]^2 \quad (76.30)$$

where M is the usual symmetric and idempotent matrix : $M = I_N - X(X'X)^{-1}X'$. Inference is then based on the standardized value: $Z(I) = [I - E(I)]/V(I)$. For normally distributed residuals, $Z(I)$ asymptotically follows a centered normal distribution. Under the null assumption of spatial independence, Moran’s I test is locally best invariant and is also asymptotically equivalent to a likelihood ratio of $H_0 : \lambda = 0$ in Eq. (76.9) or of $H_0 : \gamma = 0$ in Eq. (76.13); it therefore shares the asymptotic properties of these statistics. Moreover, Moran’s I has power against any alternative of spatial correlation, including a spatial lag alternative.

In the remainder of the section, we consider tests with a specific alternative, that is, focused tests, and concentrate on Lagrange multiplier tests that only require the estimation of the model under the null hypothesis. Some of these tests are *unidirectional* when the alternative deals with one specific misspecification; others are *multidirectional* when the alternative comprises various misspecifications.

76.3.2 Tests of a Single Assumption

76.3.2.1 Spatial Error Autocorrelation

First, consider the case where the error terms follow a spatial autoregressive model Eq. (76.9): $\varepsilon = \lambda W\varepsilon + u$. We test $H_0 : \lambda = 0$. The null corresponds to the linear classical model Eq. (76.1). The multiplier Lagrange statistic can be written the following way (Anselin 1988):

$$LM_{ERR} = \frac{[e'W\varepsilon/(e'e/N)]^2}{T} \quad (76.31)$$

where $T = tr[(W' + W)W]$, tr is the trace operator, and e is the vector of OLS regression residuals. This is equivalent to a scaled Moran coefficient. Since there is only one constraint, under the null, this statistic is asymptotically distributed as a $\chi^2(1)$.

The test statistic is the same if we specify as alternative assumption the moving-average process Eq. (76.13) with the test $H_0 : \gamma = 0$. LM_{ERR} is therefore locally optimal for the two alternatives (autoregressive and moving average). Consequently, when the null is rejected, the test does not provide any indications with respect to the form of the error process.

Pace and LeSage (2008) argue that the test of spatial error autocorrelation can be performed using a Hausman test, since under the null (model 1), there are two consistent estimators differing in efficiency (OLS and ML), and under the alternative (model 2) only one estimator is efficient (ML).

76.3.2.2 Kelejian-Robinson Specification

For the specification of the error suggested by Kelejian and Robinson (1995), a Lagrange multiplier test can also be derived following the same principle. Using notations of model Eq. (76.15), testing the null $H_0 : \varphi = 0$ yields a statistic of the form (Anselin 2001)

$$KR = \left[\frac{e'W'W\varepsilon}{e'e/N} - T_1 \right]^2 / 2 \left[T_2 - \frac{T_1^2}{N} \right] \quad (76.32)$$

where $T_1 = tr(WW^2)$ and $T_2 = tr(WW'WW')$. Under the null, this statistic is asymptotically distributed as a $\chi^2(1)$.

76.3.2.3 Common Factor Test

The *common factor test* allows choosing between a model with spatial error autocorrelation and a spatial Durbin model. The unconstrained spatial Durbin model in Eq. (76.18) and the spatial error model in Eq. (76.9) are equivalent if $H_0 : \lambda\beta + \delta = 0$. This test can be performed with the Lagrange multiplier principle. The corresponding statistic is asymptotically distributed as a $\chi^2(K - 1)$.

76.3.2.4 Test of an Endogenous Spatial Lag

In this case, the null hypothesis is $H_0 : \rho = 0$ in Eq. (76.2). The test statistic is (Anselin 1988)

$$LM_{LAG} = \frac{[e'Wy/(e'e/N)]^2}{D} \quad (76.33)$$

with $D = (WX\tilde{\beta})'M(WX\tilde{\beta})/\tilde{\sigma}^2 + tr(W'W + WW)$ where $\tilde{\beta}$ and $\tilde{\sigma}^2$ are the OLS estimates. This statistic is asymptotically distributed as a $\chi^2(1)$.

76.3.3 Tests in Presence of Spatial Autocorrelation or Spatial Lag

In specification testing, it is useful to know if the model contains both a spatial error autocorrelation and an endogenous spatial lag. In this respect, Anselin et al. (1996) note that LM_{ERR} is the test statistic corresponding to $H_0 : \lambda = 0$ when assuming a correct specification for the rest of the model, that is, $\rho = 0$. However, if $\rho \neq 0$, this test is not valid anymore, even asymptotically as it is not distributed as a centered χ^2 . Hence, valid statistical inference necessitates taking account of a possible endogenous variable when testing spatial error autocorrelation and vice versa.

Facing this problem, three strategies are possible. First, one can perform a *joint test* of the presence of an endogenous spatial lag and a spatial error autocorrelation. However, if the null is rejected, the exact nature of spatial dependence is not known. Second, another solution consists in estimating a model with an endogenous spatial lag and then tests for residual spatial autocorrelation and vice versa. Third, Anselin et al. (1996) suggest *robust tests* based on OLS residuals in the simple model but that are capable of taking account a spatial error autocorrelation when testing endogenous spatial lag and vice versa.

76.3.3.1 Joint Test

The first approach is the test of the joint null hypothesis $H_0 : \lambda = \rho = 0$ in a model containing both a spatial lag and a spatial error:

$$\begin{aligned} y &= \rho W_1 y + X\beta + \varepsilon \\ \varepsilon &= \lambda W_2 \varepsilon + u \end{aligned} \quad (76.34)$$

The Lagrange multiplier test is based on the OLS residuals. The test statistic is (Anselin 1988)

$$SARMA = \frac{[(\tilde{d}_\lambda)^2 D + (\tilde{d}_\rho)^2 T_{22} - 2\tilde{d}_\lambda \tilde{d}_\rho T_{12}]}{DT_{22} - T_{12}^2} \tag{76.35a}$$

or

$$SARMA = \frac{\tilde{d}_\lambda}{T} + \frac{(\tilde{d}_\lambda - \tilde{d}_\rho)^2}{D - T} \text{ if } W_1 = W_2 \tag{76.35b}$$

where $\tilde{d}_\lambda = (e'We)/(e'e/n)$, $\tilde{d}_\rho = (e'Wy)/(e'e/n)$, and $T_{ij} = tr[W_iW_j + W'_jW_j]$. Under the null, *SARMA* is asymptotically distributed as a $\chi^2(2)$. If the null is rejected, the exact nature of spatial dependence is not known. Extensions of these principles to joint tests in *SARMA* (p,q) models are derived in Anselin (2001).

76.3.3.2 Conditional Tests

This approach consists in performing a Lagrange multiplier test for a form of spatial dependence when the other form is not constrained. For instance, we test $H_0 : \lambda = 0$ in presence of ρ . The null corresponds to the spatial lag model, whereas the alternative corresponds to Eq. (76.31). The test is then based on the residuals of model Eq. (76.2) estimated by maximum likelihood. The test statistic is as follows (Anselin 1988):

$$LM_{ERR}^* = \frac{\hat{d}_\rho^2}{T_{22} - (T_{21A})^2 \hat{V}(\hat{\rho})} \tag{76.36}$$

where $T_{21A} = tr[W_2W_1A^{-1} + W'_2W_1A^{-1}]$, $A = I_N - \hat{\rho}W_1$, $\hat{\rho}$ is the maximum likelihood estimator of ρ , and $\hat{V}(\hat{\rho})$ is the estimated variance of $\hat{\rho}$ in model Eq. (76.2). Under the null, this statistic is asymptotically distributed as a $\chi^2(1)$.

Conversely, we can also $H_0 : \rho = 0$ in presence of λ ; the test is then based on the maximum likelihood \hat{e} in the spatial error model Eq. (76.9). The statistic is (Anselin 1988)

$$LM_{LAG}^* = \frac{(\hat{e}B'BW_1y)^2}{H_\rho - H_{\theta\rho} \hat{V}(\hat{\theta}) H'_{\theta\rho}} \tag{76.37}$$

where $\theta = (\beta', \lambda, \sigma^2)$, $\hat{\theta}$ is the maximum likelihood estimator of θ , $B = I_N - \hat{\lambda}W_1$, and $\hat{V}(\hat{\theta})$ is the estimated variance-covariance matrix of $\hat{\theta}$ in model Eq. (76.9). The other terms are

$$H_\rho = tr(W_1^2) + tr(BW_1B^{-1}) + \frac{(BW_1X\hat{\beta})'(BW_1X\hat{\beta})}{\hat{\sigma}^2} \tag{76.38}$$

$$H_{0\rho} = tr \left[\begin{array}{c} \frac{(BX)'BW_1X\hat{\beta}}{\hat{\sigma}^2} \\ tr(W_2B^{-1})BW_1B^{-1} + tr(W_2W_1B^{-1}) \\ 0 \end{array} \right] \quad (76.39)$$

Under the null, this statistic is asymptotically distributed as a $\chi^2(1)$.

76.3.3.3 Robust Tests

The third approach, suggested by Anselin et al. (1996), consists in using robust tests to a local misspecification. For instance, LM_{ERR} is adjusted so that its asymptotic distribution remains a centered $\chi^2(1)$, even in local presence of ρ . This test can be done using the OLS residuals of the simple model Eq. (76.1). Assuming $W_1 = W_2$, the modified statistic for the test $H_0 : \lambda = 0$ is

$$RLM_{ERR} = \frac{(\tilde{d}_\lambda - TD^{-1}\tilde{d}_\rho)^2}{[T(1 - TD)]} \quad (76.40)$$

Similarly, the test statistic of $H_0 : \rho = 0$ in local presence of λ is

$$RLM_{LAG} = \frac{(\tilde{d}_\lambda - \tilde{d}_\rho)^2}{D - T} \quad (76.41)$$

76.3.4 Specification Search Strategies

Tests based on Lagrange multiplier have been very popular in applied spatial econometrics in *specification search*, as they only require the estimation of the model under the null, typically, the simple model estimated by OLS. They can be combined to develop a *specific-to-general* sequential specification search strategy, that is, a forward stepwise specification search, whenever no a priori spatial specification has been chosen.

The first step consists in estimating the simple model Eq. (76.1) by means of OLS and in performing Moran's *I* test and the *SARMA* test. The rejection of the null in both cases indicates omitted spatial autocorrelation but not the form taken by this autocorrelation.

If the null hypothesis is rejected, it may be a sign of model misspecification. For instance, using a Monte Carlo experiment, McMillen (2003) shows that incorrect functional forms or omitted variables that are correlated over space might produce spurious spatial autocorrelation. It may therefore be useful to include in the model, if possible, additional variables. It can be exogenous additional variables that may eliminate or reduce spatial dependence, or exogenous spatial lags, corresponding in total or in part to the initial explanatory variables.

If the addition of exogenous variables has not eliminated spatial autocorrelation, a model incorporating a spatial lag and/or a spatial error must be estimated.

The choice between these two forms of spatial dependence can be done by comparing the significance levels of LM_{ERR} Eq. (76.31) and LM_{LAG} Eq. (76.33) and their robust versions RLM_{ERR} Eq. (76.40) and RLM_{LAG} Eq. (76.41): if LM_{LAG} (resp. LM_{ERR}) is more significant than LM_{ERR} (resp. LM_{LAG}) and RLM_{LAG} (resp. RLM_{ERR}) is significant but not RLM_{ERR} (resp. RLM_{LAG}), a spatial lag (resp. a spatial error) must be included in the regression model (Anselin and Florax 1995).

Once the spatial lag or the spatial error model has been estimated, three additional tests can be implemented. On the one hand, for a spatial lag model, LM_{ERR}^* allows checking whether an additional spatial error is still necessary. On the other hand, for a spatial error model, LM_{LAG}^* allows checking whether an additional spatial lag is still necessary. The common factor test allows checking whether the restriction $H_0 : \lambda\beta + \delta = 0$ is rejected or not. If not, Eq. (76.18) reduces to the spatial error model Eq. (76.9).

There are several drawbacks with this classical specific-to-general approach. First, the significance levels of the sequence of tests are unknown. Second, every test is conditional on arbitrary assumptions that may be tested later. The inference is then invalid if these assumptions are indeed rejected. As a consequence, the results of this approach is subject to the order in which the tests are carried out and whether or not adjustments are made in the significance levels of the sequence of tests.

Alternatively, a *general-to-specific* search strategy, that is, a forward stepwise specification search, can be implemented based on the spatial Durbin model Eq. (76.18) as it encompasses most spatial specifications. Model Eq. (76.18) is estimated, and testing is performed using Wald statistics or likelihood ratio statistics. Then, the failure to reject the common factor constraints suggests a spatial error model, while rejection of these constraints suggests a spatial lag model. In the first case, the significance of the spatial error coefficient is tested; if it is significant, the final specification is the error model Eq. (76.9); if it is not, the final model is the simple model Eq. (76.1). Likewise, in the second case, the significance of the spatial lag coefficient is tested; if it is not significant, the final model selection is the standard regression model. Simulation experiments performed by Florax et al. (2003) compare the specific-to-general and the general-to-specific strategies and provide some evidence of better performances of the forward strategy, in terms of power and accuracy.

76.3.5 Non-nested Tests

The basis of these specification search strategies above is that the competing models are nested within a more general model (spatial Durbin model). However, for non-nested alternatives, other strategies must be devised. For instance, Kelejian and Piras (2011) have extended the J -test procedure to a spatial framework. The null hypothesis corresponds to a spatial error-spatial lag model as in Eq. (76.34) with similar weights, while the alternative hypothesis corresponds to a set of G models that differ with the model in H_0 with respect to the specification of the regressor matrix, the weighting matrix, the disturbance term, or a combination of these three.

76.3.6 Spatial Autocorrelation and Spatial Heterogeneity

Spatial autocorrelation and spatial heterogeneity are often both present in regressions. We have already underlined that heteroscedasticity is implied by the presence of a spatial lag or a spatial error term. More generally, these two effects entertain complex links. First, there may be observational equivalence between these two effects in a cross section (Anselin and Bera 1998). Secondly, heteroscedasticity and structural instability tests are not reliable in the presence of spatial autocorrelation. Conversely, spatial autocorrelation tests are affected by heteroskedasticity. Thirdly, spatial autocorrelation is sometimes the result of unmodeled parameter instability. In other words, if space-varying relationships are modeled within a global regression, the error terms may be spatially autocorrelated. All these elements suggest that both aspects cannot be considered separately. We briefly review here some tests that have tackled this issue.

76.3.6.1 Spatial Autocorrelation and Heteroscedasticity

First, a joint test of spatial error autocorrelation and heteroscedasticity consists in the sum of a Breusch-Pagan test and the LM_{ERR} (Anselin 1988). The resulting statistic is asymptotically distributed as a $\chi^2(P)$, where P is the number of variables that affect the variance (Eq. 76.23). Alternatively, Kelejian and Robinson (1998) derive a joint test for spatial autocorrelation and heteroscedasticity that does not require the normality assumption for the error terms and the regression model to be linear.

Conditional tests may also be performed. On the one hand, a Lagrange multiplier test of spatial autocorrelation in a regression with heteroscedastic error terms may be derived. Let $\hat{\Omega}$ be the estimated diagonal variance-covariance matrix, then the heteroscedastic LM statistics becomes (Anselin 1988):

$$LM = \frac{(e' \hat{\Omega}^{-1} W e)^2}{tr(WW + W' \hat{\Omega}^{-1} W \hat{\Omega})'} \quad (76.42)$$

where e is the vector of residuals in the heteroscedastic regression. This statistic is asymptotically distributed as a $\chi^2(1)$.

On the other hand, a test of heteroscedasticity in a spatial lag model or a spatial error model can be performed. In the first case, a Breusch-Pagan statistic is computed on the ML residuals, while in the second case, it is performed on spatially filtered residuals in the ML estimation.

76.3.6.2 Spatial Autocorrelation and Parameter Instability

In the case of discrete parameter heterogeneity under the form of spatial regimes in a homoscedastic model, a test of equality of some or all parameters between regimes can be performed using a standard Chow test. However, when error spatial

autocorrelation and/or heteroscedastic is present, this must be adjusted. Formally, without loss of generality, consider a model with two regimes:

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} X_1 & 0 \\ 0 & X_2 \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \end{bmatrix} + \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \end{bmatrix} \tag{76.43}$$

Let $\varepsilon = [\varepsilon'_1 \ \varepsilon'_2]$ and the variance-covariance matrix: $\Psi = E(\varepsilon\varepsilon')$. The test of parameter stability is $H_0 : \beta_1 = \beta_2$.

When $\Psi = \sigma^2\Omega$, then the test statistic is (Anselin 1988)

$$C_G = \frac{\hat{e}'_c \hat{\Omega}^{-1} \hat{e}_c - \hat{e}'_L \hat{\Omega}^{-1} \hat{e}_L}{\hat{\sigma}^2} \tag{76.44}$$

where \hat{e}_c is the vector of estimated residuals of the constrained model and \hat{e}_L the vector of estimated residuals of the unconstrained residuals. This statistic is asymptotically distributed as a $\chi^2(K)$, where K is the number of explanatory variables in the model.

Whenever the break affects the spatial coefficient, Mur et al. (2010) suggest LM tests. For instance, assume a spatial lag model where a simple break (such a center vs. periphery) only affects the parameter of spatial dependence:

$$\begin{aligned} y &= \rho_0 W y + \rho_1 W^* y + X\beta + \varepsilon \\ \varepsilon &\rightarrow iid(0, \sigma^2 I_N) \end{aligned} \tag{76.45}$$

where ρ_0 is the spatial lag coefficient pertaining to the second regime, ρ_1 represents the difference between the first regime and the second regime, and W^* is a weights matrix defined as $w^*_{ij} = w_{ij}$ if location i or location j belongs to the first regime and $w^*_{ij} = 0$ otherwise. Then the LM statistic for the test $H_0 : \rho_1 = 0$ is

$$LM_{LAG}^{BREAK} = \frac{\left[\frac{y' W^* \tilde{\varepsilon}}{\hat{\sigma}^2} - tr \tilde{A}^{-1} W^* \right]^2}{\hat{\sigma}^2} \tag{76.46}$$

where $\tilde{\varepsilon}$ is the vector of residuals of the ML estimation of Eq. (76.2), $\tilde{\sigma}^2$ is the corresponding estimated variance, $\tilde{A} = I_N - \tilde{\rho}W$ where $\tilde{\rho}$ is the ML estimation in Eq. (76.2), and $\hat{\sigma}^2$ is the ML estimated variance corresponding to the linear restriction of the null. This statistic is asymptotically distributed as a $\chi^2(1)$.

A spatial error model with a structural break affecting the spatial error parameter is

$$\begin{aligned} y &= X\beta + \varepsilon \\ \varepsilon &= \lambda_0 W \varepsilon + \lambda_1 W^* \varepsilon + u \\ u &\rightarrow iid(0, \sigma^2 I_N) \end{aligned} \tag{76.47}$$

The LM statistic for the test $H_0 : \lambda_1 = 0$ is as follows:

$$LM_{LAG}^{BREAK} = \frac{\left[\frac{\tilde{\varepsilon}' W^* \tilde{B} \tilde{\varepsilon}}{\hat{\sigma}^2} - tr \tilde{B}^{-1} W^* \right]^2}{\hat{\sigma}^2} \quad (76.48)$$

where $\tilde{\varepsilon}$ is the vector of residuals of the ML estimation of Eq. (76.9), $\hat{\sigma}^2$ is the corresponding estimated variance, $\tilde{B} = I_N - \tilde{\lambda} W$ where $\tilde{\lambda}$ is the ML estimation in Eq. (76.9), $\hat{\sigma}^2$ is the ML estimated variance corresponding to the linear restriction of the null. This statistic is asymptotically distributed as a $\chi^2(1)$.

76.4 Conclusion

The objective of this chapter was to provide a concise review of specification issues in spatial econometrics. We focused on the way spatial effects may be incorporated into regression models and on specification testing. We first presented the most commonly used spatial specifications in a cross-sectional setting in the form of linear regression models including a spatial lag and/or a spatial error term, heteroscedasticity, or parameter instability. Second, we presented a set of specification tests that allow checking deviations from a standard, that is, nonspatial, regression model. An important space has been devoted to LM tests as they only require the estimation of the model under the null. Unidirectional, multidirectional, and robust LM tests are now in the standard toolbox of spatial econometrics. They are still frequently used in applied work, even though the technical/numerical difficulties associated to the estimation of spatial models have become much more tractable, even for very large samples. Because of the complex links between spatial autocorrelation and spatial heterogeneity, we have given some attention to the specifications incorporating both aspects and to the associated specification tests.

Abstract

Past applications of spatial regression models have frequently interpreted the parameter estimates of models that include spatial lags of the dependent variable incorrectly. A discussion of issues surrounding proper interpretation of the estimates from a variety of spatial regression models is undertaken. We rely on scalar summary measures proposed by LeSage and Pace (Introduction to

spatial econometrics. Taylor Francis/CRC Press, Boca Raton, 2009) who motivate that these reflect a proper interpretation of the *marginal effects* for the nonlinear models involving spatial lags of the dependent variable. These nonlinear spatial models are contrasted with linear spatial models, where interpretation is more straightforward. One of the major advantages of spatial regression models is their ability to quantify spatial spillovers. These can be defined as situations where nonzero cross-partial derivatives exist that reflect impacts on outcomes in region i arising from changes in characteristics of region j . Of course, these cross-partial derivatives can be interpreted as impacts of changes in an own region characteristic on other regions or changes in another regions' characteristic on the own region. The ability to produce empirical estimates along with measures of dispersion that can be used for inference regarding the statistical significance, magnitude, and spatial extent of spillovers provides a major motivation for using spatial regression models.

77.1 Introduction

Spatial spillovers reflect a major theme in regional science. A loose definition of spillovers in a spatial context would be that changes occurring in one region exert impacts on other regions. For example, changes in tax rates by one jurisdiction might exert an impact on tax rate setting decisions of nearby regions, a phenomenon that has been labeled tax mimicking and yardstick competition between local governments (Allers and Elhorst 2005; Deskins and Hill 2010). Other examples include situations where home improvements made by one homeowner exert a beneficial impact on the selling prices of neighboring homes, innovation by university researchers diffuses to nearby firms, air or water pollution generated in one region spills over to nearby regions, etc. We will provide a more formal definition of spatial spillovers in this chapter.

It would be of interest to be able to test for the presence of statistically significant spatial spillovers and to quantify the magnitude and spatial extent of these if they exist. For example, in the context of tax mimicking, a test for the statistical significance of spillovers where changes in tax rates in region i exert a statistically significant effect on future tax rate changes in other regions' $j \neq i$ would provide evidence regarding the presence or absence of tax mimicking. Knowing the sign and magnitudes of spillovers would aid in discerning the nature of the mimicking behavior. An empirical estimate of the spatial extent of the spillovers would also be useful for studying this type of phenomena. For example, how many neighboring regions (on average over the sample of regions observed) are impacted as a result of a change in tax rates by the typical region i ? Spatial regression models provide one way to obtain answers to questions of this type.

We draw a distinction between *global and local spillovers*, an idea discussed in Anselin (2003). Assuming that possible connections exist among regions, global spillovers arise when changes in a characteristic of one region impact all regions' outcomes. This applies even to the region itself since impacts can pass to the

neighbors and back to the own region (feedback). Specifically, global spillovers impact the neighbors, neighbors to the neighbors, neighbors to the neighbors to the neighbors, and so on. Local spillovers represent a situation where the impacts fall only on nearby or immediate neighbors, dying out before they impact regions that are neighbors to the neighbors. Therefore, the *feedback effects* that arise in the case of global spillovers do not accompany local spillovers.

Feedback effects arise when changes to own region/entity characteristics exert an impact on outcomes in the own and neighboring regions/entities, which produce additional changes or feedback effects on outcomes in the own region. As an example, when a homeowner *A* improves the value of their property, this exerts a beneficial impact on the selling price of home *A* plus that of neighboring homes, say *B*. However, an increase in the selling price of neighboring homes *B* will produce a beneficial feedback effect on the selling price of home *A*. These feedback effects have sometimes been labeled *self-reinforcing effects* or virtuous cycles, with regional economic growth often being characterized as this type of phenomena. Growth can start with an exogenous technological innovation that leads to learning curve effects and economies of scale. This in turn leads to reduced costs and improved production efficiencies which result in lower average market prices. As prices decrease, consumption and aggregate output increase, and with increased levels of output, there are more learning and scale effects that start a new cycle. The feedback effects of global spillovers and the absence of these for local spillovers make it useful to draw a distinction between alternative approaches that can be used to model these two phenomena.

77.2 Spatial Regression Models

We discuss interpretation of the *marginal effects estimates* and how they relate to spatial spillovers for a host of spatial regression models in this section of this chapter. Applied studies in the literature that use the various models for the purpose of drawing inferences about local and global spillovers are discussed in the next section of the chapter.

77.2.1 Spatial Error Models

The *spatial error model* (SEM) (Ord 1975; Anselin 1988) and *spatial moving average* (SMA) (Haining 1990; Fingleton 2001) error models are shown in Eqs. (77.1) and (77.2), where we introduce these models as a contrast to other models that will be discussed. These models do not allow for spatial spillovers arising from changes in characteristics of one region on outcomes observed in other regions. We are relying on a definition of spillovers introduced by LeSage and Pace (2009) who define spatial spillovers as nonzero cross-partial derivatives $\partial y_j / \partial x_i$. This means that changes to explanatory variables in region *i* impact the dependent variable values in region $j \neq i$:

$$y = X\beta + u, \quad u = (I_n - \rho W)^{-1}\varepsilon \quad (77.1)$$

$$y = X\beta + u, \quad u = (I_n + \theta W)\varepsilon \quad (77.2)$$

In these equations, the $n \times 1$ vector y represents a cross-sectional dependent variable that exhibits variation across spatial observational units, and the $n \times k$ matrix X represents explanatory variables that usually include a vector of ones. The scalar parameters ρ and θ measure the strength of spatial dependence with boundaries on the permissible (stationary) parameter space determined by minimum and maximum eigenvalues of the $n \times n$ matrix W (see LeGallo, ► Chap. 76, “Cross-Section Spatial Regression Models,” for details concerning the permissible parameter space). For simplicity, we assume that W has all real eigenvalues and that the principal eigenvalue equals 1. The matrix W provides a (normalized) structure of connectivity between the observations, and in spatial regression models, *each observation is a region*. In a spatial context, connectivity might be defined as *neighboring regions* using nonzero elements in the i, j th position of the matrix W to denote that region j is a neighbor to region i . The matrix W has row sums of one and a main diagonal with zeros (so regions cannot be neighbors to themselves). The $n \times 1$ vector ε is a disturbance term usually assumed to be normally distributed with zero mean, constant variance σ^2 , and zero covariance across observations.

The parameters of the models are β, ρ, θ , and σ^2 which can be estimated using maximum likelihood, Bayesian, or instrumental variable methods (see ► Chap. 78, “Maximum Likelihood Estimation,” Mills and Parent ► Chap. 79, “Bayesian MCMC Estimation” and Prucha and Jennish ► Chap. 80, “Instrumental Variables/Method of Moments Estimation” for details concerning estimation).

For both the SEM and SMA models, the cross-partial derivatives in Eq. (77.4) (spillovers) are zero by design, as in the case of nonspatial regression models. The SEM model estimate $\hat{\beta}_r$ for the r th variable in the explanatory variables matrix X (and associated measure of dispersion) forms the basis for inference regarding how changes this explanatory variable in region i will impact the i th region values of the dependent variable, and this scalar estimate averages over all $i = 1, \dots, n$ observations. As noted, for nonlinear models, we need to rely on marginal effects when interpreting parameter estimates, rather than the coefficient estimates associated with parameters β of the model. In the case of the SEM model, the parameter estimate equals the average marginal effect of the own variable (which LeSage and Pace (2009) label the average direct effect) on the dependent variable y . Further, the average marginal effect of the spillovers (which LeSage and Pace (2009) label the average indirect effect) is 0, as shown in Eq. (77.4):

$$\partial y_i / \partial x_i^r = \beta_r \quad (77.3)$$

$$\partial y_j / \partial x_i^r = 0 \quad (77.4)$$

These models do allow for diffusion of shocks or disturbances across observations/regions. This can be seen by considering the matrix inverse expression for the SEM disturbances, which can be expressed using an infinite series expansion: $(I_n - \rho W)^{-1} = (I_n + \rho W + \rho^2 W^2 + \rho^3 W^3 + \dots)\varepsilon$. The matrix inverse $(I_n - \rho W)^{-1}$ exists under the typical assumptions made regarding the scalar parameter ρ that measures the strength of spatial dependence in the dependent variable and the spatial weight matrices W employed in these models (see ► Chap. 76, “Cross-Section Spatial Regression Models”).

If we consider a scalar shock δ to a single region i , reflected by $\varepsilon_i + \delta$, which results in a new vector $\tilde{\varepsilon}$, then we have $(I_n + \rho W + \rho^2 W^2 + \rho^3 W^3 + \dots)\tilde{\varepsilon}$ as the new disturbance vector. The first term $I_n \tilde{\varepsilon}$ will exert an impact on the disturbance for region i , whereas the second term $\rho W \tilde{\varepsilon}$ will impact disturbances of regions that neighbor observation i . This is because the matrix–vector product $W \tilde{\varepsilon}$ produces a resulting vector that reflects a linear combination of shocks from observations neighboring each observation. The change in disturbance $\varepsilon_i + \delta$ of observation i will be included in the linear combination of shocks from observations that neighbor i . Powers of the matrix W when used to form matrix–vector products such as $W^2 \tilde{\varepsilon}$ will form linear combinations based on neighbors to the neighbors of each observation, so the shock to observation i will exert an impact on *second-order* neighboring observations to i . Second-order neighbors are neighbors to the neighbors. A similar statement applies to higher-order powers $W^3 \tilde{\varepsilon}$, $W^4 \tilde{\varepsilon}$, and so on; these form linear combinations involving neighbors to the neighbors, neighbors to the neighbors to the neighbors, etc. The implication is that the SEM model allows for diffusion of shocks that arise for a single observation to other observations, with a decay of influence for higher-order neighbors. The decrease in magnitude of impact for higher-order neighbors is a consequence of the fact that $\rho < 1$ and the principal eigenvalue of the row-normalized matrix W is one. The SEM model allows for *global diffusion* of shocks to other observations. We note also that feedback effects arise here, consistent with the distinction made earlier about global versus local phenomena. This can be seen by recognizing that the matrix W contains zeros on the main diagonal, but the matrix W^2 does not. Since W^2 contains nonzero elements in positions reflecting neighbors to neighbors of each observation, and each observation is a neighbor to its neighbor, there are nonzero elements on the diagonal. These nonzero diagonal elements capture the feedback effect of the diffusion arising from a shock to region i . Of course, similar statements apply to higher powers of the matrix W .

The SMA model allows for *local diffusion* of a shock to the disturbance of region i . Using our vector $\tilde{\varepsilon}$, we have $(I_n + \theta W)\tilde{\varepsilon} = \tilde{\varepsilon} + \theta W \tilde{\varepsilon}$, where the scalar parameter θ determines the magnitude of this impact. This means that a shock to the disturbance of region/observation i will have a direct impact arising from $\tilde{\varepsilon}$ and indirect impact only on neighboring observations $\theta W \tilde{\varepsilon}$. Feedback effects are ruled out since the matrix W contains zeros on the diagonal. Diffusion to higher-order neighbors is also ruled out by the lack of terms involving higher powers of the matrix W .

77.2.2 Spatial Lag of X Models

Two other spatial regression models that LeSage and Pace (2009) label a spatial lag of X (SLX) and spatial Durbin error model (SDEM) models are shown in Eqs. (77.5) and (77.6):

$$y = \alpha I_n + X\beta + WX\theta + \varepsilon \quad (77.5)$$

$$y = \alpha I_n + X\beta + WX\theta + u, \quad u = (I_n - \rho W)^{-1} \varepsilon \quad (77.6)$$

These models allows for *local spatial spillovers* which can be directly calculated using the coefficients θ . This can be seen by considering the matrix expression for the partial derivative of y with respect to changes in the r th explanatory variable shown in Eq. (77.7):

$$\partial y / \partial x^{r'} = (I_n \beta_r + W \theta_r) \quad (77.7)$$

An implication of this model is that changes in the characteristics of the r th variable for a single observation i can potentially impact all observations in the vector y . Since we could consider changes in each observation $i = 1, \dots, n$, we have an $n \times n$ matrix of responses in y . This observation was made by Kim et al. (2003) as well as Kelejian et al. (2006). LeSage and Pace (2009) made the point that an $n \times n$ matrix of partial derivative responses poses a real problem for reporting estimates of the marginal impacts from these models. Consider that an application involving the 3,109 counties in the lower 48 US states would produce a $3,109 \times 3,109$ matrix of responses for each of the r explanatory variables (although many of these responses would equal 0 if W is sparse). A further issue it that we would like to have measures of dispersion for our marginal effects estimates that would allow us to draw inferences regarding the statistical significance of these.

A solution to these two issues was proposed by LeSage and Pace (2009), who suggested using the average of the main diagonal elements of the $n \times n$ matrix $(I_n \beta_r + W \theta_r)$ in Eq. (77.7) to produce a scalar summary measure of the direct effects. In addition, they proposed using an average of the (cumulated) off-diagonal elements as a scalar summary of the cumulative indirect effects. LeSage and Pace (2009) also provide an approach to calculating measures of dispersion for these scalar summary estimates, specifically standard deviations that can be used to construct t -statistics. This allows for standard regression-based interpretation of the marginal effects estimates from spatial regression models.

For the case of the SLX and SDEM models, these calculations simplify considerably. Since the main diagonal of the matrix W contains zeros, and the rows of the matrix W sum to one, this leads to the simple conclusion that the coefficient β_r reflects direct effects while θ_r captures spatial spillovers. The t -statistics reported by standard regression software algorithms should also provide a valid basis for

inference regarding the statistical significance of these effects estimates. The SDEM model allows for these same local spillovers with regard to the explanatory variables but also models global spatial diffusion of shocks that arise in the disturbance structure of the model, using the spatial autoregressive process $u = \rho Wu + \varepsilon$. To produce valid t -statistics, software algorithms for estimating spatial autoregressive error models would be required. Of course, one could also produce a model that relies on the spatial moving average process for the disturbances if there was interest in modeling local spatial diffusion of shocks that arise in the disturbances.

For the SDEM and SLX models, the coefficients in the vector θ represent local spillovers, since there is an impact only on immediately neighboring observations. We note that estimates from these two models should be similar, but in the face of spatial dependence in the disturbances, SDEM model estimates should be more efficient. The partial derivative expressions for both models are the same, but improved efficiency for the case of the SDEM model could impact inferences regarding significance of the direct and indirect effects estimates. Pace and LeSage (2008) provide a *Hausman test* that could be used to test for equality of the SLX and SDEM model coefficients. An absence of equality for these two sets of coefficients may provide evidence against the SDEM model in favor of a spatial lag variant such as the SAR or SDM models (see LeSage and Pace (2009)).

In these cases, interpretation of the coefficient estimates for β as a slope indicating how changes in X produce changes in y (on average over the sample) are valid, as in linear regression. Interpretation of the coefficient θ as reflecting how changes in the average neighboring characteristics impact y is also valid. Returning to our example where y reflects property values and X characteristics, the coefficient θ measures how changes in neighboring properties' characteristics impact the value of a typical property (on average over the sample). It is important to note that in this case there are no feedback effects like those described for the case of the SAR and SDM models. It is also true that the impacts arising from changes in properties' characteristics are restricted to fall only on neighboring properties, which is consistent with our definition of local spillovers.

77.2.3 Spatial Lag of y Models

The SAR and SDM models are shown in Eqs. (77.8) and (77.9), where y is an $n \times 1$ vector of outcomes and X is an $n \times k$ matrix of explanatory variables (excluding the constant term) with associated $k \times 1$ parameter vector β . The $n \times k$ matrix WX has been labeled a *spatial lag* of the explanatory variables and represents a linear combination of characteristics from neighboring regions/entities, with associated parameters γ . Similarly, the $n \times 1$ vector Wy is a spatial lag of the dependent variable, reflecting a linear combination of neighboring region values for the dependent variable. The intercept coefficient is α and $\mathbf{1}_n$ is an $n \times 1$ vector of ones. It is typically assumed that ε is normally distributed and obeys the Gauss-Markov assumptions:

$$y = \alpha I_n + \rho W y + X \beta + \varepsilon \quad (77.8)$$

$$y = \alpha I_n + \rho W y + X \beta + W X \gamma + \varepsilon \quad (77.9)$$

An examination of the data generating process for these models shown in Eqs. (77.10) and (77.11) makes it clear that they reflect a nonlinear relationship between y and the right-hand side terms I_n, X and ε :

$$y = (I_n - \rho W)^{-1}(\alpha I_n + X \beta + \varepsilon) \quad (77.10)$$

$$y = (I_n - \rho W)^{-1}(\alpha I_n + X \beta + W X \gamma + \varepsilon) \quad (77.11)$$

As already noted, the inverse $(I_n - \rho W)^{-1}$ can be expressed as an infinite sequence: $I_n + \rho W + \rho^2 W^2 + \rho^3 W^3 + \dots$, and the matrix product $W X$ reflects a linear combination of the explanatory variables from neighboring regions. The matrix product $W^2 X$ creates a linear combination involving neighbors to the neighboring regions, or what are sometimes called second-order neighbors. As noted, diagonal elements of W^2 are not zero, since regions will by definition be neighbors to their neighbors. This means that feedback effects are present in models involving higher-order neighbors. As a concrete example, consider a homeowner A improving her property (the matrix X might contain property characteristics and the vector y property values), which has a beneficial spillover effect on the value of a neighboring property B (as well as on property A of course). However, in the SAR and SDM models, a change in the value of neighboring property B will feedback on the value of property A since the vector $W y$ included in the model would contain the increased property value of the neighbor. A similar statement regarding nonzero diagonal elements applies to higher-order matrix products such as $W^3 X$ which reflects a linear combination of neighbors to the neighbors, to the neighbors, and so on for higher powers. This is consistent with our definition of global spillovers. From the model statements in Eqs. (77.8) and (77.9), we can see the source of feedback works through impacts on the price of neighboring properties.

One implication of the nonlinear relationship in the SAR and SDM models between y and X is that the coefficients α, β , and γ cannot be interpreted as if they reflect linear regression slope estimates. This type of situation arises in a number of other nonlinear regression models such as probit and Tobit. The econometrics literature interprets coefficients from these models using marginal effects that reflect partial derivatives indicating how changes in each explanatory variable impact (or effect) the expected y outcomes. It should be clear that we need to take a similar approach for our nonlinear relationships between y and X in the SAR and SDM models.

That approach is based on the $n \times n$ matrices of partial derivatives for these models, shown in Eq. (77.12) for the SAR and Eq. (77.13) for the SDM:

$$\partial y / \partial x^r = (I_n - \rho W)^{-1} I_n \beta_r \quad (77.12)$$

$$\partial y / \partial x^r = (I_n - \rho W)^{-1} (I_n \beta_r + W \gamma) \quad (77.13)$$

As in the case of the SLX and SDEM models, there is a need to produce scalar summary measures of the $n \times n$ matrices of partial derivatives. We can do this following the suggestion of LeSage and Pace (2009), using the mean of the main diagonal elements of the $n \times n$ matrices in Eqs. (77.12) and (77.13) to produce a scalar summary of the *direct effects*. These show how changes in the r th explanatory variable for the i th region impact the i th region's dependent variable, for $i = 1, \dots, n$. Using the mean of these n , different values produces a scalar summary that can be interpreted as representing how a change in the r th explanatory variable in the typical or representative region impacts outcomes y for the typical region.

For the case of linear regression relationships where $\rho = 0$ so observations are assumed to be independent, the partial derivatives $\partial y_i / \partial x_i^r = \beta_r, i = 1, \dots, n$. This means there is no need to produce a scalar summary estimate based on the mean of these n different partial derivatives in linear regression models.

Indirect effects representing the impact on the j th region outcomes y_j from a change in the r th explanatory variable from the i th region are captured by the off-diagonal elements of the $n \times n$ matrices in Eqs. (77.12) and (77.13). Specifically, the elements in the i th row show $\partial y_j / \partial x_i^r, j \neq i, j = 1, \dots, n$, reflecting how changes in each of the $j \neq i, j = 1, \dots, n$ or other regions' r th explanatory variable impact outcomes in the i th region. Since these are partial derivatives, the off-diagonal elements in the i th column represent $\partial y_j / \partial x_i^r, j \neq i, j = 1, \dots, n$ or how changes in the r th variable in region i impact outcomes across all regions $j \neq i$. LeSage and Pace (2009) suggest using the mean of the sum of off-diagonal elements from each row to produce a scalar summary measure of *cumulative indirect effects* or spatial spillovers. They note that the numerical magnitude of these equals the mean of the off-diagonal elements from each column, which would produce the same scalar summary measure of cumulative indirect effects.

In the case of linear regression relationships where $\rho = 0$ and observations are independent, the partial derivatives $\partial y_i / \partial x_i^r = 0$, so there are no spatial spillovers or indirect effects.

Elhorst (2010) notes that for the SAR model all coefficients $\beta^r, r = 1, \dots, k$ are multiplied by the same matrix $(I_n - \rho W)^{-1}$ (see Eq. (77.12)), so this model implies that the ratio between the indirect and direct effects is the same for every explanatory variable. The magnitude determining this ratio will depend only on the spatial dependence parameter ρ and the spatial weight matrix W . Another implication of the relationship between direct and indirect effects for the SAR model is that the sign of spillovers (indirect effects) and direct effects must be the same for the r th variable and will be determined by the sign of the coefficient estimate β_r . Of course, the signs can vary across the different explanatory variables in the model.

The relationship between direct and indirect effects in the SDM (and SLX and SDEM) models is not subject to these constraints. For these models, we can have positive (or negative) direct effects associated with negative (or positive)

indirect effects for the r th variable, so that spillover impacts might work in the opposite direction of direct impacts arising from changes in each explanatory variable.

To illustrate these issues, consider a cross-sectional model of state-level cigarette sales (an $n \times 1$ vector y) as a function of two explanatory variables, state-level cigarette taxes and income and a constant (an $n \times 3$ matrix X). In the SDM, SLX, or SDEM models, an increase in state i 's tax on cigarettes may generate a direct effect that decreases sales of cigarettes in state i (the dependent variable y_i) (on average across all states) but increases cigarette sales in neighboring states (y_j , a positive cumulative indirect effect averaged over all states), due to the presence of cross-border shopping for cigarettes in lower-tax neighboring states. This would not be possible in the SAR model, where the direct and indirect effects must have the same sign. For the SAR model, it would also be the case that the relative size of the direct and indirect effects for a change in tax rates (one explanatory variable in the model) must be the same as the relative size of the direct and indirect effects arising from a change in state income (another explanatory variable in the model). Practitioners should be aware of these facets of the SAR, SDM, SLX, and SDEM models to make an appropriate choice of model specification for the particular situation being modeled.

77.2.4 Measures of Dispersion for the Effects Estimates

In addition to calculating point estimates for the direct, indirect, and total effects associated with changing explanatory variables in the various types of spatial regression models, we require measures of dispersion for inference. Given an estimate of the variance (standard deviation) for the scalar summary point estimates, we can test hypotheses regarding the significance of the various types of effects for each of the explanatory variables used in the model.

In the case of SEM, SLX, and SDEM models, traditional standard deviations and asymptotic t -statistics based on maximum likelihood (or Bayesian) estimation would provide a valid basis for inference regarding the effects estimates. Of course for the SEM, there are only direct effects, since this model assumes indirect (spillover) effects are zero. For the SLX model, use of the t -statistic for the spatially lagged explanatory variables based on standard least-squares estimates would provide a valid basis for inference regarding significance of the direct and indirect or spillover effects for each variable. Coefficients associated with the explanatory variables X represent direct effects while those associated with WX are the indirect effects. If one were interested in significance of the total effect, this would require calculating a t -statistic for a distribution reflecting the sum of the coefficients on both X and WX , and this is typically not a part of standard regression software.

In the case of the SDEM model, asymptotic t -statistics from maximum likelihood, Bayesian, or instrumental variables estimation on the variables X and WX would provide a valid basis for inference regarding direct and indirect effects respectively. As noted for the case of the SLX model, measures of dispersion for

the total effects would require consideration of dispersion for a distribution based on the sum of the direct plus indirect effects.

Inference for the SAR and SDM models regarding the direct, indirect, and total effects is more involved. The point estimates for β do not directly measure the partial derivative effects, so reported t -statistics cannot be used as a basis for inference.

For maximum likelihood SAR and SDM estimates, measures of dispersion can be constructed by simulating values for the parameters from the estimated variance-covariance matrix. (See Pace ► [Chap. 78, “Maximum Likelihood Estimation”](#) for a discussion of the form taken by the variance-covariance matrix.) These simulated values (say 1,000 values) for the model parameters ρ, β can be used in Eqs. (77.12) or (77.13) for the SAR or SDM models to produce 1,000 values for the scalar summary effects estimates. Taking the median of these simulated summary measures would provide a point estimate for the summary measures. We take the median in this situation since the summary measures are not symmetrically distributed. For example, the total effect for the SAR model equals $\tilde{\beta}_r (1 - \tilde{\rho})^{-1}$. Even if $\tilde{\beta}$ and $\tilde{\rho}$ follow normal distributions, the total impact statistic will not follow a normal distribution and the median can provide a better measure of the central tendency in this situation. Similarly, one can use other measures of dispersion such as the scaled median absolute deviation (1.48 MAD) to provide a measure of dispersion of the median. Use of the median and the scaled MAD allows inference on the direct, indirect, and total impacts. LeSage and Pace (2009) provide a computationally efficient approach to processing the draws for the parameters to produce empirical distributions for the direct, indirect, and total effects estimates. This computationally efficient approach has been implemented in the Spatial Econometrics Toolbox for MATLAB (LeSage 1999), the R-language routines (Bivand and Albrecht 2000), and the Stata package for spatial regression (Drukker et al. 2001).

For SAR and SDM models estimated using Bayesian Markov chain Monte Carlo as described in ► [Chap. 79, “Bayesian MCMC Estimation,”](#) the draws used to produce point estimates can be used in place of parameter draws made based on the maximum likelihood estimate of the variance-covariance matrix. These draws can be used in conjunction with the computationally efficient formulas from LeSage and Pace (2009).

SAR and SDM models estimated using instrumental variable methods can produce draws using an asymptotic approximation to the variance-covariance matrix. (See Prucha and Jennish ► [Chap. 80, “Instrumental Variables/Method of Moments Estimation”](#) for details concerning this type of estimation and the variance-covariance matrix.) These draws can be used in conjunction with the computationally efficient formulas from LeSage and Pace (2009).

77.2.5 Partitioning Global Effects Estimates Over Space

For effects estimates involving local spillovers, these fall only on immediately neighboring regions and do not generate feedback effects. In contrast, we have used

global spillovers to reflect situations where there are feedback effects and spillovers fall on neighbors to neighbors, neighbors to neighbors to neighbors, and so on for higher-order neighbors.

For cases involving global spillovers, we might be interested in the pattern of decay of influence in the direct and indirect effects as we consider impacts on first-, second-, third-, and higher-order neighbors.

If we consider the matrix inverse in Eqs. (77.12) and (77.13), $(I_n - \rho W)^{-1}$ can be expressed as an infinite series: $I_n + \rho W + \rho^2 W^2 + \rho^3 W^3 + \dots$; it should be clear that we can partition the effects estimates by order of the matrix W . For example, expressions for the impacts on second-order neighbors (those involving W^2) based on the $n \times n$ matrix of partial derivatives are shown in Eqs. (77.14) and (77.15) for the SAR and SDM models:

$$\partial y / \partial x^{r'} = \rho^2 W^2 \beta_r \quad (77.14)$$

$$\partial y / \partial x^{r'} = \rho^2 W^2 (I_n \beta_r + W \gamma) \quad (77.15)$$

Scalar summaries can be constructed for these two $n \times n$ matrices using diagonal and off-diagonal elements as described in Sect. 77.2.3. Indirect effects (scalar summaries) constructed from the off-diagonal elements of these matrices would show the (average) spillover impacts falling only on second-order neighbors. Direct effects (scalar summaries) based on the main diagonal elements of these matrices would be feedback effects on the own region arising from second-order neighbors.

77.3 Applications of Spatial Regression Models

Applications of the various spatial regression models that have appeared in the literature illustrating correct interpretation are presented in this section.

77.3.1 Spatial Error Models

Bell and Bockstael (2000) use a spatial error model in an application involving land parcels. The hedonic model uses a sample of 1,000 residential sales transactions involving the assessed value of improved land parcels on which homes were built in the previous year. The goal is to examine which property and environmental/locational characteristics influence the new home sales prices. Explanatory variables include things like the (log) of assessed value of improvement in the land parcel, size of the parcel, travel distance to the two nearest major metropolitan areas, planned infrastructure characteristics such as sewers, public and private open space surrounding the homes, and measures of density and land use types for surrounding areas.

Estimates for the various parcel characteristics from the SEM can be interpreted as the (average) direct impact on the selling price arising from changes in the

various characteristics, just as in ordinary least squares. This simplicity arises from the implicit assumption of no spillovers, only contagion arising from shocks to the disturbances.

Bell and Bockstael (2000) rely on three different (row-normalized) contiguity-based weight matrices that assign values of 0 or 1 to neighboring observations that are within 200, 400, and 600 m distances of each observation. Estimation results from models using these three matrices are compared to a fourth (row-normalized) matrix where inverse distance-based weights were assigned to each neighboring observation within 600 m. They rely on a spatial error model (SEM) shown in Eq. (77.16) and compare estimates from least squares, maximum likelihood, and generalized moments, with the latter two sets of estimates constructed using the four different types of spatial weight matrices:

$$y = X\beta + u \quad (77.16)$$

$$u = \rho Wu + \varepsilon \quad (77.17)$$

An implicit assumption of the SEM model is that there are no omitted variables that are correlated with included explanatory variables. The presence of omitted variables leads to an SDM specification (LeSage and Pace 2009, pp. 27–28). A simple test for the appropriateness of the SEM would be to compare least-squares (OLS) estimates for the coefficients β to those from the SEM since we know these should theoretically be the same. This should be true irrespective of the spatial weight matrix used, since changes in the spatial weight specification could lead to changes in measures of dispersion (e.g., t -statistics), but not significant differences in the coefficients β . Any (significant) differences between estimates from these two models should reside in the measures of dispersion which would have an impact on the t -statistics, but not the point estimates for β .

Pace and LeSage (2008) use this idea to develop a formal Hausman specification test for significant differences between OLS and SEM estimates for β . Intuitively, significant differences in OLS and SEM estimates for β point to model misspecification that should lead us to reject the SEM model as an appropriate choice.

Examining estimates from Table 2 in Bell and Bockstael (2000), it is clear that five of the ten coefficients β from OLS estimation versus maximum likelihood estimation of the SEM model differ by more than 1.67 standard deviations. Table 77.1 presents their OLS and maximum likelihood SEM estimates constructed using an inverse distance weight matrix based on a 600 m cutoff (from Table 2 in their paper), along with standard errors and a t -test for significant differences between these.

There is one coefficient where the SEM estimate is 2.8 standard deviations away from the OLS, two cases where the two sets of estimates are 1.99 standard deviations apart, and two more that are different using the 90 % level of significance. Of the ten coefficients, five are likely to be significantly different, suggesting the SEM model represents a misspecification. This type of empirical comparison of OLS and SEM estimates should be a standard part of empirical studies using the SEM specification.

77.3.2 SLX and SDEM Models

An example that uses the SDEM model is LeSage and Ha (2012), who study the impact of migration on county-level social capital. Social capital is sometimes thought to be embodied in the *structure and relations between people*, which would suggest that social capital is *place based*, since the structure and relations between people exist at some particular location in space. Other definitions that emphasize the place-based nature of social capital rely on the concept of *associational density* which measures the number of civic and social organizations (per capita), again at some particular location in space. Others have emphasized a view of social capital that focuses on the structure of relations between people, using trust as a measure of the strength between individuals, with trust purported to promote positive economic performance of regional economies. When people move, they may take their trusting attitudes with them, so the case for social capital as entirely place based may not be the entire story.

Their SDEM model takes the form in Eq. (77.18), where W_n and W_f represent migration-weighted spatial weight matrices. The matrix W_n identifies neighboring counties within 40 miles and assigns relative weights to these based on in-migration magnitudes. The matrix W_f identifies neighboring counties more than 40 miles away from each county that provide in-migration to each county i in the sample and weighs these according to in-migration magnitudes. The matrix V used to model dependence in the model disturbances was a spatial contiguity weight matrix, with equal weights assigned to all contiguous counties:

$$\begin{aligned}
 y &= X\beta + W_n X\theta + W_f X\gamma + u \\
 u &= \rho V u + \varepsilon
 \end{aligned}
 \tag{77.18}$$

Pace and Zhu (2012) point out that a desirable aspect of the model in Eq. (77.18) is that dependence in the disturbances is modeled separately from spillovers, which is not the case for the SAR and SDM models. For the SAR model, the dependence

structure for the disturbances is restricted to be the same as that for the *mean model*, which can be seen from $y = (I_n - \rho W)^{-1} X\beta + (I_n - \rho W)^{-1} \varepsilon$. This implies that the expectation for y is a function of ρ and W , $E(y) = (I_n - \rho W)^{-1} X\beta$, and the disturbance covariance, $\Omega = \sigma^2[(I_n - \rho W)^{-1}(I_n - \rho W')^{-1}]$, takes the same functional form. An implication of this is that misspecification in either the disturbances or mean model will contaminate the other part of the model.

The SDEM model in Eq. (77.18) allows *separation* of the (local) spillover impacts on county-level social capital levels arising from changes in population characteristics of nearby counties (providing in-migrants to each county in the sample) versus (local) spillover impacts that arise from changes in population characteristics of far away (outside the region) counties (providing in-migrants to each county) and global contagion impacts from shocks to the errors. An important point is that local spillovers need not be defined as those involving only nearby counties; we can consider spillovers in far away counties as well with this type of model. The intuition behind local spillovers is that the spatial extent of these falls only on first-order neighbors, and a model of local spillovers exhibits no feedback effects.

In terms of the application to migration impacts on social capital levels, the model allows us to consider how a change in educational attainment levels of population in counties within the region impact social capital and how similar changes in educational attainment for population in counties outside the region (providing in-migrants to each county) impact levels of social capital. As is conventional in regression models, the coefficient estimates θ and γ provide answers to this type of question by averaging over all observations/counties in the sample, so we interpret these to represent impacts on the typical county.

This type of model allows us to focus on whether there are important differences in the magnitude of impact associated with in-migration from within and outside the region. Are some changes in characteristics of in-migrants from nearby counties significant/insignificant while the same characteristics of in-migrants from outside the region are insignificant/significant?

A specification test to rule out the presence of omitted explanatory variables that are correlated with included variables should be employed here. Theoretically, we know that SLX and SDEM model estimates for the coefficients θ and γ should be the same, with differences residing in the t -statistics. If omitted variables that are correlated with the included explanatory variables exist, there would be a significant difference between SLX and SDEM estimates for β . LeSage and Ha (2012) provide a comparison of SLX and SDEM estimates in their Table 2, where no significant differences exist.

77.3.3 SAR and SDM Models

Kirby and LeSage (2009) use an SDM specification to consider changes in the (logged) number of workers in the US census tracts with commuting times exceeding 45 min one way, between 1990 and 2000. They motivate their investigation by

noting that the percentage of the US workers with these long commute times in 1990 was 12.5 %, compared to 15.4 % in 2000, an increase of more than 10 %. Spillover impacts from an increase in commuters traveling long distances to work would seem global in nature, since the congestion effects of more travelers on one segment of a metropolitan area roadway network impact travel times of other travelers on the entire network. Additionally, feedback effects seem likely since congestion arising from commuting decisions by workers in one tract will spillover to neighboring tracts, which in turn create congestion feedback to the own tract. Intuitively, congestion on roadways does not obey census tract boundaries, but spills over to the neighboring tracts. Any traffic backups on a road segment in neighboring tracts are likely to cross tract boundaries back into the own-tract roadway.

The SDM model in Eq. (77.19) is used to examine factors (X) that explain tract-level variation in the (logged) number of workers with long commute times (y), and the model includes these same characteristics of neighboring census tracts (WX):

$$y = \rho W y + \alpha I_n + X \beta + WX \theta + \varepsilon \quad (77.19)$$

The motivation for these explanatory variables in the context of modeling long commuting times is that socioeconomic demographic characteristics of persons living in neighboring census tracts should represent important explanatory variables. For example, if there are a large number of retired persons living in neighboring tracts, this should result in less congestion during commute-to-work times.

They consider changes in both direct and indirect effects for models estimated using cross-sectional samples of all census tracts in the lower 48 states for the 1990 and 2000 periods. In the presence of significant indirect (spillover) effects, past studies that ignore these will produce biased and inconsistent estimates of how socioeconomic demographic characteristics impact commuting times for population living in the tracts. The analysis considers suites of variables that reflect *location decisions of households* (e.g., housing tenure, modes of transportation, residence versus work locations in cities versus suburbs), *age and gender and income distribution of resident population* (e.g., the number of persons in various age and gender categories, household income, and educational attainment), and *geographical characteristics of the tracts* including such things as public transport use, land and water area, and highway lane miles reflecting supply side considerations.

Based on a comparison of direct, indirect, and total effects estimates from the 1990 and 2000 models, they conclude that the suite of variables reflecting the age and gender distribution of population in the tracts represents the primary explanation for changes in the number of workers with long commute times between 1990 and 2000. This is in contrast to other studies that emphasize a rapid rise in household income leading to the desire for larger homes located farther from central business districts (Gordon et al. 2009). The spillover impacts of the number of employed females in the 1990 model was positive, suggesting that more employed females in a tract produced an increase in long commute times for

neighboring tract commuters. In contrast, for the 2000 relationships, spillovers associated with employed females were negative, so that more employed females in a tract reduced long commute times for workers located in neighboring tracts. Opposite signs were found for changes in spillovers associated with employed males, providing results that are consistent with observations made by others regarding changes in age and gender impacts on commuting behavior (Crane and Chatman 2004).

77.4 Conclusion

An important motivation for use of spatial regression models is that they allow regional scientists to quantify spatial spillovers, which represent a major theme in regional science. Past studies using spatial regression models frequently interpreted the model estimates incorrectly, which tended to obscure this valuable aspect of spatial regression models.

We draw on past work by LeSage and Pace (2009) that formally defines spatial spillovers in the context of spatial regression models. An important distinction in applied modeling can be drawn between local and global spillovers. Global spillovers arise when changes in a characteristic of one region impact outcomes in more than just immediately neighboring regions. Global impacts fall on neighbors to the neighbors, neighbors to the neighbors to the neighbors, and so on. In contrast, local spillovers represent a situation where the impacts fall only on nearby or immediate neighbors, dying out before they impact regions that are neighbors to the neighbors. Another distinction between local and global spillovers is that feedback effects arise in the case of global spillovers, but not in the case of local spillovers.

Different types of spatial regression models should be used to model local versus global spillovers. Reasoning about the local versus global nature of spillovers in particular applications seems a useful approach to selecting a model specification from the family of spatial regression models. Past work by practitioners may have placed too much emphasis on statistical tests based on model fit to distinguish between alternative specifications from the family of spatial regression models. It might be worthwhile to devote more effort to reasoning about the likely nature of spatial spillovers in particular applied situations.

Abstract

Maximum likelihood estimation has been the standard method employed for estimating spatial econometric models. This chapter introduces these methods, examines the specific case of a spatial error model, and provides an example based on a large data set. In addition, the chapter sets forth various solutions to the computational difficulties that arise for large data sets.

78.1 Introduction

At least since Ord (1975), maximum likelihood estimation has been the standard method employed for estimating spatial econometric models. Maximum likelihood methods work under the simple, but powerful, idea that if the observed data come from some *data-generating process* or DGP based on a distribution and constant parameters, then inverting the process enables estimation of the parameters conditional on the observed data. In other words, for an assumed DGP, which values of the parameters would be in accord with having observed these data? The likelihood function has the same mathematical form as a density or distribution function but a different interpretation and properties.

Maximum likelihood methods provide a coherent approach to estimation and inference with attractive statistical properties. In the absence of misspecification, in most settings, maximum likelihood estimates are efficient in large samples.

This chapter briefly presents some spatial likelihoods in Sect. 78.2, sets forth the maximum likelihood approach in Sect. 78.3, works through an example based on the spatial error model in Sect. 78.4, goes into many of the computational aspects of maximum likelihood in Sect. 78.5, and summarizes the key ideas in Sect. 78.6.

78.2 Likelihoods

Since every different distribution has its own likelihood function, there are an enormous number of likelihood functions that have been introduced in the literature. Since dependent variables could be continuous, discrete, or a combination of both (as in the case of Tobit), this implies a variety of likelihood functions. In addition, the way that dependence between observations is specified affects the form of the likelihood function.

We present two distinct types of likelihood, one for the case involving normally distributed dependent data in 2.1 and one for the case of binary dependent variable observations in 2.2 where implied (latent) disturbances follow a multivariate normal distribution.

78.2.1 Likelihood with Continuous y and Normal Disturbances

Regression, whether linear or nonlinear, is the most commonly performed statistical procedure in regional science. Specifically, the DGP in Eq. (78.1) relates a given n by k full-rank matrix X that contains n observations on k explanatory variables and an n by 1 vector of observations on the dependent variable y as a function of a k by 1 parameter vector β and an n by 1 vector of disturbances ε that follows a multivariate normal distribution. The disturbance distribution is shown

in Eq. (78.2), where $\Omega(\lambda)$ is the variance-covariance matrix that depends on a scalar parameter λ and a scalar variance parameter σ^2 :

$$y = f(\beta|X) + \varepsilon \quad (78.1)$$

$$\varepsilon \sim N(0, \sigma^2\Omega(\lambda)) \quad (78.2)$$

For this DGP, the relevant log of the likelihood $L(\omega)$ appears in Eq. (78.3), where ω is a $k + 2$ by 1 parameter vector shown in Eq. (78.4) and r corresponds to the unadjusted errors in Eq. (78.5):

$$L(\omega) = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{1}{2} \ln |\Omega(\lambda)| - \frac{r'\Omega^{-1}r}{2\sigma^2} \quad (78.3)$$

$$\omega = [\beta' \quad \sigma^2 \quad \lambda] \quad (78.4)$$

$$r = y - X\beta \quad (78.5)$$

If a ω^* maximizes $L(\omega)$, this vector becomes the maximum likelihood estimate, which we label $\tilde{\omega}$.

In practice, the main computational constraint is the computation of the log-determinant of the n -dimensional variance-covariance matrix. This issue will be discussed below in Sect. 78.5.

78.2.2 Likelihood with Binomial y and Normal Disturbances

For the case of spatial dependence in the disturbance structure, the model in Eq. (78.6) represents a general data-generating process (DGP) with multivariate normal disturbances given in Eq. (78.7). The n by 1 vector \underline{y} represents unobserved utility/profits, and y is an associated 0,1 vector reflecting the observed decisions as in Eq. (78.8). Like the typical binary probit model, the parameter σ^2 is set to 1 to achieve identification as shown in Eq. (78.9). The link between the latent \underline{y} and the observed y appears in Eq. (78.10): (Reference the ► Chap. 81, “Limited and Censored Dependent Variable Models” by Cara Wang on spatial probit models here.)

$$\underline{y} = X\beta + \varepsilon \quad (78.6)$$

$$\varepsilon \sim N(0, \sigma^2\Omega(\lambda)) \quad (78.7)$$

$$y = 0, 1 \quad (78.8)$$

$$\sigma^2 = 1 \quad (78.9)$$

$$y_i > 0 \rightarrow y_i = 1 \text{ otherwise } y_i = 0 \text{ for } i = 1 \dots n \quad (78.10)$$

The log-likelihood in Eq. (78.11) involves the multivariate joint normal cumulative density function given the pattern of observed binary outcomes y and observed explanatory variables X :

$$L(\omega) = \ln \Phi_n(\omega|y, X) \quad (78.11)$$

Although this is simple conceptually, in practice, this requires computing the integral of a truncated n -dimensional normal distribution. For large n , this is known to be a difficult computational problem (Phinikettos and Gandy 2011). However, it is computationally possible using the GHK (Geweke-Hajivassiliou-Keane) simulator which arose out of the work by Geweke (1991), Hajivassiliou and McFadden (1990), and Keane (1994). In a spatial context, Beron and Vijverberg (2004) were the first to estimate spatial models using this technique, and recently, Pace and LeSage (2011) and Zhu and Pace (forthcoming) have used the sparsity of Ω to greatly accelerate computing the likelihood.

78.3 Inference and Estimation

Given a likelihood, one can follow at least two main approaches in using it for estimation and inference: the *Bayesian* approach and the maximum likelihood approach. This section introduces a simple maximum likelihood approach in 3.1 and sets forth the conventional maximum likelihood approach to estimation and inference based on derivatives in 3.2.

78.3.1 Simplest Approach to Likelihood Estimation and Inference

Maximization could come about through derivatives, grid searches, or a number of other techniques that have been suggested in the literature. One can compare the maximum likelihood estimate $\tilde{\omega}$ to some restricted estimate ω_0 using the log of the *likelihood ratio* in Eq. (78.12). Under standard likelihood theory, the *deviance* given in Eq. (78.13) is distributed as χ^2 with degrees of freedom (df) equal to the number of restrictions as in Eq. (78.14):

$$\ln LR = L(\omega_0) - L(\tilde{\omega}) \quad (78.12)$$

$$\text{Deviance} = -2 \ln LR \quad (78.13)$$

$$\text{Deviance} \sim \chi^2(\text{df}) \quad (78.14)$$

As an example, consider ordinary least squares (OLS) where we rely on a single data sample. The (log) likelihood for this model is a restricted version of the general normal model in Eq. (78.2), with the restriction being that $\lambda = 0$. Testing for consistency of the sample with the OLS versus the general model could be viewed as a test of the restriction that $\lambda = 0$. If OLS estimation of β and σ^2 produced an estimated value of the log-likelihood function of -100.0 , while estimation of β , λ , and σ^2 using the general model yielded a value of -75.0 , the deviance would equal 50.0 . Under the null hypothesis that $\lambda = 0$, the deviance would have a χ^2 distribution with one degree of freedom. This has a critical value at the one percent level of 6.63 , making it very unlikely that the disturbances are independent.

A related statistic is the *signed root deviance* which equals the square root of the deviance times the sign of the corresponding parameter (Chen and Jennrich 1996). In the example above, if $\lambda > 0$, the signed root deviance would equal to $\sqrt{50}$ or 7.07 , and this quantity can be interpreted like a *t*-statistic.

78.3.2 Variance-Covariance Matrix Approach to Likelihood Inference

The most common approach to estimation uses optimization in conjunction with partial derivatives to derive first-order conditions and second derivatives to arrive at a variance-covariance matrix for the parameter estimates (Cramer 1986; Davidson and MacKinnon 2004).

Specifically, the partial derivatives of the log-likelihood with respect to the parameters are termed the *Fisher's score function* or *score* as in Eq. (78.15). In other words, these are the *gradients* of the log-likelihood:

$$g(\omega) = \frac{\partial L(\omega)}{\partial \omega} \quad (78.15)$$

The *Hessian* in Eq. (78.16) contains the second partial derivatives of the log-likelihood:

$$H(\omega) = \frac{\partial^2 L(\omega)}{\partial \omega \partial \omega'} \quad (78.16)$$

The negative of the Hessian evaluated at the maximum likelihood estimates shown in Eq. (78.17) has been labeled the *observed information matrix*, and the expected value of the negative of the Hessian shown in Eq. (78.18) is referred to as the *information matrix*:

$$\tilde{J}(\omega) = -H(\omega) \quad (78.17)$$

$$I(\omega) = -E(H(\omega)) \quad (78.18)$$

Assuming the correct model specification, large samples imply Eq. (78.19):

$$I(\omega) = \tilde{J}(\omega) \quad (78.19)$$

For both of these information matrices, the variance-covariance matrix applicable to the parameter estimates is simply the inverse of the respective information matrices as in Eqs. (78.20) and (78.21):

$$V(\omega, I(\omega)) = I(\omega)^{-1} \quad (78.20)$$

$$V(\omega, \tilde{J}(\omega)) = \tilde{J}(\omega)^{-1} \quad (78.21)$$

Given the true variance-covariance matrix $V(\omega)$ and true parameters ω , the implied distribution of the estimates is shown in Eq. (78.22):

$$\tilde{\omega} \sim N(\omega, V(\omega)) \quad (78.22)$$

Of course, we do not know the true parameters, so Eqs. (78.23) and (78.24) provide a feasible version of Eq. (78.22):

$$\tilde{\omega} \sim N(\tilde{\omega}, V(\tilde{\omega}, I(\tilde{\omega}))) \quad (78.23)$$

$$\tilde{\omega} \sim N(\tilde{\omega}, V(\tilde{\omega}, \tilde{J}(\tilde{\omega}))) \quad (78.24)$$

Intuitively, if the second derivatives are negative in sign and large in magnitude (especially for elements on the diagonal of the Hessian or expected Hessian), this means that the log-likelihood is decreasing quickly for points away from the maximum likelihood estimate. The inverse of the negative of these negative, large magnitude second derivatives would yield small, positive variances for the respective parameter estimates.

In terms of the derivative approach to estimation, the gradient and the Hessian enable use of *Newton–Raphson* optimization, with the typical iteration step used to move from an intermediate value at step i to a new intermediate value for step $i + 1$ shown in Eq. (78.25):

$$\omega^{(i+1)} = \omega^{(i)} - H(\omega^{(i)})^{-1} g(\omega^{(i)}) \quad (78.25)$$

As with all iterative procedures, updated values continue based on these steps until convergence, which is defined by a predefined criterion on how close the gradient $g(\omega^{(i)})$ or the adjustment $H(\omega^{(i)})^{-1} g(\omega^{(i)})$ should be to a vector of zeros.

Fisher scoring is an optimization technique particularly well suited to maximum likelihood. Its optimization step Eq. (78.26) is a variation on the Newton–Raphson step where $-H(\omega)$ is replaced by the information matrix $I(\omega)$.

The technique derives its name since the score vector $g(\omega)$ is pre-multiplied by the inverse of the information matrix:

$$\omega^{(i+1)} = \omega^{(i)} + I(\omega^{(i)})^{-1} g(\omega^{(i)}) \quad (78.26)$$

In summary, the derivative-based approach outlined in this section for optimizing the log-likelihood and producing estimates can be used for inference works in a wide variety of settings. The next section provides specifics for this approach in the case of a *spatial error model* (SEM) specification.

78.4 Spatial Error Model Example

In this section, we apply the approach outlined above to the spatial error model, whose DGP appears in Eqs. (78.27)–(78.29):

$$y = X\beta + \varepsilon \quad (78.27)$$

$$\varepsilon \sim N(0, \sigma^2 \Omega) \quad (78.28)$$

$$\Omega = (I_n - \lambda W)^{-2} \quad (78.29)$$

We further assume that the n by n nonnegative matrix W with zero main diagonal is symmetric and thus has all real eigenvalues and eigenvectors (see Ord (1975) for the information matrix when using nonsymmetric W). In addition, we assume that the maximum eigenvalue of W equals 1. This means that $\Omega(\lambda)$ is symmetric and positive definite when $\lambda \in (-v_{\min}^{-1}, 1)$, where v represents the n by 1 vector of eigenvalues from W . We also assume an exogenous n by k matrix of explanatory variable observations X . As before, β is a k by 1 parameter vector, and σ^2 is a positive scalar parameter.

The normal log-likelihood appears in Eq. (78.30) with previous definitions repeated in Eq. (78.31). The spatial dependence structure of the error model appears in Eq. (78.32), which leads to the determinant expressions in Eq. (78.33). These relations enter into the spatial error model log-likelihood shown in Eq. (78.34). The spatial error model leads to a sum-of-squared error term Q that is quadratic in the dependence parameter λ as shown in Eq. (78.35):

$$L(\omega) = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{1}{2} \ln |\Omega(\lambda)| - \frac{r' \Omega^{-1} r}{2\sigma^2} \quad (78.30)$$

$$\omega = [\beta' \quad \sigma^2 \quad \lambda]', \quad r = y - X\beta \quad (78.31)$$

$$\Omega^{-1} = A'A, \quad A = I_n - \lambda W, \quad Q = r' \Omega^{-1} r \quad (78.32)$$

$$\ln |\Omega(\omega)| = -\ln |\Omega(\omega)^{-1}| = -2 \ln |I_n - \lambda W| \quad (78.33)$$

$$L(\omega) = -\frac{n}{2} \ln(2\pi\sigma^2) + \ln |I_n - \lambda W| - \frac{Q}{2\sigma^2} \quad (78.34)$$

$$Q = r'A^2r = r'r - 2\lambda r'Wr + \lambda^2 r'W^2r \quad (78.35)$$

The gradient or score vector $g(\omega)$ values for the spatial error model appear in Eq. (78.36):

$$g(\omega) = \begin{bmatrix} \frac{\partial L(\omega)}{\partial \beta} \\ \frac{\partial L(\omega)}{\partial \sigma^2} \\ \frac{\partial L(\omega)}{\partial \lambda} \end{bmatrix} = \begin{bmatrix} \sigma^{-2} X'A^2r \\ -\frac{n}{2}\sigma^{-2} + \frac{1}{2}Q\sigma^{-4} \\ -\text{tr}(B) + \sigma^{-2}r'WA r \end{bmatrix} \quad (78.36)$$

where use is made of the definitions in Eqs. (78.37) and (78.38). Note, matrix functions involving the same square matrix such as WA^{-1} commute, and so, this also equals $A^{-1}W$. This property along with symmetric W helps simplify the expressions:

$$B = WA^{-1} = A^{-1}W \quad (78.37)$$

$$\alpha = -\text{tr}(B^2) \quad (78.38)$$

The expression for α in Eq. (78.38) follows Ord (1975), but there is an omitted minus sign in Ord (1975, p. 124) that was corrected here.

Taking partial derivatives of the gradient leads to the Hessian (H) in Eq. (78.39) and expected Hessian $E(H)$ in Eq. (78.40):

$$H = \sigma^{-2} \begin{bmatrix} -X'A^2X & -\sigma^{-2}X'A^2r & -2X'AWr \\ & \frac{n}{2}\sigma^{-2} - Q\sigma^{-4} & -\sigma^{-2}r'WA r \\ & & \alpha\sigma^2 - r'W^2r \end{bmatrix} \quad (78.39)$$

$$E(H) = \begin{bmatrix} -\sigma^{-2}X'A^2X & 0_{k \times 1} & 0_{k \times 1} \\ 0_{1 \times k} & -\frac{n}{2} & -\sigma^{-2}\text{tr}(B) \\ 0_{1 \times k} & -\sigma^{-2}\text{tr}(B) & 2\alpha \end{bmatrix} \quad (78.40)$$

As before, this leads to the observed information matrix in Eq. (78.41) and information matrix in Eq. (78.42), with estimates and associated variance-covariance matrix given in Eqs. (78.43) and (78.44):

$$\tilde{J}(\omega) = -H(\omega) \quad (78.41)$$

$$I(\omega) = -E(H(\omega)) \quad (78.42)$$

$$\tilde{\omega} \sim N(\tilde{\omega}, V(\tilde{\omega}, I(\tilde{\omega}))) \quad (78.43)$$

$$\tilde{\omega} \sim N(\tilde{\omega}, V(\tilde{\omega}, \tilde{J}(\tilde{\omega}))) \quad (78.44)$$

As an illustrative example that compares these methods, we consider a model where the dependent variable was year 2000 logged median house prices in 62,226 US Census tracts and a set of explanatory variables taken from the 1990 Census. Specifically, the explanatory variables were median house age (Hage), employment (Employ), median years of education (Edu), median age of the population (Age), and number of households (HHs). All of these variables were logged. In addition, the model includes an intercept and spatially lagged versions of the explanatory variables. LeSage and Pace (2009) term this the *spatial Durbin error model* or SDEM. The coefficients on the explanatory variables themselves represent the *direct* effects, and the coefficients on the spatially lagged explanatory variables represent the *indirect* effects (LeSage and Pace 2009) (reference to the ► Chap. 77, “Interpreting Spatial Econometric Models” by LeSage and Pace on interpreting spatial regression models here).

The SDEM model offers several advantages. First, the estimates are easily interpreted. Second, in contrast to the usual lag of y models, the dependence parameter λ does not affect the conditional mean from the model. In the traditional lag of y models, an incorrect specification of the disturbances could affect the direct and indirect effects extracted from the model. Since the disturbance parameter in the SDEM is separated from the conditional mean, this is a case of a *separable* model as discussed by Pace and Zhu (2012). Third, the SDEM should arrive at the correct direct and indirect effects even with misspecification of the disturbances (with enough observations).

The estimates from the SDEM model are shown in the first columns of Table 78.1, with those for the SLX model in the last columns. All three methods of calculating t -statistics are reported for the SDEM model, with the column t_I representing information matrix results, t_H the Hessian, and t_{dev} the signed root deviances.

Estimates of the direct effects show the anticipated signs so that older housing reduces the expected future price, while employment, education, and age of the population (a proxy for wealth) increase the expected future price. In terms of the *local spillovers* or indirect effects, these all have the same signs as the direct effects, and so, the spillovers in this case all reinforce the direct effects. In other words, the total effects are all larger than the direct effects for this example.

From the standpoint of the three methods used for inference (likelihood ratio, observed information matrix, and information matrix), these all produce similar t -statistics on the explanatory variables. However, the t -statistics on $\tilde{\lambda}$ do vary. This arises partly because the distribution of $\tilde{\lambda}$ is not quadratic over all the domain of λ

Table 78.1 *t*-Statistics across methods

Model	SDEM model				SLX model	
	$\tilde{\beta}$	t_I	t_H	t_{dev}	$\hat{\beta}$	t

(although it can be locally quadratic), and it may point to some misspecification. Much of this comes from fatter tails in the residuals than found in a normal distribution. In cases involving misspecification of the disturbances, maximum likelihood is consistent but not asymptotically efficient. Normal maximum likelihood applied to data with non-normal disturbances is termed *quasi-maximum likelihood*.

See Mardia and Marshall (1984), Anselin (1988), Griffith (1989), and Haining (1990) for more on the derivative approach to spatial model estimation and inference. See Burrige (2012) for the necessary derivatives for more general spatial models with normal disturbances.

78.5 Computational Details

Even though computational power has greatly increased since Ord's seminal article in 1975 on normal maximum likelihood for spatial models, a brute force approach to estimation for large n can still encounter difficulties. However, a number of techniques can greatly reduce the computational effort required in normal maximum likelihood. These include use of profile or concentrated log-likelihoods (5.1), sparse matrices (5.2), and various approaches to calculating the log-determinant term (5.3).

78.5.1 Concentrated Log-Likelihood

Beginning with the spatial error model log-likelihood in Eq. (78.45),

$$L(\omega) = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{1}{2} \ln |\Omega(\lambda)| - \frac{r' \Omega(\lambda)^{-1} r}{2\sigma^2} \quad (78.45)$$

substitution of the solutions to the first-order conditions ($g(\beta)$, $g(\sigma^2)$) given by Eqs. (78.46) and (78.47) into Eq. (78.45) yields $L_p(\lambda)$, a function of only the parameter λ :

$$\beta = (X'A^2X)^{-1}X'A^2y \quad (78.46)$$

$$\sigma^2 = \frac{1}{n}Q(\lambda) \quad (78.47)$$

$$L_p(\lambda) = \kappa + \ln |I_n - \lambda W| - \frac{n}{2} \ln(Q(\lambda)) \quad (78.48)$$

The univariate function $L_p(\lambda)$ in Eq. (78.48) is termed a *concentrated* or *profile* log-likelihood. The value of λ^* that maximizes $L_p(\lambda)$ also maximizes $L(\omega)$ given Eqs. (78.46) and (78.47). Since $L_p(\lambda)$ is univariate, it is easier to optimize. Note that the variance of λ^* implied solely by the concentrated log-likelihood second derivative with respect to λ does not match the variance of λ coming from the information matrix approach. However, given the variance of λ from the concentrated log-likelihood, a transformation can be made to obtain the exact value of the variance when following the information matrix approach (Davidson and MacKinnon 2004; LeSage and Pace 2009, p. 56–59).

78.5.2 Sparsity

In the SEM example, the variance-covariance matrix appears in Eq. (78.49), and the inverse of the variance-covariance matrix, known as the *precision matrix* which is labeled Ψ , appears in Eq. (78.50):

$$\Omega = (I_n - \lambda W)^{-2} = A^{-2} \quad (78.49)$$

$$\Psi = \Omega^{-1} = (I_n - \lambda W)^2 = A^2 \quad (78.50)$$

In time series analysis, an AR(1) process corresponds to a case where the equivalent of A is triangular with at most a single off-diagonal nonzero in each row. In that case of the n^2 elements making up the n by n matrix A , there are less than $2n$ nonzero elements, which can be expressed as a density of $2n/n^2 = 2/n$ nonzeros. For the MA(1) process, the same holds true for the equivalent of A^{-1} . In other words, for simple time series processes, either the variance-covariance matrix or the precision matrix contains many zero elements.

This is often true for spatial processes, since the most common spatial weight matrix W contains nonzero elements for regions/observations where borders of two regions touch. This leads to an average of approximately 6 nonzeros for each row of W or a density of $6/n$ elements. A nearest-neighbor-based W would

have a density of m/n , where m is the number of neighbors. A similar number exists for distance-based spatial weight matrices where a cutoff distance is used to assign zero values for regions beyond the cutoff. Matrices with a low density of nonzero elements (or equivalently a high proportion of zeros) are said to be *sparse*.

Sparsity is important since almost every operation involving matrix computations can be accelerated by only performing required operations on the nonzero elements. For example, an n by n dense matrix M leads to order of n^3 computations to produce the matrix M^2 , while it may require only order of n computations to produce the same matrix result with a sparse matrix. In other words, a successful sparse matrix implementation of the estimation problem may lead to computational work that is linear in n , while a dense matrix implementation could lead to work that rises with the cube of n .

78.5.3 Log-Determinant Calculations

There are a number of ways to attack the problem of calculating the log-determinant term in the log-likelihood function. These include closed-form solutions, eigenvalue approaches, Gaussian elimination approaches such as the Cholesky or LU decomposition, and approximations or bounds to the log-determinant. This section outlines these approaches and provides an empirical comparison in the last section.

Closed Form In some special cases, the log-determinant has a closed form. For example, many systems on regular grids have explicit closed-form solutions, or these can be easily extrapolated from a sequence of numerical determinants (LeSage and Pace 2009; Pace and LeSage 2009). Also, W based on just the single closest neighbor has a simple form of $n_{sp} \ln(1 - \lambda^2)$, where n_{sp} is the number of symmetric pairs of closest neighbors in W (Pace and Zou 2000). Finally, the log-determinant term vanishes when using a matrix exponential form of a spatial model, since the determinant of e^W equals $e^{\text{tr}(W)}$ which equals 1, and thus, the log-determinant equals 0 (LeSage and Pace 2007).

Eigenvalues Eigenvalues provide one of the most useful summaries of a matrix. For example, given the n by 1 vector of eigenvalues v from the spatial weight matrix W , the computation of the log-determinant in Eq. (78.51) and other quantities such as $\text{tr}(W^j)$ in Eq. (78.52) or $\text{tr}(WA^{-1})$ in Eq. (78.53) is simplified:

$$\ln |I_n - \lambda W| = \sum_{i=1}^n \ln(1 - \lambda v_i) \quad (78.51)$$

$$\text{tr}(W^j) = \sum_{i=1}^n v_i^j \quad (78.52)$$

$$\text{tr}(WA^{-1}) = \sum_{i=1}^n (1 - \lambda v_i)^{-1} v_i \quad (78.53)$$

Ord (1975) laid out the means of computing the spatial error model and the spatial lag of y model using eigenvalues and showed a useful similarity transformation that allows treating a row-stochastic (in linear algebra terms) W_{rs} (defined in Eqs. (78.54) and (78.55)) as a symmetric matrix in Eq. (78.56). Let R be an n by n diagonal matrix with the row sums of some underlying symmetric binary weight matrix B . In this case,

$$W_{rs} = R^{-1}B \quad (78.54)$$

$$I_n = W_{rs}I_n \quad (78.55)$$

$$W_{ss} = R^{-1/2}BR^{-1/2} \quad (78.56)$$

where the row-stochastic W_{rs} has the same real eigenvalues as the symmetric W_{ss} . In fact, both have a maximum eigenvalue of 1. This allows working with W_{ss} instead of W_{rs} when calculating the eigenvalues which increases the speed and typical accuracy of those calculations. Although there are some assertions in the literature that the eigenvalues of W_{rs} or W_{ss} cannot be calculated accurately for $n > 1,000$, this is rarely or ever true for W used in practice. Eigenvalue routines can encounter difficulties when the underlying eigenvalues are not distinct. If the underlying binary weight matrix B is symmetric, both W_{rs} or W_{ss} have distinct, real eigenvalues, and this will facilitate finding their eigenvalues. To give a specific example of the accuracy, we computed the eigenvalues for W_{ss} based on contiguity for 20,000 observations based on random locations. As a check, the sum of the eigenvalues should equal $\text{tr}(W_{ss}) = 0$, and these actually equaled 2.456×10^{-11} . In addition, we also compared the eigenvalue method to the Cholesky method (to be described shortly) and found for $\lambda = 0.9$, the difference in the two log-determinant values equaled 1.819×10^{-12} .

The main problem with eigenvalues is calculating these for large n . Most algorithms require dense matrices, which leads to storage issues as this requires working with n^2 elements. In the case of 20,000 observations, this uses 2.98 gigabytes per matrix, and in the case of the census tract example above with 62,226 observations, this would require 28.85 gigabytes per matrix. Moreover, most programs require at least twice the working space as the actual storage space needed. In addition, the calculation time rises with the cube of n , and so, this becomes another limiting factor. For example, it took 18.27 min to calculate the eigenvalues on the 20,000 by 20,000 matrix. The estimated time for a 62,226- by 62,226-sized matrix would be 9.17 h. Although this is becoming somewhat more feasible, many problems are still not feasible when using eigenvalues alone. Fortunately, there are alternative approaches that avoid these problems.

Gaussian Elimination Methods The quickest and most stable numerical method for finding log-determinants uses methods based on some form of Gaussian elimination. For symmetric W , this involves the Cholesky decomposition in Eq. (78.57) which reduces a symmetric, positive-definite matrix such as A into

the product of Cholesky triangular matrices U (the upper Cholesky triangle) in Eq. (78.57). The diagonal elements of U , U_{ii} for $i = 1 \dots n$, are termed the *pivots* and are all strictly positive. The sum of the log of the pivots equals the log-determinant of a triangular matrix. Because the Cholesky triangle is one version of the *square root* of A , the log-determinant of A is twice that of the log-determinant of U in Eq. (78.58):

$$I_n - \lambda W = U^t U \quad (78.57)$$

$$\ln |I_n - \lambda W| = 2 \sum_{i=1}^n \ln(U_{ii}) \quad (78.58)$$

For nonsymmetric W , there is the related LU decomposition.

An advantage of the Cholesky or LU decompositions over the eigenvalue approach is that these methods take advantage of sparsity better than most eigenvalue methods. Especially, under certain orderings of the observations (George and Liu 1981; Pace and Barry 1997), the Cholesky triangles such as U stay relatively sparse.

Approximations A number of approximations to the log-determinant term have been proposed. For example, Martin (1993) proposed using the exact traces of the powers of W in the context of a power series as an approximation as in Eq. (78.59). However, the difficulty of computing the exact traces for dense W reduces the utility of the method:

$$|I_n - \lambda W| \approx \sum_{j=0}^m \lambda^j \text{tr}(W^j) \quad (78.59)$$

Barry and Pace (1999) built upon this approximation and used the additional approximation in Eq. (78.60), where M is a n by n matrix and u is a n by 1 vector composed of unit-independent normal deviates. This approximation rests on the properties of the unit normal *iid* distribution so that $E(u_i^2) = E(\chi_{1df}^2) = 1$ and $E(u_i u_j) = 0$ as shown in Eqs. (78.60)–(78.62):

$$\text{tr}(M) \approx u^t M u \quad (78.60)$$

$$E(u_i M_{ii} u_i) = E(u_i^2 M_{ii}) = E(\chi_{1df}^2) M_{ii} = M_{ii} \quad (78.61)$$

$$E(u_i M_{ij} u_j) = 0 \quad (78.62)$$

With this method, they were able to approximate the log-determinant of a 1,000,000 by 1,000,000 matrix using a 133 MHz Pentium processor with 64 megabytes of memory. Note that $W^2 u$ is just $W(Wu)$ and $W^3 u$ is just $W(W^2 u)$ and so forth. Therefore, computing the moments just requires a sparse matrix–vector

Table 78.2 Times and accuracy across methods

n	Eigenvalues	Cholesky	MC	$\hat{\lambda}_c$	$\hat{\lambda}_{mc}$
1,000	0.167	0.087	0.073	0.873	0.872
2,500	2.431	0.058	0.076	0.877	0.876
5,000	18.371	0.141	0.141	0.876	0.876
10,000	136.372	0.443	0.261	0.864	0.864
15,000	448.853	0.670	0.329	0.869	0.869
20,000	1,096.045	0.967	0.475	0.870	0.870
50,000		2.584	1.323	0.869	0.869
100,000		5.628	2.415	0.868	0.868
1,000,000		132.649	22.747	0.871	0.871

operation. Also, given the estimated moments $\text{tr}(W^j)$, the overall log-determinant involves only a few calculations when recomputing $|I_n - \lambda W|$ for different values of λ . LeSage and Pace (2009, p. 99) also suggest using some of the lower ($j = 1, \dots, 4$ or $j = 1, \dots, 6$) exact moments as in Martin (1993) to improve accuracy. Some of these require little computational effort as $\text{tr}(W^2)$ for symmetric W is just the sum of all elements in W squared, which does not involve much work for sparse W . Zhang et al. (2007) improve on this algorithm, testing possible draws for quality by comparing the exact and approximate traces and retaining only the best draws.

Other approximations in the literature include approaches based on characteristic polynomials (Smirnov and Anselin 2001; Griffith 2004), Chebyshev polynomials (Pace and LeSage 2004), and extrapolation (Pace and LeSage 2009). Also, there are log-determinant bounds such as a simple quadratic inequality in Pace and LeSage (2002).

Comparisons Table 78.2 compares the time required to compute a vector of log-determinants for varying values of λ and shows the estimated dependence parameter $\hat{\lambda}$ when using the Cholesky approach and the Monte Carlo log-determinant approximation based on four exact moments, 16 trials, and $m = 50$ iterations. As can be seen, using eigenvalues is feasible for problems involving up to 20,000 observations but becomes too demanding in both time and storage to proceed beyond that level. The Cholesky approach is feasible for all sample sizes, and the Monte Carlo log-determinant approximation works well for all sizes but only has a material advantage over the Cholesky approach for $n = 100,000$ or more. Using eigenvalues or the Cholesky approach yielded estimates of $\hat{\lambda}$ that were equal to three decimal places, and the Monte Carlo log-determinant approximation led to the same $\hat{\lambda}$ as the Cholesky for samples sizes of 2,500 or greater. In fact, rerunning the Monte Carlo log-determinant approximation with only two trials gave the same result as 16 trials but cut the time to 4.68 s from 22.75 s (on a 2.89 GHz Sandy Bridge CPU, Lenovo x220 laptop with 16 GB RAM).

Bivand (2010) compared the eigenvalue, Cholesky, Monte Carlo, and fifth degree Chebyshev log-determinant approaches and found they all performed well in terms of accuracy. In addition, he discussed and pointed out some errors in an earlier paper by Walde et al. (2008) regarding the various methods.

78.6 Conclusions

In terms of spatial econometrics for normally distributed (but dependent) disturbances, maximum likelihood methods have gone from being a challenging numerical problem limited to small sample sizes at the time of Ord (1975) to becoming routine and applicable to any sized data set. Part of this improvement over time arises from computational advances, but we should not overlook the role played by selecting approaches or techniques that are well suited to the case of spatial data when sparse connectivity structures are present. At this time, there are still challenges for more complicated likelihood problems such as those involving limited and dependent variables. It seems plausible that these currently challenging problems will become more routine over time as computational capacity expands and algorithms for specific problems improve.

Acknowledgments I would like to thank Mark Mclean, James LeSage, and Shuang Zhu for their very helpful comments.

Abstract

This chapter provides a survey of the recent literature on Bayesian inference methods in regional science. This discussion is presented in the context of the Spatial Durbin Model (SDM) with heteroskedasticity as a canonical example. The overall performance of different hierarchical models is analyzed. We extend the benchmark specification to the dynamic panel data model with spatial

dependence. An empirical illustration of the flexibility of the Bayesian approach is provided through the analysis of the role of knowledge production and spatiotemporal spillover effects using a space-time panel data set covering 49 US states over the period 1994–2005.

79.1 Introduction

Applied work in regional science is increasingly confronted with the task of analyzing data that are geographically referenced and temporally correlated, with many potential predictors. Up until the 1990s, virtually all of the empirical work in regional science employed frequentist statistical methods. The landmark work by Anselin (1988) reviews this literature and provides arguably the most comprehensive coverage of spatial econometrics in regional science.

In the early 1990s, the development of Markov Chain Monte Carlo (MCMC) methods revolutionized applications of the Bayesian approach to statistical inference. The revival of interest in the Bayesian approach has rapidly extended into spatial econometrics and geo-statistics. MCMC techniques, applied creatively, allow for the sophisticated modeling of large data sets with time dependence and cross-sectional correlation. Recent developments in Bayesian methods allow full Bayesian analysis of sophisticated multilevel models for complex geographically referenced data (Banerjee et al. 2004; LeSage and Pace 2009). This approach also offers full inference for non-Gaussian spatial data, spatiotemporal data, and, for the first time, solutions to problems of interpretation for models incorporating geographic and temporal dependence.

Analyzing a variety of panel data models, Chib (2008) underlines how the approach allows for the complex analysis of continuous, censored, count, and multinomial responses under weaker assumptions than required by previously developed methods. For instance, the Bayesian approach does not require the strict exogeneity assumption in the presence of endogenous covariates. Based on this panel setting, a growing number of studies examine spatial and temporal effects in multinomial or multivariate discrete response data. For example, Wang et al. (2012) develop a dynamic spatial ordered probit model and use it to analyze land development intensities. Discrete choice modeling with spatial dependence has been deeply analyzed using mainly the Bayesian approach (an extensive review can be found in LeSage and Pace 2009).

The development of new theoretical and empirical models in regional science to analyze, among other things, regional economic growth (Ertur and Koch 2007; LeSage and Fischer 2008), land use and conservation (Wang et al. 2012), industrial localization (Kakamu et al. 2012), geography of innovation (Autant-Bernard and LeSage 2011; Parent and LeSage 2008) highlights the flexibility of the Bayesian approach. There are additional problems that arise in the modeling process, such as model comparison and predictive performance, that have proven problematic in the

past, but can now also be addressed in a relatively straightforward manner using Bayesian inference and MCMC methods.

The rapid growth in availability of software incorporating MCMC methods has contributed to the dissemination and use of Bayesian methods in empirical work in regional science. A wide range of toolboxes contain all the standard procedures for empirical analysis. A comprehensive collection of routines can be found in one of the best known toolboxes for spatial data analysis, the spatial econometric toolbox of James LeSage (<http://spatial-econometrics.com/>). These routines are implemented within the MATLAB environment and contain the most advanced tools for spatial analysis and model interpretation. An increasingly attractive alternative is based on the development of statistical packages in the open source *R* environment (<http://r-project.org/>). An extensive collection of geo-statistics toolboxes are developed using Bayesian techniques. It is also worth mentioning the significant impact of open source software such as Winbugs. This has been used to make some significant contributions to empirical analysis in regional science.

This chapter presents recent econometric advances in the treatment of complex spatial and spatiotemporal data sets, and outlines a comprehensive approach to dealing with spatial and time effects from a Bayesian econometric perspective. The main objective is to illustrate how Bayesian techniques can help to understand a number of spatial theories and empirical models that have been developed for the practice of regional science and policy analysis. This discussion is presented in the context of the Spatial Durbin Model (SDM) as a canonical example.

The SDM is presented in the next section. Because the Bayesian method is inextricably tied to MCMC sampling, we provide a brief overview of MCMC methods in [Sects. 79.3, 79.4, and 79.5](#). [Section 79.6](#) then applies MCMC methods to the SDM to demonstrate some recent Bayesian research relevant for spatial econometric modeling, particularly with regard to problems of heteroskedasticity and spatial dependence in a panel data setting. The model is extended to include time dependence, and a substantive application of the methodology to regional growth models with interregional technological dependence is then provided in [Sect. 79.7](#). Lastly, [Sect. 79.8](#) summarizes and provides some concluding thoughts that relate to the future of Bayesian econometrics in regional science.

79.2 Spatial Regression and Prior Modeling

The Bayesian approach to spatial modeling relies extensively on the idea of a hierarchical prior which is used to model spatial dependence and heterogeneity. Suppose we have a cross-sectional sample of N independent observations y_i , $i = 1, \dots, N$ that are linearly related to a set of $N \times k$ explanatory variables X and are believed to be spatially correlated. As a benchmark, we will start with the Spatial Durbin Model, which can be motivated by concern over omitted variables or spatial heterogeneity (see LeSage and Pace 2009). This specification includes spatial lags of the explanatory variables as well as the dependent variable.

A representation of the Bayesian SDM is shown in Eq. (79.1):

$$\begin{aligned}
 y &= \rho W y + \iota_n \alpha + X \beta + W X \gamma + \varepsilon \\
 \varepsilon &\sim N(0, \sigma_\varepsilon^2 \Lambda^{-1}) \\
 \Lambda &\equiv \text{diag}(1/\lambda_1, \dots, 1/\lambda_n) \\
 \lambda_i &\sim \chi_v^2/v
 \end{aligned} \tag{79.1}$$

where W is a known $N \times N$ spatial weight matrix whose diagonal elements are zero, ι_n is a $1 \times N$ column vector of ones, and the strength of the spatial dependence is measured by the parameter ρ . The W matrix defines the structure of the dependence between (spatial) observational units. We also assume that W is normalized from a symmetric matrix, so that all eigenvalues are real and less than or equal to one. Different normalization methods can be used. For example, unlike the traditional row-normalization, the spectrally normalized matrix preserves the symmetry by dividing each element by the modulus of the largest eigenvalues (Barry and Pace 1999).

We add a normal-inverse gamma prior for β and σ_ε , and we introduce a uniform prior distribution for the parameter ρ . Intuitively, if we were to simply treat Λ as N unrestricted parameters, a degrees-of-freedom problem would arise. Geweke (1993) proposes a set of N independent, identically distributed, chi-square distributions as prior information for the variance scalars λ_i ,

$$p(\Lambda) = \prod_{i=1}^n \text{Ga}\left(\lambda_i \mid \frac{v}{2}, \frac{v}{2}\right) \tag{79.2}$$

The parameter v represents the single parameter of the Gamma distribution equivalent to a chi-square distribution, allowing us to estimate the N variance scaling parameters λ_i by adding only a single parameter to the model. Geweke (1993) shows that this approach to modeling the disturbances is equivalent to a model that assumes a Student- t distribution for the errors. Another way to view this is that using a t distribution to deal with heteroskedasticity is equivalent to a scale mixture of normals when the mixing distribution is a Gamma distribution. That is, assuming that λ_i are independent $N(0, \sigma_\varepsilon^2 \lambda_i^{-1})$ with prior for λ_i given in Eq. (79.2) is equivalent to the assumption that the error distribution is a weighted average of different normal distributions, each with a different variance. Additional flexibility in modeling heterogeneity can be achieved by introducing a prior hyperparameter for v that follows an exponential distribution governing the degrees of freedom that controls thickness of the tails in the Student- t error distribution (Geweke 1993).

79.3 Bayesian Inference via MCMC

As can be seen from Eq. (79.1), spatial models tend to have fairly high parameter dimensionality. This is because the minimal level of complexity needed to

adequately deal with variations in neighboring structure is rather high. As a result, analytical derivation of closed form expressions for Bayesian posterior distributions is not usually possible for these models. Fortunately, MCMC methods are a tailor-made solution to this problem as they provide approximations to posterior distributions in complex settings up to an arbitrary degree of numerical accuracy.

MCMC techniques allow simulation of a sample from any distribution by embedding it as a limiting distribution of a Markov chain, then simulating from the chain until it approaches equilibrium. This is essentially achieved by reverse engineering with the goal of finding a Markov chain algorithm that will ultimately converge upon the target distribution. Analogs of the law of large numbers and central limit theorems (see [Sect. 79.3.2](#) below) exist for Markov chains that ensure that most of the simulated values from a chain can be used to provide information about the distribution of interest. The degree of accuracy can then be increased arbitrarily simply by increasing the simulated sample size.

A large theoretical literature now exists that sets out the conditions under which the MCMC chain converges to the target posterior. These conditions are surprisingly weak, though there is usually no way to guarantee that they hold in practice. However, a high degree of confidence that the Markov chain has converged can often be achieved, especially if care is taken to follow the suggestions in [Geyer \(2011\)](#) and employ the diagnostic tools discussed in [Sect. 79.5](#) below.

In the last two decades, powerful MCMC techniques have been developed to obtain random draws from a very wide class of conditional distributions under remarkably general conditions. Even when the conditional distributions are too complex for Gibbs MCMC, Metropolis-Hastings (MH) algorithms can be employed to ensure that the appropriate limiting distribution is maintained by rejecting unwanted moves in a chain. We will assume the availability of algorithms to draw pseudo-random numbers from a variety of standard distributions. Methods for doing so have been thoroughly studied and are now widely available in most statistical software (see [Geman and Lopes 2006](#), Chap. 1, for a good exposition).

79.3.1 A Brief Review of MCMC Theory

Monte Carlo methods originate from early work by Stanislaw Ulam and were used during World War II at Los Alamos in the development of the atomic bomb ([Metropolis and Ulum 1949](#)). [Metropolis et al. \(1953\)](#) was the pioneering paper on MCMC, but it was overlooked by statisticians, partly because it was published in a chemistry journal and partly because of the primitive level of computer technology available at the time, making computational methods prohibitively expensive for most statistical applications. [Hastings \(1970\)](#) generalized the Metropolis algorithm, but it was not until the late 1980s and early 1990s that widespread recognition of the practical importance of these algorithms occurred among statisticians. [Geman and Geman \(1984\)](#) developed the Gibbs sampler for use in image processing, and [Tanner and Wong \(1987\)](#) developed the data augmentation

approach and were arguably the first to recognize the potential for Bayesian MCMC inference. However, it was the classic expository paper by Gelfand and Smith (1990) that brought the Gibbs sampler to the attention of a wider audience. This led to the rapid development of a generic set of MCMC tools for Bayesian inference and subsequently revolutionized the field of statistics.

Most of the theoretical developments in MCMC were achieved in the 1990s. The research drive in MCMC methods over the last decade has shifted to developing more efficient computational tools. While advances in computer technology have continued to rapidly reduce the computational costs of simulation techniques, this has led to the analysis of more and more complex models. Researchers in MCMC methods continue to push the frontier of what is currently computationally feasible and there is need for a high level of computational efficiency in this environment. Many of the spatial models employed in empirical research, however, are not of such a high order of complexity, and can now be analyzed quickly and easily on any standard computer. Further, the level of complexity of the models that can be analyzed without being overly concerned with efficiency has grown dramatically in the last decade. In short, the last couple of decades have led to revolutionary changes in our ability to statistically analyze complex spatial models and problems.

79.3.2 Stationary Distributions and a Central Limit Theorem for MCMC

The goal of Bayesian computation is to obtain a sample of draws $\theta^{(t)}$, $t = 1, \dots, M$, from the posterior distribution of the unknown quantity θ , with a large enough sample that quantities of interest can be estimated with reasonable accuracy. MCMC simulation is a general method based on drawing values of θ from distributions that result in a sample from the target posterior distribution, $p(\theta/y)$. The sample is drawn sequentially, with the t th draw, $\theta^{(t)}$, depending only on the previous draw, $\theta^{(t-1)}$. This dependence on only the previous draw is the defining property of a Markov chain, which makes MCMC a practical application of Markov chain theory. Some understanding of the theory of Markov chains is thus helpful in practice, particularly in evaluating the performance and convergence of MCMC chains. This section provides a very brief review. Complete reviews can be found in many texts, including Gelman et al. 2004 and Gamerman and Lopes 2006.

A key requirement for the application of MCMC methods is the convergence of the chain to a stationary distribution. A distribution p is said to be a stationary distribution of a chain with transition probabilities $\pi = \pi(x, y)$ if $p = p\pi$. If the stationary distribution p exists and $\lim_{n \rightarrow \infty} p\pi^n = p$, then, independently of the initial distribution of the chain, p^n will approach p , as $n \rightarrow \infty$.

Ergodicity concerns ensuring that the chain will visit all possible values under the support of the distribution of interest (the stationary distribution) with nonzero probability. A chain is ergodic if it is aperiodic (so it cannot get stuck cycling in one subregion of the parameter space) and positive recurrent (which essentially means that as $n \rightarrow \infty$, the probability of visiting every possible state is nonzero).

For a Markov chain, $\theta = (\theta^{(1)}, \theta^{(2)} \dots, \theta^{(n)})$, the ergodic average of a real-valued function of θ , $h(\theta)$ is the average $\bar{h}_n = (1/n) \sum_{t=1}^n h(\theta^{(t)})$.

If the chain is ergodic and $E_p[h(\theta)] < \infty$ for the unique limiting distribution p , then

$$\bar{h}_n \xrightarrow{a.s.} E_p[h(\theta)] \text{ as } n \rightarrow \infty \quad (79.3)$$

This result is a Markov chain equivalent of the Law of Large Numbers (see Gamerman and Lopes 2006, p. 125).

If a chain is uniformly (geometrically) ergodic and $h^2(\theta)(h^{2+\varepsilon}(\theta))$ is integrable with respect to p for some $\varepsilon > 0$, then we can obtain a Central Limit Theorem for Markov chains:

$$\sqrt{n} \frac{\bar{h}_n - E_p[h(\theta)]}{\tau} = \sqrt{n_{\text{eff}}} \frac{\bar{h}_n - E_p[h(\theta)]}{\sigma} \xrightarrow{d} N(0, 1) \text{ as } n \rightarrow \infty \quad (79.4)$$

where $\sigma^2 = \text{var}(h(\theta))$ is the variance of the limiting distribution p , $\tau^2 = \sigma^2(1 + 2 \sum_{k=1}^{\infty} \rho_k)$ is the limiting sample variance of the estimate \bar{h}_n , and

$$n_{\text{eff}} = n \left/ \left(1 + 2 \sum_{k=1}^{\infty} \rho_k \right) \right. \quad (79.5)$$

is the inefficiency factor due to autocorrelation in the Markov chain, indicated by $\rho_k = \text{cov}(h(\theta^{(t)}), h(\theta^{(t-k)}))/\sigma^2$. The inefficiency factor n_{eff} is used in practice to measure the “effective” random iid sample size of the MCMC chain by replacing the theoretical autocorrelations, ρ_k , with consistent sample estimates.

Equation (79.3) provides theoretical support for evaluating ergodic averages as estimates, and Eq. (79.4) supports evaluating approximate confidence intervals. Tierney (1994) provides proofs of ergodicity for the Markov chains in common use for MCMC simulation, so that the above results apply. See Gamerman and Lopes (2006) for further discussion.

One further point worth highlighting is the concept of a reversible Markov chain. A chain is said to be reversible if

$$p(x) = \pi(x, y) = p(y)\pi(y, x) \text{ for all } x, y \in S \quad (79.6)$$

where the state space S is the appropriate subset of \mathbb{R}^n representing the support of x, y .

Equation (79.6) is known as the “detailed balance equation” because it equates the rates of moves through states (so balanced) for every possible pair of states (hence detailed). This leads to the key result. If there is a distribution p satisfying the detailed balance equation (79.6), for an irreducible chain, then the chain is positive recurrent and reversible with stationary distribution p . Metropolis et al. (1953) showed that it is then *always* possible to construct a Markov chain with stationary distribution p by finding transition probabilities $\pi(x, y)$

satisfying Eq. (79.6). This provides an algorithm for constructing Markov chains that has weak requirements and so has wide applicability. The above results, in particular, convergence to the limiting distribution, the ergodic theorem, and the central limit theorem all hold for continuous state spaces with only minor technical modifications required (see Gamerman and Lopes 2006).

The above theory provides the means by which sampling from virtually any posterior distribution p can be achieved. The basic Metropolis algorithm is to set p as the limiting distribution of an ergodic Markov chain with transition kernel π . The various algorithms that build on this, in particular Gibbs sampling and Metropolis-Hastings (MH), are concerned with various methods of providing proposal distributions π to be sampled from.

79.4 MCMC Algorithms

The main workhorse MCMC method is Gibbs sampling, which is a special case of the MH algorithm that is very simple to use in practice. The Gibbs sampler requires knowledge of the full conditional distributions (up to an unknown constant) and so is not always usable, but simplifies the task and speeds up MCMC computations when it can be used. The MH algorithm does not require knowledge of the full conditionals and is often used in conjunction with the Gibbs sampler to obtain draws for the unknown parameters for which the full conditionals are not available.

79.4.1 Gibbs Sampling

The Gibbs sampler is an MCMC method that has wide applicability in spatial econometric modeling. Suppose we have a set of k parameter vectors, $\theta_1, \theta_2, \dots, \theta_k$, where each θ_i could be a scalar or a vector of parameter (to be drawn as a block). For example, in a linear regression model $y = X\beta + e$, $e \sim N(0, \sigma^2 I)$, it is convenient to separate the unknown parameters into two blocks, treating the regression coefficients as one $(1 \times k)$ vector, so $\theta_1 = \beta$, and the variance separately as a scalar, $\theta_2 = \sigma^2$.

The Gibbs sampler can be used if we can sample from the full conditionals. The generic Gibbs sampler algorithm is to draw one value for each θ_i from its conditional distribution and cycle through these conditionals repeatedly. For each iteration, $t = 1, 2, \dots, M$, and arbitrary starting values $\theta_2^{(0)}, \theta_3^{(0)}, \dots, \theta_k^{(0)}$, the algorithm is,

- Draw $\theta_1^{(t)}$ from $p(\theta_1^{(t)} | \theta_2^{(t-1)}, \theta_3^{(t-1)}, \dots, \theta_k^{(t-1)}, y)$.
- Draw $\theta_2^{(t)}$ from $p(\theta_2^{(t)} | \theta_1^{(t)}, \theta_3^{(t-1)}, \dots, \theta_k^{(t-1)}, y)$.
- \vdots
- Draw $\theta_k^{(t)}$ from $p(\theta_k^{(t)} | \theta_1^{(t)}, \theta_2^{(t)}, \dots, \theta_{k-1}^{(t)}, y)$.

The above conditional distributions are the transition distributions of a Markov chain that converges (under very general conditions) to a unique stationary target

distribution that is the posterior distribution $p(\theta_i|y)$. In the linear regression example, we typically specify a normal prior distribution for β and an inverted-gamma prior for σ^2 . The Gibbs sampler for this model is then to cycle through the two conditionals, drawing $\beta^{(t)}$ from $N(\beta^{(t)}|\sigma^{2(t-1)}, y)$ and $\sigma^{2(t)}$ from $IG(\sigma^{2(t)}, |\beta^{(t)}, y)$.

The Gibbs sample for each parameter, $\theta_i^{(t)}$, $t = 1, 2, \dots, M$ then approximates a sample from the marginal posterior $p(\theta_i|y)$. This approximation can be made arbitrarily accurate by increasing the sample size, M . Given that it is now computationally inexpensive to obtain tens of thousands of draws on any standard computer for all but the most complex and highly dimensional models, Gibbs sampling is an easy way to draw posterior inferences concerning any unknown quantities in a model.

79.4.2 Metropolis-Hastings (MH)

MH algorithms are a general family of MCMC methods that use simulations from almost any arbitrary density π to actually generate draws from an equally arbitrary given target density p . Further, these algorithms allow for the dependence of π on the previous simulation, so the choice of π does not require a particularly elaborate construction a priori, but can take advantage of the local characteristics of the stationary distribution.

The use of a chain produced by an MCMC algorithm with stationary distribution p is fundamentally identical to the use of an iid sample from p in the sense that the ergodic theorem guarantees the (almost sure) convergence of the empirical average to the posterior expectation:

$$\frac{1}{M} \sum_{t=1}^M h(\theta^{(t)}|y) \xrightarrow{a.s.} E_p[h(\theta|y)]$$

A sequence $\theta^{(t)}$ produced by an MCMC algorithm can thus be employed just as an iid sample. An excellent introduction to Metropolis-Hastings algorithms is provided by Chib and Greenberg (1995).

79.4.2.1 The Metropolis Algorithm

The Metropolis et al. (1953) algorithm is a special case of the MH algorithm which draws from a transition distribution $\pi(\theta^{(t)}|\theta^{(t-1)})$ that must be symmetric, i.e., $\pi(\theta^{(t)}|\theta^{(t-1)}) = \pi(\theta^{(t-1)}|\theta^{(t)})$. This simplifies the algorithm in that the proposed transition distribution does not need to be evaluated at each accept-reject step since it does not appear in α (see below). Starting values, $\theta^{(0)}$, are often simply arbitrarily chosen to represent a draw from a preliminary crude approximate estimate of the posterior distribution, or are drawn from the prior distribution. Several runs of the algorithm using different starting values can be employed to diagnose convergence to the target posterior. Given starting values, for $t = 1, 2, \dots, M$, the algorithm is

- Draw $\theta^{(t)}$ from the transition distribution $\pi(\theta^{(t)}|\theta^{(t-1)})$.
- Calculate

$$\alpha = \frac{p(\theta^{(t)}|y)}{p(\theta^{(t-1)}|y)}$$

- Accept $\theta^{(t)}$ with probability $= \min(\alpha, 1)$, otherwise set $\theta^{(t)} = \theta^{(t-1)}$ (i.e., keep the previous draw).

This last step is accomplished by drawing a uniform random variate r in the $[0,1]$ interval and accepting $\theta^{(t)}$ if $\min(\alpha, 1) \geq r$.

The algorithm requires the ability to calculate the acceptance-rejection ratio α for all $(\theta^{(t)}, \theta^{(t-1)})$ and to draw $\theta^{(t)}$ from the proposal distribution $\pi(\theta^{(t)}|\theta^{(t-1)})$ for all θ and t . To prove that the sequence $\theta^{(t)} = t, 1, 2, \dots$ converges to a sample from the target distribution, we need (a) that the simulated sequence is a Markov chain with a unique stationary distribution and (b) that this stationary distribution equals the target posterior distribution. This holds if the Markov chain is irreducible, aperiodic, and nontransient. Except for trivial exceptions, the distribution is aperiodic and nontransient for a random walk on any proper distribution, and is irreducible if the random walk has a positive probability of eventually reaching any state from any other state (i.e., the transition distribution must be able to eventually visit all possible states with nonzero probability). The acceptance step and definition of α ensures, by construction, that the stationary distribution is the target posterior (see Gelman et al. 2004).

79.4.2.2 Metropolis-Hasting Algorithm

Hastings (1970) developed the MH algorithm as a generalization of the Metropolis algorithm such that the transition distribution is not required to be symmetric. In this case, the acceptance rule becomes

$$\alpha = \frac{p(\theta^{(t)}|y)/\pi(\theta^{(t)}|\theta^{(t-1)})}{p(\theta^{(t-1)}|y)/\pi(\theta^{(t-1)}|\theta^{(t)})}$$

Allowing asymmetric accept-reject rules can be useful in increasing the speed of convergence of the Markov chain. Proof of convergence to a unique stationary distribution is the same as for the Metropolis algorithm. That this stationary distribution is the target distribution follows from the definition of α (see Gelman et al. 2004). The Gibbs sampler can also be shown to be a special case of the MH algorithm with $\alpha = 1$ always, where the transition distribution is selected to be the conditional distribution $p(\theta^{(t)}|\theta^{(t-1)}|y)$.

79.4.3 Choice of Proposal Distribution

A good transition distribution is one for which, for any θ , it is easy to sample from $\pi(\theta^{(t)}|\theta^{(t-1)})$, it is easy to compute α , each accepted iteration moves a reasonable

distance in the parameter space (so that the Markov chain does not move too slowly), and the rejection rate is not too high (so that the chain does not remain in the same place too often). Note that only the ratios $\pi(\theta^{(t)}|\theta^{(t-1)})/\pi(\theta^{(t-1)}|\theta^{(t)})$ and $p(\theta^{(t)}|y)/p(\theta^{(t-1)}|y)$ are required, so we only need the kernels of these distributions.

While there are an infinite variety of possibilities, there are two main methods typically used for selecting the transition distribution. Random walk MH employs a transition distribution centered at the previous draw, so the draws follow a random walk over the support of the posterior. It is the most commonly used method because of its simplicity, its validity in most situations, and it does not require in-depth a priori knowledge of the transition distribution. The main alternative is the independent draw MH, which can be considerably more efficient, but requires a transition distribution that is a close approximation to the target distribution. The MH acceptance step is used to correct the approximation in the independent draw MH, with the goal being to accept as many draws as possible. If the posterior can be approximated fairly accurately with some confidence, then using the independent MH makes a lot of sense. Otherwise, the random walk MH tends to be the default choice.

The random walk MH with a normal transition kernel centered on the current draw, and with covariance matrix $= c^2\hat{\Sigma}$, where $\hat{\Sigma}$ is an approximate estimate of the posterior covariance matrix, has transition matrix

$$\pi(\theta^{(t)}|\theta^{(t-1)}) \sim N(\theta^{(t-1)}, c^2\hat{\Sigma})$$

The algorithm is then

- Start with $\theta^{(0)}$.
- Draw $\theta^{(t)} = \theta^{(t-1)} + \varepsilon$, $\varepsilon \sim N(0, c^2\hat{\Sigma})$.
- Compute $\alpha = \min\{1, p(\theta^{(t)}|y)/p(\theta^{(t-1)}|y)\}$.
- With probability α , accept $\theta^{(t)}$, otherwise set $\theta^{(t)} = \theta^{(t-1)}$.
- Repeat as necessary.

The most efficient choice of the scale term for the normal random walk MH is $c \approx 2.4/\sqrt{k}$, where k is the dimension of θ (the number of parameters). This parameter, c , can be tuned by initial runs of the MH algorithm so that the acceptance rate is between 0.2 and 0.5, with the upper end appropriate in one dimension and the lower end for higher dimensions ($k > 5$), according to Gelman et al. (2004). While this algorithm can be improved in many ways, it has proved effective in many problems even with moderately large $k \lesssim 50$.

The independent draw MH takes the transition distribution to be independent of the current chain, so $\pi(\theta^{(t)}|\theta^{(t-1)}) = \pi(\theta^{(t)})$, and $\theta^{(t)}$ is drawn directly from this distribution, replacing the random walk step in the above algorithm. If $\pi(\theta^{(t)})$ is a good approximation to $p(\theta^{(t)}|y)$, then most draws will be accepted and we obtain a chain with almost no autocorrelation.

79.5 Practical Considerations

In practical application, both MCMC and Bayesian inference involve a number of choices concerning various parameters that must be selected a priori. The need to select prior distributions has, at least in the past, been a conceptual hurdle that slowed the widespread acceptance of Bayesian theory. With regard to MCMC, choice of burn-in sample size, tuning acceptance-rejection rate, length of MCMC chain needed, whether to use one chain or parallel chains, use every subsequent (accepted) draw or only keep every k th draw (and hence choose k), and appropriate choice and monitoring of convergence diagnostics represent only a partial list of the decisions the applied researcher has to make.

Fortunately, most of the anguish over these questions that was present in the 1990s has subsided as a combination of theoretical advances and practical experience provided reasonable answers. Bayesian inference and MCMC techniques have something of a parallel recent history in this regard. Development and extensive use of a widely accepted standard menu of relatively noninformative proper priors, coupled with demonstration of the robustness of posterior inference to reasonable variations in the parameters of these priors, along with many practical examples of their use, has essentially eliminated the controversy over the use of priors and hence Bayesian inference (see, e.g., Gelman et al. 2004). During the same period, appropriate procedures and choices for setting up, fine-tuning, and monitoring MCMC chains have become routine.

The two main practical issues that arise when using MCMC are as follows:

- (i) The early iterations can be misrepresentative of the target distribution since approximate convergence is likely to not have been reached yet; so inclusion of these early iterations will influence the posterior inference. We must therefore be sure to run the simulation algorithm for long enough to be confident that approximate convergence has been achieved and discard the early (burn-in) portion of the sample.
- (ii) The Markov chain can often be correlated. Inference from correlated draws is less precise than from the same number of independent draws because there is less new information in each correlated draw. Correlation in the draws can therefore make the sampling algorithm inefficient if a large number of draws is necessary to achieve a relatively small effective equivalent sample size of independent draws. To monitor this, we view the autocorrelation function (ACF) and calculate the effective sample size, Eq. (79.5).

We outline these procedures and give further references below. Geyer (2011) is an essential reference for anyone using MCMC methods in practice.

79.5.1 Setting Up and Monitoring MCMC Chains

Theoretically at least, many of the apparent problems that were of concern initially have turned out to be easily resolved. There is no theoretical justification for using any burn-in period, using parallel chains instead of just one chain, not using all

subsequent draws, or even for many of the convergence diagnostics originally developed. The short answer to all these issues is that one should simply run one chain for a longer time (number of iterations) to gain more confidence concerning convergence. Geyer (2011) argues that using a single longer chain is the best approach once variations in starting values have been explored. If long burn-in periods are required, or if the chains have very high autocorrelations, using a number of smaller chains may result in each not being long enough to be of any value. Where nonconvergence could be an issue (i.e., nonstandard problems), Geyer recommends at least one run of an MCMC chain overnight – “what better way for your computer to spend its time?” (Geyer 2011, p. 19).

The Gibbs sampler is the simplest of the MCMC algorithms and so is usually employed if sampling from the conditional posterior distributions is possible. If it is not possible to use the Gibbs sampler, the random walk Metropolis algorithm provides a relatively simple way to obtain an MCMC sample since we do not need to evaluate the transition distribution in the acceptance step. The computational power now available to the average user is such that obtaining MCMC sample sizes up to order 10^6 is already a fairly trivial task for many standard models. As a result, efficiency is no longer a real concern in many practical applications. In addition, a few easily implemented diagnostic tools have become standard, mainly:

- (a) Visual inspection of the chain itself (a simple time plot) to observe if the chain appears to have settled into a stationary path
- (b) Inspection of the ACF for the chain to check for excessive time dependence, requiring a larger number of draws (checking the effective sample size of independent draws by viewing the ACF for every k th draw)
- (c) Initially running the chain several times from a diverse set of starting values to check if the chain converges to the same stationary path each time
- (d) Tuning the acceptance rate for any MH steps to be somewhere between about 0.2 and 0.5
- (e) Calculation of numerical standard errors (NSEs) and an estimate of the effective sample size, n_{eff} , from Eq. (79.5)

A number of excellent monographs now exist that cover these issues in far more detail than is possible here. Of particular relevance for spatial modeling are Chib (2008) and, especially, LeSage and Pace (2009).

79.5.2 Other Tools and Post-Sampling Inference

When running an MCMC chain, the number of iterations should never be fixed in advance. Deciding on the length of an MCMC run is a sequential process where the MCMC chains are examined after pilot runs and new simulations (or new samplers) are chosen on the basis of these pilot runs. For many situations, an MCMC sample of 100 independent draws is sufficient for reasonable posterior summaries, so even with a fairly high degree of correlation in the chain, several thousand draws are generally more than sufficient for accurate posterior inference, provided we are

confident that the chain has converged (see Gelman et al. 2004). Further, we can compare sample standard errors with numerical standard errors to ensure the numerical accuracy is adequate, and run the chain for longer if it is not.

Once an MCMC sample is obtained, standard sample estimates of posterior moments and quantiles can be calculated for the unknown quantities directly, e.g., the posterior mean of any function, $h(\theta)$, of the unknown parameter θ , is estimated up to an arbitrary degree of numerical accuracy by

$$\bar{h}(\theta) = \sum_{t=1}^M h(\theta^{(t)})/M$$

The marginal posterior distribution can be examined by viewing histogram plots of the MCMC sample or fitting a smoothed kernel density estimate to the sample frequencies.

A widely used approach that reduces the variance of these estimators, especially useful for quantiles and tail area calculations, is known as Rao-Blackwellization, as it is derived from the application of the Rao-Blackwell Theorem. It can be shown that if the posterior conditional on some other parameter in the model, ϕ , can be evaluated using the MCMC samples for both θ and ϕ , the estimator

$$\bar{h}_{\phi}(\theta) = \sum_{t=1}^M \sum_{j=1}^M h(\theta^{(t)})p(\theta^{(t)}|\phi^{(j)}, y)/M$$

dominates the unconditional sample estimator defined previously, $\bar{h}(\theta)$, in terms of variance (and squared error loss).

79.6 MCMC Inference for the SDM with Marginal Augmentation

For the Student- t SDM, as given by Eq. (79.1), the Gibbs sampler can be slow to converge because of posterior dependence among the variance parameters of σ_{ϵ}^2 and Λ . Paradoxically, adding an additional parameter can improve the speed of convergence of the Markov chain simulation. This marginal augmentation or parameter expansion is a technique developed by Meng and Van Dyk (1999) to improve the rate of convergence of the MCMC algorithm. The idea is to reduce the correlation between draws via a working parameter that is not part of the original observed data model. Unlike conditional augmentation, where the working parameter is fixed at a specific value, marginal augmentation minimizes the augmented information by marginalizing over the working parameter. Note that not introducing a working parameter is, in fact, implicitly conditioning on a specific value. Avoiding this conditioning by modeling and integrating out that working parameter can increase the variability in the augmented data and thus reduces the augmented information. Data augmentation and parameter expansion methods dramatically increase the generality and applicability of this approach.

Focusing on the Student-t SDM defined in Eq. (79.1), convergence can be very slow between the homoskedastic variance σ_ε^2 and the heteroskedastic term Λ . If a posterior draw for σ_ε^2 is close to zero, then the draw for Λ will also be sampled with values near zero, and so on. Following Meng and Van Dyk’s parameter expansion approach, we can reduce the correlation by adding a new working parameter whose only role is to allow the Gibbs sampler to move in more directions and thus improve the convergence. To accomplish this, we rewrite Eq. (79.1) as

$$\begin{aligned}
 y &= \rho Wg + \iota_n \alpha + X\beta + WX\gamma + \frac{\sigma_\varepsilon^2 z}{\sqrt{\Lambda}} \\
 z &\sim N(0, I_N) \\
 \Lambda &\equiv \text{diag}(\lambda_1, \dots, \lambda_n) \\
 \lambda_i &\sim \chi_v^2/v
 \end{aligned}
 \tag{79.7}$$

The expanded model is

$$\begin{aligned}
 y &= \rho Wy + \iota_n \alpha + X\beta + WX\gamma + \frac{\sqrt{\omega}\sigma_\varepsilon^2 z}{\sqrt{q}} \\
 z &\sim N(0, I_N) \\
 q &\equiv \text{diag}(q_1, \dots, q_n) \\
 q_i &\sim \omega \chi_v^2/v
 \end{aligned}
 \tag{79.8}$$

The parameter $\omega > 0$ can be viewed as an additional scale parameter. In this new specification, q plays the role of $\omega\Lambda$. Thus, introducing ω does not alter the model we are fitting.

Note that since $q_i = \omega\lambda_i$, then λ_i corresponds to q_i when $\omega = 1$. We expect marginal augmentation with a working prior independent of $\theta = (\beta, \rho, \sigma_\varepsilon^2)$ to improve the rate of convergence. We choose $p(\omega)$ to be the proper conjugate prior for ω in $p(Y, \lambda|\theta, \omega)$, namely, $\delta \chi_\gamma^{-2}$, where $\delta > 0, \gamma > 0$. As in Meng and van Dyk (1999), we use the standard improper prior $p(\beta, \log \sigma_\varepsilon^2) \propto 1$. Under this prior, Geweke (1993) shows that the posterior mean and standard deviation exist only if the prior $p(v)$ is null in the interval 0–4. We will assume the latter prior to be exponential $p(v) = \exp(-v/v_0)$. The MCMC algorithm for this expanded model has the following steps:

- (a) $q_i | \beta, \sigma_\varepsilon^2, \rho, \omega, Y \sim \frac{\omega}{(y_i - \rho \sum_j w_{ij} y_j - x_i \beta)^2 / \sigma_\varepsilon^2 + v} \chi_{v+1}^2$ independently for $i = 1, \dots, n$.
- (b) $\omega | Y, q \sim \frac{\delta + v \sum_{i=1}^n q_i}{\chi_{\gamma+nv}^2}$.
- (c) $\beta | \sigma_\varepsilon^2, Y, q, \rho, \omega \sim N(c, T)$, where $c = (X'qX)^{-1} X'q(I_n - \rho W)y$ and $T = \omega \sigma_\varepsilon^2 (X'qX)^{-1}$.
- (d) $\sigma_\varepsilon^2, Y, q, \omega \sim \frac{\sum_{i=1}^n q_i (y_i - \rho \sum_j w_{ij} y_j - x_i \beta)^2}{\omega \chi_{n+1}^2}$.

- (e) $\rho|\beta, \sigma_\varepsilon, q \propto |I_n - \rho W| \exp\left\{-\frac{1}{2\sigma_\varepsilon^2} e' q e\right\}$, where $(I_n - \rho W)y - X\beta$.
- (f) $v|y, q \propto \left(\frac{v}{2}\right)^{\frac{Nv}{2}} \Gamma\left(\frac{v}{2}\right)^{-N} \exp(\eta v)$, with $\eta = \frac{1}{v_0} + \frac{1}{2} \sum_{i=1}^N [\ln(q_i^{-1} + q_i)]$.

The first four steps involve Gibbs sampling, but the last two posterior densities are non-standard, and a Metropolis-Hastings step is implemented. A random walk MH algorithm with a normal increment random variable is therefore used for these steps, as described in Sect. 79.4.2.

Given these conditional distributions, we can implement a data augmentation algorithm with marginal augmentation. At iteration $(t + 1)$, we draw $q^{(t+1)}$ from the conditional with marginal augmentation,

$$p(q|\beta, \sigma_\varepsilon^2, \rho, Y) = \int p(q|\mu, \sigma_\varepsilon^2, Y, \omega)p(\omega)d\omega \tag{79.9}$$

The implementation of this marginal augmentation is performed using the following scheme:

- (a) Step 1: Draw ω from its prior $p(\omega)$ and then q from $p(q|\beta, \sigma_\varepsilon^2, Y, \omega)$.
- (b) Step 2: Given q , $(\beta, \sigma_\varepsilon, \rho)$ is generated from $p(\beta, \sigma_\varepsilon, \rho|Y, q) = \int p(\beta, \sigma_\varepsilon, \rho|Y, q)p(\omega|Y, q)d\omega$ by first drawing ω from the posterior $p(\omega|Y, q)$, then drawing $\beta, \sigma_\varepsilon$, and ρ given ω their posterior distributions.

As a comparison, the conditional augmentation approach would fix $\omega = 1$ and ignore its posterior distribution.

A Monte Carlo experiment was conducted to evaluate the performance of the above sampling method and compare the conditional versus the marginal augmented methods. The data generating process is shown in Eq. (79.10).

$$\begin{aligned} y &= \rho Wy + \iota_n \alpha + X\beta + WX\gamma + \frac{\sigma_\varepsilon^2 z}{\sqrt{\Lambda}} \\ z &\sim N(0, I_N) \\ \Lambda &= \text{diag}(\lambda_1, \dots, \lambda_n) \\ \lambda_i &\sim \chi_v^2/v \end{aligned} \tag{79.10}$$

The spatial weight matrix W was generated using random points in conjunction with the MATLAB Delaunay routine to produce a symmetric contiguity weight matrix that is then row-normalized (see Chap. 4 in LeSage and Pace 2009). Explanatory variables x_{it} were generated from zero mean independent normal distributions with a variance of four ($N(0, 4)$). A discussion about the impact of the choice of the hyperparameters δ and γ for the prior distribution of ω can be found in Meng and van Dyk (1999). We set $\gamma = 2$ and $\delta = 0.001$. Table 79.1 presents posterior means, standard deviations, and numerical standard error (NSE) measures of the accuracy associated with estimates based on marginal versus conditional data augmentation steps.

Table 79.1 Monte Carlo simulations for $n = 500$ and 1,000 iterations

Parameter	True value	Marginal DA, $\omega \sim \delta \chi_v^{-2}$			Conditional DA $\omega = 1$		
		Mean	S.D.	NSE	Mean	S.D.	NSE
ρ	0.7	0.6957	0.0086	0.6785	0.6977	0.0046	0.6882
β	1	1.0011	0.0096	0.9820	1.0020	0.0100	0.9820
γ	1	0.9722	0.0266	0.9820	1.0492	0.0352	0.9838
σ_ε^2	1	0.9979	0.7109	0.3096	0.9434	0.7515	0.2782
v	4	4.0224	0.0111	4.0015	4.0456	0.0423	4.0015

The marginal augmentation is less sensitive to the choice of starting value and decreases the numerical standard errors. Conditioning on the working parameter $\omega = 1$, reduces the speed of convergence of the chain. The parameter of σ_ε^2 clearly needs more iterations to be completely independent from the initial iterations under the conditional marginal data augmentation.

79.7 Spatiotemporal Model

In this section, the SDM with heteroskedasticity is extended into a dynamic panel data model that accommodates spatial dependence. A variety of models that control for serial correlation and spatial dependence across locations have been explored (see Lee and Yu 2010; for a complete review). Yu et al. (2008) analyze a specification that allows for both time and spatial dependence as well as a cross-product term reflecting spatial dependence at a one-period time lag. This last term can be interpreted as the spatial diffusion that takes place over time. Parent and LeSage (2012) extend this approach, introducing a space-time filter that can be applied to the dependent variable or the error term. This filter implies a constraint on the mixing term that reflects spatial diffusion or space-time covariance. Parent and LeSage (2012) show that this constraint allows for a number of simplifications in the Bayesian MCMC estimation scheme.

The space-time filter is applied to the following panel data model with random effects and heteroskedastic disturbances across locations:

$$\begin{aligned}
 y_t &= \iota_N \alpha + x_t \beta + W x_t \gamma + \eta_t \quad t = 0, \dots, T \\
 \eta_t &= \mu + \frac{\sigma_\varepsilon^2 z_t}{\sqrt{\Lambda}} \\
 z_t &\sim N(0, I_N) \\
 \Lambda &\equiv \text{diag}(\lambda_1, \dots, \lambda_n) \\
 \lambda_i &\sim \chi_v^2/v
 \end{aligned}
 \tag{79.11}$$

where $y_t = (y_{1t}, \dots, y_{Nt})'$ is the $N \times 1$ vector of observations for the t th time period, ι_N is an $N \times 1$ column vector of ones, x_t denotes the $N \times k$ matrix of non-stochastic regressors and μ is an $N \times 1$ column vector of

random effects, with $\mu_i \sim N(0, \sigma_\mu^2)$. The random error terms $\varepsilon_t = \sigma_\varepsilon^2 z_t / \sqrt{\Lambda}$ are assumed to be independent and identically distributed with zero mean and a variance $\sigma_\varepsilon^2 \Lambda^{-1}$. We make the traditional assumption that μ is uncorrelated with ε_t , and Λ represents the heteroskedastic covariance matrix.

To define the time filter, let C be the Prais-Winsten transformation, where ϕ is the autoregressive time dependence parameter. This filter is defined as:

$$C = \begin{pmatrix} \psi & 0 & \dots & 0 \\ -\phi & 1 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \dots & -\phi & 1 \end{pmatrix} \tag{79.12}$$

Specification of ψ , the (1,1) element in C , depends on whether the first period is modeled or assumed to be known. For simplicity, we will assume the first observations to be known. The space filter is defined as a nonsingular matrix $B = (I_N - \rho W)$, where ρ is a scalar spatial dependence parameter and W is the known $N \times N$ spatial weight matrix as above. The proposed space-time filter then corresponds to the Kronecker product of the matrices C and B ,

$$C \otimes B = I_{N,T+1} - \rho I_{T+1} \otimes W - \phi L \otimes I_N + (\rho \times \phi) L \otimes W \tag{79.13}$$

where L is a $(T + 1) \times (T + 1)$ matrix based on the time-lag operator. This filter implies a restriction that the parameter associated with spatial effects from the previous period ($L \otimes W$) is equal to $-\rho \times \phi$. Parent and LeSage (2012) show that applying this space-time filter to the dependent variable greatly simplifies the estimation procedure when an optimal predictor is used to model the first observation. They also advocate that imposing this constraint would simplify the interpretation of the marginal effects.

We decide to ignore the issues pertaining to prediction of the first period cross section values, and apply the filter to the dependent variable resulting in a model specification

$$\begin{aligned} (C \otimes B)y &= I_{N,T+1}\alpha + x\beta + (I_{T+1} \otimes W)x\gamma + \eta \\ \eta &\sim N(0, \tilde{\Omega}) \end{aligned} \tag{79.14}$$

where $y = (y'_0, \dots, y'_T)'$, $x = (x'_0, \dots, x'_T)'$ and

$$\tilde{\Omega} = \sigma_\mu^2 (J_{T+1} \otimes I_N) + \sigma_\varepsilon^2 I_{T+1} \otimes \Lambda_N^{-1} \tag{79.15}$$

with $J_{T+1} = I_{T+1} I'_{T+1}$.

A number of studies have treated the parameter $\rho \times \phi$ associated with the cross-product term in different ways. Anselin (1988) proposed a related “time-space dynamic model” specification explored by Yu et al. (2008) who relaxed the implied

constraint $\theta = -\rho \times \phi$ and estimated an unrestricted parameter θ . We will start with this general specification and show that the constraint implied by the space-time filter is relevant and makes the model easy to interpret. Since we ignore the first period, the general panel data model specification with random effects for $t = 1, \dots, T$, is given by

$$\begin{aligned} y_t &= \phi y_{t-1} + \rho W y_t + q W y_{t-1} + \iota_N \alpha + x_t \beta + W x_t \gamma + \eta_t \\ \eta_t &= \mu + \varepsilon_t \end{aligned} \tag{79.16}$$

One advantage of the Bayesian MCMC scheme we propose for this specification is that it does not require integration over the random effects that appear in the likelihood. However, integration over these parameters can reduce serial dependence in the MCMC samples of parameters drawn. A formal expression of posterior distributions for this specification can be found in Parent and LeSage (2012). The only difference relies on the heteroskedastic term λ_i that is generated from the following chi-square distribution:

$$\lambda_i | \beta, \sigma_\varepsilon^2, \rho, \omega, Y \sim \frac{\chi_{v+T}^2}{\sigma_\varepsilon^{-2} e_i' e_i + v} \quad i = 1, \dots, n \tag{79.17}$$

where

$e_i = y_i - \phi y_{i,-1} - \rho \sum_{j=1}^N w_{i,j} y_j - \theta \sum_{j=1}^N w_{i,j} y_{j,-1} - \alpha \iota_T - x_i \beta - \sum_{j=1}^N w_{i,j} x_j \gamma$, $y_i = (y_{i, 1}, \dots, y_{i, T})'$ and $y_{i,-1} = (y_{i, 0}, \dots, y_{i, T-1})'$. We also set the hyperparameter $v = 4$, consistent with our prior belief in heteroskedasticity.

79.7.1 Empirical Application

In this empirical illustration, we model and estimate the presence of interregional technological dependence. We rely on a simple model of semi-endogenous growth developed by Jones (2002). This empirical analysis shows that implementing spatial and time dependence conveys important information regarding to what extent innovative activities spill over to neighboring states.

Based on the model described by Jones (2002), we propose a dynamic specification where the stock of knowledge in the neighboring regions has spillover effects on the growth rate of ideas in region i :

$$\frac{\dot{A}_i(t)}{A_i(t)} = \delta L_i(t)^\lambda A_i(t)^{\gamma-1} \prod_{j \neq i} A_j(t)^{\psi w_{ij}} \tag{79.18}$$

According to Eq. (79.18), the number of new ideas produced at any point in time is driven by the number of researchers and the existing stock of ideas in region i as well as in neighboring regions. The parameter λ represents the effect of research on new ideas and allows for the possibility of duplication. For now, we assume $|\gamma| < 1$ and $|\psi| < 1$, but stability conditions are discussed in more detail later. Based on

Parent (2012), we define the connectivity structure W using a measure of both geographical as well as technological proximity. The spatial weight scheme is based on the concept of five nearest neighbors where these five neighbors will receive varying weights based on the measure of technological proximity.

Parent (2012) shows that using the log-linearization of Eq. (79.18) around the vector of steady state growth rates g_A , where $A(t)$ and $L(t)$ are growing at constant rates, corresponds to

$$\frac{\dot{A}_i(t)}{A_i(t)} = g_A(1 - \log(g_A/\delta)) + g_A \left[\lambda \log(L_i(t)) - (1 - \gamma) \log(A_i(t)) + \sum_{(j \neq i)} \psi w_{ij} \log(A_j(t)) \right] \tag{79.19}$$

and we can rewrite Eq. (79.19) as

$$\log(A_i(t + 1)) = \phi \log(A_i(t)) + \sum_{(j \neq i)} \theta w_{ij} \log(A_j(t)) + \alpha + \beta \log(L_i(t)) \tag{79.20}$$

where $\phi = -g_A(1 - \gamma) + 1$, $\theta = g_A\psi$, $\alpha = g_A(1 - \log(g_A/\delta))$ and $\beta = g_A\lambda$.

The parameter θ captures the impact of accessible external ideas on regional innovative activities also called interregional knowledge spillovers. We can add to the econometric specification problems noted by Jones' (2002) omitted variables bias that would arise from excluding $\sum_{(j \neq i)} \theta w_{ij} \log(A_j(t))$ from the model by assuming $\psi = 0$, leading to $\theta = g_A\psi = 0$.

We extend the theoretical framework Eq. (79.20), where the diffusion process is similar to an autoregressive model where spatial interaction occurs with a lag of one period. We introduce the traditional simultaneous spatial lags used in cross-sectional models from the spatial econometrics literature, where the right-hand-side variable takes the form $\sum_{(j \neq i)} \rho w_{ij} \log(A_j(t + 1))$.

The stock of patents per capita for state i at the period t results in the following regression:

$$\begin{aligned} \log(A_{it}) &= \alpha + \sum_{(j \neq i)} \rho w_{ij} \log(A_{j,t}) + \phi \log(A_{i,t-1}) + \sum_{(j \neq i)} \theta w_{ij} \log(A_{j,t-1}) \\ &+ \beta \log(L_{i,t-1}) + \gamma W \log(L_{i,t-1}) + \eta_{it} \\ \eta_{it} &= \mu_i + \varepsilon_{it}. \end{aligned} \tag{79.21}$$

Externalities generated by one region are allowed to influence neighboring regions within the same (annual) time period (the spatial effect), the same region in subsequent periods (the time effect), as well as neighboring regions in subsequent periods (the space-time diffusion effect). This space-time dynamic allows us to compare the relative importance of contemporaneous spatial dependence with time dependence and spatial interaction from the previous periods.

To estimate this model, we must measure the stock of ideas. Observable measures of new ideas at a regional or international level are never perfect. We organize the analysis by focusing on the observed number of US domestic patents, a useful indicator of the state level of realized innovation for a given period. We estimate the knowledge production function using a dataset on patenting activity and its determinants covering the period 1994–2005 and 49 states. (The District of Columbia is treated as a state and the states of Alaska and Hawaii are omitted.) The data include patents granted per capita for each state in each year along with measures of the factor inputs in the production function for ideas/knowledge.

Skilled labor $L_i(t)$ for each state i at time period t is measured using two explanatory variables: $doc_i(t)$, the number of doctoral recipients, and $expRD_i(t)$, total research and development expenditures as a percentage of gross state product. Total R&D expenditures are calculated by adding all sources of funds: industry, public and private nonprofit institutes, and universities.

79.7.2 Estimation Results

Estimation results are presented in [Table 79.2](#), based on a sample of 50,000 draws collected after a burn-in period of 10,000 draws. In the following discussion of the parameter estimates we relied on 5 and 95 percentage points of the highest posterior density intervals (HPDI) to draw inferences regarding whether the posterior means were different from zero.

As explained in LeSage and Pace (2009), low levels of spatial dependence between neighboring regions can over time lead to a significant amount of interconnectivity between regions in the long-run knowledge production process. Ignoring the low levels of observed spatial dependence will have dramatic impacts on the long-run estimates and inference regarding the regional knowledge production and diffusion process.

Traditionally, a positive effect of spatial dependence is interpreted as local spillover effects related to the presence of knowledge stocks in neighboring regions. Parent and LeSage (2008) make the point (in the context of European regions) that positive spatial dependence of this type may arise when regions possess the ability to absorb and to adopt new technologies of their neighbors. Further, R&D activities can increase the incidence of technology diffusion by enhancing a region's absorptive capacity. Positive spatial dependence found here using the space-time model leads to an inference that R&D expenditures will directly increase the level of innovation occurring in a region over time.

In fact, as explained by Debarsy, Ertur, and LeSage (2012), a change to explanatory variable r at time t will have direct and indirect impacts on the own- and other-region-dependent variable values at time t , as well as impacts on both own and other regions in future time periods. This diffusion over space as time passes arises when the model includes nonzero time dependence captured by the parameter ϕ .

Turning to the restriction implied by the space-time filter $\theta = -\rho \times \phi$, estimation results presented in [Table 79.2](#) reveal that this restriction is consistent with the

Table 79.2 Estimation results

Parameter	Post. mean	S.D.	Lower 0.05	Upper 0.95
<i>Constant</i>	0.2949	0.1403	0.0949	0.5444
<i>doc</i>	0.0028	0.0130	-0.0161	0.0274
<i>expRD</i>	0.0602	0.0256	0.0214	0.1046
<i>W doc</i>	-0.0260	0.0168	-0.0587	0.0006
<i>W expRD</i>	-0.0354	0.0268	-0.0825	0.0040
ρ	0.4157	0.0353	0.3607	0.4807
ϕ	0.9152	0.0632	0.7320	0.9657
θ	-0.3798	0.0413	-0.4477	-0.2999
σ_{μ}^{-2}	0.0102	0.0113	0.0012	0.0354
σ_e^{-2}	0.0145	0.0013	0.0125	0.0168

data for both specifications. The partial derivatives for this situation are shown in Eq. (79.22) for the case where we change the explanatory variable $x_t^{(r)}$ at time period 1, and measure the impacts at a one- through t -period horizon. Since the estimation results confirm the time-separability constraint $\theta = -\rho \times \phi$, the partial derivative can be rewritten as

$$\frac{\partial y_t}{\partial x_1^{(r)}} = (\phi^{t-1} + \phi^{t-2} + \dots + \phi + 1)B^{-1}(I_N\beta_r + W\gamma_r) \quad (79.22)$$

This greatly simplifies interpretability of the dynamic responses for any number of time periods. Given estimates for the parameters β_r , ρ , and ϕ , we can easily calculate dynamic responses for any number of time periods. In fact, the diffusion over time and space takes the form of time discounting based on the time dependence parameter ϕ of the contemporaneous spatial effects captured by the $N \times N$ matrix B^{-1} .

Table 79.2 shows scalar summary measures of the effects estimates for spatial dependence ($\rho = 0.42$) that is relatively weaker than time dependence $\phi = 0.92$, which leads to larger time and space-time diffusion effects relative to the spatial effects. Based on the stationary conditions defined by Parent and LeSage (2012), the process is stationary since $\phi + \rho + \theta < 1$ and $\phi - (\rho - \theta) > -1$.

Table 79.3 reports cumulative spatial effects decomposed into direct, indirect, and total effects. The direct effects correspond to own-partial derivatives that measure the impact on region i from changes in the explanatory variable value of region i . However, these include some feedback impacts discussed in LeSage and Pace (2009), since changes in region i influence the neighbors and region i is in turn influenced by its neighbors. The indirect effects are cumulated over neighboring spatial regions and correspond to the cross-partial derivatives, and the final column shows the total effects which is the sum of the direct and indirect effects. In our model, the spatial effects are separable from the time effects, and these do not change over time since the spatial configuration of the regions remains the same and

Table 79.3 Scalar summary estimates of the R&D effects

	Lower 0.05	Median expRD	Upper 0.95
Spatial effects			
Direct	0.0225	0.0632	0.1099
Indirect	0.0141	0.0398	0.0692
Total effects	0.0366	0.1030	0.1790
Cumulative effects			
Direct	0.1812	0.5096	0.8855
Indirect	0.1140	0.3208	0.5574
Total effects	0.2952	0.8304	1.4429

we restrict the spatial dependence parameter to be fixed over all time periods. The differences between the cumulative total effects and the spatial effects reflect the importance of the time effects. In the case of R&D expenditures, we see a 0.5096 direct cumulative effect value and a direct spatial effect of 0.0632, so the difference of 0.4464 represents cumulative direct time effects (which we calculated over a 14-year horizon). In comparison with the coefficient estimate of 0.0602 from [Table 79.2](#) for this variable, the direct effects estimate reported in [Table 79.3](#) includes a feedback loop that arises in our space-time dynamic panel model.

Consistent with the ideas-based growth literature, the results suggest that the level of innovation is positively influenced by the level of effort devoted to the ideas sector. Expenditures on R&D have a more permanent impact on the growth process if a highly skilled labor force eases the adoption of new technologies. Of course, this is consistent with the observation that regions with advanced levels of technology often have strong links with education, especially at the doctoral level. Thus, more education should lead to higher rates of technological progress via improvements in labor force quality. However for both models, the effect of the variable *LDoc* is not statistically significant.

As shown in Parent (2012), these results confirm that interactions between regions are spatially limited and localized spillovers effects can lead to regional clusters with persistently different levels of innovative activity.

79.8 Conclusion

This chapter shows how the Bayesian approach provides a complete inferential toolkit for a variety of cross-sectional and panel data spatial models. Bayesian methods have recently produced some remarkably efficient solutions to complex inference problems. The approach is based on a combination of hierarchical prior modeling and MCMC simulation methods. Interestingly, this approach is able to tackle estimation and model interpretation in situations that are quite challenging by other means.

Marginal data augmentation improves the convergence properties of the MCMC sampler. This method expands the parameter space with a working parameter that is only identifiable given the augmented data. Placing a prior distribution directly on the identifiable parameters results in enormous computational gain. This prior specification can make the model easier to estimate and interpret in many complex cases like multivariate and multinomial discrete choice models.

While this chapter is necessarily too brief to provide a self-contained guide, hopefully it sheds enough light on the main conceptual issues to demonstrate that using Bayesian MCMC inferential tools allows for broad generality in model specification, and is relatively simple to use in practice. The growth of Bayesian MCMC spatial econometric methods continues at a rapid pace as the Bayesian approach becomes more widely understood and as software and computing power become more readily available.

Abstract

The chapter discusses generalized method of moments (GMM) estimation methods for spatial models. Much of the discussion is on GMM estimation of Cliff-Ord-type models where spatial interactions are modeled in terms of spatial lags. The chapter also discusses recent developments on GMM estimation from data processes which are spatially α -mixing.

I.R. Prucha

80.1 Introduction

Spatial econometric models have a long history. Paelink and Klaassen (1979) may arguably be viewed as the first comprehensive volume covering spatial econometrics. Anselin (2010) provides a recent review of the development of the field of spatial econometrics over the last thirty years. Important texts include Anselin (1988), Arbia (2006), Cliff and Ord (1973, 1981), Cressie (1993), Haining (2003), and LeSage and Pace (2009).

Spatial models provide a formal expression of Tobler's (1970) first law of geography stating that "Everything is related to everything else, but near things are more related to each other." An important aspect of spatial econometrics is the focus on the explicit modeling and empirical estimation of pathways of spatial interactions. That is, an important aspect is the focus on exploring the structure of spatial interactions and not just on accounting for cross-sectional correlation in the computation of standard errors for parameter estimators.

Much of the spatial econometrics literature has focused on cross-sectional data or panel data where the time dimension is small. A reason is that in situations where the time dimension, say T , is large relative to the cross-sectional dimension, say n , we can often simply employ classical methods for the estimation of simultaneous time series models to estimate general forms of spatial interactions. If the time dimension T is one or small, estimation will only be possible if we impose some parsimonious structure on the form of spatial interactions.

The development of a formal theory of estimation of spatial models has lagged behind corresponding developments for inference from time series data. A formal theory of inference requires the use of limit theorems, such as laws of large numbers and central limit theorems. In a time series setting, there is a natural ordering of the data which can be exploited in deriving such limit theorems. In a spatial setting, there is no natural ordering of the data, which made the development of such limit theorems more challenging.

Arguably the most widely used class of spatial models consists of variants of the ones considered in Cliff and Ord (1973, 1981). In these models spatial interactions are modeled in terms of spatial lags, i.e., in terms of weighted averages of observations from neighboring units, where the weights are typically modeled as inversely related to some measure of distance. Historically, Cliff-Ord-type models have been estimated by maximum likelihood (ML) methods. (See Pace, ► Chap. 78, "Maximum Likelihood Estimation", as well as Mills and Parent, ► Chap. 79, "Bayesian MCMC Estimation".) However, one of the difficulties with ML is that the likelihood depends on the determinant of an $n \times n$ matrix, which limits its application to small and medium sample sizes due to the computational burden (unless the problem is sparse, special structure is available, etc.). Another issue was the lack of formal results concerning its asymptotic properties. In light of this, Kelejian and Prucha (1998, 1999) suggested a generalized method of moments (GMM) estimator for a spatial-autoregressive model with autoregressive

disturbances and established basic asymptotic properties for the estimator.¹ Conley (1999) considered GMM estimation within the context of α -mixing spatial processes and developed an asymptotic theory within this context.

Since those early contributions, there has been a growing literature on GMM estimation for spatially dependent data. The aim of this chapter is to provide some guidance through that literature and to provide some insights into the subtle differences in asymptotic results. Basic reasons for these differences can be found in the moment conditions employed by respective GMM estimators and whether or not an estimator is a one-step or a two-step estimator.

Owing to space limitations, the literature cited in this chapter is incomplete, and not all contributions and extensions of interest are covered. Also, the focus of this chapter is solely on GMM estimation. It does not cover maximum likelihood estimation or testing procedures (apart from Wald tests that can be constructed in the usual way based on results for the asymptotic distribution of GMM estimators). Also, the chapter does not cover inference for processes where cross-sectional dependence is implied by common factors.

Finally, while spatial models have a long history in geography and regional science, space is not limited to geographic space. Spatial models may more generally be viewed as a class of cross-sectional interaction models, with applications ranging from growth convergence among regions to social interactions between agents.

Section 80.2 of the chapter contains a brief and intuitive primer on GMM estimation to provide some background. Readers familiar with GMM estimation may wish to skip this section. Section 80.3 considers GMM estimation of models with spatial lags, and Sect. 80.4 considers GMM estimation for a general class of spatially mixing processes.

80.2 A Primer on GMM Estimation

80.2.1 Model Specification and Moment Conditions

Suppose the data are generated from a model

$$f(y_{in}, z_{in}, \theta_0) = u_{in}, \quad i = 1, \dots, n \quad (80.1)$$

where y_{in} denotes the dependent variable corresponding to unit i , z_{in} is a vector of explanatory variables, u_{in} is a disturbance term, θ_0 is the $K \times 1$ unknown parameter vector, and $f(\cdot)$ is a known function. The above formulation is fairly general and contains typical Cliff and Ord (1973) spatial models – possibly after some

¹Lee (2004) gives, to the best of our knowledge, first formal results for the maximum likelihood estimator of a spatial-autoregressive model. The maintained assumptions are similar to those introduced in Kelejian and Prucha (1998, 1999).

transformation to remove correlation in the disturbance term – as a special case. Additionally assume the availability of a $1 \times P$ vector of instruments h_{in} and let w_{in} be the vector of all observable variables, including instruments, pertaining to the i th unit. For simplicity of presentation, we assume in the following that the disturbances are i.i.d. $(0, \sigma^2)$ and that the instruments are non-stochastic while noting that both assumptions can be relaxed.

We also note that in allowing for the variables to depend on the sample size, we accommodate spatial lags. As an example, the explanatory variables could be of the form $z_{in} = [x_i, \bar{x}_{in}, \bar{y}_{in}]$ where x_i is some exogenous explanatory variable, and $\bar{x}_{in} = \sum_j m_{ij}x_j$ and $\bar{y}_{in} = \sum_j m_{ij}y_{jn}$ are spatial lags (where the m_{ij} denote spatial weights with $m_{ii} = 0$). However, to simplify notation for this primer, we will suppress the index n in the following.

Now suppose that we have a $S \times 1$ vector of sample moments

$$\mathbf{q}_n(\theta) = \mathbf{q}_n(w_1, \dots, w_n, \theta) = \begin{bmatrix} q_{1,n}(w_1, \dots, w_n, \theta) \\ \vdots \\ q_{S,n}(w_1, \dots, w_n, \theta) \end{bmatrix} \tag{80.2}$$

with $S \geq K$, and suppose that

$$E\mathbf{q}_n(w_1, \dots, w_n, \theta) = 0 \quad \text{if and only if} \quad \theta = \theta_0 \tag{80.3}$$

The basic idea underlying the GMM methodology is to estimate θ_0 by, say, $\tilde{\theta}_n$ such that $\mathbf{q}_n(w_1, \dots, w_n, \tilde{\theta}_n)$ is “close to zero” in the sense that a quadratic form of the sample moment vector is close to zero. More specifically, let \mathbf{Y}_n be some $S \times S$ symmetric positive semidefinite weighting matrix, then the corresponding GMM estimator is defined as

$$\tilde{\theta}_n = \arg \min_{\theta} \{ \mathbf{q}_n(w_1, \dots, w_n, \theta)' \mathbf{Y}_n \mathbf{q}_n(w_1, \dots, w_n, \theta) \} \tag{80.4}$$

A special case arises if the number of moments equals the number of unknown parameters, i.e., if $S = K$. In this case $\tilde{\theta}_n$ can typically be found as a solution to the moment condition, i.e., $\mathbf{q}_n(w_1, \dots, w_n, \tilde{\theta}_n) = 0$. Of course, in this case the weighting matrix \mathbf{Y}_n becomes irrelevant.

The classical GMM literature exploits “linear” moment conditions of the form

$$E \left\{ n^{-1} \sum_{i=1}^n h'_{ip} u_i \right\} = 0 \tag{80.5}$$

which clearly holds since $Eh'_{ip}u_i = h'_{ip}Eu_i = 0$ under the maintained assumptions. The spatial literature frequently also considers “quadratic” moment conditions. Let $A_q = (a_{ijq})$ be some $n \times n$ matrix with $tr(A_q) = 0$, and assume for ease of

exposition that A_q is non-stochastic. Then the quadratic moment conditions considered in the spatial literature are of the form

$$E \left\{ n^{-1} \sum_{i=1}^n \sum_{j=1}^n a_{ijq} u_i u_j \right\} = 0 \tag{80.6}$$

which clearly holds under maintained assumptions.²

Depending on the functional form of $f(\cdot)$, the number of moment conditions, the number of parameters, etc., the computation of the GMM estimator $\hat{\theta}_n$ defined by Eq. (80.4) may be numerically challenging. Now let $\theta_0 = [\rho'_0, \delta'_0]'$ and suppose the sample moment vector in Eq. (80.2) can be decomposed into

$$\mathbf{q}_n(w_1, \dots, w_n, \theta) = \begin{bmatrix} \mathbf{q}_n^\rho(w_1, \dots, w_n, \rho, \delta) \\ \mathbf{q}_n^\delta(w_1, \dots, w_n, \rho, \delta) \end{bmatrix} \tag{80.7}$$

such that

$$E\mathbf{q}_n^\rho(w_1, \dots, w_n, \rho, \delta_0) = 0 \quad \text{if and only if} \quad \rho = \rho_0 \tag{80.8}$$

$$E\mathbf{q}_n^\delta(w_1, \dots, w_n, \rho_0, \delta) = 0 \quad \text{if and only if} \quad \delta = \delta_0 \tag{80.9}$$

and that some easily computable initial estimator, say $\check{\delta}_n$, for δ_0 is available. In this case we may consider the following GMM estimator for ρ_0 corresponding to some weighting matrix $\mathbf{Y}_n^{\rho\rho}$:

$$\hat{\rho}_n = \arg \min_{\rho} \left\{ \mathbf{q}_n^\rho(w_1, \dots, w_n, \rho, \check{\delta}_n)' \mathbf{Y}_n^{\rho\rho} \mathbf{q}_n^\rho(w_1, \dots, w_n, \rho, \check{\delta}_n) \right\} \tag{80.10}$$

Of course, utilizing $\hat{\rho}_n$ we may further consider the following GMM estimator for δ_0 corresponding to some weight matrix $\mathbf{Y}_n^{\delta\delta}$:

$$\hat{\delta}_n = \arg \min_{\delta} \left\{ \mathbf{q}_n^\delta(w_1, \dots, w_n, \hat{\rho}_n, \delta)' \mathbf{Y}_n^{\delta\delta} \mathbf{q}_n^\delta(w_1, \dots, w_n, \hat{\rho}_n, \delta) \right\} \tag{80.11}$$

GMM estimators like $\hat{\theta}_n$ in Eq. (80.4) are often referred to as one-step estimators. Estimators like $\hat{\rho}_n$ and $\hat{\delta}_n$ in Eqs. (80.10) and (80.11) above, where the sample moments depend on some initial estimator, are often referred to as two-step estimators.

Given the moment conditions are valid, we would expect the most efficient one-step estimator to be more efficient than the most efficient two-step estimators. However, as

²Let $u = [u_1, \dots, u_n]'$, then the above moment condition can be rewritten as $E[n^{-1}u'A_qu] = \text{tr}[n^{-1}A_qEuu'] = n^{-1}\sigma^2\text{tr}(A_q) = 0$, since under the maintained assumptions $Euu' = \sigma^2I_n$.

usual, there are trade-offs. One trade-off is in terms of computation. As remarked previously, for small sample sizes ML is available as an alternative to GMM. For large sample sizes, statistical efficiency may be less important than computational efficiency and feasibility, and thus the use of two-step GMM estimators may be attractive. Also, Monte Carlo studies suggest that in many situations, the loss of efficiency may be relatively small. Another trade-off is that the misspecification of one moment condition will typically result in inconsistent estimates of all model parameters.

In the following we provide some basic results for the limiting distribution of one-step and two-step GMM estimators as background for our discussion of specific GMM estimators for respective spatial models.

80.2.2 One-Step GMM Estimation

The usual approach to deriving the limiting distribution of GMM estimators is to manipulate the score of the objective function by expanding the sample moment vector around the true parameter, using a Taylor expansion. Applying this approach to Eq. (80.4), and assuming that typical regularity conditions hold, yields

$$n^{1/2}(\hat{\theta}_n - \theta_0) = -[\mathbf{G}'\mathbf{Y}\mathbf{G}]^{-1}\mathbf{G}'\mathbf{Y}\left[n^{1/2}\mathbf{q}_n(\theta_0)\right] + o_p(1) \quad (80.12)$$

with $\mathbf{G} = p \lim_{n \rightarrow \infty} \partial \mathbf{q}_n(\theta_0) / \partial \theta$ and $\mathbf{Y} = p \lim_{n \rightarrow \infty} \mathbf{Y}_n$. Now suppose for a moment that it can be shown that

$$n^{1/2}\mathbf{q}_n(\theta_0) \xrightarrow{d} N(0, \Psi) \quad (80.13)$$

where Ψ is some positive definite matrix. Then

$$n^{1/2}(\hat{\theta}_n - \theta_0) \xrightarrow{d} N[0, \Phi] \quad (80.14)$$

with

$$\Phi = [\mathbf{G}'\mathbf{Y}\mathbf{G}]^{-1}\mathbf{G}'\mathbf{Y}\Psi\mathbf{Y}\mathbf{G}[\mathbf{G}'\mathbf{Y}\mathbf{G}]^{-1}$$

From this it is seen that if we choose $\mathbf{Y}_n = \hat{\Psi}_n^{-1}$ where $\Psi = p \lim_{n \rightarrow \infty} \hat{\Psi}_n$, the variance-covariance simplifies to

$$\Phi = [\mathbf{G}'\Psi^{-1}\mathbf{G}]^{-1}$$

Since $[\mathbf{G}'\mathbf{Y}\mathbf{G}]^{-1}\mathbf{G}'\mathbf{Y}\Psi\mathbf{Y}\mathbf{G}[\mathbf{G}'\mathbf{Y}\mathbf{G}]^{-1} - [\mathbf{G}'\Psi^{-1}\mathbf{G}]^{-1}$ is positive semidefinite, it follows that using for the weighting matrix \mathbf{Y}_n , a consistent estimator of the inverse of the limiting variance-covariance matrix Ψ of the sample moment vector yields the efficient GMM estimator.

As remarked above, for spatial estimators the sample moment vector will typically be composed of linear and quadratic moment conditions of the form given in Eqs. (80.4) and (80.5). Thus, in order to establish Eq. (80.13), we need a central limit theorem (CLT) for linear quadratic forms. Kelejian and Prucha (2001) introduced such a theorem for a single linear quadratic form under assumptions useful for spatial models. The generalization to vectors of linear quadratic forms is given in Kelejian and Prucha (2010). To provide some insight into the expressions for the asymptotic variance-covariance matrix Ψ associated with the sample moment vector underlying the spatial GMM estimators below, we next give a version of that CLT.

Theorem 1

For $r = 1, \dots, m$ let $A_{r,n} = (a_{ijr})_{i,j=1,\dots,n}$ be a $n \times n$ non-stochastic symmetric real matrix with $\sup_{1 \leq j \leq n, n \geq 1} \sum_{i=1}^n |a_{ijr}| < \infty$, and let $a_r = (a_{1r}, \dots, a_{nr})'$ be a $n \times 1$ non-stochastic real vector with $\sup_n n^{-1} \sum_{i=1}^n |a_{ir}|^{\delta_1} < \infty$ for some $\delta_1 > 2$. Let $\varepsilon = (\varepsilon_1, \dots, \varepsilon_n)'$ be a $n \times 1$ random vector with the ε_i distributed totally independent with $E\varepsilon_i = 0$, $E\varepsilon_i^2 = \sigma_i^2$, and $\sup_{1 \leq i \leq n, n \geq 1} E|\varepsilon_i|^{\delta_2} < \infty$ for some $\delta_2 > 4$. Consider the $m \times 1$ vector of linear quadratic forms $V_n = [Q_{1n}, \dots, Q_{mn}]'$ with

$$Q_{rn} = \varepsilon' A_r \varepsilon + a_r' \varepsilon = \sum_{i=1}^n \sum_{j=1}^n a_{ijr} \varepsilon_i \varepsilon_j + \sum_{i=1}^n a_{ir} \varepsilon_i$$

Let $\mu_{V_n} = EV_n = [\mu_{Q_1}, \dots, \mu_{Q_m}]'$ and $\Sigma_{V_n} = [\sigma_{Q_{rs}}]_{r,s=1,\dots,m}$ denote the mean and VC matrix of V_n , respectively, then

$$\begin{aligned} \mu_{Q_r} &= \sum_{i=1}^n a_{iir} \sigma_i^2 \\ \sigma_{Q_{rs}} &= 2 \sum_{i=1}^n \sum_{j=1}^n a_{ijr} a_{ijs} \sigma_i^2 \sigma_j^2 + \sum_{i=1}^n a_{ir} a_{is} \sigma_i^2 \\ &\quad + \sum_{i=1}^n a_{iir} a_{iis} [\mu_i^{(4)} - 3\sigma_i^4] + \sum_{i=1}^n (a_{ir} a_{iis} + a_{is} a_{iir}) \mu_i^{(3)} \end{aligned}$$

with $\mu_i^{(3)} = E\varepsilon_i^3$ and $\mu_i^{(4)} = E\varepsilon_i^4$. Furthermore, given that $n^{-1} \lambda_{\min}(\Sigma_{V_n}) \geq c$ for some $c > 0$, then

and thus,

$$\Sigma_{V_n}^{-1/2} (V_n - \mu_{V_n}) \xrightarrow{d} N(0, I_m)$$

$$n^{-1/2} (V_n - \mu_{V_n}) \sim AN(0, n^{-1} \Sigma_{V_n})$$

Remark

Note that the mean μ_{Q_r} of Q_{rn} is zero if $a_{iir} = 0$; if the ε_i are homoskedastic, i.e., $\sigma_i^2 = \sigma^2$, then $tr(A_r) = \sum_{i=1}^n a_{iir} = 0$ suffices for the mean to be zero. Next, note that the first two terms in the expression for the covariance $\sigma_{Q_{rs}}$ between Q_{rn} and Q_{sn} can be written more compactly as $2tr(A_r \Sigma A_s \Sigma) + a'_r \Sigma a_s$ with $\Sigma = diag(\sigma_i^2)$. Also note that if $a_{iir} = a_{iis} = 0$, then the last two terms drop out from the expression for covariance. Observe further that under normality, the last two terms are always equal to zero.

80.2.3 Two-Step GMM Estimation

The derivation of the limiting distribution two-step of GMM estimators is a bit more delicate. The usual approach to deriving the limiting distribution of two-step GMM estimators is to manipulate the score of the objective function by expanding the sample moment vector around the true parameter, using a Taylor expansion. Consider in particular the two-step GMM estimators for ρ_0 defined in Eq. (80.10). Applying this approach, and assuming typical regularity conditions, yields

$$\begin{aligned} & n^{1/2}(\hat{\rho}_n - \rho_0) \\ &= -[(\mathbf{G}^{\rho\rho})' \mathbf{Y}^{\rho\rho} \mathbf{G}^{\rho\rho}]^{-1} (\mathbf{G}^{\rho\rho})' \mathbf{Y}^{\rho\rho} \left[n^{1/2} \mathbf{q}_n^\rho(\rho_0, \delta_0) + \mathbf{G}^{\rho\delta} n^{1/2}(\check{\delta}_n - \delta_0) \right] + o_p(1) \end{aligned} \tag{80.15}$$

where $\mathbf{G}^{\rho\rho} = p \lim_{n \rightarrow \infty} \partial \mathbf{q}_n^\rho(\rho_0, \delta_0) / \partial \rho$, $\mathbf{G}^{\rho\delta} = p \lim_{n \rightarrow \infty} \partial \mathbf{q}_n^\rho(\rho_0, \delta_0) / \partial \delta$, and $\mathbf{Y}^{\rho\rho} = p \lim_{n \rightarrow \infty} \mathbf{Y}_n^{\rho\rho}$. From Eq. (80.1) we see that in general the limiting distribution of $\hat{\rho}_n$ will depend on the limiting distribution of $\check{\delta}_n$, unless $\mathbf{G}^{\rho\delta} = 0$, in which case we refer to $\check{\delta}_n$ as a nuisance parameter. It turns out that if ρ_0 denotes the spatial-autoregressive parameters in the disturbance process and δ_0 the vector of regression parameters, then for typical estimators $\mathbf{G}^{\rho\delta} \neq 0$. In many cases the estimator $\check{\delta}_n$ will be asymptotically linear in the sense that

$$n^{1/2}(\check{\delta}_n - \delta_0) = n^{-1/2} \mathbf{T}'_n \mathbf{u}_n + o_p(1) \tag{80.16}$$

where \mathbf{T}_n is a non-stochastic $n \times k_\delta$ matrix, where k_δ is the dimension of δ_0 , and where $\mathbf{u}_n = (u_1, \dots, u_n)'$. Now define

$$\mathbf{q}_{*n}^\rho(\rho_0, \delta_0) = \mathbf{q}_n^\rho(\rho_0, \delta_0) + n^{-1} \mathbf{G}^{\rho\delta} \mathbf{T}'_n \mathbf{u}_n \tag{80.17}$$

then Eq. (80.15) can be rewritten as

$$n^{1/2}(\hat{\rho}_n - \rho_0) = -[(\mathbf{G}^{\rho\rho})' \mathbf{Y}^{\rho\rho} \mathbf{G}^{\rho\rho}]^{-1} (\mathbf{G}^{\rho\rho})' \mathbf{Y}^{\rho\rho} \left[n^{1/2} \mathbf{q}_{*n}^{\rho}(\rho_0, \delta_0) \right] + o_p(1) \quad (80.18)$$

Now suppose that

$$n^{1/2} \mathbf{q}_{*n}^{\rho}(\rho_0, \delta_0) \xrightarrow{d} N(0, \mathbf{\Psi}_*^{\rho\rho}) \quad (80.19)$$

where $\mathbf{\Psi}_*^{\rho\rho}$ is some positive definite matrix. Then

$$n^{1/2}(\hat{\rho}_n - \rho_0) \xrightarrow{d} N[0, \mathbf{\Phi}_*^{\rho\rho}] \quad (80.20)$$

with

$$\mathbf{\Phi}_*^{\rho\rho} = [(\mathbf{G}^{\rho\rho})' \mathbf{Y}^{\rho\rho} \mathbf{G}^{\rho\rho}]^{-1} (\mathbf{G}^{\rho\rho})' \mathbf{Y}^{\rho\rho} \mathbf{\Psi}_*^{\rho\rho} \mathbf{Y}^{\rho\rho} \mathbf{G}^{\rho\rho} [(\mathbf{G}^{\rho\rho})' \mathbf{Y}^{\rho\rho} \mathbf{G}^{\rho\rho}]^{-1}$$

From this it is seen that if we choose $\mathbf{Y}_n^{\rho\rho} = \left(\tilde{\Psi}_{*n}^{\rho\rho} \right)^{-1}$ where $\mathbf{\Psi}_*^{\rho\rho} = p \lim_{n \rightarrow \infty} \tilde{\Psi}_{*n}^{\rho\rho}$, then variance-covariance simplifies to

$$\mathbf{\Phi}_*^{\rho\rho} = [(\mathbf{G}^{\rho\rho})' (\mathbf{\Psi}_*^{\rho\rho})^{-1} \mathbf{G}^{\rho\rho}]^{-1}$$

Therefore, using for the weighting matrix $\mathbf{Y}_n^{\rho\rho}$, a consistent estimator for the inverse of the limiting variance-covariance matrix $\mathbf{\Psi}_*^{\rho\rho}$ yields the efficient two-step GMM estimator.

Suppose Eq. (80.13) holds and

$$\mathbf{\Psi} = \begin{bmatrix} \mathbf{\Psi}^{\rho\rho} & \mathbf{\Psi}^{\rho\delta} \\ \mathbf{\Psi}^{\delta\rho} & \mathbf{\Psi}^{\delta\delta} \end{bmatrix}$$

then the limiting distribution of the sample moment vector $\mathbf{q}_n^{\rho}(\rho_0, \delta_0)$ evaluated at the true parameter values is given by

$$n^{1/2} \mathbf{q}_n^{\rho}(\rho_0, \delta_0) \xrightarrow{d} N(0, \mathbf{\Psi}^{\rho\rho}) \quad (80.21)$$

It is important to note that in light of Eq. (80.17) in general $\mathbf{\Psi}_*^{\rho\rho} \neq \mathbf{\Psi}^{\rho\rho}$, unless $\mathbf{G}^{\rho\delta} = 0$, and that in general $\mathbf{\Psi}_*^{\rho\rho}$ will depend on \mathbf{T}_n , which in turn will depend on the employed estimator $\hat{\delta}_n$. In other words, unless $\mathbf{G}^{\rho\delta} = 0$, for a two-step GMM estimator, we cannot simply use the variance-covariance matrix $\mathbf{\Psi}^{\rho\rho}$ of the sample moment vector $\mathbf{q}_n^{\rho}(\rho_0, \delta_0)$, rather we need to work with the variance-covariance matrix $\mathbf{\Psi}_*^{\rho\rho}$.

We next illustrate the difference between $\Psi^{\rho\rho} = (\psi_{rs}^{\rho\rho})$ and $\Psi_{*}^{\rho\rho} = (\psi_{*rs}^{\rho\rho})$ for the important special case where the moment conditions are quadratic and u_i is i.i.d. $N(0, \sigma^2)$. For simplicity assume that

$$\mathbf{q}_n^{\rho}(\rho_0, \delta_0) = n^{-1} \begin{bmatrix} \sum_{i=1}^n \sum_{j=1}^n a_{ij1} u_i u_j \\ \sum_{i=1}^n \sum_{j=1}^n a_{ij2} u_i u_j \end{bmatrix}$$

Now, for $r = 1, 2$, let a_{ir} denote the (i, r) -th element of $\mathbf{G}^{\rho\delta} \mathbf{T}'_n$, then by Eq. (80.17)

$$\mathbf{q}_{*n}^{\rho}(\rho_0, \delta_0) = n^{-1} \begin{bmatrix} \sum_{i=1}^n \sum_{j=1}^n a_{ij1} u_i u_j + \sum_{i=1}^n a_{i1} u_i \\ \sum_{i=1}^n \sum_{j=1}^n a_{ij2} u_i u_j + \sum_{i=1}^n a_{i2} u_i \end{bmatrix}$$

It then follows from Theorem 1 that

$$\psi_{rs}^{\rho\rho} = 2\sigma^4 \sum_{i=1}^n \sum_{j=1}^n a_{ijr} a_{ijs}$$

but

$$\psi_{*rs}^{\rho\rho} = 2\sigma^4 \sum_{i=1}^n \sum_{j=1}^n a_{ijr} a_{ijs} + \sigma^2 \sum_{i=1}^n a_{ir} a_{is}$$

We emphasize that the a_{ir} and a_{is} in the last sum on the r.h.s. for the expression for $\psi_{*rs}^{\rho\rho}$ depend on what estimator $\hat{\delta}_n$ is employed in the sample moment vector $\mathbf{q}_n^{\rho}(\rho, \hat{\delta}_n)$ used to form the objective function for the two-step GMM estimator $\hat{\rho}_n$ defined in Eq. (80.10). It is for this reason that in the literature on two-step GMM estimation, users are often advised to follow a specific sequence of steps, to ensure the proper estimation of respective variance-covariance matrices.

80.3 GMM Estimation of Models with Spatial Lags

As remarked in the introduction, arguably the most widely used class of spatial models are variants of the ones considered in Cliff and Ord (1973, 1981), which build on the fundamental contribution of Whittle (1954). In these models, spatial interactions are modeled in terms of spatial lags. In particular, consider the following Cliff-Ord-type model relating a cross section of n spatial units:

$$\begin{aligned} \mathbf{y}_n &= \mathbf{X}_n \beta_{0n} + \lambda_{0n} \mathbf{W}_n \mathbf{y}_n + \mathbf{u}_n \\ &= \mathbf{Z}_n \delta_{0n} + \mathbf{u}_n \\ \mathbf{u}_n &= \rho_{0n} \mathbf{M}_n \mathbf{u}_n + \varepsilon_n \end{aligned} \tag{80.22}$$

where $\mathbf{Z}_n = [\mathbf{X}_n, \mathbf{W}_n \mathbf{y}_n]$ and $\delta_{0n} = [\beta'_{0n}, \lambda_{0n}]'$. Here $\mathbf{y}_n = (y_{1,n}, \dots, y_{n,n})'$ is the $n \times 1$ vector of the dependent variable, $\mathbf{X}_n = (x_{ik,n})$ is the $n \times K$ matrix of the non-stochastic exogenous regressors, $\mathbf{W}_n = (w_{ij,n})$ and $\mathbf{M}_n = (m_{ij,n})$ are $n \times n$ observed non-stochastic weight matrices with zero diagonal elements, $\mathbf{u}_n = (u_{1,n}, \dots, u_{n,n})'$ is the $n \times 1$ vector of regression disturbances, and $\varepsilon_n = (\varepsilon_{1,n}, \dots, \varepsilon_{n,n})'$ is an $n \times 1$ vector of innovations. The vectors $\bar{\mathbf{y}}_n = (\bar{y}_{1,n}, \dots, \bar{y}_{n,n})' = \mathbf{W}_n \mathbf{y}_n$ and $\bar{\mathbf{u}}_n = (\bar{u}_{1,n}, \dots, \bar{u}_{n,n})' = \mathbf{M}_n \mathbf{u}_n$ represent spatial lags, the scalars λ_{0n} and ρ_{0n} denote the corresponding true parameters, typically referred to as spatial-autoregressive parameters, and β_{0n} is a $k \times 1$ true parameter vector. In analogy to the time series literature, the above model is often referred to as a spatial-autoregressive autoregressive (1,1) model, for short an SARAR(1, 1) model.

In the above formulation, all data vectors and matrices, as well as all parameters are allowed to depend on the sample size n , i.e., to form triangular arrays. To see why this is necessary, consider, e.g., the i th elements of the spatial lag $\bar{y}_n = \mathbf{W}_n \mathbf{y}_n$, which is given by

$$\bar{y}_{i,n} = \sum_{j=1}^n w_{ij,n} y_{j,n}$$

From this it is obvious that even if the weights $w_{ij,n}$ do not depend on n , the weighted average $\bar{y}_{i,n}$ and thus $y_{i,n}$ will depend on n . In allowing for the elements of \mathbf{X}_n to depend on n , we allow implicitly for some of the regressors to be spatial lags, e.g., the regressor matrix could be of the form $\mathbf{X}_n = [\mathbf{x}_{1,n}, \mathbf{W}_n \mathbf{x}_{1,n}, \dots]$. In allowing for the elements of the spatial weight matrices to depend on n , we allow implicitly for normalized spatial weight matrices, as is frequently the case in applications. In allowing also for the parameters to depend on n allows us to assume a common parameter space for all sample sizes; see Kelejian and Prucha (2010) for a more detailed discussion. For simplicity of notation we will, for the most part, drop again subscripts n in the following.

The spatial model (80.22) represents a system of n simultaneous equations. The reduced form of the model is given by

$$\mathbf{y} = (\mathbf{I} - \lambda_0 \mathbf{W})^{-1} \mathbf{X} \beta_0 + (\mathbf{I} - \lambda_0 \mathbf{W})^{-1} (\mathbf{I} - \rho_0 \mathbf{M})^{-1} \varepsilon \quad (80.23)$$

If $\varepsilon \sim N(0, \sigma^2 \mathbf{I})$, then clearly $\mathbf{y} \sim N(\mu_y, \Omega_y)$ with

$$\begin{aligned} \mu_y &= (\mathbf{I} - \lambda_0 \mathbf{W})^{-1} \mathbf{X} \beta_0, \\ \Omega_y &= \sigma^2 (\mathbf{I} - \lambda_0 \mathbf{W})^{-1} (\mathbf{I} - \rho_0 \mathbf{M})^{-1} (\mathbf{I} - \rho_0 \mathbf{M}')^{-1} (\mathbf{I} - \lambda_0 \mathbf{W}')^{-1} \end{aligned}$$

From this we see that while it is easy to write down the log-likelihood function for model (80.22), the computation of the ML estimator is challenging or non-feasible for larger sample sizes n . The reason is that it requires the computation of

the determinant of the $n \times n$ matrices $\mathbf{I} - \lambda_0 \mathbf{W}$ and $\mathbf{I} - \rho_0 \mathbf{M}$, which is taxing for large n unless the spatial weight matrices have structure that can be exploited.

Our discussions will also utilize the following spatial Cochrane-Orcutt transformation of Eq. (80.22):

$$\mathbf{y}_*(\rho_0) = \mathbf{Z}_*(\rho_0)\delta_0 + \varepsilon \quad (80.24)$$

where $\mathbf{y}_*(\rho_0) = \mathbf{y} - \rho_0 \mathbf{M}\mathbf{y}$ and $\mathbf{Z}_*(\rho_0) = \mathbf{Z} - \rho_0 \mathbf{M}\mathbf{Z}$. The transformed model is readily obtained by pre-multiplying Eq. (80.22) by $\mathbf{I} - \rho_0 \mathbf{M}$.

80.3.1 GMM Estimation of Spatial-Autoregressive Parameter

Motivated by the potential numerical problems in computing the ML estimator for larger sample sizes, Kelejian and Prucha (1998, 1999) introduced an alternative GMM estimation approach which remains feasible even for large sample sizes and full spatial weight matrices.³ (See Pace, ► Chap. 78, “Maximum Likelihood Estimation”.) Another motivation was that at the time there were no formal results available regarding the consistency and asymptotic normality of the ML estimator for the above model.

The GMM estimation approach put forward in Kelejian and Prucha (1998, 1999) employs the following simple quadratic moment conditions, based on the assumption that the ε_i are i.i.d. $(0, \sigma^2)$:

$$E\mathbf{n}^{-1}\varepsilon'\varepsilon = \sigma^2, \quad E\mathbf{n}^{-1}\bar{\varepsilon}'\bar{\varepsilon} = \sigma^2 n^{-1} \text{tr}(\mathbf{M}'\mathbf{M}), \quad E\mathbf{n}^{-1}\bar{\varepsilon}'\varepsilon = 0$$

with $\bar{\varepsilon} = \mathbf{M}\varepsilon$. Substituting out σ^2 yields the following two quadratic moment conditions:

$$E\mathbf{n}^{-1}\varepsilon'\mathbf{A}_1\varepsilon = 0, \quad E\mathbf{n}^{-1}\varepsilon'\mathbf{A}_2\varepsilon = 0 \quad (80.25)$$

with⁴

$$\mathbf{A}_1 = \mathbf{M}'\mathbf{M} - n^{-1} \text{tr}(\mathbf{M}'\mathbf{M})\mathbf{I}, \quad \mathbf{A}_2 = \mathbf{M} \quad (80.26)$$

We note that for the weight matrices in Eq. (80.5), we have $\text{tr}(\mathbf{A}_q) = 0$ for $q = 1, 2$, but $\text{diag}(\mathbf{A}_1) \neq 0$. Kelejian and Prucha (2010) relax the assumption that the innovations are homoskedastic and allow for heteroskedasticity of unknown form.

³Recall, e.g., that there are more than 33,000 zip codes in the U.S.

⁴To obtain the estimator of Kelejian and Prucha (1998, 1999) the matrix \mathbf{A}_1 has to be scaled by $v = 1 / \left[1 + [n^{-1} \text{tr}(\mathbf{M}'\mathbf{M})]^2 \right]$. Of course, the scaling factor only comes into play if the moment conditions are not optimally weighted, as was the case in the early literature.

More specifically, they consider the case where the ε_i are independently distributed $(0, \sigma_i^2)$ with σ_i^2 unknown.⁵ For this case they consider the following modified version of the above moment conditions where

$$\mathbf{A}_1 = \mathbf{M}'\mathbf{M} - n^{-1}diag(\mathbf{M}'\mathbf{M}), \quad \mathbf{A}_2 = \mathbf{M} \tag{80.27}$$

Note that in this specification, $diag(\mathbf{A}_q) = 0$ for $q = 1, 2$. Given this, the moment conditions in Eq. (80.25) continue to hold since $E\varepsilon'\mathbf{A}_q\varepsilon = \sum_{i=1}^n a_{q,ii}\sigma_i^2 = 0$. From this we see that, in general, moment conditions that employ weight matrices with $a_{q,ii} = 0$ and not just $tr(\mathbf{A}_q) = \sum_{i=1}^n a_{q,ii} = 0$ are robust against heteroskedasticity.

Of course, the above setup can be generalized to the case where we have S_ρ quadratic moment conditions ($q = 1, \dots, S_\rho$):

$$En^{-1}\varepsilon'\mathbf{A}_q\varepsilon = 0 \tag{80.28}$$

In light of Eq. (80.22) those moment conditions can be written equivalently as ($q = 1, \dots, S_\rho$):

$$En^{-1}\mathbf{u}'(\mathbf{I} - \rho_0\mathbf{M}')\mathbf{A}_q(\mathbf{I} - \rho_0\mathbf{M})\mathbf{u} = 0 \tag{80.29}$$

Now let $\check{\delta}$ be some initial estimator for δ_0 and let $\check{\mathbf{u}} = \mathbf{y} - \mathbf{Z}\check{\delta}$. Then we can formulate the following corresponding sample moment vector:

$$\mathbf{q}_n^\rho(\rho, \check{\delta}) = n^{-1} \begin{bmatrix} \check{\mathbf{u}}'(\mathbf{I} - \rho\mathbf{M}')\mathbf{A}_1(\mathbf{I} - \rho\mathbf{M})\check{\mathbf{u}} \\ \vdots \\ \check{\mathbf{u}}'(\mathbf{I} - \rho\mathbf{M}')\mathbf{A}_{S_\rho}(\mathbf{I} - \rho\mathbf{M})\check{\mathbf{u}} \end{bmatrix} \tag{80.30}$$

Furthermore, as in Eq. (80.10), the class of corresponding two-step GMM estimators is then given by

$$\hat{\rho} = \arg \min_{\rho} \{ \mathbf{q}_n^\rho(\rho, \check{\delta})' \mathbf{Y}_n^{\rho\rho} \mathbf{q}_n^\rho(\rho, \check{\delta}) \} \tag{80.31}$$

where $\mathbf{Y}_n^{\rho\rho}$ is a weighting matrix. As discussed in Sect. 80.2.3, the efficient choice for $\mathbf{Y}_n^{\rho\rho}$ will generally depend on the estimator $\check{\delta}$ employed in the estimation of the disturbances.

⁵Lin and Lee (2010) also allow for heteroskedastic innovations for model (80.22) with $\rho_0 = 0$.

80.3.2 GMM Estimation of Regression Parameters

In order to motivate the GMM estimator for the regression parameters δ_0 , we note that the best instruments for the r.h.s. variables of model (80.22) and (80.24) are the conditional means. Since \mathbf{X} and \mathbf{MX} are non-stochastic (and their own best instruments), we can focus on the spatial lags \mathbf{Wy} and \mathbf{MWy} . The best instruments are given \mathbf{WEy} and \mathbf{MWEy} with

$$E\mathbf{y} = (\mathbf{I} - \lambda_0\mathbf{W})^{-1} \mathbf{X}\beta_0 = \sum_{l=1}^{\infty} \lambda_0^l \mathbf{W}^l \mathbf{X}\beta_0 \quad (80.32)$$

given that spectral radius of $\lambda_0\mathbf{W}$ is less than one. To avoid issues associated with the computation of the inverse of the $n \times n$ matrix of $\mathbf{I} - \lambda_0\mathbf{W}$, Kelejian and Prucha (1998, 1999) suggest the use of an approximation of the best instruments. More specifically, in light of the last expression in Eq. (80.32), they suggest using a set of instruments \mathbf{H} which contains, say, \mathbf{X} , \mathbf{MX} , \mathbf{MWX} , \dots , $\mathbf{MW}^p\mathbf{X}$, and to compute approximators of the best instruments from a regression of the r.h.s. variables against \mathbf{H} .

For the untransformed model, this is equivalent to considering the moment condition $En^{-1}\mathbf{H}'u = 0$. Of course, the corresponding GMM estimator is just the two-stage least squares (2SLS) estimator. For the transformed model (80.24), the moment condition would be

$$En^{-1/2}\mathbf{H}'\varepsilon = 0 \quad (80.33)$$

Now let $\check{\rho}$ be some estimator for ρ_0 , then we can formulate the following corresponding sample moment vector:

$$\mathbf{q}^\delta(\check{\rho}, \delta) = n^{-1/2}\mathbf{H}'[\mathbf{y}_*(\check{\rho}) - \mathbf{Z}_*(\check{\rho})\delta] \quad (80.34)$$

Under homoskedasticity the variance-covariance matrix of the moment vector $\mathbf{q}^\delta(\rho_0, \delta_0) = n^{-1/2}\mathbf{H}'\varepsilon$ is given by $\sigma^2n^{-1}\mathbf{H}'\mathbf{H}$, which motivates the following two-step GMM estimators for δ_0 :

$$\hat{\delta} = \arg \min_{\delta} \left\{ \mathbf{q}_n^\delta(\check{\rho}, \delta)' \mathbf{Y}_n^{\delta\delta} \mathbf{q}_n^\delta(\check{\rho}, \delta) \right\} \quad (80.35)$$

with $\mathbf{Y}_n^{\delta\delta} = [n^{-1}\mathbf{H}'\mathbf{H}]^{-1}$. By observing that the quadratic form on the r.h.s. of Eq. (80.3) is just $[\mathbf{y}_*(\check{\rho}) - \mathbf{Z}_*(\check{\rho})\delta]' \mathbf{H}(\mathbf{H}'\mathbf{H})^{-1} \mathbf{H}'[\mathbf{y}_*(\check{\rho}) - \mathbf{Z}_*(\check{\rho})\delta]$, apart from some scaling factors, we see that the estimator defined by Eq. (80.35) is just the 2SLS estimator applied to the transformed model (80.24) with ρ_0 replaced by $\check{\rho}$, i.e.,

$$\hat{\delta} = [\hat{\mathbf{Z}}_*(\check{\rho})' \mathbf{Z}_*(\rho)]^{-1} \hat{\mathbf{Z}}_*(\check{\rho})' \mathbf{y}_*(\check{\rho}) \quad (80.36)$$

where $\widehat{\mathbf{Z}}_*(\check{\rho}) = \mathbf{H}(\mathbf{H}'\mathbf{H})^{-1}\mathbf{H}'\mathbf{Z}_*(\check{\rho})$. This estimator has been called the feasible generalized spatial two-stage least squares (FGS2SLS) estimator.

80.3.3 Guide to Literature

The above sections discussed basic ideas concerning moment conditions that can be exploited by GMM estimators for spatial Cliff-Ord-type models. Since the late 1990s, a considerable body of literature has developed regarding the GMM estimation of Cliff-Ord-type models. In the following we provide references to some of that literature. Naturally, given space limitations, the list of references is incomplete. Also, the list will focus on theoretical contributions and will not cover corresponding empirical work.⁶

By employing an approximation of the best instruments, the FGS2SLS estimator of Kelejian and Prucha (1998, 1999) has the advantage of remaining computational feasible even for very large sample sizes since its formulation does not involve the computation of the inverse of the $n \times n$ matrix $\mathbf{I} - \lambda_0\mathbf{W}$. However, as a result it is not fully efficient. Lee (2003) introduces a best 2SLS estimator. This estimator uses the first expression for $E\mathbf{y}$ in Eq. (80.32) in forming best instruments for $\mathbf{W}\mathbf{y}$. It is best in the sense that its asymptotic variance-covariance matrix is smallest among the class of GMM estimators based on linear moment conditions. Kelejian et al. (2004) introduce an alternative best 2SLS estimator (with identical asymptotic properties). For computational ease, this estimator uses a series approximation for the second expression for $E\mathbf{y}$ in Eq. (80.32) when forming best instruments for $\mathbf{W}\mathbf{y}$. All of the above S2SLS estimators break down if $\beta_0 = 0$, i.e., if there are no exogenous variables in the model. This is not the case with the ML estimator. As a consequence, one would expect the ML estimator, given it is computable, to increasingly outperform the above S2SLS estimators as the variation in the disturbances increases relative to the variation in the regressors. However, Das et al. (2003) provide Monte Carlo results which suggest that the loss of efficiency of 2SLS-type estimators relative to ML estimation is modest for a wide range of specifications.

The above papers establish consistency of the GMM estimator for ρ_0 , but do not derive its limiting distribution. Drukker et al. (2011) derive the joint limiting distribution for two-step GMM estimators for δ_0 and ρ_0 .

Fingleton (2008) formulates moment conditions and GMM estimators for the case where the disturbance process is an MA rather than an AR process.

Lee (2007) considers an SARAR(1,0) model, i.e., model (80.22) with $\rho_0 = 0$. He suggests augmenting the usual linear moment conditions by quadratic moment conditions and derives the best quadratic moment condition. This best quadratic moment condition involves the inverse of $\mathbf{I} - \lambda_0\mathbf{W}$. Lee shows that the corresponding best GMM estimator may have the same asymptotic distribution as

⁶For an incomplete list of empirical work see, e.g., Kelejian and Prucha (2010).

the ML estimator under normality. Also, the estimator does not break down if there are no explanatory exogenous variables. Liu et al. (2010) and Lee and Liu (2010) extend the results to one-step GMM estimators of an SARAR(1,1) and SARAR(p,q) model, respectively.

All of the above literature assumes that the basic innovations are homoskedastic. Kelejian and Prucha (2010) and Arraiz et al. (2010) consider two-step GMM estimation of an SARAR(1,1) model under the assumption that the innovations are heteroskedastic of unknown form. Badinger and Egger (2011) extend the approach the case of an SARAR(p,q) model. Lin and Lee (2010) consider one-step GMM estimation of an SARAR(1,0) with unknown heteroskedasticity, employing both linear and quadratic moment conditions.

Extensions of Cliff-Ord-type models to random and fixed effects panel data have been an important focus of recent research. Considered estimation methodologies have been GMM, quasi-ML, and Bayesian Markov Chain Monte Carlo methods.⁷ The literature on GMM estimation for panel data includes Kapoor et al. (2007), Mutl and Pfaffermayr (2011), and Yu et al. (2012). Liu and Lee (2010) discuss GMM estimation (as well as other approaches) of a Cliff-Ord-type social interaction model. (See Elhorst, ► Chap. 82, “Spatial Panel Models”.)

Kelejian and Prucha (2007) and Drukker et al. (2011) discuss GMM estimation for Cliff-Ord-type single equation models with additional outside endogenous variables. Kelejian and Prucha (2004) consider a Cliff-Ord-type simultaneous equation system and discuss both limited and full information GMM estimators.

Pinkse et al. (2002) consider a semiparametric GMM approach, which allows for the spatial weights to be modeled as unknown functions of some distance measure. We note that if we are willing to assume that the weights can be expressed as, say, a finite polynomial in distance, then the substituted model will be of the form of an SARAR(p,q) model.

80.3.4 Exemplary GMM Estimators

In the following we give an illustrative result for the limiting distribution of GMM estimators for the SARAR(1,1) model (80.22). As remarked, for two-step GMM estimation, the limiting distribution of the GMM estimator for ρ_0 will depend on the estimator for δ_0 used in constructing estimated residuals. Our illustrative example will focus on the two-step GMM estimators considered in Kelejian and Prucha (1998, 1999), which can be viewed as a special case of the GMM estimators considered in Sects. 80.3.1 and 80.3.2, with $S_\rho = 2$ and

⁷Quasi-ML and Bayesian MCMC methods are not covered by this review. For recent papers employing those methods within the context of dynamic panel data models, see, e.g., Yu et al. (2008) and Parent and LeSage (2012), respectively. There is also an important literature on testing for spatial dependence in a panel context, which is not part of this review. For a partial review of this literature see, e.g., Baltagi (2011).

$\mathbf{A}_1 = v[\mathbf{M}'\mathbf{M} - n^{-1}tr(\mathbf{M}'\mathbf{M})\mathbf{I}]$ with $v = 1/[1 + [n^{-1}tr(\mathbf{M}'\mathbf{M})]^2]$ and $\mathbf{A}_2 = \mathbf{M}$. The discussion below assumes that the assumptions maintained in that paper hold, including that the innovations ε_i are i.i.d. $(0, \sigma^2)$.

We next describe specific steps in computing the GMM estimators.

Step 1a: 2SLS Estimator

In the first step, estimate δ by 2SLS from the untransformed model (80.22), using the instrument matrix \mathbf{H} as discussed in Sect. 80.3.2. The 2SLS estimator, say $\tilde{\delta}$, is then given by $\tilde{\delta} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{y}$, where $\tilde{\mathbf{Z}} = \mathbf{P}_H\mathbf{Z}$ with $\mathbf{P}_H = \mathbf{H}(\mathbf{H}'\mathbf{H})^{-1}\mathbf{H}'$.

Step 1b: Initial GMM Estimator of ρ Based on 2SLS Residuals

Let $\tilde{\mathbf{u}} = \mathbf{u}(\tilde{\delta}) = \mathbf{y} - \tilde{\mathbf{Z}}\tilde{\delta}$ denote the 2SLS residuals. Consider the following sample moments based on estimated 2SLS residuals:

$$\mathbf{q}_n^\rho(\rho, \tilde{\delta}) = n^{-1} \begin{bmatrix} \tilde{\mathbf{u}}'(\mathbf{I} - \rho\mathbf{M}')\mathbf{A}_1(\mathbf{I} - \rho\mathbf{M})\tilde{\mathbf{u}} \\ \tilde{\mathbf{u}}'(\mathbf{I} - \rho\mathbf{M}')\mathbf{A}_2(\mathbf{I} - \rho\mathbf{M})\tilde{\mathbf{u}} \end{bmatrix} \tag{80.37}$$

The initial GMM estimator for ρ is then defined as

$$\tilde{\rho} = \arg \min_{\rho} \left\{ \mathbf{q}_n^\rho(\rho, \tilde{\delta})' \mathbf{q}_n^\rho(\rho, \tilde{\delta}) \right\}$$

Clearly $\tilde{\rho}$ is a special case of the class of estimators considered in Eq. (80.31) with $\mathbf{Y}_n^{\rho\rho} = \mathbf{I}$.

Step 2a: FGS2SLS Estimator

In the second step, reestimate δ by FGS2SLS, as discussed in Sect. 80.3.2. The FGS2SLS estimator is defined as the 2SLS estimator of the Cochrane-Orcutt transformed model (80.24) with the parameter ρ_0 replaced by $\tilde{\rho}$ computed in Step 1b. The FGS2SLS estimator is given by $\hat{\delta} = [\tilde{\mathbf{Z}}_*(\tilde{\rho})'\tilde{\mathbf{Z}}_*(\tilde{\rho})]^{-1}\tilde{\mathbf{Z}}_*(\tilde{\rho})'\mathbf{y}_*(\tilde{\rho})$ where $\tilde{\mathbf{Z}}_*(\tilde{\rho}) = \mathbf{P}_H\mathbf{Z}_*(\tilde{\rho})$.

Step 2b: Efficient GMM Estimator of ρ Based on FGS2SLS Residuals

Let $\hat{\mathbf{u}} = \mathbf{y} - \tilde{\mathbf{Z}}\hat{\delta}$ denote the FGS2SLS residuals, and let $\mathbf{q}_n^\rho(\rho, \hat{\delta})$ be defined as in Eq. (80.5) with $\tilde{\mathbf{u}}$ replaced by $\hat{\mathbf{u}}$. By Drukker et al. (2011), the corresponding efficient GMM estimator for ρ_0 based on FGS2SLS residuals is then given by

$$\hat{\rho} = \arg \min_{\rho} \left[\mathbf{q}_n^\rho(\rho, \hat{\delta})' \left(\hat{\Psi}_n^{\rho\rho} \right)^{-1} \mathbf{q}_n^\rho(\rho, \hat{\delta}) \right]$$

where $\hat{\Psi}_n^{\rho\rho} = (\hat{\psi}_{rs}^{\rho\rho})_{r,s=1,2}$ is an estimator of the variance-covariance matrix of the limiting distribution of the normalized sample moments $n^{1/2}\mathbf{q}_n^\rho(\rho, \hat{\delta})$. In particular we have⁸

⁸In the following $vec_D(\mathbf{A})$ refers to the column vector containing the diagonal elements of the matrix \mathbf{A} .

$$\begin{aligned} \widehat{\Psi}_{rs}^{\rho\rho} &= \widehat{\sigma}^4 (2n)^{-1} tr[(\mathbf{A}_r + \mathbf{A}'_r)(\mathbf{A}_s + \mathbf{A}'_s)] \\ &\quad + \widehat{\sigma}^2 n^{-1} \widehat{\mathbf{a}}'_r \widehat{\mathbf{a}}_s \\ &\quad + n^{-1} (\widehat{\mu}^{(4)} - 3\widehat{\sigma}^4) vec_D(\mathbf{A}_r)' vec_D(\mathbf{A}_s) \\ &\quad + n^{-1} \widehat{\mu}^{(3)} [\widehat{\mathbf{a}}'_r vec_D(\mathbf{A}_s) + \widehat{\mathbf{a}}'_s vec_D(\mathbf{A}_r)] \end{aligned}$$

where $\widehat{\mathbf{a}}_r = \mathbf{H}\widehat{\mathbf{P}}^* \widehat{\alpha}_r$ and

$$\begin{aligned} \widehat{\mathbf{P}}^* &= (n^{-1}\mathbf{H}'\mathbf{H})^{-1} (n^{-1}\mathbf{H}'\mathbf{Z}_*(\widetilde{\rho})) \\ &\quad \times \left[(n^{-1}\mathbf{Z}'_*(\widetilde{\rho})\mathbf{H})(n^{-1}\mathbf{H}'\mathbf{H})^{-1} (n^{-1}\mathbf{H}'\mathbf{Z}_*(\widetilde{\rho})) \right]^{-1} \\ \widehat{\alpha}_r &= -n^{-1}\mathbf{Z}'_*(\widetilde{\rho})(\mathbf{A}_r + \mathbf{A}'_r)\widehat{\varepsilon}, \end{aligned}$$

and $\widehat{\sigma}_n^2$, $\widehat{\mu}_n^{(3)}$, and $\widehat{\mu}_n^{(4)}$ are standard sample estimators of σ^2 , $\mu^{(3)} = E\varepsilon_i^3$, and $\mu^{(4)} = E\varepsilon_i^4$ based on $\widehat{\varepsilon} = (\mathbf{I} - \widetilde{\rho}\mathbf{M})\widehat{\mathbf{u}}$.

The derivation of the limiting distribution of $n^{1/2}\mathbf{q}^\rho(\rho, \widehat{\delta})$ used the CLT for linear quadratic forms given as Theorem 1. Observe that $\widehat{\alpha}_r$ is an estimator for $\alpha_r = -n^{-1}E\mathbf{Z}'_*(\rho)(\mathbf{A}_r + \mathbf{A}'_r)\varepsilon$. If the model does not contain a spatial lag in \mathbf{y} , i.e., if $\mathbf{Z} = \mathbf{X}$, then $\alpha_r = 0$ and we can then take $\widehat{\alpha}_r = 0$.

Based on Drukker et al. (2011), we now have the following result for the joint-asymptotic distribution of the final stage estimators $\widehat{\delta}$ and $\widehat{\rho}$:

$$\begin{bmatrix} \widehat{\delta} \\ \widehat{\rho} \end{bmatrix} \sim N \left(\begin{bmatrix} \delta_0 \\ \rho_0 \end{bmatrix}, n^{-1} \begin{bmatrix} \widehat{\Omega}^{\delta\delta} & \widehat{\Omega}^{\delta\rho} \\ \widehat{\Omega}^{\delta\rho'} & \widehat{\Omega}^{\rho\rho} \end{bmatrix} \right)$$

where

$$\begin{aligned} \widehat{\Omega}^{\delta\delta} &= \widehat{\mathbf{P}}^{*'} \widehat{\Psi}^{\delta\delta} \widehat{\mathbf{P}}^* \\ \widehat{\Omega}^{\delta\rho} &= \widehat{\mathbf{P}}^{*'} \widehat{\Psi}^{\delta\rho} (\widehat{\Psi}^{\rho\rho})^{-1} \widehat{\mathbf{J}} \left[\widehat{\mathbf{J}}' (\widehat{\Psi}^{\rho\rho})^{-1} \widehat{\mathbf{J}} \right]^{-1} \\ \widehat{\Omega}^{\rho\rho} &= \left[\widehat{\mathbf{J}}' (\widehat{\Psi}^{\rho\rho})^{-1} \widehat{\mathbf{J}} \right]^{-1} \\ \widehat{\Psi}^{\delta\delta} &= \widehat{\sigma}^2 n^{-1} \mathbf{H}'\mathbf{H} \\ \widehat{\Psi}^{\delta\rho} &= \widehat{\sigma}^2 n^{-1} \mathbf{H}'[\widehat{\mathbf{a}}_1, \widehat{\mathbf{a}}_2] + \widehat{\mu}^{(3)} n^{-1} \mathbf{H}' [vec_D(\mathbf{A}_1), vec_D(\mathbf{A}_{2,n})] \end{aligned}$$

where $\widehat{\mathbf{P}}^*$, $\widehat{\mathbf{a}}_r$, and $\widehat{\Psi}^{\rho\rho}$ are as defined above, and

$$\widehat{\mathbf{J}} = n^{-1} \begin{bmatrix} 2\widehat{\mathbf{u}}' \mathbf{M}' \mathbf{A}_1 \widehat{\mathbf{u}} & -\widehat{\mathbf{u}}' \mathbf{M}' \mathbf{A}_1 \mathbf{M} \widehat{\mathbf{u}} \\ 2\widehat{\mathbf{u}}' \mathbf{M}' \mathbf{A}_2 \widehat{\mathbf{u}} & -\widehat{\mathbf{u}}' \mathbf{M}' \mathbf{A}_2 \mathbf{M} \widehat{\mathbf{u}} \end{bmatrix} \begin{bmatrix} 1 \\ 2\widehat{\rho} \end{bmatrix}$$

For interpretation, observe that $\widehat{\Omega}^{\delta\delta} = \widehat{\sigma}^2 [\widehat{\mathbf{Z}}_*(\widehat{\rho})' \widehat{\mathbf{Z}}_*(\widehat{\rho})]^{-1}$, i.e., the above expression for the estimator of variance-covariance matrix of the joint distribution of $\widehat{\delta}$ and $\widehat{\rho}$ delivers the usual estimator for the variance-covariance matrix of the FGS2SLS estimator as a special case.

The above joint-asymptotic-normality result allows a joint Wald test for the absence of spatial dependencies, i.e., a joint test of $H_0 : \lambda_0 = 0, \rho_0 = 0$.

80.4 GMM Estimation of Models with Spatial Mixing

Cliff-Ord-type models are linear simultaneous equation models where mixing of the data process is achieved through the assumption that the basic innovations are independently distributed combined with assumptions on the spatial weight matrices, such as that the row and column sums of their absolute elements are bounded.

In the time series literature, a widely used notion of dependence is α -mixing. This concept has been generalized to spatial processes (or random fields). In an important paper, Conley (1999) considered GMM estimators for stationary α -mixing spatial processes. Stationarity implies that the process has constant mean and variance and that the covariances only depend on distance (in a particular direction). Many economic processes are likely to exhibit some form of non-stationarity – e.g., housing prices may increase very much as we move toward the center of a city. Thus, relaxing the stationarity assumption seemed important.

One difficulty in developing a generalized theory of inference for spatial processes was a paucity of limit theorems (laws of large numbers, uniform laws of large numbers, and central limit theorems) which are sufficiently general. In light of this, Jenish and Prucha (2009) developed limit theorems for non-stationary α -mixing spatial processes, allowing also for the locations of observations to form a nonregular grid. Still, since α -mixing is not necessarily preserved under infinite lag formations, a further expansion of the theory to a class of spatial processes, which is closed under infinite lag formations, seemed desirable. To that effect Jenish and Prucha (2012) extended the notion of near-epoch dependence from the time series literature to spatial processes. They then developed limit theorems for possibly non-stationary spatial processes which are near-epoch dependent on an α -mixing process and gave results concerning the consistency and asymptotic normality of GMM estimators for this generalized class of processes.

In a recent publication, Robinson and Thawornkaiwong (2012) consider a partially linear regression model. They define a semiparametric instrumental variable estimator and give results on its asymptotic properties, allowing for spatial dependence in the regressors and disturbances.

80.5 Conclusion

Over the last two decades, significant strides have been made toward developing a formal methodology of inference for spatial models or, more generally, for cross-

sectional interaction models. GMM estimation has been an important part of this literature. As usual, empirical work often confronts us with more challenging realities than what can be handled by existing methodologies of inference, and much more work is needed.

Acknowledgments I would like to thank James LeSage and Pablo Salinas Macario for their helpful comments on this chapter.

Abstract

In regional science, many attributes, either social or natural, can be categorical. For example, choices of travel mode, presidential election outcomes, or quality of life can all be measured (and/or coded) as discrete responses, dependent on various influential factors. Some attributes, although continuous, are subject to truncation or censoring. For example, household income, when reported, tends to be censored, and only boundary values of a range are obtained. Such categorical and censored variables can be analyzed using econometric models that are established based on the concept of “unobserved/latent dependent variable.”

e-mail: wangx18@rpi.edu

The previous examples also share another common feature: when data is collected in a spatial setting, they are all inevitably influenced by spatial effects, either spatial variation or spatial interaction. In contrast to panel data or time-series data, such variation or dependencies are two-dimensional, making it even more complicated. The need for investigating such limited and censored variables in a spatial context compels the quest for rigorous statistical methods.

This chapter introduces existing methods that are developed to analyze limited and censored dependent variables while considering the spatial effects. Different model specifications are discussed, with an emphasis on discrete response models and censored data models. Different types of spatial effects and corresponding ways to address them are then discussed. In general, when the spatial variation is of major concern, geographically weighted regression is preferred. When the spatial dependency is the primary interest, spatial filtering and spatial regression should be chosen. Techniques popularly used to estimate spatial limited variable models, including maximum simulated likelihood estimation, composite marginal likelihood estimation, and Bayesian approach, are also introduced and briefly compared.

81.1 Introduction

In studies of social behaviors and human activities, many attributes involve categorical, truncated, or censored responses in a spatial context. For example, choices of travel mode, choices of occupation, and presidential election outcomes can all be measured (and/or coded) as discrete responses, dependent on various influential factors. Household income and pavement surface deterioration levels, when reported, tend to be censored or truncated. Such categorical and/or censored variables can be analyzed using the limited dependent variable models. The previous examples also share a common feature: they all exhibit some type of spatial effects, either spatial variation or some degree of spatial dependence. For example, in studies of ecology, wealth, vehicle crashes, and epidemics, it is known that the data generation processes often vary over space. Another example is that even after controlling for household attributes, choice of travel mode is still expected to exhibit positive spatial correlations. Such correlation patterns can be partly explained by proximity because, in reality, there are always influential factors that cannot be controlled (e.g., pedestrian friendliness of all neighborhoods). The sign and magnitude of such dependence tend to vary rather gradually over space. Most likely, correlation diminishes with increases in distance between any two observation units. And in a spatial context, in contrast to time-series data, such dependencies are two-dimensional – which adds complexity. The widespread nature of such phenomena and the need for understanding these behaviors compel the quest for rigorous statistical methods for analysis of such data.

However, the handling of limited and censored dependent variables already involves specification and estimation of nonlinear models. Considering spatial

effects implies that the models have to further account for two-dimensional dependence structures across a large number of observations, leading to manipulation of high-dimensional multivariate distributions and large matrices. In recent years, many studies have attempted to enhance the behavioral consistency of model specification and the efficiency of estimation. This chapter will introduce the related methods developed to date. The following sections will first introduce conventional econometric models used for limited and censored dependent variables, followed by a discussion of spatial models, that is, how the consideration of spatial effects can be incorporated. Estimation techniques, which are critical for the application of these models, will be discussed in the end.

81.2 Limited and Censored Variable Models

Models for limited and censored variables are an important subarea of econometrics. This section will explain the specification of these models in two main categories: those for discrete responses and those for censored/truncated data.

81.2.1 Models for Discrete Responses

Models for discrete responses are often used to model choices among sets of alternatives rather than a continuous response (Greene 2002). Such models play an important role in scientific studies, both social and natural. The specification of discrete response models tends to require specific assumptions on the error term distribution. Two commonly used specifications are probit and logit models. The most basic form is a binary response, where the value of the dependent variable is either 0 or 1, indicating no or yes:

$$y_i^{\rightarrow} = X_i' \beta + \varepsilon_i \quad \text{and} \quad y_i = \begin{cases} 1 & \text{if } y_i^{\rightarrow} > 0 \\ 0 & \text{if } y_i^{\rightarrow} \leq 0 \end{cases} \quad i = 1, 2, \dots, N \quad (81.1)$$

where i indexes observations ($i = 1, 2, \dots, N$), y_i^{\rightarrow} is a latent (unobserved) dependent variable for individual i , and y_i is the observed dependent variable. X_i is a $Q \times 1$ vector of explanatory variables, and β is the set of corresponding parameters. ε_i stands for unobservable factors for observation i and is assumed to follow an identically and independently distributed (iid) standard normal distribution for a probit model or Gumbel distribution for a logit model. In other words, the actual response that is observed is a nonlinear function of latent response, which can be expressed as a linear function of explanatory variables. With this model setting, it is straightforward to show that

$$\begin{aligned} Pr(y_i = 1|X_i) &= Pr(y_i^{\rightarrow} > 0|X_i) = Pr(\varepsilon_i > -X_i' \beta|X_i) = F(X_i' \beta) \\ Pr(y_i = 0|X_i) &= 1 - F(X_i' \beta) \end{aligned} \quad (81.2)$$

where $F(\cdot)$ is the cumulative distribution function (CDF) of error term ε_i . The log-likelihood is thus

$$\ln L = \sum_{i=1}^N \{y_i \ln F(X_i'\beta) + (1 - y_i) \ln[1 - F(X_i'\beta)]\} \tag{81.3}$$

Of course, in many circumstances, the number of alternatives is more than two. If the data are ordered and each unit makes a choice from among the S alternatives, the model specification can be naturally extended from the binary choice setting, with a set of threshold parameters to distinguish different levels of response (alternatives):

$$y_i = k \text{ if } \gamma_k < y_i^- < \gamma_{k+1} \quad k = 1, 2, \dots, S \tag{81.4}$$

To some extent, the observed variable can be considered as a censored form of the latent variable: The latent variable y_i^- varies continuously, but the observed response is censored by unknown boundaries $\gamma_1 < \gamma_2 < \dots < \gamma_{S+1}$, leading to one of the integer responses $1, 2, \dots, S$. The probability for each outcome is

$$\begin{aligned} Pr(y_i = 1|X_i) &= F(\gamma_2 - X_i'\beta) - F(\gamma_1 - X_i'\beta) \\ Pr(y_i = 2|X_i) &= F(\gamma_3 - X_i'\beta) - F(\gamma_2 - X_i'\beta) \\ &\vdots \\ Pr(y_i = S|X_i) &= F(\gamma_{S+1} - X_i'\beta) - F(\gamma_S - X_i'\beta) \end{aligned} \tag{81.5}$$

where $F(\cdot)$ is still the CDF of error term ε_i , a standard normal distribution in probit model and logistic in logit model.

When the data is multinomial and unordered, a common model specification is established based on the utility maximization theory introduced by McFadden (1980). In this framework, the alternative offering the maximum utility is chosen. If U_{ik} indicates utility for individual i to select alternative $k(k = 1, 2, \dots, S)$, the observed dependent variable for observation i , y_i , will take value m if and only if U_{im} is the maximum utility among all alternatives (i.e., the most attractive option). Furthermore, one response alternative is often chosen as the “base” since preference is always a relative term. If the last alternative S is used as the base, the latent utility difference can be expressed as

$$y_{ik}^- = U_{ik} - U_{is} \quad k = 1, 2, \dots, S - 1 \tag{81.6}$$

Similarly, the latent utility difference is influenced by many factors, so

$$y_{ik}^- = X_{ik}'\beta + \varepsilon_{ik} \text{ and } y_i = m \text{ if } y_{im}^- > 0 \text{ and } y_{im}^- \geq y_{ik}^- \quad k = 1, 2, \dots, S - 1 \tag{81.7}$$

X'_{ik} is a $1 \times Q$ vector indicating the differences of explanatory variable values between alternative k and base alternative S . Subscript k implies that X'_{ik} can be alternative specific (such as cost of different modes in the analysis of travel mode choice). Conventional models used for analyzing unordered categorical data are multinomial logit or multinomial probit models. When the iid assumption is potentially violated, there are other derived forms to deal with the correlated errors, for example, the nested logit model which requires prespecified error correlation structure and the random parameter (mixed) logit (probit) models that assume parameters follow random distributions.

81.2.2 Models for Censored and Truncated Data

A sample is considered “truncated” when it is only a subset of a larger population. For example, when studies on expenditures are based on observations with positive expenditures, those with no expenditures are “truncated.” A similar and more common problem is “censoring,” meaning that rather than observing the exact value, only the boundary value of a range is observed. With the previous example, if expenditure over \$10,000 is coded as \$10,000, it is censored from above. Censored and truncated data are not representative of the population, and estimators that ignore this problem will be inconsistent, leading to incorrect marginal effects (Greene 2002). To some extent, truncated and censored regressions are similar to binary and ordered-response models. A latent dependent variable is posited taking the form $y_i^{\rightarrow} = X_i' \beta + \varepsilon_i$, then for truncated (from below at 0) regression, the observed dependent variable will be

$$y_i = y_i^{\rightarrow} \quad \text{if } y_i^{\rightarrow} > 0 \tag{81.8}$$

If ε_i follows a normal distribution with zero mean and variance σ^2 , it can be shown that the conditional mean of the dependent variable is

$$\begin{aligned} E(y_i | y_i^{\rightarrow} > 0) &= E(X_i' \beta + \varepsilon_i | X_i' \beta + \varepsilon_i > 0) = X_i' \beta + E(\varepsilon_i | \varepsilon_i > -X_i' \beta) \\ &= X_i' \beta + \sigma \frac{\phi\left(\frac{X_i' \beta}{\sigma}\right)}{\Phi\left(\frac{X_i' \beta}{\sigma}\right)} \end{aligned} \tag{81.9}$$

where $\phi(\cdot)$ and $\Phi(\cdot)$ are the probability density function (PDF) and cumulative distribution function (CDF) of a standard normal distribution, respectively. In other words, because of the truncation, the mean of the dependent variable is no longer a linear function of X_i' . For censored (also from below at 0) regression, or Tobit model, the observed dependent variable will be

$$y_i = \begin{cases} y_i^{\rightarrow} & \text{if } y_i^{\rightarrow} > 0 \\ 0 & \text{if } y_i^{\rightarrow} \leq 0 \end{cases} \tag{81.10}$$

The censored conditional mean is thus $E(y_i|X_i) = Pr(y_i^{\rightarrow} \leq 0)0 + Pr(y_i^{\rightarrow} > 0)E(y_i|y_i^{\rightarrow} > 0)$, and with results for the truncated mean, it can be shown that

$$\begin{aligned} E(y_i|X_i) &= 0 + \Phi\left(\frac{X_i'\beta}{\sigma}\right) \left(X_i'\beta + \sigma \frac{\phi\left(\frac{X_i'\beta}{\sigma}\right)}{\Phi\left(\frac{X_i'\beta}{\sigma}\right)} \right) \\ &= \Phi\left(\frac{X_i'\beta}{\sigma}\right) X_i'\beta + \sigma \phi\left(\frac{X_i'\beta}{\sigma}\right) \end{aligned} \quad (8.1.11)$$

The above derivation can be easily extended to other truncation/censoring threshold values and the double truncation/censoring situation. As these conditional means are nonlinear, ordinary least square (OLS) will no longer yield consistent estimates of β . A rich body of literature related to generalization of censored models can be found in discussions of sample selection models and treatment effects models. It should be mentioned that, to some extent, duration models and count data models can be also considered as members of the limited dependent variable model family. Although their specification forms differ significantly from the previously discussed models, the notion behind their model specification is similar. If further investigation of these models is of interest, readers are referred to work by Greene (2002) which provides more in-depth discussion of these models.

81.3 Models Incorporating Spatial Effects

Methods for dealing with spatial effects in limited and censored dependent variable models can be categorized into the three types. The first method is geographically weighted regression (GWR), where the consideration is mainly about the spatial variation of behavioral parameters. The second method, spatial filtering, has been applied more broadly. This approach essentially attempts to “filter” spatial effect by explicitly controlling for variables that represent the spatial dependency. The third method is spatial regression, which incorporates spatial effects explicitly in the model specification, either through the spatial autocorrelation of (dependent and independent) variables, the autocorrelation of error terms, or both. This section introduces the basic concepts of these methods and discusses how these approaches can be integrated into the limited and censored dependent variable models.

81.3.1 Geographically Weighted Regression

GWR is established based on the assumption that relationships between variables vary from location to location; therefore, parameters should exhibit significant spatial variation. The flexible specification of GWR can be used to examine the stability and robustness of parameter estimates over space. The formulation of

GWR is fairly straightforward: Instead of a global regression that implies one data generation process dominates the whole population, the model is now localized by allowing for one unique data generation process per observation. Taking a binary model, for example, instead of a universal regression model for the latent variable $y_i^* = X_i'\beta + \varepsilon_i$, the parameters are allowed to be local, that is,

$$y_i = X_i'\beta(u_i, v_i) + \varepsilon_i \text{ and } y_i = \begin{cases} 1 & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases} \quad i = 1, 2, \dots, N \quad (81.12)$$

where (u_i, v_i) indicate the coordinates of observation i and $\beta(u_i, v_i)$ is a continuous function of the map coordinates. The key advantage of GWR is that it explicitly allows for local spatial effects in relatively standard regression models (Fotheringham 2003). Still using the binary choice model as the example, with GWR, the log-likelihood for the j^{th} observation will be

$$\ln L_j = \sum_{i=1}^N \{w_{ji} \{y_i \ln F(X_i'\beta_j) + (1 - y_i) \ln [1 - F(X_i'\beta_j)]\}\} \quad (81.13)$$

where w_{ji} is the weight for the i^{th} data point with respect to the j^{th} regression point, normally higher for data points close to the j^{th} regression point and decays over distance. Comparing this expression with Eq. (81.3), it can be observed that the key differences are that each observation now has its own parameter values and that the regression is influenced more by data points nearby. Selecting weight function, or kernel, to define w_{ji} is often the most challenging step of GWR. The main considerations are the representation of point proximity and selection of bandwidth distance (or the cutoff distance over which the data points no longer influence the regression). Fotheringham (2003) describes a variety of weight specification alternatives, with Gaussian weights and their bi-square variation as the most commonly used options. The integration of GWR into limited dependent variable models is straightforward and has been applied in many studies. LeSage (1999) provided MATLAB code for estimating binary logit and probit GWR models, using crime data as an illustration. Atkinson et al. (2003) used a binary logit GWR model to identify relationships between geomorphological controls and riverbank erosion. McMillan and McDonald (1999) extended the use of GWR into multinomial discrete response analysis by specifying a multinomial logit GWR model to analyze the influence of transportation access on land use in Chicago. Luo and Wei (2009) analyzed land-use conversion (from barren, crop/grassland, forest, and water uses to urban land use) via a multinomial logit GWR model.

81.3.2 Spatial Filtering

When spatial interaction, rather than spatial variation, is the major concern, the approaches used to address the spatial dependency include spatial filtering and

spatial regression. “Spatial filtering” has many different definitions in existing literature. The most unrestricted definition is to simply construct and control for some spatial variables so that conventional statistical models based on uncorrelated errors could still apply. For example, Dugundji and Walker (2005) considered spatial network independencies in their mixed logit model when studying mode choice behavior. In most recent studies, “spatial filtering” is referred as the semiparametric approaches that separate spatial dependencies by dividing original variables into filtered nonspatial variables and spatial variables. The division is often achieved using local spatial statistics such as distance-based eigenvector procedure (Dray et al. 2006), G-statistics-based approach (Getis 1995), and eigenfunction-based procedure (Griffith 2000). The local spatial statistics such as Getis’ G_i and Moran’s I were originally developed as diagnostics to disclose local spatial dependencies that are not indicated by their global counterparts. For example, Getis’ G_i is established based on an indicator $G_i(d)$, which is essentially a weighted average of observation values around observation i :

$$G_i(d) = \frac{\sum_j w_{ij} x_j}{\sum_j x_j}, \text{ all } j \neq i \quad (81.14)$$

where w_{ij} is the element of a row-standardized geographic connectivity matrix W and d indicates the distance or other predefined connectivity index. Getis (1995) then used the difference between observed value $G_i(d)$ and expected value $E(G_i)$, to separate spatial from nonspatial effects. In other words, observed variables were filtered as

$$x_i^- = x_i \frac{E(G_i)}{G_i(d)} = \frac{x_i \left[\frac{\sum_j w_{ij}}{n-1} \right]}{G_i(d)} \quad (81.15)$$

After all variables (both dependent and explanatory variables) have been filtered by such procedure, and the spatial dependency is considered removed, the conventional models introduced previously can be used directly for data analysis. Other spatial filtering techniques use different approaches to filter the spatial effects, but they all rely on the construction and manipulation of a spatial weight matrix W , which is used to represent the spatial dependency structure. The key challenge for this approach is to choose proper regional weighting scheme, or the construction of W .

81.3.3 Spatial Regression

Similar to spatial filtering, spatial regression models also directly address the spatial dependencies by incorporating spatial effects in the model specification. The key difference between spatial regression and spatial filtering is that, although spatial

regression may also use spatially lagged explanatory and/or response variables, as in the spatial filter models, many of the variables are treated as endogenous. LeSage and Pace (2009) summarized the motivations of using spatial regression models for data analysis. There is a big family of spatial regression models, including spatial autoregressive (SAR), spatial moving average (SMA), spatial Durbin (SDM), and spatial error (SEM), with SAR and SEM as the most commonly used specifications. Many existing works (Anselin 2003; LeSage and Pace 2009) have provided extensive technical discussions on these models and the underlying spatial stochastic processes. In general, SAR and SEM are used for dependent variables and error terms, respectively. Both are used rather regularly by researchers, thanks to their flexibility and applicability. The former case is also called “spatial lag,” while the latter is often called “spatial error.” By using these two specifications, it is assumed that the spatial process follows a recursive pattern. In a linear model setting, SAR is expressed as

$$y = \rho W y + X\beta + \varepsilon \quad \text{or} \quad y = (I - \rho W)X\beta + (I - \rho W)\varepsilon \quad \varepsilon \sim N(0, \sigma^2 I_n) \quad (81.16)$$

where W still denotes the geographic connectivity matrix, ρ is the spatial coefficient, representing the magnitude of overall neighborhood influence, and I_n is an n by n identity matrix.

The SEM incorporates the spatial effects in error terms:

$$y = X\beta + u \quad u = \lambda u + \varepsilon \quad \varepsilon \sim N(0, \sigma^2 I_n) \quad (81.17)$$

where u is the vector of overall errors, λ is the spatial coefficient for error terms, indicating the contribution of neighboring observations on each other’s uncertainty, and ε now indicates the part of error or uncertainty caused by each observation itself. These spatial processes can be easily applied in the context of limited and censored dependent variable models by incorporating them in the formulation of latent dependent variables. For example, a SAR probit model is simply

$$y^* = (I - \rho W)X\beta + (I - \rho W)\varepsilon \quad \varepsilon \sim N(0, \sigma^2 I_n) \quad \text{and still } y = \begin{cases} 1 & \text{if } y^* > 0 \\ 0 & \text{if } y^* \leq 0 \end{cases} \quad (81.18)$$

Many studies have used spatial regression models to analyze limited and censored dependent variables. For example, Beron and Vijverberg (1999) specified probit models with both spatial errors and spatial lags. Smith and LeSage (2004) incorporated a regional effect in a probit model and used Bayesian techniques to analyze the 1996 presidential election results. LeSage and Pace (2009) discussed specification of a spatial autoregressive multinomial probit model. Wang and Kockelman (2009) developed a spatial ordered probit model with temporal correlation, and Wang et al. (2012) further extended the models to the analysis of multinomial, unordered responses.

81.4 Estimation Approaches

A common approach for estimating limited and censored dependent variable models is the maximum likelihood estimation (MLE) technique (see Pace, ► Chap. 78, “Maximum Likelihood Estimation”). When the models are further complicated by the consideration of spatial dependency, implying interdependence of observations, the joint distribution of the entire sample is no longer the product of their marginal distributions; hence, the log-likelihood is no longer additively separable one-dimensional probabilities. The calculation of high-dimensional distribution requires the manipulation of large matrices and a high-dimensional integral. The MLE approach thus becomes ineffective facing such heavy, sometimes impossible computational burdens. Alternative estimation approaches have been explored by researchers. For example, Pinkse and Slade (1998) used the generalized method of moments (GMM) to estimate a probit model with spatial error components (see Prucha, ► Chap. 80, “Instrumental Variables/Method of Moments Estimation” for details concerning estimation). Klier and McMillen (2008) used GMM to estimate a spatial logit model for analyzing the clustering of auto supplier plants in the USA. McMillen (1995) used simulated likelihood strategies to estimate spatial multinomial probit models. Vijverberg (1997) used recursive importance sampling (RIS) to approximate the n -dimensional log-likelihood in a spatial probit model. Bhat (2011) suggested a maximum approximate composite marginal likelihood (MACML) method, which essentially decomposes multidimensional autocorrelation into pairwise correlation. Smith and LeSage (2004), LeSage and Pace (2009), and Wang and Kockelman (2009) used Bayesian framework in their studies of spatial discrete response models. In general, the estimation approaches discussed in existing literature can be categorized into four types: maximum simulated likelihood estimation (MSLE), GMM, MACML, and Bayesian techniques. Among them, the use of GMM is relatively limited because it requires orthogonality, which cannot be conveniently derived in multiple-response models. This section will briefly introduce the other three estimation techniques that are used more dominantly in practice: MSLE, MACML, and Bayesian techniques.

81.4.1 Maximum Simulated Likelihood Estimation (MSLE)

The notion of MSLE is that, since the direct derivation of complex statistical models is impractical (e.g., when a likelihood function involves a multidimensional integral), a simulated likelihood that approximates the original likelihood is used instead. When approximated appropriately, the key model features in the original model are retained, but computational burden is alleviated. For example, in a SAR multinomial probit model where the probability involves multivariate normal cumulative density function

$$Pr(\mathbf{V} < \mathbf{v}) = \Phi(\mathbf{V}_1 < v, \mathbf{V}_2 < v_2, \mathbf{V}_2 < v_3, \dots, \mathbf{V}_1 < v_1) \quad (81.19)$$

where V is a vector of joint events and v is the corresponding thresholds. $\Phi(\cdot)$ still indicates the CDF of a normal distribution. The joint probability can be decomposed into the product of conditional densities:

$$Pr(V < v) = \int_{-\infty}^{v_1} \int_{-\infty}^{v_{I-1}} \cdots \int_{-\infty}^{v_1} \phi(V_I|V_{i < I})\phi(V_{I-1}|V_{i < I-1}) \cdots \phi(V_1)dV_1 \cdots dV_I \quad (81.20)$$

The above distribution involves an intractable integral. One approach used to simulate this joint probability is GHK (Geweke-Hajivassiliou-Keane) simulator, which is considered most effective among traditional techniques. The GHK method uses the Cholesky decomposition to generate recursive ordering. Furthermore, instead of using the conditional probabilities reliant on the random event $V_{i < I}$ and calculating the multidimensional integral, a set of realized discrete V values are used. Each time-specific V values are given, denoted as \tilde{V} , the product of these conditional probabilities could be easily calculated based on these specific realizations, leading to an approximation of the original likelihood:

$$\tilde{Pr}(V < v) = \int_{-\infty}^{v_1} \phi(V_I|\tilde{V}_{i < I})dV_I \int_{-\infty}^{v_{I-1}} \phi(V_{I-1}|\tilde{V}_{i < I-1})dV_{I-1} \cdots \int_{-\infty}^{v_1} \phi(V_1)dV_1 \quad (81.21)$$

“Simulated likelihood” generates the \tilde{V} vector values for multiple times (denoted as R). As Train (2003) explains, the simulation bias and noise are inversely proportional to R . Besides increasing R , researchers have also found that use of quasi-random numbers may enhance the performance of simulation. For example, Train (2003) suggested Halton sequences and its related variants, and Wang and Kockelman (2008) assessed several quasi-random number generation techniques and recommended the use of scrambled Halton sequence based on its performance on spatial data.

Beron and Vijverberg (1999) used the GHK method, also called recursive importance sampling (RIS), when estimating spatial probit models. However, one limitation is that the computational time of GHK increases exponentially with sample size, making it infeasible to handle large sample size. In a recent study, Pace and LeSage (2011) recognized the fact that spatial dependency often decays fast and leads to sparse matrix, which can be exploited with a sparse GHK procedure to improve the efficiency of spatial probit models for large-sized samples.

81.4.2 Composite Marginal Likelihood

Rather recently, some researchers have proposed the use of simplified pseudo-likelihoods that shares similar notion with MSLE but is claimed to be more efficient. The composite marginal likelihood (CML) method is one such approach, building pseudo-likelihoods by compounding low-dimensional “marginal” probabilities. CML studies date back to the 1970s, when the method was referred to as a partial likelihood, pseudo-likelihood, or quasi-likelihood approach. The term “composite

likelihood” was first proposed in 1988, and the approach has been gaining popularity since 2004, as more and more time-series and spatial-data studies have confronted estimation barriers. The method seeks computational savings at the cost of some loss in estimator efficiency. Popularly adopted approaches include the following:

- (a) Univariate distributions, which ignore dependence across observations, so the likelihood is referred to as an independent likelihood (IL). The use of univariate probabilities ignores all correlations and thus cannot recover parameters representing error correlation (and spatial) effects, but it will still lead to consistent estimators for the primary variables.
- (b) Bivariate distributions, which result in a pairwise likelihood (PL) function, or the multiple of pairwise marginal likelihoods:

$$PL(\beta; y) = \prod_{i=1}^{N-1} \prod_{j=i+1}^N f(y_i, y_j; \beta)^{w_{ij}} \quad (81.22)$$

where $f(\cdot)$ indicates the pairwise marginal likelihoods, i, j are two among a total of N observations, and w_{ij} denotes the weight assigned to the corresponding pairwise likelihood, normally set to be 1. Similarly, one can reflect three-way dependencies, using observation triplets, or combine the IL and PL likelihoods. Varin (2008) has described CML properties in detail, including the application of CML in spatial econometric settings. Of course, the suitability of a CML approach depends on whether it is appropriate to replace a high-dimensional joint distribution with low-dimensional marginal distributions. In general, for spatial data, where there are long sequences of correlated response values, CML inference retains good properties “provided that the data may be seen as formed by pseudo independent subsets. This is the case of stationary time-series and spatial processes with good mixing properties as an autocorrelation function exponentially decaying to zero.” (Varin 2008) In other words, if the autocorrelation dies down quickly, so observations are only weakly correlated with those “far” from their location, CML estimators tend to be quite efficient. If, instead, the spatial autocorrelation is rather global and does not decay fast, the convergence of CML estimators may be slow or even fail. The CML approach is now being tested by researchers from a wide spectrum of disciplines, including gene mapping and population dynamics. Bhat (2011) further extended CML and developed the maximum approximate composite marginal likelihood (MACML) by integrating the multivariate standard normal cumulative distribution (MVNCD) function approximation and the CML. The MVNCD function approximation (i.e., the “MA” part of MACML) changes the following joint probability $Pr(V < v) = \Phi(V_1 < v, V_2 < v_2, V_3 < v_3, \dots, V_I < v_I)$ into the product of a bivariate marginal probability and a univariate conditional probability:

$$Pr(V < v) = Pr(V_1 < v_1, V_2 < v_2) \times \prod_{i=3}^I Pr(V_i < v_i | V_1 < v_1, V_2 < v_2, \dots, V_{i-1} < v_{i-1}) \quad (81.23)$$

where the meaning of V and v is the same as those in Eq. (81.19). The right-hand side univariate conditional probability can be further approximated using linear regression models because

$$\begin{aligned} &Pr(V_i < v_i | V_1 < v_1, V_2 < v_2, \dots, V_{i-1} < v_{i-1}) \\ &= E\left(\widetilde{I}_i | \widetilde{I}_1 = 1, \widetilde{I}_2 = 1, \widetilde{I}_3 = 1, \dots, \widetilde{I}_{i-1} = 1\right) \end{aligned} \quad (81.24)$$

where \widetilde{I}_i is a binary indicator corresponding to $V_i < v_i$. Essentially, the MA part handles the correlation within one event (observation), and the CML takes care of the correlation across events (observations). Bhat (2011) discussed MACML's application in spatial data sets. If the spatial dependency is global (extending across all Q observations), there will be $Q(Q-1)/2$ pairs of bivariate probabilities. Bhat (2011) claims that "... in a spatial case where dependency drops quickly with inter-observation distance, the pairs formed from the closest observations provide much more information than pairs that are very far away. ... Typically, in a spatial context, there appears to be an optimal distance for inclusion of observation pairs. This distance threshold may be set based on knowledge about the spatial process or based on testing the efficiency of estimators with varying values of the distance threshold. Using such a distance threshold effectively reduces the number of pairwise terms in the CML function." Paleti and Bhat (2011) also compared the performance of CML to the conventional MSLE approach and concluded that the CML approach recovers the parameter well and is more efficient than MSLE. Bhat and coauthors then applied MACML in various settings involving spatial limited dependent variable models: Ferdous and Bhat (2012) used a spatial panel ordered-response model to analyze the urban land-use development intensity patterns; Ferdous et al. (2011) applied CML in a hazard-based specification to study the nonmotorized mode use; and Sener and Bhat (2011) applied CML to a copula-based spatial unordered response model structure to analyze teenagers' activity participation rates.

81.4.3 Bayesian Approach

Another technique used popularly to estimate complex spatial models is the Bayesian approach. In contrast to classical statistical analysis, the Bayesian approach is rather straightforward in both model estimation and result interpretation. Bayesian framework relies on a set of conditional distributions to deduce each parameter's marginal distribution. In this way, it decomposes multilayered probability specifications into a set of simpler subproblems. A Bayesian approach also allows direct interpretation of parameter estimates and probabilities, since it yields estimates of parameter distributions (rather than classical point estimates, which rely on asymptotic normality). Another advantage of Bayesian approach is that one can integrate established intuition and experience with new information found in sample data through the use of prior or constrained distributions. Thanks to its many advantages,

the Bayesian framework has recently attracted the attention of numerous regional scientists (LeSage and Pace 2009; Smith and LeSage 2004; Wang et al. 2012; Wang and Kockelman 2009). Essentially, Bayesian approaches rest on the basic property of conditional probability known as Bayes' rule:

$$\pi(\beta|y, x) = \frac{\pi(\beta|X)\pi(y|\beta, X)}{\pi(y|X)} \propto \pi(\beta|X)\pi(y|\beta, X) \quad (81.25)$$

Normally, the explanatory variables X are irrelevant to the parameters (as in most cases), so $\pi(\beta|X) = \pi(\beta)$. This is known as the prior, or prior distribution of the random parameters β . One can incorporate intuition and/or experience in this prior distribution. $\pi(y|\beta, X)$ is the likelihood function of y given X and β . Apparently, Bayesian methods integrate information from two sources: one's beliefs and sample data. Together, they lead to updated information on β , producing a posterior distribution of β , which is denoted as $\pi(\beta|y, X)$.

For example, in a SEM multinomial discrete response setting, where Eq. (81.7) is further allowed to incorporate spatial effects in error terms so that

$$\varepsilon_{ik} = \lambda_k \sum_{\substack{j=1 \\ j \neq i}}^N w_{ijk} \varepsilon_{jk} + \theta_{ik} \quad (81.26)$$

where λ_k indicates the spatial coefficient. Let the error terms θ_{ik} between alternatives follow multivariate normal distribution $\theta_i \sim N(0, B)$; then the covariance matrix of ε is Ω , a function of λ_k and B . According to Eq. (81.24), the joint posterior distribution for all parameters can be expressed as

$$p(y^{\rightarrow}, \beta, \lambda_k, B|y, X) \propto p(y|y^{\rightarrow})p(y^{\rightarrow}|\beta, \lambda_k, B)\pi(\beta)\pi(\lambda_k)\pi(B) \quad (81.27)$$

As the equations only require proportionality, the conditional posterior distributions of all parameters can be derived by extracting only items that contain them, as follows:

$$p(\beta|\dots) \propto p(y^{\rightarrow}|\beta, \lambda_k, B)\pi(\beta) \quad (81.28)$$

$$p(y^{\rightarrow}|\dots) \propto p(y|y^{\rightarrow})p(y^{\rightarrow}|\beta, \lambda_k, B) \quad (81.29)$$

$$p(B|\dots) \propto P(y^{\rightarrow}|\beta, \lambda_k, B)\pi(B) \quad (81.30)$$

$$p(\lambda_k|\dots) \propto p(y^{\rightarrow}|\beta, \lambda_k, B)\pi(\lambda_k) \quad (81.31)$$

The $p(y|y^{\rightarrow})$ and $p(y^{\rightarrow}|\beta, \lambda_k, B)$ can be derived easily from the model specification. The challenge is to choose appropriate priors. When no established intuition or experience is available, diffuse (also called noninformative or flat) priors are often preferred, reflecting the notion of "letting the data speak for themselves."

For example, if it is assumed that β has normal priors with hyperparameters β_0 and Θ_β , that is,

$$\pi(\beta) \sim N(\beta_0, \Theta_\beta) \quad (81.32)$$

Then the conditional posterior distribution can be derived as

$$p(\beta | \dots) \propto \exp\left(-\frac{1}{2}([y^\rightarrow - X\beta]' \Omega^{-1} [y^\rightarrow - X\beta] + [\beta - \beta_0]' \Theta_\beta^{-1} [\beta - \beta_0])\right) \quad (81.33)$$

It can be observed that such a posterior distribution is essentially a weighted average of β 's prior distribution and sample data information. The weights are the *inverse* of the variance-covariance matrices or associated “uncertainty” levels. Conditional posterior distributions of other parameters can be derived in similar ways. Once derived, they can be estimated using Monte Carlo Markov Chain (MCMC) simulation technique, where the values of parameters are drawn sequentially from these distributions, leading to estimation of each parameter’s distribution (see Mills and Parent, ► [Chap. 79](#), “Bayesian MCMC Estimation”).

81.5 Conclusions

Variables can be limited, censored, or truncated for various reasons. Although the forms of models for handling these variables are different, they share one thing in common: the use of latent dependent variables. The observed dependent variables are often expressed as nonlinear functions of the latent variables, which are usually linear functions of explanatory variables. By using latent variables as the bridge, it is convenient to extend the spatial considerations, commonly seen in linear models, into these nonlinear model settings. When the spatial variation of the data generation process is of major concern, geographically weighted regression is preferred. When interest is mainly on prediction or analysis of primary variables, spatial filtering is a powerful tool. When spatial effects need to be explicitly identified and interpreted, spatial regression models are a good choice. Of course, these specifications can also be combined when both spatial variation and dependency need to be addressed.

When the limited and censored dependent variable models are further complicated by the consideration of spatial effects, since the model likelihood becomes multilayered and intractable. In order to obtain consistent and efficient estimators, the selection of estimation techniques is a key consideration. The popular techniques used in practice include maximum simulated likelihood estimation, composite marginal likelihood estimation, and Bayesian approaches. Each of these approaches has its advantages and limitations. The selection of estimation approaches needs to take into account the underlying spatial effects, sample size, model form, and available information. For example, when spatial autocorrelation decays fast, composite marginal likelihood performs well. When established intuition needs to be integrated, the Bayesian approach is proved to be a good framework.

Abstract

This chapter provides a survey of the existing literature on spatial panel data models. Both static and dynamic models will be considered. The chapter also demonstrates that spatial econometric models that include lags of the dependent variable and of the independent variables in both space and time provide a useful tool to quantify the magnitude of direct and indirect effects, both in the short term and long term. Direct effects can be used to test the hypothesis as to whether a particular variable has a significant effect on the dependent variable in its own economy and indirect effects to test the hypothesis whether spatial spillovers exist. To illustrate these models and their effects estimates, a demand model for cigarettes is estimated based on panel data from 46 US states over the period 1963–1992.

82.1 Introduction

Spatial econometrics deals with interaction effects among geographical units, such as zip codes, neighborhoods, municipalities, counties, regions, states, or countries. Examples are economic growth rates of OECD countries over T years, monthly unemployment rates of EU regions in the last decade, and annual tax rate changes of all jurisdictions in a country since the last election. Spatial econometric models can also be used to explain the behavior of economic agents other than geographical units, such as individuals, firms, or governments, but this type of research is still in its infancy. Examples are research productivity of N universities located in a particular country and consumption of the representative consumer in each zip code of the trade area of a commercial firm.

In modeling terms, three different types of interaction effects can be distinguished: endogenous interaction effects among the dependent variable (Y), exogenous interaction effects among the independent variables (X), and interaction effects among the error terms (ε). Originally, the central focus of spatial econometrics has been on one type of interaction effect in a single-equation cross-sectional setting (► [Chap. 66](#), “Exploratory Spatial Data Analysis”). Usually, the point estimate of the coefficient of this interaction effect was used to test the hypothesis as to whether spatial spillover effects exist. Most of the work was inspired by research questions arising in regional science and economic geography, where the units of observations are geographically determined and the structure of the dependence among these units can somehow be related to location and distance. However, more recently, the focus has shifted to models with more than one type of interaction effects, to panel data, and to the marginal effects of the explanatory variables in the model rather than the point estimates of the interaction effects.

In this chapter, we review and organize this recent literature. In [Sect. 82.2](#), we present the linear regression model with spatial interaction effects for cross-sectional data and in [Sect. 82.3](#) its extension to panel data. In [Sect. 82.4](#), the latter model is further extended to include dynamic effects in both space and time. In [Sect. 82.5](#), we provide so-called effects estimates (► [Chap. 73](#), “Geographically Weighted Regression”), which are required for making correct inferences regarding the effect of independent variables on the dependent variable. In [Sect. 82.6](#), we estimate a demand model for cigarettes based on panel data from 46 US states over the period 1963–1992 to empirically illustrate the different models. This data set is taken from Baltagi (2005) and has been used for illustration purposes in other studies too. Finally, we conclude this chapter with a number of important implications for econometric modeling of relationships based on spatial panel data.

82.2 Linear Spatial Dependence Models for Cross-Sectional Data

The standard approach in most empirical work is to start with a nonspatial linear regression model and then to test whether or not the model needs to be extended

with spatial interaction effects. This approach is known as the specific-to-general approach. The nonspatial linear regression model takes the form

$$Y = \alpha \mathbf{1}_N + X\beta + \varepsilon \quad (82.1)$$

where Y denotes an $N \times 1$ vector consisting of one observation on the dependent variable for every unit in the sample ($i = 1, \dots, N$), $\mathbf{1}_N$ is an $N \times 1$ vector of ones associated with the constant term parameter α , X denotes an $N \times K$ matrix of exogenous explanatory variables with parameters β contained in a $K \times 1$ vector, and $\varepsilon = (\varepsilon_1, \dots, \varepsilon_N)^T$ is a vector of disturbance terms. The ε_i are independently and identically distributed error terms for all i with zero mean and variance σ^2 . Since the linear regression model is commonly estimated by ordinary least squares (OLS), it is often labeled the OLS model. Furthermore, even though the OLS model in most studies focusing on spatial interaction effects is rejected in favor of a more general model, its results often serve as a benchmark.

The opposite approach is to start with a more general model that nests a series of simpler models, which would ideally represent all alternative economic hypotheses requiring consideration. Generally, three different types of interaction effects may explain why an observation associated with a specific location may be dependent on observations at other locations:

- (i) Endogenous interaction effects, where the decision of a particular unit A (or its economic decision makers) to behave in some way depends on the decision taken by other units, among which, say, unit B,

$$\text{Dependent variable } y \text{ of unit A} \leftrightarrow \text{Dependent variable } y \text{ of unit B} \quad (82.2)$$

Endogenous interaction effects are typically considered as the formal specification for the equilibrium outcome of a spatial or social interaction process, in which the value of the dependent variable for one agent is jointly determined with that of the neighboring agents. In the empirical literature on strategic interaction among local governments, for example, endogenous interaction effects are theoretically consistent with the situation where taxation and expenditures on public services interact with taxation and expenditures on public services in nearby jurisdictions (Brueckner 2003).

- (ii) Exogenous interaction effects, where the decision of a particular unit to behave in some way depends on independent explanatory variables of the decision taken by other units

$$\text{Independent variable } x \text{ of unit B} \rightarrow \text{Dependent variable } y \text{ of unit A} \quad (82.3)$$

Consider, for example, the savings rate. According to standard economic theory, saving and investment are always equal. People cannot save without investing their money somewhere, and they cannot invest without using somebody's savings. This is true for the world as a whole, but it is not true

for individual economies. Capital can flow across borders; hence the amount an individual economy saves does not have to be the same as the amount it invests. In other words, per capita income in one economy also depends on the savings rates of neighboring economies. It should be stressed that, if the number of independent explanatory variables in a linear regression model is K , the number of exogenous interaction effects might also be K , provided that the intercept is considered as a separate variable. In other words, not only the savings rate but also other explanatory variables may affect per capita income in neighboring economies. It is for this reason that economic growth in both the theoretical and the empirical literature on economic growth and convergence among countries or regions is not only taken to depend on the initial income level and the rates of saving, population growth, technological change, and depreciation in the own economy but also on those of neighboring economies (Ertur and Koch 2007; Elhorst et al. 2010).

(iii) Interaction effects among the error terms

$$\text{Error term } u \text{ of unit A} \leftrightarrow \text{Error term } u \text{ of unit B} \quad (82.4)$$

Interaction effects among the error terms do not require a theoretical model for a spatial or social interaction process but, instead, are consistent with a situation where determinants of the dependent variable omitted from the model are spatially autocorrelated and with a situation where unobserved shocks follow a spatial pattern. Interaction effects among the error terms may also be interpreted to reflect a mechanism to correct rent-seeking politicians for unanticipated fiscal policy changes (Allers and Elhorst 2005).

A full model with all types of interaction effects takes the form

$$Y = \rho WY + \alpha t_N + X\beta + WX\theta + u \quad (82.5a)$$

$$u = \lambda Wu + \epsilon \quad (82.5b)$$

where the variable WY denotes the endogenous interaction effects among the dependent variables, WX the exogenous interaction effects among the independent variables, and Wu the interaction effects among the disturbance terms of the different units. ρ is called the spatial autoregressive coefficient and λ the spatial autocorrelation coefficient, while θ , just as β , represents a $K \times 1$ vector of fixed but unknown parameters. W is a nonnegative $N \times N$ matrix of known constants describing the arrangement of the units in the sample. Its diagonal elements are set to zero by assumption, since no unit can be viewed as its own neighbor.

Three methods have been developed to estimate models that include interaction effects. One is based on maximum likelihood (ML) or quasi-maximum likelihood (QML), one on instrumental variables or generalized method of moments (IV/GMM), and one on the Bayesian Markov Chain Monte Carlo (MCMC)

approach. QML and IV/GMM estimators are different in that they do not rely on the assumption of normality of the disturbances. Detailed descriptions of these estimation techniques can be found in Anselin (1988), Lee (2004), Kelejian and Prucha (1998), LeSage and Pace (2009), ► Chap. 67, “Spatial Clustering and Autocorrelation in Health Events,” ► Chap. 69, “Spatial Dynamics and Space-Time Data Analysis,” and ► Chap. 72, “Bayesian Spatial Statistical Modeling”.

Technically, there are no obstacles to estimating a model with interaction effects among the dependent variable, the independent variables, and the disturbance terms. Often, however, the parameters cannot be interpreted in a meaningful way since the different types of interaction effects cannot be distinguished from each other. Lee et al. (2010) prove that there is at least one spatial weights matrix so that all parameters are identified. They consider G groups, each consisting of N_g cross-sectional units, and assume that the elements of the spatial weights matrix measuring the interaction effects are $w_{ij} = 1/(N_g - 1)$ if units i and j belong to the same group (except if $i = j$) and zero otherwise. Starting with this spatial weights matrix, it is shown that the parameters are identified either if both N and N_g tend to infinity, with at least two units in each group, or if the number of units in each group does not tend to infinity faster than or equal to the number of groups. Whether the parameters are also identified for other specifications of the spatial weights matrix still needs to be investigated. If not, the best option is to exclude the spatially autocorrelated error term and to consider a model with endogenous and exogenous interaction effects “only.” This model is known as the spatial Durbin model. Only is put in quotation marks, because this model covers $K + 1$ of the $K + 2$ potential interaction effects. According to LeSage and Pace (2009, pp. 155–158), the cost of ignoring spatial dependence in the dependent variable and/or in the independent variables is relatively high since the econometric literature has pointed out that if one or more relevant explanatory variables are omitted from a regression equation, the estimator of the coefficients for the remaining variables is biased and inconsistent. In contrast, ignoring spatial dependence in the disturbances, if present, will only cause a loss of efficiency.

82.3 Linear Spatial Dependence Models for Panel Data

In recent years, the spatial econometric literature has exhibited a growing interest in the specification and estimation of econometric relationships based on spatial panels. This interest can be partly explained by the increased availability of more data sets in which a number of spatial units are followed over time and partly by the fact that panel data offer researchers extended modeling possibilities as compared to the single-equation cross-sectional setting. Panel data are generally more informative, and they contain more variation and less collinearity among the variables. The use of panel data results in a greater availability of degrees of freedom and hence increases efficiency in the estimation. Panel data also allow for the specification of more complicated behavioral hypotheses, including effects that cannot be addressed using pure cross-sectional data (see Baltagi 2005 and the references therein).

The extension of the spatial econometric model, presented in Eqs. (82.5a, 82.5b), for a cross section of N observations to a space-time model for a panel of N observations over T time periods is obtained by adding a subscript t , which runs from 1 to T , to the variables and the error terms of that model

$$Y_t = \rho WY_t + \alpha_{1N} + X_t\beta + WX_t\theta + u_t \quad (82.6a)$$

$$u_t = \lambda Wu_t + \varepsilon_t \quad (82.6b)$$

This model can be estimated along the same lines as the cross-sectional model, provided that all notations are adjusted from one cross section to T cross sections of N observations.

However, the main objection to pooling the data like this is that the resulting model does not account for spatial and temporal heterogeneity. Spatial units are likely to differ in their background variables, which are usually space-specific time-invariant variables that do affect the dependent variable, but which are difficult to measure or hard to obtain. Examples of such variables abound: one spatial unit is located at the seaside, the other just at the border; one spatial unit is a rural area located in the periphery of a country, the other an urban area located in the center; norms and values regarding labor, crime, and religion in one spatial unit might differ substantially from those in another unit. Failing to account for these variables increases the risk of obtaining biased estimation results. One remedy is to introduce a variable intercept μ_i representing the effect of the omitted variables that are peculiar to each spatial unit considered. In sum, spatial-specific effects control for all time-invariant variables whose omission could bias the estimates in a typical cross-sectional study. Similarly, the justification for adding time period-specific effects ξ_t is that they control for all spatial-invariant variables whose omission could bias the estimates in a typical time-series study (Baltagi 2005). Examples of such variables also exist: one year is marked by economic recession, the other by a boom; changes in legislation or government policy can significantly affect the functioning of an economy as from the date of implementation, as a result of which before and after observations might be significantly different from one another.

The space-time model in Eqs. (82.6a, 82.6b) extended with spatial-specific and time-period-specific effects reads as

$$Y_t = \rho WY_t + \alpha_{1N} + X_t\beta + WX_t\theta + \mu + \xi_t 1_N + u_t \quad (82.7a)$$

$$u_t = \lambda Wu_t + \varepsilon_t \quad (82.7b)$$

where $\mu = (\mu_1, \dots, \mu_N)^T$. The spatial- and time period-specific effects may be treated as fixed effects or as random effects. In the fixed effects model, a dummy variable is introduced for each spatial unit and for each time period (except one to avoid perfect multicollinearity), while in the random effects model, μ_i and ξ_t are

treated as random variables that are independently and identically distributed with zero mean and variance σ_μ^2 and σ_ξ^2 , respectively. Furthermore, it is assumed that the random variables μ_i , ξ_i , and ε_{it} are independent of each other.

The estimation of static spatial panel data models is extensively discussed in Elhorst (2003, 2010a) and Lee and Yu (2010a). The first presents the ML estimator of the spatial lag model and of the spatial error model extended to include fixed effect or random effects. Further note that the spatial Durbin model can be estimated as a spatial lag model with explanatory variables $[X \text{ WX}]$ instead of X . The response parameters of the fixed effects models can be estimated by concentrating out the fixed effects first, called demeaning (see Baltagi (2005) for mathematical details). The resulting equation can then be estimated by the ML estimation procedure developed by Anselin (1988) for the spatial lag model, provided that this procedure is generalized from one single cross section of N observations to T cross sections of N observations. The estimation of the random effects model is somewhat more complicated.

Lee and Yu (2010a) show that the ML estimator of the spatial lag and of the spatial error model with spatial fixed effects, as set out in Elhorst (2003, 2010a), will yield an inconsistent parameter estimate of the variance parameter (σ^2) if N is large and T is small and inconsistent estimates of all parameters of the spatial lag and of the spatial error model with spatial and time-period fixed effects if both N and T are large. To correct for this, they propose a simple bias correction procedure based on the parameter estimates of the uncorrected approach. Matlab routines for both the fixed effects and the random effects spatial lag model, as well as the fixed effects and the random effects spatial error model are provided at www.regoningen.nl/elhorst. Recently, these routines have been updated for the bias correction procedure of Lee and Yu (2010a).

82.4 Dynamic Linear Spatial Dependence Models for Panel Data

To make the spatial panel data model, presented in Eqs. (82.7a, 82.7b), dynamic, one might add time lags of the variables Y_t and WY_t to get

$$Y_t = \tau Y_{t-1} + \rho WY_t + \eta WY_{t-1} + \alpha_{tN} + X_t \beta + WX_t \theta + \mu + \xi_{tN} + u_t \quad (82.8)$$

This model is known as a dynamic spatial Durbin model (Debarsy et al. 2012). Similarly, one might consider time lags of the variables X_t and WX_t and of the error terms u_t and Wu_t , but according to Anselin et al. (2008), the parameters of such a model will not be identified.

Three methods have been developed in the literature to estimate models that have mixed dynamics in both space and time. One method is to bias-correct the maximum likelihood (ML) or quasi-maximum likelihood (QML) estimator, one method is based on instrumental variables or generalized method of moments (IV/GMM), and one method utilizes the Bayesian Markov Chain Monte Carlo (MCMC) approach.

Yu et al. (2008) construct a bias-corrected estimator for a dynamic model (Y_{t-1} , WY_t and WY_{t-1}) with spatial fixed effects. Lee and Yu (2010b) extend this study to include time-period fixed effects. They first estimate the model by the ML estimator for the spatial lag model with spatial (and time-period) fixed effects, conditional upon the first observation of every spatial unit in the sample due to the regressors Y_{t-1} and WY_{t-1} . Next, they provide a rigorous asymptotic theory for their ML estimator and suggest a bias-corrected ML estimator when both the number of spatial units (N) and the number of time points (T) in the sample go to infinity such that the limit between N and T exists and is bounded between zero and infinity ($0 < \lim(N/T) < \infty$). In the words of Lee and Yu (2010c, p. 2), this condition implies that “ $T \rightarrow \infty$ where T cannot be too small relative to N .” The bias correction is derived for both normally distributed error terms (ML) and for error terms that do not rely on the normality assumption (QML). In the latter case, the first four moments are required. Finally, it is to be noted that this bias-corrected ML estimator can also be used when either the variable Y_{t-1} or the variable WY_{t-1} is eliminated from the model.

Elhorst (2010b) investigates the small sample properties of the bias-corrected ML estimator. For this purpose, he extends the unconditional ML estimator proposed by Hsiao et al. (2002) with the variable WY_t , as well as the Bhargava and Sargan (1983) approximation that is used to determine the expected value and the variance of the first first-differenced observations in the sample. One of his conclusions is that the parameter estimate ρ of the variable WY_t is still considerably biased when using this unconditional ML estimator. However, if the parameter estimate ρ is based on the bias-corrected ML estimator and the other parameters, given ρ , on the unconditional ML estimator, then this so-called mixed estimator outperforms the bias-corrected estimator of Yu et al. (2008) for small values of T ($T = 5$).

A couple of studies have considered IV/GMM estimators, building on previous work of Arellano and Bond (1991) and Blundell and Bond (1998). Elhorst (2010b) extends the Arellano and Bond difference GMM estimator to include endogenous interaction effects and finds that this estimator can still be severely biased, especially with respect to the parameter estimate ρ of the variable WY_t . He notes a bias of 0.061. The explanation for this can be found in Lee and Yu (2010c). They find that a 2SLS estimator like the Arellano and Bond GMM estimator which is based on lagged values of Y_{t-1} , WY_{t-1} , X_t , and WX_t is not consistent due to too many moments and that the dominant bias is caused by the endogeneity of the variable WY_t rather than the variable Y_{t-1} . To avoid these problems, they propose an optimal GMM estimator based on linear moment conditions, which are standard, and quadratic moment conditions, which are implied by the variable WY_t , and therefore not standard in dynamic panel data models. They prove that this GMM estimator is consistent, also when T is small relative to N .

Parent and LeSage (2010, 2011) point out that the Bayesian MCMC approach considers conditional distributions of each parameter of interest conditional on the others, which leads to some computational simplification. Just as Elhorst (2010b), they treat the first-period cross section as endogenous, using the Bhargava and

Sargan (1983) approximation, and find that the correct treatment of the initial observations (endogenous instead of exogenous) is important, especially in cases when T is small.

82.5 Direct and Spatial Spillover Effects

Many empirical studies use point estimates of one or more spatial regression model specifications to test the hypothesis as to whether or not spatial spillovers exist. One of the key contributions of LeSage and Pace's book (2009, p. 74) is the observation that this may lead to erroneous conclusions and that a partial derivative interpretation of the impact from changes to the variables of different model specifications represents a more valid basis for testing this hypothesis.

By rewriting the spatial econometric model with dynamic effects in space and time in Eq. (82.8) as

$$Y_t = (I - \rho W)^{-1}(\tau I + \eta W)Y_{t-1} + (I - \rho W)^{-1}(X_t\beta + WX_t\theta) + R \quad (82.9)$$

where R is a rest term containing the intercept and the error terms, the matrix of partial derivatives of the expected value of Y with respect to the k th explanatory variable of X in unit 1 up to unit N at a particular point in time can be seen to be

$$\left[\frac{\partial E(Y)}{\partial x_{1k}} \quad \dots \quad \frac{\partial E(Y)}{\partial x_{Nk}} \right]_t = (I - \rho W)^{-1}[\beta_k I_N + \theta_k W] \quad (82.10)$$

These partial derivatives denote the effect of a change of a particular explanatory variable in a particular spatial unit on the dependent variable of all other units in the *short term*. Similarly, the *long-term* effects can be seen to be

$$\left[\frac{\partial E(Y)}{\partial x_{1k}} \quad \dots \quad \frac{\partial E(Y)}{\partial x_{Nk}} \right] = [(1 - \tau)I - (\rho + \eta)W]^{-1}[\beta_k I_N + \theta_k W] \quad (82.11)$$

LeSage and Pace (2009) and Debarsy et al. (2012) define the direct effect as the average of the diagonal elements of the matrix on the right-hand side of Eq. (82.10) or Eq. (82.11) and the indirect effect as the average of either the row sums or the column sums of the non-diagonal elements of these matrices (since the numerical magnitudes of these two calculations of the indirect effect are the same, it does not matter which one is used). The outcomes are independent from the time index; this explains why the right-hand sides of these equations do not contain the symbol t . The expressions in Eqs. (82.10) and (82.11) also show that short-term indirect effects do not occur if both $\rho = 0$ and $\theta_k = 0$, while long-term indirect effects do not occur if both $\rho = -\eta$ and $\theta_k = 0$.

Using the expressions in Eqs. (82.10) and (82.11), it is also possible to indicate the disadvantages of certain parameter restrictions put forward in previous studies (see Elhorst (2012) for an overview). The disadvantage of not considering

exogenous interaction effects (WX_t), that is, by imposing the restriction $\theta = 0$, is that the ratio between the indirect effect and the direct effect becomes the same for every explanatory variable; if this ratio happens to be p percent for one variable, it is also p percent for any other variable. The disadvantage of excluding contemporaneous endogenous interaction effects (WY_t) by imposing the restriction $\rho = 0$ is that the matrix $(I - \rho W)^{-1}$ degenerates to the identity matrix, as a result of which the indirect effects in the short term only depend on θ . This loss of flexibility makes the model less suitable for empirical research focusing on short-term effects. The disadvantage of imposing the restriction $\eta = -\tau\rho$ is that the ratio between the indirect effect and the direct effect of a particular explanatory variable remains constant over time; if this ratio happens to be p percent for one variable in the short term, it is also p percent in the long term. Note that this restriction implies that η , the parameter associated with lagged endogenous interaction effects, is equal to $-\tau\rho$, the two parameters of the dependent variables respectively lagged in time and lagged in space. In other words, just as the two previous restrictions, it eliminates one type of interaction effects. Finally, if lagged endogenous interaction effects (WY_{t-1}) are eliminated from the model, that is, $\eta = 0$, no prior restrictions are imposed on the direct and indirect effects estimates, even though it is clear that still some flexibility of the model will be lost.

82.6 Empirical Illustration

Baltagi and Li (2004) estimate a demand model for cigarettes based on a panel from 46 US states in which real per capita sales of cigarettes by persons of smoking age (14 years and older) measured in packs of cigarettes per capita (C_{it}) is regressed on the average retail price of a pack of cigarettes measured in real terms (P_{it}) and on real per capita disposable income (Y_{it}). Moreover, all variables are taken in logs. Whereas Baltagi and Li (2004) use the first 25 years for estimation to reserve data for out of sample forecasts, we use the full data set covering the period 1963–1992. This data set can be downloaded freely from www.wiley.co.uk/baltagi/, while an adapted version is available at www.regroningen.nl/elhorst. More details, as well as reasons to include state-specific effects (μ_i) and time-specific effects (ξ_t), are given in Baltagi (2005). The spatial weights matrix is specified as a row-normalized binary contiguity matrix whose elements are one if two states share a common border and zero otherwise.

Column (1) of Table 82.1 reports the estimation results when adopting a non-dynamic spatial Durbin model without spatial and time-period fixed effects and column (2) when including these effects. To investigate whether or not the fixed effects are jointly significant, one may test the hypothesis $H_0: \mu_1 = \dots = \mu_N = \xi_1 = \dots = \xi_T = \alpha$, where α is the intercept of the model without fixed effects. To test this (null) hypothesis, one may perform a likelihood-ratio (LR) test, which is based on the log-likelihood function values of both models. The number of degrees of freedom is equal to the number of restrictions that needs to be imposed on the fixed effects to get one overall intercept, which in this particular case is $N + T - 1$. The outcome of this test ($2 \times (1691.4 - 475.5) = 2431.8$ with

Notes: t-values in parentheses

$N + T - 1 = 46 + 30 - 1 = 75$ df) justifies the extension of the model with spatial and time-period effects. Note that one may also separately test for the inclusion of spatial fixed effects and time-period fixed effects.

It is to be noted that the coefficient of any variable that does not change over time or only a little cannot be estimated when controlling for spatial fixed effects. Similarly, the coefficient of any variable that does not change across space or only a little cannot be estimated when controlling for time-period fixed effects. For many empirical studies, this is a reason not to control for fixed effects, for example, because such time-invariant or space-invariant variables are the main focus of the analysis. However, if one or more relevant explanatory variables are omitted from the regression equation, when they should be included, the estimator of the coefficients of the remaining variables is biased and inconsistent. This also holds true for fixed effects and is known as the omitted regressor bias.

Instead of fixed effects, we can also treat μ and ξ as random effects. Hausman specification test can then be used to test the random effects model against the fixed effects model. However, whether the random effects model is an appropriate specification if the population may be said to be sampled exhaustively, such as all counties of a state or all regions in a country, remains controversial. A detailed discussion of this issue can be found in Elhorst (2012).

The main shortcoming of a non-dynamic spatial Durbin model is that it cannot be used to calculate short-term effects estimates of the explanatory variables. This is made clear in Table 82.2, which reports the corresponding effects estimates of the models presented in Table 82.1; since a non-dynamic model only produces long-term effects estimates, the cells reporting short-term effects estimates are left empty.

The direct effects estimates of the two explanatory variables reported in column (2) of Table 82.2 are significantly different from zero and have the expected signs. Higher prices restrain people from smoking, while higher-income levels have

Notes: t-values in parentheses

a positive effect on cigarette demand. The price elasticity amounts to -1.013 and the income elasticity to 0.594 . Note that these direct effects estimates are different from the coefficient estimates of -1.001 and 0.603 reported in column (2) of [Table 82.1](#) due to feedback effects that arise as a result of impacts passing through neighboring states and back to the states themselves.

The spatial spillover effects (indirect effects estimates) of both variables are negative and significant. Own-state price increases will restrain people not only from buying cigarettes in their own state but to a limited extent also from buying cigarettes in neighboring states (elasticity -0.220). By contrast, whereas an income increase has a positive effect on cigarette consumption in the own state, it has a negative effect in neighboring states. We come back to this result below. Further note that the non-dynamic spatial Durbin model without spatial and time-period effects indicates a positive rather than a negative spatial spillover effect of price increases and that only a positive outcome would be consistent with Baltagi and Levin (1992), who found that price increases in a particular state – due to tax increases meant to reduce cigarette smoking and to limit the exposure of non-smokers to cigarette smoke – encourage consumers in that state to search for cheaper cigarettes in neighboring states. However, there are two reasons why this comparison is invalid. First, whereas Baltagi and Levin's (1992) model is dynamic, it is not spatial. They do consider the price of cigarettes in neighboring states, but not any other spatial interaction effects. Second, whereas our model contains spatial interaction effects, it is not (yet) dynamic. For these reasons, it is interesting to consider the estimation results of our dynamic spatial panel data model.

Column (3) of [Table 82.2](#) reports the direct and indirect effects of the dynamic model, both in the short term and long term. Consistent with microeconomic theory, the short-term direct effects appear to be substantially smaller than the long-term direct effects: -0.262 versus -1.931 for the price variable and 0.099 versus 0.770 for the income variable. This is because it takes time before price and income changes fully settle. The long-term direct effects in the dynamic spatial Durbin

model, on their turn, appear to be greater (in absolute value) than their counterparts in the non-dynamic spatial Durbin model: -1.931 versus -1.013 for the price variable and 0.770 versus 0.594 for the income variable. Apparently, the non-dynamic model underestimates the long-term effects. The short-term spatial spillover effect of a price increase turns out to be positive; the elasticity amounts to 0.160 and is highly significant (t-value, 3.49). This finding is in line with the original finding of Baltagi and Levin (1992) in that a price increase in one state encourages consumers to search for cheaper cigarettes in neighboring states. The negative spatial spillover effect of a price increase we found earlier for the non-dynamic spatial Durbin model demonstrates that a non-dynamic approach falls short here. Although greater and again positive, we do not find empirical evidence that the long-term spatial spillover effect of a price increase is also significant. A similar result is found by Debarsy et al. (2012). It is to be noted that they estimate the parameters of the model by the Bayesian MCMC estimator developed by Parent and LeSage (2010, 2011), whereas we use the bias-corrected ML estimator developed by Lee and Yu (2010b). Furthermore, the spatial weights matrix used in that study is based on lengths of state borders in common between each state and its neighboring states, whereas we use a binary contiguity matrix.

The long-term spatial spillover effect of the income variable derived from the dynamic spatial panel data model appears to be positive, which suggests that an income increase in a particular state has a positive effect on smoking not only in that state itself but also in neighboring states. Furthermore, the spatial spillover effect is smaller than the direct effect, which makes sense since the impact of a change will most likely be larger in the place that instigated the change. However, the spatial spillover effect of an income increase is not significant. A similar result is found by Debarsy et al. (2012). Interestingly, the spatial spillover effect of the income variable in the non-dynamic spatial panel data model appeared to be negative and significant. Apparently, the decision whether to adopt a dynamic or a non-dynamic model represents an important issue. Some researchers prefer simpler models to more complex ones (Occam's razor). One problem of complex models is overfitting, the fact that excessively complex models are affected by statistical noise, whereas simpler models may capture the underlying process better and may thus have better predictive performance. However, if one can trade simplicity for increased explanatory power, the complex model is more likely to be the correct one.

To investigate whether the extension of the non-dynamic model to the dynamic spatial panel data model increases the explanatory power of the model, one may test whether the coefficients of the variables Y_{t-1} and WY_{t-1} are jointly significant using an LR test. The outcome of this test ($2 \times (2,623.3 - 1,691.4) = 1,863.8$ with 2 df) evidently justifies the extension of the model with dynamic effects.

One potential objection to the dynamic spatial Durbin model might be that its parameters are still not identified (Anselin et al. 2008). To investigate this, we carried out a Monte Carlo simulation experiment. The basic idea is to randomly draw (e.g., 1,000 times) the error terms based on σ^2 of the estimated equation, to generate the dependent variable given this error term and the independent variables

Table 82.3 Identification of parameters

Determinant/parameter	Dynamic spatial Durbin model with fixed effects

*Based on column (3) of [Table 82.1](#)

and their coefficient estimates reported in column (3) of [Table 82.1](#), and then to reestimate the model. On average, these results should be similar to those of the “original” parameter estimates. The results reported in [Table 82.3](#) show that the biases in the coefficient estimates, based on 1,000 replications, in this particular case are small. The largest bias is found in the coefficient of the spatial lag of the price variable W*Log(P); its original coefficient is 0.170, while its simulated coefficient is 0.182, which represents a bias of 0.012 or 7.1 % of the original parameter value. Although the impact of this bias on the direct and indirect effects estimates is negligible, a more careful elaboration of the identification issue is the topic of further research.

82.7 Conclusion

Spatial econometric models that include lags of the dependent variable and of the independent variables in both space and time provide a useful tool to quantify the magnitude of direct and indirect effects, both in the short term and long term. A demand model for cigarettes based on panel data from 46 US states over the period 1963–1992 is used to empirically illustrate this. Direct effects should be used to test the hypothesis as to whether a particular variable has a significant effect on the dependent variable in its own economy rather than the coefficient estimate of that variable. Similarly, indirect effects should be used to test whether or not spatial spillovers exist rather than the coefficient estimate of the spatially lagged dependent variable and/or the coefficient estimates of the spatially lagged independent variables.

One difficulty is that it cannot be seen from the coefficient estimates and the corresponding standard errors or t-values (derived from the variance-covariance matrix) whether the direct and indirect effects in a spatial econometric model are significant. This is because these effects are composed of different coefficient estimates according to complex mathematical formulas and the dispersion of these effects depends on the dispersion of all coefficient estimates involved. Fortunately, some individual researchers have made software available at their Web sites programmed in Matlab or R that calculates these effects and

their corresponding standard errors or t-values. Nevertheless, the availability of easier accessible packages such as Stata would probably encourage much more applied researchers to use these kinds of models and to report direct and indirect effects estimates in addition to the point estimates of the parameters of the model. This is important since eventually only these effects estimates should be used to draw inferences regarding the relationships we are modeling.

Abstract

Spatial interaction or gravity models have been used in regional science to model flows that take many forms, for example, population migration, commodity flows, traffic flows, and knowledge flows, all of which reflect movements between origin and destination regions. This chapter focuses on spatial autoregressive extensions to the conventional least-squares gravity models that relax the assumption of independence between flows. These models, proposed by LeSage and Pace (2008, Spatial econometric modeling of origin-destination flows. *J Reg Sci* 48(5):941–967, 2009), define spatial dependence in this type of setting to mean that larger observed flows from an origin region A to

a destination region Z are accompanied by (i) larger flows from regions nearby the origin A to the destination Z , say regions B and C that are neighbors to region A , which they label origin dependence; (ii) larger flows from the origin region A to regions neighboring the destination region Z , say regions X and Y , which they label destination dependence; and (iii) larger flows from regions that are neighbors to the origin (B and C) to regions that are neighbors to the destination (X and Y), which they label origin-destination dependence. Spatial spillovers in these models can take the form of spillovers to both regions/observations neighboring the origin or destination in the dyadic relationships that characterize origin-destination flows as well as network effects that impact all other regions in the network. We set forth a simulation approach for these models that can be used to produce scalar expressions for the various types of spillover impacts that arise from changes in the explanatory variables of the model.

83.1 Introduction to Gravity or Spatial Interaction Models

Gravity models have often been used to explain origin-destination (OD) flows that arise in regional science such as trade, transportation, and migration. In the regional science literature, the gravity model has been labeled a spatial interaction model (Sen and Smith 1995) because the regional interaction is directly proportional to the product of regional size measures. In the case of interregional commodity flows, the measure of regional size is typically gross regional product or regional income. The model predicts more interaction in the form of commodity flows between regions of similar (economic) size than regions dissimilar in size. For the case of migration flows, population would be a logical measure of regional size, and in other contexts such as knowledge flows between regions, LeSage, Fischer, and Scherngell (2007) use regional knowledge stocks measured by patents to reflect size.

Theoretical motivations for spatial interaction modeling are numerous, for example, Wilson (1967) and Roy (2004) provide a macroeconomic statistical equilibrium development, Smith (1975) and Sen and Smith (1995) rely on a microeconomic choice-theoretic approach, and Fischer (2002) and Fischer and Reismann (2002) take a neural network approach that treats spatial interaction models as universal function approximations.

Historically, motivations for these models took the view that spatial interaction implies movement of entities, and that this has little to do with spatial association (Getis 1991). These models attempt to explain variation in observed flows between origin and destination regions using (i) *origin-specific* attributes that characterize the ability of the origins to generate outflows, (ii) *destination-specific* attributes that attract inflows, and (iii) variables reflecting the spatial separation of origin and destination regions. The traditional assumption was that including *separation variables* (such as distance, borders, language, and cultural differences between regions) should fully account for observed spatial dependence in flows. Curry (1972) was an earlier dissenter from this view, advancing a theoretical motivation for the presence of spatial dependence in flows after conditioning on conventional

variables, and Griffith and Jones (1980) reported spatial correlation in residuals of conventional spatial interaction models. The notion that use of distance functions in conventional spatial interaction models effectively captures spatial dependence in the interregional flows being analyzed was further challenged by Porojan (2001) for the case of international trade flows, and Lee and Pace (2005) for retail sales. Both studies reported residuals from conventional models that exhibited spatial dependence. Despite these findings, most applied work continued to assume independence between flow observations relying on conventional least-squares models to explain observed variation in flows. One exception is Bolduc, Laferriere, and Santarossa (1992) who explicitly model the disturbances using a spatial autoregressive process.

LeSage and Pace (2008) define spatial dependence in a spatial interaction setting to mean that larger observed flows from an origin region A to a destination region Z are accompanied by (i) larger flows from regions nearby the origin A to the destination Z , say regions B and C that are neighbors to region A , which they label *origin dependence*; (ii) larger flows from the origin region A to regions neighboring the destination region Z , say regions X and Y , which they label *destination dependence*; and (iii) larger flows from regions that are neighbors to the origin (B and C) to regions that are neighbors to the destination (X and Y), which they label *origin-destination dependence*. Using this definition of spatial dependence, modeling of spatial dependence in regional flows requires a spatial autoregressive specification.

LeSage and Pace (2008) show how to produce maximum likelihood estimates for a spatial autoregressive specification of the spatial interaction model. This model includes spatial lags of the dependent variable similar to conventional spatial autoregressive models in an effort to directly model spatial dependence in flows. Fischer and Griffith (2008) use the approach introduced by LeSage and Pace (2008) to include spatial lags for the model disturbances. LeSage and Pace (2009) show how to produce Bayesian Markov Chain Monte Carlo estimates for their spatial econometric variant of the spatial interaction model. While the motivation provided by LeSage and Pace (2008) for the spatial econometric approach to spatial interaction modeling is purely econometric, Behrens, Ertur, and Koch (2012) provide a theoretical justification for such models.

Section 83.2 introduces the conventional spatial interaction model that assumes independence between observed flows and relies on ordinary least-squares estimation methods.

In Sect. 83.3, we introduce the spatial autoregressive extension of LeSage and Pace (2008). Section 83.4 discusses a number of problems that arise in applied modeling of regional flows that can invalidate use of maximum likelihood (or Bayesian) estimation of the model from LeSage and Pace (2008). These problems provide fertile ground for future research in spatial interaction modeling.

While the focus in LeSage and Pace (2008, 2009) was on maximum likelihood and Bayesian estimation of spatial autoregressive interaction models, there is also a need to consider how estimates from these models should be properly interpreted. The subject of interpreting estimates from independent and spatial autoregressive

spatial interaction models is taken up in Sect. 83.5. We set forth a simulation approach for these models that can be used to produce scalar expressions for the various types of spillover impacts that arise from changes in the explanatory variables of the model. Spatial spillovers in these models can take the form of spillovers to both regions/observations neighboring the origin or destination in the dyadic flow relationships that characterize origin-destination flows as well as network effects that impact all other regions in the network. We also make the point that interpretation of estimates from conventional independent spatial interaction models may be improved using this approach.

83.2 Gravity or Spatial Interaction Models Based on Independence

Regression models attempt to explain variation in the n^2 flows between the n regions in a closed network of regional flows. The $n \times n$ flow matrix Y is converted to an $n^2 \times 1$ vector by stacking columns. The flow matrix might be arranged so the i, j th element reflects a flow from region j to region i , which has been labeled an origin-centric flow arrangement by LeSage and Pace (2008). Many trade models rely on the convention that the i, j th element of the flow matrix represents a flow from region i to j , which would be a destination-centric arrangement of the flows. If we let y^o denote the origin-centric vector of flows and y^d a vector created by stacking columns from a destination-centric arrangement, there is a vec-permutation matrix P that can be used to relate these two different orderings. Specifically, $Py^o = y^d$, and using properties of permutation matrices, $y^o = P^{-1}y^d = P'y^d$.

A regression model that has been labeled a gravity model captures the notion that the size of the two regions and the distance between them are important factors that determine the magnitude of flows between regions. For example, if one starts with the standard gravity model (c.f., Eq. (6.4) in Sen and Smith 1995) shown in Eq. (83.1) and applies a log transformation, the regression in Eq. (83.2) arises.

$$\mu(i,j) = CX_o(i)X_d(j)H(i,j) \quad (83.1)$$

In Eq. (83.1), $\mu(i,j)$ represents the expected flows from region i to region j (assuming a destination-centric flow matrix), while $X_d(i)$, $X_o(j)$ denote sizes of the destination and origin and $G(i,j)$ represents resistance or deterrence to flows between the origin and destination, typically modeled using some function of distance between regions i and j . To facilitate the log transformation, $X_o(i)$ can be specified using $X_o(i)^{\beta_o}$ and similarly, $X_d(j) = X_d(j)^{\beta_d}$, while $H(i,j)$ is some function of distance between regions i and j , for which we might use a power function, $D(i,j)^\gamma$, where $D(i,j)$ is the distance between regions i and j .

A point made by LeSage and Pace (2009) is that conventional work with these models has relied on mathematics emphasizing dyads i, j which has severe limitations for thinking about flows in the context of a network. Spatial dependence

reflects relationships between observations, and is typically modeled using vectors and spatial weight matrices to express relations between observations. LeSage and Pace (2008) use the matrix/vector representation of the log-transformed dyad expression in Eq. (83.1) shown in Eq. (83.2), which more closely mirrors notation from conventional regression modeling. It should also be noted that another population formulation directly models flows as: $F(i, j) = \exp\left(\sum_{k=1}^R \beta_k \log X_{kij}\right) + \varepsilon_{ij}$, where the disturbance term is additive. This produces a Poisson model suitable for flows taking the form of counts and requires maximum likelihood estimation (Gourieroux et al. 1984).

$$y = \alpha \iota_{n^2} + X_o \beta_o + X_d \beta_d + \gamma g + \varepsilon \quad (83.2)$$

In Eq. (83.2), y is an $n^2 \times 1$ vector of (logged) flows constructed by stacking the columns of the $n \times n$ flow matrix Y , where we will assume a destination-centric organization throughout this chapter. Similarly, applying the log transformation to the $n \times n$ matrix of distances $D(i, j)$ between the n destination and origin regions and stacking the columns results in a vector of logged distances g , with associated coefficient γ . LeSage and Pace (2008) show that $X_o = \iota_n \otimes X$, where X is an $n \times R$ matrix of characteristics for the n regions, \otimes represents a Kronecker product, and ι_n is an $n \times 1$ vector of ones. In the simplest case, X might represent a vector with the appropriate size measure for each region, but without loss of generality this may be a matrix containing R characteristics of the regions that are thought to explain variation in flows. We note that this represents a general case where the same set of explanatory variables is used for both origins and destinations. A special case might involve selection of a subset of variables in the matrix X for use as origin characteristics, and another subset of variables for the destination characteristics. However, the general case maybe the preferred approach to specification, since inclusion of additional unimportant explanatory variables does not bias least-squares estimates, whereas exclusion of important explanatory variables can result in omitted variables bias.

The Kronecker product repeats the same values of the n regions in a strategic fashion to create a vector (or matrix) of sizes associated with each origin region, hence use of the notation X_o to represent these explanatory variables reflecting origin characteristics. Ultimately, use of Kronecker products in conjunction with matrix algebra allowed LeSage and Pace (2008) to express simple estimators that avoid storing multiple copies of the same numerical values, which is computationally inefficient. The matrix/vector $X_d = X \otimes \iota_n$ arranges the n regional characteristics to match the vector y , producing explanatory variables associated with each destination region. The vectors β_o and β_d are $R \times 1$ parameter vectors associated with the origin and destination region characteristics, respectively. The scalar parameter γ reflects the effect of the vector of logged distances g on flows, which is traditionally thought to be negative. The parameter α denotes the constant term parameter, and the $n^2 \times 1$ vector ε represents zero mean, constant variance, zero covariance disturbances, consistent with the Gauss-Markov least-squares assumptions. We note that the assumption of normally distributed disturbances consistent with least-squares implies that the dependent variable flows are also normally

distributed. This is not consistent with some flows which represent count data, for example, counts of persons migrating or commuters traveling from one region to another. However, the log transformation may help to produce more normally distributed flows. We will have more to say about this issue in Sect. 83.4, where problems that affect maximum likelihood estimation of spatial interaction models are discussed.

LeSage and Pace (2008) note that the algebra of Kronecker products can be used to avoid the need to form $n^2 \times R$ matrices X_o, X_d which require a great deal of computer storage involving repeated numerical values. This can be seen by examining the $(2R + 2) \times (2R + 2)$ moment matrix formed using: $Z = (1_{n^2} \ X_o \ X_d \ g)$ shown in Eq. (83.3), where we use G to represent the $n \times n$ matrix of logged distances.

$$Z'Z = \begin{pmatrix} n^2 & 0_k & 0_k & i'_n G 1_n \\ 0'_k & nX'X & 0'_k 0_k & X'G 1_n \\ 0_k & 0'_k 0_k & nX'X & X'G 1_n \\ i'_n G 1_n & i'_n G'X & i'_n G'X & tr(G^2) \end{pmatrix} \tag{83.3}$$

Similarly, the matrix product $Z'y$ involving the matrix Z' of dimension $(2R + 2) \times n^2$ and the $n^2 \times 1$ vector of flows can be formed as shown in Eq. (83.4), where tr denotes the trace operator.

$$Z' \text{vec}(Y) = \begin{pmatrix} i_n^2 \\ X'_o \\ X'_d \\ g' \end{pmatrix} y = \begin{pmatrix} i'_n Y 1_n \\ X'Y 1_n \\ X'Y' 1_n \\ tr(GY) \end{pmatrix} \tag{83.4}$$

This allows calculation of the parameter estimates $\delta = (\alpha \beta_o \beta_d \gamma)'$ using only the $n \times R$ matrix X , the $n \times n$ flow matrix Y , and the $n \times n$ matrix of logged distances G that appear in $Z'Z$ and $Z'y$, as shown in Eq. (83.5).

$$\hat{\delta} = [(1/n^2)Z'Z]^{-1} (1/n^2)Z'y \tag{83.5}$$

Interpretation of the estimates β_o, β_d has followed that used in typical regression, where these parameters reflect the influence (positive or negative) of changes in origin and destination characteristics on the magnitude of flows. Since the model has been log-transformed, these estimates can be interpreted as elasticities. A negative estimate for the r th destination characteristic indicates that this reduces flows to the destination, whereas a positive coefficient points to a factor that increases flows to the destination. A similar interpretation applies to the coefficients β_o , which measure the positive or negative influence of origin characteristics on flows. We will have more to say about this approach to interpreting the coefficients β_o, β_d later. The coefficient γ should be negative, consistent with the notion that (logged) distance acts as a friction to reduce flows.

83.3 Spatial Autoregressive Interaction Models

Intuitively, changes to the characteristics of a single region i will impact both inflows and outflows to all other regions engaged or connected with region i as either an origin or destination. For example, a (*ceteris paribus*) decrease in taxes in region i would lead to inflows of population to this region from (potentially) all other regions and a decrease in outflows of population to (potentially) all other regions.

LeSage and Pace (2008) suggest that flows across networks involving origins and destinations are likely to exhibit spatial dependence. They define spatial dependence in this type of setting to mean that larger observed flows from an origin region A to a destination region Z are accompanied by (i) larger flows from regions nearby the origin A to the destination Z , say regions B and C that are neighbors to region A , which they label origin dependence; (ii) larger flows from the origin region A to regions neighboring the destination region Z , say regions X and Y , which they label destination dependence; and (iii) larger flows from regions that are neighbors to the origin (B and C) to regions that are neighbors to the destination (X and Y), which they label origin-destination dependence.

Casual observation of migration flows in a network of counties is consistent with this type of observation. If there are a large number of migrants moving away from a county A (say a county near the Detroit metropolitan area), we would expect to see migrants also moving away from other counties B and C near Detroit (presumably due to unfavorable labor market conditions). Similarly, if a large number of migrants are moving into a county Z (say a county in the Austin metropolitan area), we would expect to see migrants also moving into other counties X and Y in the Austin metropolitan area (presumably because of favorable labor market conditions).

LeSage and Pace (2008, 2009) propose a spatial regression extension of the independent empirical gravity model from Eq. (83.2) shown in Eq. (83.6).

$$\begin{aligned}
 Ay &= \alpha I_{n^2} + X_o \beta_o + X_d \beta_d + g\gamma + \varepsilon & (83.6) \\
 A &= (I_{n^2} - \rho_o W_o)(I_{n^2} - \rho_d W_d) \\
 &= (I_{n^2} - \rho_o W_o - \rho_d W_d + \rho_w W_w) \\
 W_o &= I_n \otimes W \\
 W_d &= W \otimes I_n \\
 W_w &= W_o \otimes W_d = W_d \otimes W_o = W \otimes W
 \end{aligned}$$

The term A can be viewed as a spatial filter that captures origin-based dependence, destination-based dependence, and origin-destination-based dependence. (The filter implies a restriction that $\rho_w = -\rho_o \rho_d$. This restriction need not be imposed during estimation, so we address the more general case here and allow for an unrestricted parameter ρ_w .) The model and associated data generating

process (DGP) for the spatial autoregressive interaction model take the forms shown in Eqs. (83.7) and (83.8), respectively, where we rely on the earlier definitions of Z and δ .

$$y = \rho_o W_o y + \rho_d W_d y + \rho_w W_w y + Z\delta + \varepsilon \quad (83.7)$$

$$y = (I_{n^2} - \rho_o W_o - \rho_d W_d + \rho_w W_w)^{-1} (Z\delta + \varepsilon) \quad (83.8)$$

The spatial lag formed by the matrix product $W_d y$ extracts flows from neighbors to each destination region in the vector of origin-destination flow dyads to form a linear combination of flows from neighboring destinations. In the case where the $n \times n$ spatial weight matrix W represents a fixed number, say m , of equally weighted nearest neighbors, the spatial lag vector would contain an average of flows from the m neighboring destinations. The matrix W is a conventional (row-normalized) spatial weight matrix of the type used in cross-sectional regressions involving n regions. This spatial lag captures destination-based dependence, with the parameter ρ_d measuring the strength of destination-based dependence.

A similar interpretation applies to the spatial lag formed by the product $W_o y$, which reflects a linear combination of flows from regions neighboring the origin, again for each origin-destination dyad in the flow vector. The scalar parameter ρ_o reflects the strength of origin-based dependence. The spatial lag $W_w y$ forms a linear combination of flows from neighbors to the origin and flows from neighbors to the destination, and the parameter ρ_w represents the magnitude of this type of dependence.

The stability restrictions for the spatial dependence parameters require that $1/\lambda_{\min} < \rho_o + \rho_d + \rho_w < 1$, where λ_{\min} is the minimum eigenvalue of the matrix W . In practice, values of -1 are often used to replace $1/\lambda_{\min}$, since this avoids the need to calculate the minimum eigenvalue of the matrix W .

LeSage and Pace (2008) provide details concerning maximum likelihood estimation for the spatial autoregressive interaction model, and LeSage and Pace (2009) set forth a Bayesian MCMC estimation scheme. Both of these exploit the computationally efficient moment matrices involving the sample data expressed using the smaller dimension matrices.

83.4 Problems That Arise in Applied Modeling of Flows

Maximum likelihood estimation methods require that the disturbances in the model follow a normal distribution, which implies that the dependent variable flows are also normally distributed. As already noted, many flows are more properly viewed as count data magnitudes, for example, flows of population or commuters migrating or traveling between regions. There are limitations to the ability of the log transformation to convert count data to a form consistent with a normal

distribution, especially when a large number of flows between regions take on zero values. For a flow matrix involving small regions, there are likely to be a large number of zero flow magnitudes. For example, migration flows between US counties in the contiguous states over a 5-year period exhibit zeros for over 90 % of the county-to-county flows. A solution for problems involving large numbers of zero flows as well as small flows would be development of Poisson variants of the spatial autoregressive spatial interaction model. Some work has been done in this area. Lambert, Brown, and Florax (2010) set forth a two-stage estimation procedure for a spatial autoregressive Poisson model, that is one not representing a spatial interaction model. LeSage, Fischer, and Scherngell (2007) introduce spatially structured origin and destination effects in a Poisson model involving counts of interregional patent citations, but their model does not involve spatial lags of the dependent variable. LeSage and Llano (2006) introduce a Tobit variant of a model that contains spatially structured origin and destination effects parameters, which can address cases involving smaller numbers of zero flows. Ranjan and Tobias (2007) also use a Tobit approach but rely on semi-parametric origin and destination effects parameters. The use of Tobit models is an attempt to address a common practice where practitioners modify the dependent variable vector using: $\ln(1 + y)$ to accommodate the log transformation. Since this transformation ignores the mixed discrete/continuous nature of the flow distribution, it should lead to downward bias in the coefficient estimates for the model. An appropriate approach to addressing the problem of a large number of zero flows as well as small flows and the count nature of many flows remains an area for future research.

Another factor contributing to non-normality in flow magnitudes is the presence of large flows within regions, those located on the main diagonal of the flow matrix, relative to smaller flows between regions, those on the off-diagonal elements. Since the objective of spatial interaction modeling is typically a model that explains variation in interregional flows, practitioners often view intraregional flows as a nuisance. Some common practices are (i) to simply set observed intraregional flows to zero values (Tiefelsdorf 2003; Fischer et al. 2006) and (ii) introduce dummy variables for these observations (Behrens et al. 2012). For the case of the independence model, these approaches are fine, but they can have adverse impacts on spatial autoregressive interaction models. Inclusion of zero magnitudes for intraregional flows in a model that includes spatial lags such as W_{oy} , W_{dy} will produce aberrant observations when these flows become part of the linear combination of neighboring values to the origin or destination.

LeSage and Pace (2008) propose using a separate set of explanatory variables in the spatial autoregressive interaction specification to deal with large flow magnitudes on the main diagonal of the flow matrix. This separate model is embedded into the specification by adjusting the explanatory variables matrices X_o , X_d and the intercept vector t_n to have zero values for the n observations associated with the main diagonal elements (intraregional flows) of the flow matrix. They then introduce an additional explanatory variables matrix containing only n nonzero observations, those associated with intraregional flows that were set to zero in the

matrices X_o, X_d . In addition, new intercept vectors are introduced: one that contains zeros for observations associated with intraregional flows and ones for all others, and a second that contains ones for only the intraregional flow observations.

This approach allows nonzero intraregional flows to be included in the dependent variable vector y which is used to form the spatial lags W_{oy}, W_{dy}, W_{wy} . The part of flow variation associated with the large diagonal elements is explained by the embedded model variables allowing the coefficient estimates associated with the adjusted explanatory variables to more accurately characterize variation in interregional flows. LeSage and Fischer (2010) provide an example of the improvement that arises from this approach.

Assuming the problems of zero flows and the count nature of some flow magnitudes can be solved for the case of the spatial autoregressive spatial interaction model, there is still the issue of how to properly interpret estimates from this model.

83.5 Interpreting Spatial Interaction Models

A first point to note is that we should not interpret the coefficient estimates β_d, β_o and γ as if they were least-squares estimates that reflect partial derivative changes in the dependent variable associated with changes in the explanatory variables. LeSage and Pace (2009) point out that this mistaken approach to spatial autoregressive (SAR) models has been used in much of the past spatial econometrics literature.

We present a method that can be used to relate changes in characteristics of a single region i to flows across the $n \times n$ network of flows between the n regions for the case of the spatial autoregressive interaction model. This issue has not been tackled in the literature, yet it is essential for interpreting the coefficient estimates β_o, β_d in the spatial autoregressive interaction model.

83.5.1 A Numerical Illustration for the Nonspatial Gravity Model

Prior to setting forth our method for quantifying how changes in the r th characteristic of region i impact flows, we provide a simple numerical illustration to fix ideas. Using the DGP in Eq. (83.8), we generated a set of flows using $n = 8$ regions with $\beta_d = 1, \beta_o = 0.5, \delta = -0.5, \rho_d = 0.4, \rho_o = 0.4$, and $\rho_w = -\rho_o \times \rho_d = -0.16$. No disturbance term was used, and the single vector $x' = (40 \ 30 \ 20 \ 10 \ 7 \ 10 \ 15 \ 25)$ was used, so we have the case where $R = 1$. A set of n latitude and longitude coordinates (both equal to 1, 2, ..., 8) were used to produce an n^2 vector of (logged) distances g and the associated spatial weight matrix W based on two nearest (distanced) neighbors. The systematic order of the latitude-longitude coordinates produces regions configured to lie on a line, with a simplified spatial weight matrix configuration. For example, region 3 has regions 2 and 4 as the two nearest neighbors, region 4 has

regions 3 and 5 as the two neighbors, and so on. This greatly simplifies things relative to real-world data. The weight matrix for our example is shown in Eq. (83.9).

$$W = \begin{pmatrix} 0.0 & 0.5 & 0.5 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.5 & 0.0 & 0.5 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.5 & 0.0 & 0.5 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.5 & 0.0 & 0.5 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.5 & 0.0 & 0.5 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.5 & 0.0 & 0.5 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.5 & 0.0 & 0.5 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.5 & 0.5 & 0.0 \end{pmatrix} \tag{83.9}$$

A discrete change in each element/region $i = 1, \dots, 8$ of the vector x of one unit was made and the discrete changes arising in the $n \times n$ flow matrix as a result of these perturbations were recorded. For each change in the value x_i for a single region i , a new flow matrix was generated and subtracted from the original flow matrix to illustrate how changes in the characteristics of a single region impact the matrix of flows.

An important point to note here is that unlike the conventional spatial autoregressive model where the matrix X contains characteristics for each of the n regions, the matrices X_o, X_d in the spatial autoregressive interaction model strategically repeats values of the $n \times R$ matrix X to form $n^2 \times R$ matrices $X_o = \mathbf{1}_n \otimes X, X_d = X \otimes \mathbf{1}_n$. An implication is that when we change the characteristic/element of a single region i (which we denote using x_i), it produces a set of changes in n elements of the matrix X_o and changes in n elements of the matrix X_d . Together, this set of $2n$ altered values in the matrices X_o, X_d produce the change in flows that results from changing characteristics of the i th region, that is $x_i + 1$. This has computational implications for how we calculate the effects arising from changes in the explanatory variables of this model. Unlike the conventional SAR model, we do not need to calculate changes in each of the n^2 elements of the vectors X_o and X_d to produce scalar summary measures of the impact of these changes on the flows. Although this approach is valid, it requires more computational effort. Instead we can consider only n changes in each observation i of the matrix/vector X as producing a total derivative response. There will be a vector of $n^2 \times 1$ responses in the flows (which can be viewed as a change in the $n \times n$ flows matrix Y) arising from a change in a single characteristic of the i th region, x_i . This single element total derivative change works through a series of $2n$ associated changes that arise in the $n^2 \times R$ model explanatory variables X_o, X_d .

Intuitively, increasing a single region i 's characteristic (say the size of region x_i) means this region will (i) attract more inflows as a destination from all n regions (including itself which takes the form of more intraregional flows within region i) and (ii) produce increased outflows to all n regions (including itself). This facet of changes in the characteristic of a single region is what accounts for the model repeating the same altered value of x_i (the new size for region i) n times in the vector/matrix X_o , and n times in X_d . Given this, it is computationally inefficient to consider conventional partial derivatives that would independently change each of

the n^2 elements in X_o or X_d and examine their impact on the flow matrix. Changes to individual elements of X_o and X_d need not be considered given the structure of the model (and associated data generating process).

There may be applied modeling situations where different explanatory variables are used to model the origin and destination characteristics of the regions that are thought to be important for explaining variation in flows. In these situations, the argument used above regarding changes to a single explanatory variable x_i for each region will not be valid. The more computationally inefficient approach of using conventional partial derivatives that would independently change each of the n^2 elements in X_o and X_d would need to be used in order to examine the impact of these changes on the flow matrix. We discuss this type of situation when providing a numerical illustration.

Results showing the changes in the $n \times n$ flow matrix associated with a change in the third region's characteristic, x_3 , by one unit for the case of the independent (nonspatial) gravity model in Eq. (83.2) are shown in Eq. (83.10). These were produced by setting $\rho_o = \rho_d = \rho_w = 0$ in the spatial gravity model from Eq. (83.8), which results in the independent gravity model from Eq. (83.2).

$$\Delta Y / \Delta x_3 = \begin{pmatrix} 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.50 & 0.50 & 1.50 & 0.50 & 0.50 & 0.50 & 0.50 & 0.50 \\ 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \end{pmatrix} \quad (83.10)$$

The role of the independence assumption is clear in Eq. (83.10), where we see from row 3 that the change of outflows from region 3 to all other regions equals 0.5, which is the value of the coefficient β_o in our example. Similarly, column 3 exhibits identical changes in inflows to region 3, taking the value 1 of the coefficient β_d in our example. The diagonal (3,3) element reflects a response equal to $\beta_o + \beta_d$, the sum of the changes in flows into and out of region 3, reflecting the change in intraregional flows arising from the change in x_3 . We have only $2n$ nonzero changes in flows by virtue of the independence assumption. All changes involving flows into and out of regions other than region 3 are zero.

Our method for producing scalar summary measures of the impacts arising from changes in characteristics of the regions involves averaging over the cumulative flow impacts associated with changes in all regions, $i = 1, \dots, n$, analogous to the approach taken by LeSage and Pace (2009) for the conventional SAR model. Doing this produces $\sum_{i=1}^n (\Delta Y / \Delta x_i)$, a cumulative total effects (TE) matrix shown in Eq. (83.11), which is the sum of $n = 8$ different changed flow matrices of the type shown in Eq. (83.10) for the case where $i = 3$. This matrix (TE) can be decomposed into flow matrices reflecting origin effects (OE), destination effects (DE), network effects (NE), and intraregional effects (IE) arising from changing a single characteristic in all regions by one unit.

$$TE = \begin{pmatrix} 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \\ 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \\ 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \\ 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \\ 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \\ 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \\ 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \\ 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 & 1.5 \end{pmatrix} \tag{83.11}$$

The matrix of cumulative intraregional effects can be constructed using the main diagonal elements of the TE matrix, $IE(i, i) = \sum_{i=1}^n (\Delta Y_{(i,i)} / \Delta x_i)$. The matrix of (cumulative) intraregional effects is shown in Eq. (83.12), where we see that these are identical and equal to the value of the coefficients $\beta_o + \beta_d$ from our example. These are located on the main diagonal which reflects changes in intraregional flows.

$$IE = \begin{pmatrix} 1.5 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 1.5 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 1.5 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 1.5 & 0.0 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 1.5 & 0.0 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 1.5 & 0.0 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 1.5 & 0.0 \\ 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 0.0 & 1.5 \end{pmatrix} \tag{83.12}$$

The matrix of (cumulative) origin effects can be constructed using the i th row of the flow changes matrix excluding the intraregional effect from the diagonal element. Specifically, $OE(i, \cdot) = \sum_{i=1}^n (\Delta Y_{(i,\cdot)} / \Delta x_i) - IE(i, i)$, where we use $OE(i, \cdot)$ and $\Delta Y_{(i,\cdot)}$ to denote the i th row of the OE matrix and flow changes matrix ΔY . The result is shown in Eq. (83.13), where we see that these are identical and equal to the value of the coefficient β_o from our example. The main diagonal is zero since this reflects changes in intraregional flows which we have excluded from our definition of origin effects.

$$OE = \begin{pmatrix} 0.0 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 \\ 0.5 & 0.0 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 \\ 0.5 & 0.5 & 0.0 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 \\ 0.5 & 0.5 & 0.5 & 0.0 & 0.5 & 0.5 & 0.5 & 0.5 \\ 0.5 & 0.5 & 0.5 & 0.5 & 0.0 & 0.5 & 0.5 & 0.5 \\ 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.0 & 0.5 & 0.5 \\ 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.0 & 0.5 \\ 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.5 & 0.0 \end{pmatrix} \tag{83.13}$$

The matrix DE of (cumulative) destination effects is based on using the i th column of the flow changes matrix, excluding the intraregional effect from the diagonal element. Of course, the OE and DE definitions would reverse if we were

relying on an origin-centric flow matrix instead of the destination-centric one. Specifically, $DE(., i) = \sum_{i=1}^n (\Delta Y_{(.,i)} / \Delta x_i) - IE(i, i)$, where we use $DE(., i)$ and $\Delta Y_{(.,i)}$ to denote the i th column of the DE matrix and flow changes matrix ΔY . The result is shown in Eq. (83.14), where we see that these are identical and equal to the value of the coefficient β_d from our example. Again, the main diagonal is zero since this reflects changes in intraregional flows which we have excluded from our definition of destination effects.

$$DE = \begin{pmatrix} 0.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 \\ 1.0 & 0.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 \\ 1.0 & 1.0 & 0.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 \\ 1.0 & 1.0 & 1.0 & 0.0 & 1.0 & 1.0 & 1.0 & 1.0 \\ 1.0 & 1.0 & 1.0 & 1.0 & 0.0 & 1.0 & 1.0 & 1.0 \\ 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 0.0 & 1.0 & 1.0 \\ 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 0.0 & 1.0 \\ 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 1.0 & 0.0 \end{pmatrix} \tag{83.14}$$

The matrix of cumulative network effects represents all flow changes that spill-over on regions other than the origin and destination region whose characteristics were changed. This can be constructed by subtraction: $TE - IE - OE - DE = NE$. For the nonspatial gravity model, the cumulative network effects matrix NE contains all zeros, since this model does not allow for spillovers to regions not involving origin and destination regions by virtue of the independence assumption. Scalar summary measures of the total effects as well as the decomposition into origin, destination, intraregional, and network effects can be constructed using averages of the (matrices) of cumulated changes in flows. This is accomplished by averaging over row-sums and then column-sums, which follows the approach taken by LeSage and Pace (2009) for the SAR model. This produces the results shown in the first column of Table 83.1. (One can also average over column-sums and then row-sums to produce identical results as noted by LeSage and Pace (2009).)

Applying our decomposition with this computationally inefficient approach would lead to scalar summary measures for the impact of changing all elements in the vector X_o presented in the second column of Table 83.1. Similarly, our decomposition with this approach would lead to scalar summary measures for the impact of (independently) changing each element in the vector X_d shown in the third column of Table 83.1. The sum of these two sets of scalar summary effects estimates constructed using independent changes in all elements of X_o and X_d shown in the fourth column of Table 83.1 equals the result shown in the first column. We will see that this is also the case for the spatial autoregressive variant of the gravity model.

An important point to note is that this approach differs from the conventional interpretation of nonspatial gravity models where the coefficient β_o is interpreted as a partial derivative reflecting the impact of changes in origin characteristics and β_d that is associated with changing destination characteristics. Although the conventional approach that used the coefficient sum $\beta_o + \beta_d$ as a measure of the total effect on flows arising from changes in origin and destination characteristics would

Table 83.1 Scalar summary measures of effects for the nonspatial model from a change in the (single) characteristic x averaged over all regions $i = 1, \dots, 8$

	Δx_i	$\Delta X_{o,i}$	$\Delta X_{d,i}$	$\Delta X_{o,i} + \Delta X_{d,i}$
Origin effects	0.4375	0.4375	0.0000	0.4375
Destination effects	0.8750	0.0000	0.8750	0.8750
Intraregional effects	0.1875	0.0625	0.1250	0.1875
Network effects	0.0000	0.0000	0.0000	0.0000
Total effects	1.5000	0.5000	1.0000	1.5000

produce a correct inference, the appropriate decomposition into origin, destination, and intraregional effects has been missing from this literature.

Another point is that one can use changes in each element of the $n^2 \times 1$ vectors X_o and X_d to arrive at the same scalar summary measures as shown in Table 83.1. However, this would require that we sequence through changes in n^2 individual elements of X_o and also n^2 elements of X_d , recording the change in the $n \times n$ matrix of flows that arise from this sequence of $2n^2$ changes, which is computationally much more difficult. We would also need to aggregate the changes in flows arising from changes in both X_o and X_d to produce final results. To avoid this, we can exploit the special structure of the $n^2 \times R$ matrices X_o, X_d as they relate to the underlying $n \times R$ matrix X .

As noted above, there could be applied modeling situations where practitioners choose to include a specific characteristic only in the X_o or X_d vector, but not in both. As an example, consider a model for commuting-to-work flows. The number of residents might be used as a size measure for origin regions whereas the number of business establishments might be used as a size measure for the destination regions. In this case, it might be more appropriate for interpretative purposes to report separately scalar effects summaries arising from the calculations involving changing all elements in the vector X_o and X_d . We will have more to say about this in the next section.

83.5.2 A Numerical Illustration for the Spatial Gravity Model

Using the same numerical values set forth in the previous section, but setting $\rho_o = \rho_d = 0.4$ and $\rho_w = -\rho_o\rho_d = -0.16$, we carried out the same experiment where each value of $x_i, i = 1, \dots, 8$ was changed by one unit. The resulting changes in the flow matrix were recorded, with the total flow effects arising from the change in x_3 shown in Eq. (83.15).

$$\Delta Y / \Delta x_3 = \begin{pmatrix} 0.688 & 0.688 & 2.064 & 0.612 & 0.309 & 0.246 & 0.233 & 0.233 \\ 0.688 & 0.688 & 2.064 & 0.612 & 0.309 & 0.246 & 0.233 & 0.233 \\ 1.376 & 1.376 & 2.752 & 1.300 & 0.997 & 0.934 & 0.921 & 0.921 \\ 0.650 & 0.650 & 2.026 & 0.574 & 0.271 & 0.208 & 0.195 & 0.195 \\ 0.498 & 0.498 & 1.875 & 0.423 & 0.119 & 0.056 & 0.044 & 0.044 \\ 0.467 & 0.467 & 1.843 & 0.391 & 0.088 & 0.025 & 0.012 & 0.012 \\ 0.460 & 0.460 & 1.837 & 0.385 & 0.082 & 0.018 & 0.006 & 0.006 \\ 0.460 & 0.460 & 1.837 & 0.385 & 0.082 & 0.018 & 0.006 & 0.006 \end{pmatrix} \quad (83.15)$$

One difference between this spatial model result and the nonspatial model is the presence of network effects, shown by the nonzero elements in rows and columns other than 3. This means that a change in say the attractiveness of region 3 impacts flows throughout the network. Of course, the largest impacts reside in the 3rd row and column, since the change in attractiveness of region 3 has the largest impact on flows into and out of region 3 from all other regions. The magnitude of impact declines as we move further from the (3,3) element in the up/down or left/right direction in column and row 3. This arises due to decay with higher-order neighbors typical of spatial autoregressive processes. We see a similar pattern for elements not in the third row and column, where the change in flows decline in magnitude for elements further away from the (3,3) element. This reflects a decline in the magnitude of network spillovers with an increase in the number of paths through which the flows must pass.

It is also important to note that the interpretation of partial derivatives in cross-sectional spatial models such as this is that these reflect a long-run, steady-state equilibrium. The estimated changes in flows would be those that arise in response to the increased attractiveness of region 3 as we move to a new steady-state equilibrium. For example, we would conclude that changes in the attractiveness of region 3 would produce these changes in flows throughout the network, reflecting the level of flows we would expect to see in a new steady-state equilibrium.

Applying our approach for calculating scalar summary measures of the impacts arising from changes in characteristics of the regions described in the previous section we arrive at $TE = \sum_{i=1}^n (\Delta Y / \Delta x_i)$, shown in Eq. (83.16). The most obvious facet of the cumulative TE matrix is that the effects are much larger than in the case of the nonspatial gravity model. An examination of the components' (IE, OE, DE, NE) decomposition shows the source of these differences in effects on flows arising from changes in regional characteristics. A similarity with the nonspatial model TE matrix is that total effects are identical for all observations/regions, which is always the case for SAR models. This is because the spatial weight matrix W has row-sums of unity (see Elhorst 2010).

$$TE = \begin{pmatrix} 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \\ 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \\ 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \\ 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \\ 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \\ 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \\ 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \\ 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 & 4.166 \end{pmatrix} \quad (83.16)$$

The cumulative intraregional effects matrix is shown in Eq. (83.17), where we see that the values are not equal to $\beta_o + \beta_d$ as in the nonspatial model. They are also not equal to the diagonal elements from the cumulative TE matrix. This is because there are feedback loops that arise in spatial models, where impacts on neighbors work their way back to the own region. To see this, consider that spatial

autoregressive models rely on a data generating process: $y = (I_n - \rho W)^{-1}(X\beta + \varepsilon)$, where the matrix inverse can be expressed as an infinite series: $I_n + \rho W + \rho^2 W^2 + \rho^3 W^3 + \dots$. The matrix W has zeros on the main diagonal, but the matrices W^2, W^3, \dots do not. This is because by virtue of the definition of a second-order neighbor reflected by the matrix W^2 , region i is a second-order neighbor to itself, a neighbor to a neighboring region. The feedback effects on intraregional flows account for some of the difference between the value of 4.166 for the main diagonal of the TE matrix in the spatial model and the nonspatial model, where we found a value of 1.5.

$$IE = \begin{pmatrix} 2.632 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 \\ 0.000 & 2.747 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 \\ 0.000 & 0.000 & 2.752 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 \\ 0.000 & 0.000 & 0.000 & 2.728 & 0.000 & 0.000 & 0.000 & 0.000 \\ 0.000 & 0.000 & 0.000 & 0.000 & 2.728 & 0.000 & 0.000 & 0.000 \\ 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 2.752 & 0.000 & 0.000 \\ 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 2.747 & 0.000 \\ 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 2.632 \end{pmatrix} \quad (83.17)$$

The nonzero network effects (NE) account for the remaining differences, as can be seen from the diagonal of the matrix for these cumulative effects, shown in Eq. (83.18). (The values from the diagonal of NE and IE do not exactly equal those of TE because digits were truncated when forming the matrices for presentation.) Nonzero network effects also feedback onto intraregional flows, and these account for a large part of the difference between the spatial and nonspatial model effects estimates. An important point to keep in mind is that variation in all of the effects estimates over the regions might be greater than in our simple example, where the spatial configuration of the regions represents one of the simplest. The magnitudes of network effects will depend on the spatial configuration of the regions involved, with regions that have more links to other regions experiencing larger network effects relative to regions that are relatively more isolated with less links to other regions.

$$NE = \begin{pmatrix} 1.533 & 0.869 & 1.148 & 1.406 & 1.456 & 1.451 & 1.456 & 1.533 \\ 0.869 & 1.419 & 0.804 & 1.303 & 1.404 & 1.410 & 1.417 & 1.494 \\ 0.996 & 0.767 & 1.414 & 0.855 & 1.310 & 1.388 & 1.411 & 1.489 \\ 1.398 & 1.289 & 0.847 & 1.437 & 0.868 & 1.302 & 1.397 & 1.480 \\ 1.480 & 1.397 & 1.302 & 0.868 & 1.437 & 0.847 & 1.289 & 1.398 \\ 1.489 & 1.411 & 1.388 & 1.310 & 0.855 & 1.414 & 0.767 & 0.996 \\ 1.494 & 1.417 & 1.410 & 1.404 & 1.303 & 0.804 & 1.419 & 0.869 \\ 1.533 & 1.456 & 1.451 & 1.456 & 1.406 & 1.148 & 0.869 & 1.533 \end{pmatrix} \quad (83.18)$$

The cumulative OE and DE matrices for the spatial model are shown in Eqs. (83.19) and (83.20), where we also see values that differ over the regions

and exhibit magnitudes greater than the 0.5 and 1.0 values representing coefficients β_o, β_d from the nonspatial model. As in the other cases, these reflect changes in flows arising from interactions modeled by origin-, destination-, and origin-destination dependence in the spatial gravity model. Intuitively, changing the characteristics of a single region will impact inflows to and outflows from that region, but also impact flows to regions neighboring the origin and impact flows to regions neighboring destination regions, and impact flows from regions neighboring the origin to regions neighboring the destination.

$$OE = \begin{pmatrix} 0.000 & 1.243 & 0.954 & 0.893 & 0.880 & 0.878 & 0.877 & 0.877 \\ 1.358 & 0.000 & 1.298 & 0.995 & 0.932 & 0.919 & 0.916 & 0.916 \\ 1.376 & 1.376 & 0.000 & 1.300 & 0.997 & 0.934 & 0.921 & 0.921 \\ 1.005 & 1.005 & 1.292 & 0.000 & 1.289 & 0.989 & 0.929 & 0.929 \\ 0.929 & 0.929 & 0.989 & 1.289 & 0.000 & 1.292 & 1.005 & 1.005 \\ 0.921 & 0.921 & 0.934 & 0.997 & 1.300 & 0.000 & 1.376 & 1.376 \\ 0.916 & 0.916 & 0.919 & 0.932 & 0.995 & 1.298 & 0.000 & 1.358 \\ 0.877 & 0.877 & 0.878 & 0.880 & 0.893 & 0.954 & 1.243 & 0.000 \end{pmatrix} \quad (83.19)$$

$$DE = \begin{pmatrix} 0.000 & 2.053 & 2.064 & 1.867 & 1.829 & 1.837 & 1.832 & 1.755 \\ 1.938 & 0.000 & 2.064 & 1.867 & 1.829 & 1.837 & 1.832 & 1.755 \\ 1.793 & 2.022 & 0.000 & 2.010 & 1.859 & 1.843 & 1.833 & 1.755 \\ 1.763 & 1.871 & 2.026 & 0.000 & 2.009 & 1.875 & 1.840 & 1.756 \\ 1.756 & 1.840 & 1.875 & 2.009 & 0.000 & 2.026 & 1.871 & 1.763 \\ 1.755 & 1.833 & 1.843 & 1.859 & 2.010 & 0.000 & 2.022 & 1.793 \\ 1.755 & 1.832 & 1.837 & 1.829 & 1.867 & 2.064 & 0.000 & 1.938 \\ 1.755 & 1.832 & 1.837 & 1.829 & 1.867 & 2.064 & 2.053 & 0.000 \end{pmatrix} \quad (83.20)$$

Using the same approach set forth in the previous section to produce scalar summary measures of the total effects, as well as the decomposition into origin, destination, intraregional, and network effects by averaging the matrices produced the results given in the second column of [Table 83.2](#).

The third and fourth columns show results based on calculating flow matrix responses to changes in each element of the $n^2 \times 1$ vectors X_o, X_d , which were added to produce the fifth column. In this case where a single characteristics vector x was used to form X_o and X_d , these equal the scalar summary effects produced by considering only n changes in elements of x_i .

Consider again the example involving commuting-to-work flows, where the number of residents is used as a size measure for origin regions and the number of business establishments as a size measure for the destination regions, so X_o and X_d are distinct. Interpreting results for this type of model would require reporting both columns three and four from [Table 83.2](#). Summing these two different scalar summary measures would make less sense in this situation, since changes in X_o do not imply changes in X_d and vice versa. This would lead to a slight change in interpretation, where changes in X_o (residents at the origin) lead to an origin, destination, intraregional, network, and total effects on flows, as do changes in X_d

Table 83.2 Scalar summary measures of effects for the spatial interaction model arising from a change in a single characteristic x averaged over all regions $i = 1, \dots, 8$

	Δx_i	$\Delta X_{o,i}$	$\Delta X_{d,i}$	$\Delta X_{o,i} + \Delta X_{d,i}$
Origin effects	0.9129	0.7920	0.1209	0.9129
Destination effects	1.6445	0.0605	1.5840	1.6445
Intraregional effects	0.3394	0.1131	0.2263	0.3394
Network effects	1.2698	0.4233	0.8466	1.2698
Total effects	4.1667	1.3889	2.7778	4.1667

(business establishments at the destination). This type of model specification could be viewed as an a priori zero restriction on the coefficient for the characteristic residents at the destination as well as a zero restriction on the coefficient for business establishments at the origin. It should be possible to include the full set of explanatory variables (residents and business establishments) in the set of model characteristics for both origins and destinations and then test the validity of the a priori zero restrictions. This would involve a test for significant differences between the full and nested model scalar summary effects estimates. If there are no differences in conclusions regarding the size and significance of the scalar summaries, then the restrictions are consistent with the sample data.

83.6 Conclusion

Recently introduced spatial autoregressive extensions of the spatial interaction model hold a great deal of promise for regional modeling of flows. However, there are still a great many obstacles to the wide use of these models in applied situations. First, these models require flow magnitudes that can be transformed to reflect a normal distribution. This is not the case for flow matrices containing a large number of zero values, large diagonal elements reflecting intraregional flows, or count magnitudes. There is a need for future research regarding implementation of a spatial autoregressive Poisson interaction model.

Beyond the issue of estimating model parameters, there is also a need to carefully consider how these parameters are interpreted. In the case of the independent spatial interaction model, changes in characteristics of a single region can exert impacts on inflows from all other regions, outflows to all other regions, as well as intraregional flows. These impacts can be measured by considering rows and columns of the flow matrix. We set forth a proposal for calculating scalar measures of impact that average over changes applied to a single explanatory variable (regional characteristic) for all regions. The approach allows separation of row/column and diagonal element impacts arising in the flow matrix, which we label origin, destination, and intraregional effects. Past applications of regression-based spatial interaction models that assume flows are spatially independent seem to have overlooked this aspect of the partial derivative impacts associated with changes in characteristics of regions.

For the case of the spatial autoregressive interaction model, interpretation of the model estimates in terms of their partial derivative impacts on flows is more complicated.

Changes to a single region's characteristics can impact not only inflows from all other regions, outflows to all other regions, and intraregional flows, but also all other flows in the flow matrix. These impacts can be measured using changes taking place in rows, columns, and the diagonal and off-diagonal elements of the flow matrix as a result of a change to a single region's characteristic. We propose a scheme for calculating scalar summary measures for these impacts that we label origin, destination, intraregional, and network effects.

Specifics regarding simulation of the partial derivative impact estimates based on the estimated distribution for the model parameters were not discussed here. This would require using the estimated variance-covariance matrix for the model parameters to generate draws for each model parameter. These could be used in conjunction with the approach proposed here to produce a distribution of the scalar estimates for the various types of impacts. These empirically derived distributions could serve as the basis for inference regarding significance of the various types of impacts.

Subject Index

A

ABA. *See* Activity-based analysis (ABA)

Abatement games, 952, 954

ABM. *See* Agent-based modeling (ABM)

Absolute advantages, 905–907

Absolute β -convergence, 299–300, 307, 308

Absorptive capacity, 208, 210, 379, 386,

392, 395, 396, 408, 417, 425,

427, 429, 433, 434, 436,

463–465, 467, 486, 656

Accessibility, 396, 402–405, 743, 745,

748–751, 753, 756, 823–824,

826, 828–829

Accessibility to

employment centers, 80, 81, 90

knowledge, 402–405, 427

product and factor markets, 115

Access to screening, care and treatment, 1321

Accountability, 369

Action, 592–594, 598–605

Activity

implementation, 717

pattern, 707–710, 718, 722

scheduling, 707, 708, 717, 719,

720, 723

space, 708

Activity-based, 763

Activity-based analysis (ABA), 705–723

Activity-based approach, 690, 706–708, 710

Activity-based models, 689, 691

Actors, 490–497, 499–502

Actual spending *vs.* some proxy, 361

Adaptability, 625, 626

Adaptation, 611, 617–618, 620, 621, 623,

624, 627, 937, 938

Adaptive-cycle model, 598

Adjacency, 1256, 1259, 1268–1270

matrix, 1268–1270

Adjacent possible, 469, 471

Adjoint variables, 249–250

Adjustment

cost, 865, 867, 868

path, 286

Advantages, 476–477, 479, 483, 484

Age, 111, 116–118, 122

Agency, 619

Agent, 1115, 1118

Agent-based modeling (ABM), 502, 717, 719,

720, 723, 750, 752–753, 830, 837,

1115, 1124, 1126, 1128, 1192,

1217–1231

Age structure, 1094

Agglomeration, 76, 85–88, 199–204, 335, 337,

461, 470, 476–477, 479, 483, 484,

541, 542, 545–552, 554–556,

558–560, 563–566, 651, 663–664,

854, 869–871

economies, 36, 53, 56, 148, 266, 383, 403,

409, 421, 422, 432, 476, 477, 485,

508, 509, 513, 520–521, 524–525,

529, 531, 532, 549, 551, 563, 566,

614–616, 632, 634, 636–638, 640,

642–644, 651, 829–830, 835, 1041,

1043, 1049

effects, 632–639, 642, 918

externalities, 335, 477, 485–487

forces, 441

Aggregate behavior, 1219, 1227, 1230

Aggregate place-to-place migration, 6

Aggregation, 1157–1170

Aggregative fallacy, 1345

Aging population, 24

Agriculture, 1050, 1053–1055, 1057–1065

AIC. *See* Akaike information criterion (AIC)

Airline, 1256, 1267, 1270–1271

Akaike information criterion (AIC),

1439–1442

Allocation of land, 511, 525

All-or-nothing assignment, 769

Alternative segments, 781–782
