Regional Science at Full Gallop: Editorial Introduction

Manfred M. Fischer and Peter Nijkamp

1 Aims and Scope

This Springer *Handbook of Regional Science* is meant to be a major reference work. It brings systematically together a varied set of major contributions to regional science that may be considered to be landmarks of advanced collective knowledge in the field. It was conceived to provide an understanding of major developments in regional science, in theory, methodology, and application. The various contributions are not purely theoretical or applied in nature, but offer a tertiary literature overview of advances in the field over the past few decades. The growth pace of regional science has been so fast that it is highly unlikely that a single scholar could have command of either the full spectrum of technical research tools, the broad multidimensional array of theoretical contributions, or the varied range of operational frameworks and studies in regional science.

Regional science has over the past half a century indeed turned into a broad multidisciplinary orientation on regional and urban issues, combining – and being a complement to – regional economics, social and economic geography, urban economics, transportation science, environmental science, political science, and planning theory. Regional science has also developed a powerful scientific toolbox that is nowadays being used in many spatial analyses. A major aim of the present handbook is to make major developments in regional science accessible to a broad set of students, researchers, practitioners, and teachers, as well as to provide a strategic source of reference for many interested scientists in the years to come.

It should be noted that regional science has – apart from a few notable exceptions – not been served very well with advanced textbooks, which makes access of regional science theory and method to advanced students and interested scholars rather difficult. This multi-volume handbook aims to provide a genuine and appealing entry to a rich and expanding scientific field, in which the interface of social sciences and space is highlighted from an analytical perspective.

2 A Short History

Regional science as a broadly recognized scientific domain has been brought to fruition only over the last 50 years. This does not imply that in previous periods there was no interest in spatial issues. On the contrary, already the grandfather of economics, Adam Smith, analyzed the relationship between location and trade, by emphasizing the importance of accessibility in spatial connectivity. And many other classical scholars, e.g., Ricardo, Malthus, Quesnay, and several others, have addressed – often implicitly – important issues of the space-economy. Of course, there is also a range of recognized predecessors of regional science, in particular, von Thünen, Weber, Palander, Predöhl, and Lösch. But the real history of regional science started with the seminal contributions of Walter Isard, who laid the foundation for a rigorous analytically oriented regional science since the mid 1950s. The framework developed by him had a theoretical foundation, a strong methodological orientation, and a strong emphasis on applied modeling of real-world phenomena and processes, seen from a multidisciplinary perspective.

It is noteworthy that Isard did not only provide original contributions to regional science in a strict sense, but also to ecological science, transportation science, and even conflict management. His approach is a perfect example of the multidisciplinary nature of regional science. This interdisciplinary character is also the key feature of the present handbook. Contributors of the various chapters originate from several disciplines which all together make up the constituents of regional science. These contributions follow the strict methodological requirements imposed in the early genesis of regional science, in which quantitative analysis and multidisciplinary approach are key.

A major recurrent theme in regional science is location and agglomeration theory. Location and agglomeration derive their importance from distance frictions, economies of scale, and proximity and connectivity, which are inherent in the spatial behavior of economic agents (households, firms, public actors). This theme forms the prominent historical perspective for regional science. And therefore, in the next sections we will concisely address this theme.

3 Location and Agglomeration Theory

Locations and agglomerations are spatial phenomena par excellence. They were historically – next to spatial interactions, e.g., through transport or trade – the most obvious subject matters of research in regional science. And over the decades, regional science has built up a strong tradition in analytical research on the determinants or drivers of location in the space-economy. Location theory does not only include industrial location decision, but also residential location and

facility location, including the spatial interactions between locations (allocation) and the spatial concentration of activities (agglomeration).

Location and agglomeration theory is concerned with the question where and why economic activity can be found. It addresses the spatial behavior of all agents, not only from a point perspective (i.e., the location), but also from a spatial pattern and geographical structure perspective (i.e., agglomerations and interdependencies). Individual location decisions were already studied more than a century ago by von Thünen and Weber, while geographical clusters and spatial interactions were already studied by regional scientists *avant la lettre* (e.g., Marshall, Palander, Christaller, Predöhl, Perroux, Myrdal, Hägerstrand, and many others). Regional science from a locational angle did not only spur innovative, theoretical, and methodological research on the space-economy but also applied policy research (e.g., on growth poles, industrial districts, etc.). This has also prompted a far-reaching research interest in regional development in a broad sense or regional economic growth in a more limited sense. Recent examples can be found in the endogenous growth theory, the New Economic Geography, or the neo-innovation theory.

In the same vein, housing markets and labor markets have become foci of regional science research, often from an urban economics perspective. In this context, land rent and mobility behavior are related to modern location and agglomeration analysis. Urban dynamics – including urban sprawl and the emergence of the “New Urban World” – has consequently also become a prominent direction in regional science research, along with transportation research and, more recently, digital infrastructure and geoscience research.

The reader will note that the present handbook does not contain a particular section devoted to location, allocation, and agglomeration. The editors have deliberately decided not to include a special section on these topics, for the simple reason that in the rich history of regional science location and agglomeration theories have increasingly become mainstream with more integrative spatial research themes, such as regional growth, regional innovation, spatial labor and housing markets, spatial modeling, and so forth. From this perspective, there is no evident or compelling need for a dedicated location/agglomeration section. There are many contributions in this handbook that address locational issues, but often embedded in a broader spatial context. Since “location is everywhere,” the editors feel that a separate section on location is no longer warranted.

4 Organization of the Handbook

The design of this handbook follows strict logical principles. There are nine major parts (sections), each of which consists of a set of systematically organized chapters. Though each author is responsible for the contents of his or her chapter,

a strict review procedure has been adopted, by both the section editors and the editors-in-chief. The handbook editors and the section editors have critically reviewed each individual contribution. This has not only ensured a strict quality control on each submitted chapter, but also a functional coherence and integration of all chapters and sections. And therefore, this handbook is more than a collection of loose chapters.

Clearly, in an interdisciplinary setting, a subdivision of a domain into sections and chapters is never watertight, but in our view the current structure of the handbook serves as a useful structuring of central themes in regional science. This opus contains nine overarching themes:

- Regional housing and labor markets
- Regional economic growth
- Innovation and regional economic development
- New economic geography and evolutionary economic geography
- Location and interaction
- Environmental and natural resources
- Spatial analysis and geocomputation
- Spatial statistics
- Spatial econometrics

These themes will now successively be discussed in a succinct way. This will be done in a rather novel way. Rather than offering summaries of each of the nine sections and of all 83 chapters of this handbook – which would be a boring and voluminous task – we will employ a so-called content cloud analysis which maps out in a visually appealing way the most prominent terms and concepts used in each individual section as well as in the handbook as a whole. A content cloud analysis is based on a systematic digital search algorithm, through which the most relevant substantive items – in terms of frequency – can be traced and identified, and next be included in a multicolor visualization, in which commonalities and frequencies of such items can be shown through color intensities and font sizes. This will be done here for all nine sections and for the entire opus, followed by a concise exposition. This way of systematizing the structure and context of this handbook offers also a key to trace cross-references through the subject index composed for this work.

5 Regional Housing and Labor Markets

Spatial housing and labor market research has been a focal point of attention in the long-standing history of regional science. Housing and labor markets are the cornerstones of regional science, as they related to both residential and firm locational behavior. They have been extensively treated in the history of spatial – urban and regional – research. The various contributions in this section extend the traditional focus in this field by including also migration, job search, poverty, real estate, and market-based evaluations. The content cloud associated with the nine chapters in this section is depicted in [Fig. 1](#).

Fig. 1 Content cloud of the Section on “Regional Housing and Labor Market”

This content cloud contains evidently labor, housing markets, (un)employment, and wage(s) as prominent items. But also terms like supply and demand, property, mobility, households, rents, and locations and hedonic values are clearly present. This colorful spectrum appears to present a balanced treatment of concepts one might expect in a section on housing and labor markets.

6 Regional Economic Growth

Regional economic growth issues have inspired a wealth of research – both theoretically and politically oriented – on the drivers and implications of

7 Innovation and Regional Economic Development

The third section of this handbook is devoted to innovation and regional economic development. It contains various important contributions on the spatial pattern of innovations, in combination with knowledge diffusion and absorption. Important elements are in particular externalities, innovative milieus, learning regions, human capital in cities, and digital infrastructures. This section offers a wealth of systematic insights into spatial dynamics and regional development.

This is confirmed by the content cloud related to this section (see Fig. 3). Keywords which stand out here are in particular: knowledge, networks, spillovers,

Fig. 3 Content cloud of the Section on “Innovation and Regional Economic Development”

and proximity. But also items such as interaction, diffusion, externalities, and learning are well represented. All in all, this section provides a collection of critical concepts that are key to a treatment of innovation and regional development.

8 New Economic Geography and Evolutionary Economic Geography

In the past decades, much attention has been devoted to new conceptualizations of spatial dynamics. The present section offers various interesting contributions on new economic geography and evolutionary economic geography. Rather than discussing whether we have here old wines in new bottles, the various chapters offer a systematic positioning of these issues in the regional science history and, more broadly, in modern economic growth theory. In this vein, also due attention is paid to institutional frameworks, to endogenous location and trade, to evolutionary perspectives and path dependencies, as well as to agglomeration externalities and the role of technological change.

The wealth of information contained in the front section of this handbook is substantiated by the content cloud mapped out in [Fig. 4](#). Items like markets, cities, agents, location, competition, and agglomeration dominate the scene in this content cloud, followed by important terms such as innovation, knowledge, equilibrium, proximity, and clusters. This information mapping clearly confirms the solidity of the topical choice on the theme of new economic geography and evolutionary economic geography.

9 Location and Interaction

Spatial interdependencies have always been at the heart of regional science research. Such interdependencies are clearly related in transport flows and mobility patterns, but go also much further. The present section on location and interaction does not only offer an account of travel patterns, transportation analysis, and network models, but also provides new insights into activity-based analysis, social network configurations, and spatial land-use models. This overview is then extended toward adjacent domains, such as supply chains, complex spatial systems, market areas, trade and migration, and input-output linkages. This rather comprehensive section illustrates the rich heritage which has been gathered in the spatial modeling history in regional science.

The latter observation is confirmed by the content cloud in [Fig. 5](#), which offers a visual mapping of key concepts in the fifth section of the handbook. Clearly, transport, mobility, networks, trade, and travel are prominently present in this cloud, but also terms like complexity, social, public, time, and change show up. This indicates that this section treats a variety of relevant concepts that may be seen as essential for a section on location and interaction.

Fig. 4 Content cloud of the Section on “New Economic Geography and Evolutionary Economic Geography”

10 Environmental and Natural Resources

Environmental and natural resources have been seen as major drivers of regional development since the early history of regional science. But its importance has not changed over the past decades, partly due to the awareness of the necessity of these resources for human survival, partly due to new emerging issues such as ecological sustainability, spatial resilience, or climate change. The present section on environmental and natural resources aims to provide up-to-date insights into the

Fig. 6 Content cloud of the Section on “Environmental and Natural Resources”

uncertainty, social, and public are present. This cloud shows that the position of environmental and natural resources is well anchored in regional science.

11 Spatial Analysis and Geocomputation

The section on spatial analysis and geocomputation offers an overview of achievements in a rapidly evolving research field in regional science. It provides relevant contributions to geographic information science, geovisualization, geospatial

Fig. 7 Content cloud of the Section on “Spatial Analysis and Geocomputation”

analysis, and geocomputation. This collection of advances is complemented with a useful state-of-the-art overview on the modifiable area unit problem (MAUP), spatiotemporal data mining, and Bayesian spatial analysis. To complete this interesting overview, several chapters have also been added to deal with cellular automata, agent-based models, spatial microsimulation, and spatial network analysis. Most of these topics have attracted major research interest in recent decades and may be seen as important contributions to the methodology of regional science.

The above observations are confirmed by the information contained in the content cloud associated with this section on spatial analysis and geocomputation (see Fig. 7). Keywords in this cloud are, apart from spatial and data: network,

distribution, space-time, attributions, graphs and maps. But also related terms play a significant role, such as: scale, visualization, location, behavior, and change. All in all, the above description suggests that this section covers a wide variety of research tools and concepts in modern regional science.

12 Spatial Statistics

Spatial statistics has become a rapidly growing research area in regional science, especially in the context of exploratory spatial data analysis. This section offers interesting horizons for new insights into spatial statistical data analysis. Spatial clustering, spatial dynamics and space-time data analysis, ecological inferences, and multilevel statistical analysis are important topics considered in this eighth section. Other advanced items that are treated in this section are inter alia: Bayesian statistical analysis, geographical weighted regression, geostatistical modeling and spatial filtering techniques, and geostatistical modeling and spatial interpolation. It is evident that this section contains a wealth of recent insights into the research potential of sophisticated statistical research techniques in regional science.

These findings are in agreement with the results of the content cloud presented in [Fig. 8](#). Apart from evident terms like regressions, spatial, or random, also various other items are presented, such as sampling, multilevel, and inference of software. In addition, relevant concepts like risk, variogram, eigenvectors, or neighborhood are included. This means that the present section on spatial statistics provides an extremely useful overview of the statistical toolbox of modern regional science research.

13 Spatial Econometrics

Spatial econometrics refers to the econometric toolbox applied to and adjusted specifically for spatially interdependent phenomena and processes. It has already quite a long history and gradually evolved into an important subfield within regional science. This section on spatial econometrics offers an up-to-date overview of advances in the flourishing research domain. Next to general overviews, also various specific topics are treated here, such as maximum likelihood estimation methods, Bayesian estimation techniques, instrumental variable methods, and the like. In addition, various advanced techniques are presented as well, in particular, limited and censored dependent variable models, spatial panel models, and spatial econometric origin-destination (OD) flow models. This section forms – next to the previous sections – a balanced representation of the toolkits of quantitative regional science research.

The content cloud in [Fig. 9](#) offers a confirmation of the above-mentioned remarks. Next to emphasis on standard terms like spatial effects and spatial models, we find also a prominent position for such concepts as explanatory, distribution,

Fig. 8 Content cloud of the Section on “Spatial Statistics”

flows, specification, and dependence. Furthermore, also various other important terms come to the fore here, in particular: distance, interaction, neighbors, chains, destinations, lags, and spillovers. It goes without saying that this research field still shows rapid dynamics, with many more advances to come in the future.

14 Synthesis of Concepts

The *Handbook of Regional Science* covers a wide variety of concepts, methods, frameworks, and research tools. The terms with the highest frequency of

Fig. 9 Content cloud of the Section on “Spatial Econometrics”

appearance through the entire handbook are summarized in the content cloud in Fig. 10. This figure offers indeed a balanced representation of the main substance issues covered by this handbook. This is further confirmed by the content cloud in Fig. 11 which is based on a systematic screening and recording of the main concepts included in the subject index of this handbook. Both figures depict largely the same type of information and may be seen as the main ingredients of this volume.

Abstract

This chapter traces the development of the role of economic opportunities in the study of migration. From the earliest years of internal migration as a recognized field of study, scholars in many social science disciplines believed that such opportunities were key determinants of migration. However, during the late nineteenth and early twentieth centuries, the lack of statistical measures of income and wages at subnational levels prevented empirical testing of the economic opportunity hypothesis. During this time, much rural-to-urban migration was occurring, and the presumption was that these flows were being driven by perceived urban–rural differences in economic well-being. The first formal measures used by economists in the 1930s were regional unemployment rates, and these rates proved to be significant determinants of migration during the Depression, but did not always hold up to scrutiny in later years. As aggregate income measures became increasingly available after 1960, they were incorporated in migration models, but their empirical success also was limited. Finally, the availability of microdata that

e-mail: Michael.Greenwood@Colorado.EDU

reflects personal employment status and household income has allowed numerous advances in our understanding of various migration phenomena and also has helped clear up many dilemmas regarding earlier migration studies that used aggregate data.

1.1 Introduction

The earliest work on migration recognizes the importance of *economic opportunity* as a key *determinant of migration*, if not the single most important determinant. In his classic nineteenth-century article, Ravenstein (1885, p. 181) leaves little doubt that he believed employment and wage opportunities were the major “determinants” of migration: “In most instances it will be found that they did so (leave their homes) in search of work of a more remunerative or attractive kind than that afforded by the places of their birth” (parentheses are mine). Later, he wrote that “the call for labour in our centres of industry and commerce is the prime cause of these currents of migration” (p. 198). Ravenstein does, however, recognize that the motives for migration are “various.”

For many years after Ravenstein’s work, very little research focused on internal US migration, which D.S. Thomas (1938) attributes to a scholarly focus on US immigration during the period often referred to as “the age of mass migration.” However, with the imposition of binding immigration quotas in 1921 and even more restrictive quotas in 1924, followed by the Great Depression in the 1930s, immigration fell sharply, and internal migration (especially rural-to-urban, South to North, and East to West migration) claimed an important place in the study of US migration. Now economists began to focus on *internal migration* as a field of study rather than more or less exclusively on immigration. With the economists came a much more specific concern for the importance of economic opportunities as a major force underlying migration. This was a concern that they carried over from their work on international migration.

During the 1930s, in a series of articles published in *Oxford Economic Papers* that was one of the most empirically sophisticated studies of its time, Makower et al. (1938, 1939, 1940) not only anticipated the *gravity model* of migration, but they also stressed the importance of economic opportunities as measured by the unemployment rate: “Quite a close relationship was found between discrepancies in the unemployment rates and migration of labour where allowance was made for the size of the insured population and the distance over which migrants had to travel” (1938, p. 118). At about the same time, Hicks (1932, p. 76) was arguing that “differences in net economic advantages, chiefly differences in wages, are the main causes of migration.”

Ravenstein was a British geographer, whereas Hicks and Makower, Marschak, and Robinson were British economists. Understandably, their focus was primarily on Great Britain. In the United States, prominent demographer Warren Thompson was further stressing the importance of economic opportunities: “The distribution of population always has been, and still is, determined chiefly by the economic

necessities of individuals, families, or larger groups, although social usages, personal preferences, and group traditions have always interfered with the free play of the economic factors in this process” (1936, p. 250). At about the same time, economist Carter Goodrich et al. were focusing on economic opportunities during the Depression in *Migration and Economic Opportunity* (1936). Much *rural-to-urban migration* occurred during the 1930s, and the Carter group was asking questions like would the migrants be better off if they were back in the rural communities from which they had departed.

Another famous work by one of the all-time best migration researchers appeared just after the Goodrich book. This was D.S. Thomas’s (1938) *Research Memorandum on Migration Differentials*. This contribution contains surprisingly little reference to economic differences as main determinants of migration. However, Thomas clearly thought that such differences were among the top determinants: “It goes without saying that there are other important factors (among the determinants of migration) in addition to community structure, distance, and phase of the business cycle, but we regard these three as fundamental” (1938, p. 6) (parentheses mine). Her reference to “phase of the business cycle” has to refer to economic opportunities. Her focus was mainly on migration differentials, or *selective migration*, like age and sex, and it was apparently too early for her to see how economic opportunities could play a major role in the determination of who moves. For example, age selection is importantly determined by economic opportunities in the sense that migration tends to occur at early ages because to postpone moving means sacrificing the monetary returns that are discounted least.

The Carter study was conducted primarily at the University of Pennsylvania, so it is perhaps not surprising that one of the primer migration studies of the 1950s and 1960s was conducted at this University as well. Led by S. Kuznets and D.S. Thomas, the University of Pennsylvania group published *Population Redistribution and Economic Growth in the United States, 1870–1950* (1957, 1960, 1964). This research also emphasized the importance of economic opportunities: “the distribution of a country’s population at any given time may be viewed as a rough adjustment to the distribution of economic opportunities” (Kuznets and Thomas 1957, p. 2). Thus, from the very beginning of migration research as a recognized discipline for study, economic opportunities were viewed as important determinants of migration, and perhaps as the single most important set of determinants, and this view was held by scholars in several social science disciplines.

In the sense that it can be valued, either directly in the market or indirectly through imputation, almost anything may be viewed as an “economic opportunity” (Greenwood 1997). Thus, for example, *location-specific amenities*, such as desirable (or undesirable) aspects of climate, have “values” that are reflected in labor and/or land markets. However, in this chapter, my emphasis is on more traditional measures of economic opportunities. These measures include (i) *wages and incomes* and (ii) job opportunities as reflected in *employment, employment growth, unemployment rates*, and “*crowding out*.”

Although many models that concern less-developed countries are similar in their formulation to counterparts for developed countries, my focus in this chapter is

specifically on developed countries. Several very good survey articles are available on migration in less-developed countries. Especially in the context of less-developed countries, the so-called *new economics of migration* provides certain new and different perspectives on economic opportunities. In traditional approaches to migration, individuals who are presumed to be utility maximizers make the decision to migrate or not, but in this new theory, migration decisions are made by larger groups such as families. Remittances play a key role in the sense that a (*family*) member may be sent away for the express purpose of sending funds back “home.” Thus, economic opportunities are viewed in a somewhat different sense in this approach.

1.2 Measuring Economic Opportunities

In the earliest empirical studies of internal migration, economic opportunities did not play a key role because statistical measures of such opportunities simply were not available at subnational (spatial) levels. The best alternative appears to have been a focus on migration to cities, where economic opportunities were presumably seen as superior to those in the rural areas from which the migrants were coming. This orientation is clearly apparent in Ravenstein (1889) second paper and in numerous papers discussed in Thomas (1938).

Since those early days when almost no regional measures of economic well-being were available for inclusion in migration models, numerous measures have been developed and used to reflect economic opportunities. As noted above, county unemployment rates were used to study internal migration in Great Britain during the 1930s. By 1960, Easterlin (1960) had developed estimates of *US regional and state per capita income* back to 1840, as well as estimates of service income per worker at the state level. The former estimates were subsequently used in studies of historical US internal migration. In the USA, various census measures that reflected statewide mean or median income were being employed to study interstate migration. Such measures along with aggregate unemployment rates also were employed to study other geographic configurations like substate areas. Not only were such measures used to analyze primary migration, but they also were used to study secondary moves (like return and onward migration).

During the 1960s and 1970s, studies that used *aggregate place-to-place migration* measures or that studied *in- and out-migration* or *net migration* often adopted income, unemployment rates, contemporaneous employment growth (in simultaneous-equation models), and lagged employment growth (to avoid simultaneity problems). Such studies frequently used these variables defined for places of origin (to reflect forces that might push potential migrants out or encourage them to stay) and for places of destination (to reflect forces that would attract or pull migrants or, alternatively, discourage them from coming). In other instances, ratios of destination to origin variables were adopted, but these measures in the then frequently estimated double-log, *modified gravity models* constrained the coefficients on the origin and destination variables to be the same except for sign.

Before the availability of data sets like the Census Public Use Microdata Samples (PUMS), researchers were constrained to the use of aggregate measures of income and unemployment rates. Generally, they had no other option. In studies of aggregate migration, an unavoidable problem with such measures is that area averages may have little relevance to actual or even potential migrants (unless everyone is regarded as a potential migrant, which is a distinct possibility). I next turn to a discussion of some of the issues tied to the use of these aggregate measures.

1.3 Unemployment Rates

As a regional characteristic, unemployment rates presumably reflect the tightness of the regional labor market. Thus, relatively higher unemployment rates characterize regions with labor markets that should encourage out-migration and discourage in-migration. The opposite is true of regions with relatively low unemployment rates. As a personal characteristic, unemployment reflects a situation in which the individual's opportunity cost of migrating is lower and his incentive to find a job anywhere, importantly in other regions as well as in his current region of residence, is higher.

The earliest study of which I am aware that uses unemployment rates in a formal regression analysis is the Makower, Marschak, and Robinson study (1939) noted above. These economists had data from the Oxford Employment Exchange that indicated the number of persons who entered the unemployment insurance system in specific counties other than Oxford and who were residing in Oxford in 1936. Although their information included such personal characteristics as sex, age, industry of employment both before and after the move, and county of origin, they aggregated the data to the county level, presumably because at that early date, they did not know how to analyze microdata. Makower, Marschak, and Robinson defined what they called the "*relative unemployment discrepancy*" as "the ratio of the difference between the unemployment rate in the county (or Division) and the unemployment rate in the whole country, to the unemployment rate in the whole country" (1939, p. 81). Their regression results indicated that "there was a very clear correspondence between variations in the relative unemployment of the county and variations in the gains and losses by migration" (1939, p. 82). The work of these authors was important for reasons that go well beyond their use of unemployment rates in a regression analysis. They were the first researchers of whom I am aware that formally estimated a gravity model of spatial interaction, although they did not refer to their model as such. They were the first to actually estimate a distance elasticity of migration, which they called the *coefficient of spatial friction* (1938).

Focusing on approximately the same period as Makower, Marschak, and Robinson, but for the United States, Bogue et al. (1957) also provide an early regression analysis that incorporates (male) unemployment rates. They employ census data to study 1935–1940 (gross in-, gross out-, and net-) migration flows

(defined as rates) for metropolitan versus nonmetropolitan state subregions. They provide regression results for migration from both metropolitan and nonmetropolitan subregions to both metropolitan and nonmetropolitan subregions. In this analysis, unemployment rates fail to be positive and statistically significant only for total migration from nonmetropolitan areas and for migration from nonmetropolitan areas to other nonmetropolitan areas (but the signs remain positive). In their regressions for in-migration and net migration, the signs on all unemployment-rate coefficients are negative, as anticipated, and highly significant (which for these authors is 5 %).

The early multiple-regression analyses of Makower, Marschak, and Robinson and Bogue, Shryock, and Hoermann are noteworthy because they were conducted at a time before the availability of computers. They also are noteworthy because their authors obtained expected signs and statistically significant coefficients on unemployment-rate variables. For many years and for many studies after these early efforts, the results on unemployment-rate variables were not to be so uniformly “correct.” In fact, in modified gravity models, the findings associated with unemployment-rate variables were among the most consistently troublesome in terms of signs and significance levels. (“Modified (or extended) gravity models” are models in which absolute migration from i to j , or the rate of migration from i to j , is a function of the basic variables of the gravity model (distance from i to j , population of i , population of j) and additional variables, such income in i and in j , unemployment rate in i and in j , and numerous other possible variables).

Many examples are available of studies that obtain unexpected signs or insignificant coefficients on an unemployment-rate variable (Greenwood 1975a). As indicated in Greenwood (1975a, p. 403), “the failure of unemployment rates to appear to influence migration in the expected direction and/or with the expected relative magnitude has been attributed to the simultaneous-equations bias inherent in single-equation, multiple regression models. This bias is likely to be particularly marked in those studies that employ explanatory variables defined for the end of the period to analyze migration that occurred over the period, because migration is itself likely to influence end-of-period economic conditions.” In Greenwood (1975b), I examine these hypotheses with US census data on 1955–1960 and 1965–1970 metropolitan in- and out-migration, using explanatory variables defined for the beginning-of-period, end-of-period, and, alternatively, changes over the period. The models are estimated by ordinary least squares and by two-stage least squares. For the most part, no matter how the unemployment-rate variables are defined and no matter how they estimated, the coefficients tend with few exceptions to be statistically insignificant. The major exception is for metropolitan in-migration from nonmetropolitan areas, for which the sign is almost always negative and significant. When the absolute change in unemployment is included as endogenous in a simultaneous-equation model, for 1955–1960 migration, this variable tends to have the expected positive sign in the out-migration regressions and the expected negative sign in the in-migration regressions, and in both cases, the variable is significant. However, for 1965–1970 migration, the results are not so clean.

An alternative explanation for unanticipated findings on unemployment-rate variables was provided by Lansing and Mueller (1967). As stated in my 1975 article, they argue that “unemployment tends to be highest among the least mobile groups in the labor force—among persons in blue-collar occupations, among those with low skill and educational levels, and among the young. . . .the unemployed tend to be workers who ordinarily would not consider migration as one of their options” (1975a, p. 403). The Lansing and Mueller hypothesis clearly relates to *personal unemployment*. However, Current Population Survey data have for many years indicated that the unemployed are more likely to migrate than the employed. Of course, such cross-tabs do not control for many other personal characteristics such as those noted by Lansing and Mueller.

The solution to much of the mystery associated with unemployment-rate variables awaited the availability of microdata. At the time my 1975 survey was written, only three of the 251 articles referenced in the paper utilized microdata. Soon after the publication of this article, the microdata revolution began in earnest. DaVanzo (1978), who used microdata from the Panel Study of Income Dynamics (PSID), provided important new insights into the unemployment-rate puzzle. Quoting from my 1985 survey, DaVanzo “shows that families whose heads are looking for work are more likely to move than families whose heads are not looking. Moreover, the unemployed are more likely to move than the employed. Higher area unemployment rates encourage the out-migration of those who are unemployed, but exert little influence on those who have a job” (1985, p. 532). This last finding has important implications for studies of (aggregate) migration that employ aggregate regional characteristics, including the regional unemployment rate. Even in the DaVanzo study, only a fraction of the unemployed actually migrate. The unemployed constitute a small fraction of the labor force and a much smaller fraction of the population, and the unemployed who actually migrate are a smaller fraction still. In aggregate studies, the numbers of individuals who actually migrate due to unemployment may simply be too small to be reflected in the empirical results.

Navratil and Doyle (1977) use *microdata* in combination with aggregate data to directly address the question of the influence of aggregation on elasticities estimated in migration models. They study 1965–1970 migration of white males, white females, black males, and black females, with 82 county groups contained within specific states serving as the observation base (with about 220,000 individuals). In one model, they use aggregate proxies for personal characteristics (like group-specific age and group-specific unemployment rate) in combination with general area characteristics (like the unemployment rate). In a second model, they replace the group-specific characteristics with personal characteristics (such as a dichotomous variable for unemployed vs. employed), and they retain the general area characteristics. The general unemployment rate is negative and significant only for white females when the first type of model is estimated and only for white males in the second (probit) type of model. Among the aggregate personal characteristics, the unemployment rates are never significant, but when they are replaced with a dummy variable reflecting personal employment status, the unemployment

variable is positive and highly significant for all four groups. Thus, individuals who were unemployed at the beginning of the migration interval (1965) were more likely to have migrated between 1965 and 1970, but in no way was such a finding possible to obtain with aggregate data alone.

1.4 Income, Earnings, and Wages

For economists, from the earliest studies, income or wage differences were considered to be the most basic of the determinants of migration. This position was strongly held with regard to both internal and international migration. Hicks's reference to the main drivers of migration noted above ("chiefly differences in wages") is a good example of the dominant position of wage or income differences in the thinking of economists. However, the empirical evidence on income and/or wages has not been uniformly in support of this hypothesis. Whereas some results strongly support the position, other evidence is more mixed. Moreover, one of the basic ideas in the neoclassical model is that migration should itself cause wage differences to narrow and migration to diminish over time, other factors held constant. However, the empirical results regarding this hypothesis also have been mixed.

Economic historians have developed a great deal of evidence that wage differences (or *wage gaps*) between the United States and various European countries were primary determinants of migration between Europe and America during much of the nineteenth and the early twentieth centuries, but the importance of wages declined as the gaps narrowed later in the nineteenth century. Thus, at least with respect to historical US immigration from Europe, empirical findings are consistent with wage gaps between the US and the European source countries providing a major impetus to migration, these gaps narrowing due importantly to the equilibrating effects of mass migration from Europe to the Americas, and in turn emigration from northern and western Europe to the Americas diminishing as the nineteenth century progressed.

Early studies of internal migration did not include wages or income, presumably because no measure was available. For example, Makower, Marschak, and Robinson include only the relative unemployment rate (along with distance and population) in their regression. Bogue, Shryock, and Hoermann employ a variable they refer to as "level of living index" (1957, p. 74). Even D.S. Thomas's famous *Migration Differentials* book contains limited reference to income or wages. In a later paper (1958) discussed below, she uses real per capita gross national product.

Contrary to historical studies of US immigration from Europe, modified gravity models of internal US migration (that became popular during the 1960s) frequently yielded unexpected signs and/or statistically insignificant coefficients on origin and destination income variables, especially on origin variables. Negative signs were typically expected on origin-income variables and positive signs on their destination counterparts, since higher income was expected to discourage out-migration and encourage in-migration. Many examples are available.

Proponents of the equilibrium hypothesis (that wage or income differences are compensating differences that reflect the values of location-specific amenities) claim to have provided an explanation for the unexpected signs and insignificant coefficients on income variables. However, even in the presence of various amenity variables, many models continued to yield unexpected findings.

One of the most understudied aspects of migration research is the *temporal relationship* between *cyclical economic activity* and migration. Although the topic has been of interest and concern for many years, good temporal data on migration prevented any in-depth analyses of the relationship. One of the Oxford studies of Makower et al. (1939) is the earliest of which I am aware that addresses the issue. Their data covered the period 1923–1937. They conclude that “the data of the Oxford study suggested that mobility increased with prosperity during the period 1933–7. . . While it suggests that mobility was reduced during the slump of 1931, it confirms the rise in mobility during the recovery. Thus mobility fluctuates in harmony with the trade cycle. It was found, further, that ‘short-distance’ movements were less sensitive to the slump than ‘long-distance’ movements” (1939, p. 94). They attribute the cyclical nature of migration to out-of-pocket expenses: “in times of . . . prolonged unemployment, people find it more difficult to raise the money necessary for migrating” (1938, p. 118).

Another early study that attempted to uncover the relationship between cyclical activity and interstate migration was conducted by D.S. Thomas (1958). She and her research team at the University of Pennsylvania had developed fairly detailed state-specific net migration estimates by age and sex for each intercensal decade from 1870 to 1950. As indicated above, in her famous monograph on differentials in migration, she had noted that “phase of the business cycle” was one key to understanding migration differentials, but then she provided little or no empirical support for her hypothesis. With more detailed migration estimates, she now returned to this relationship. Her measure of economic activity was novel. She fit “six successive thirty-one year linear trends to annual data on gross national product per capita, in constant prices, beginning with the first year of each decade, cumulating the absolute deviations from each trend over each decade, and expressing their algebraic sums as percentages of corresponding cumulative trend values” (1958, p. 317). She then classified decades between 1880 and 1940 as relatively high versus relatively low in terms of economic activity. Her basic conclusion was that “young males, seeking economic betterment, (showed) a correspondingly greater *intensity* of migration during high than during low activity periods” (1958, p. 319) (parentheses mine).

Later, Greenwood et al. (1986) used annual (1957–1975) data from the One Percent Continuous Work History Sample of the US Social Security Administration to study the linkage between employment change and migration. They conclude that in an average year two additional local jobs attract about one additional employed migrant. However, like Thomas, they also find that the migrant-attractive power of an additional job behaves cyclically, rising during upswings and falling during downswings. They speculate that when the costs of migration are relatively high, such as during cycle troughs, a greater degree of *migrant self-selection* occurs,

and thus, migrant quality in terms of human capital rises. The opposite occurs during cyclical upswings. More recently, Saks and Wozniak (2011) examine long-distance migration over the business cycle. Using a variety of data sets, they too conclude that migration is procyclical, which they attribute to greater net benefits to moving during cyclical upturns. Moreover, similar to the earlier finding of Thomas, they argue that younger workers are especially procyclical in their migration behavior, presumably due to better economic conditions during cycle upswings.

In the end, we should recognize that the “*net wage*” or the “net income differential” is critical. Such a net value is corrected for state and local tax differences as well as differences in the values of publically provided goods and services. In the USA, state income *taxes* vary from none to significant percentages of taxable income, and many benefits also differ greatly across states and localities. Such *benefits* include differences in per student expenditures on K-12 education, as well as assistance for needy families in the form of food stamps, housing, and other services. A number of studies have addressed the importance of various types of state and/or local taxes and/or public expenditures in migration decisions, and I will not treat this literature in any detail here.

1.5 Employment Opportunities

Among those variables that reflect economic opportunities, the most consistently significant are those that proxy the availability of *jobs*. This condition tends to be true whether employment opportunities are measured as contemporaneous employment change (in simultaneous-equation models), lagged employment change, or employment rate.

Several studies of historical migration, as well as a number of those dealing with contemporary migration, assert that migrants crowd out others in the sense that the migrants encourage the out-migration of prior residents or discourage the in-migration of potential new residents. Presumably, underlying this phenomenon is competition for jobs, although cultural and other differences between immigrants and natives also could be responsible in part. The historical studies have focused on the manner in which the location of immigrants in northern US cities influenced South to North migration of the native born. During the late nineteenth and early twentieth centuries, as immigration from Europe surged, migration from South to North ebbed, and when immigration ebbed, this internal flow surged. Collins (1997) provides strong empirical support for this phenomenon. Thus, historically, broad regional growth patterns were significantly affected by immigration and by immigrant settlement patterns. Even during the Great Depression, when immigration was very low and immigrants were not a major issue, internal migrants to US cities caused the out-migration of longer-term residents. Boustan and Fishback (2010) show that during the 1930s for every 10 new migrants, 1.9 residents departed; moreover, another 2.1 individuals were unable to find a relief job, and 1.9 more moved from full-time to part-time work.

A number of studies have examined the location of the foreign born and the internal migration of the native born in the United States. The basic conclusion of

much of this work is nicely summarized in the early study by Filer (1992, p. 267): “It is clear that there is a strong relation between the arrival of immigrants in a local labor market and the mobility patterns of native workers. The higher the concentration of recent immigrants in an area, the less attractive that area appears to have been for native workers.” Filer’s focus is on Standard Metropolitan Statistical Areas and 1975–1980 net internal migration flows.

More recent studies examine various groups of internal migrants and more recent periods (such as 1985–1990 and 1995–2000), but many of these studies arrive at essentially the same conclusion. For example, Frey and Liaw (2005) use *microdata* and logit analysis to study both in and out interstate migration patterns for 1995–2000 and, after controlling for numerous personal and area characteristics, conclude that “Our results generally show no race-specific flight of whites alone from (states with large numbers of low-skilled immigrants), but rather show an accentuated out-migration of all race-ethnic groups from states with . . . high levels of foreign-born immigration” (p. 246, parentheses mine). Moreover, they find that “for every 100 new low-skilled immigrants to California there would be a net out-migration of fifty-one low-skilled domestic migrants” (p. 213). Similarly, Borjas (2006), using data from the 1960, 1970, 1980, 1990, and 2000 censuses and focusing on various skill groups, finds a powerful effect of immigrants on native internal migration amounting to two fewer natives wishing to live in a state if ten more immigrants settle there. The effect is somewhat greater at the metropolitan level, and more in line with the estimates of Frey and Liaw.

This literature is related to an old issue in migration. What is the *migrant-attractive power* of a job? Perhaps the earliest study to directly address this question is Muth’s (1971) “Migration: Chicken or Egg?” study. He found that three more jobs attracted two more employed net migrants. This was the direct effect of an additional job and does not take into account the indirect and induced effects that result from the migrant’s influence on jobs. However, this is only one possible outcome regarding the direct effect of employment on migration. Consider the following relationship: $M = f(\Delta E)$, where M refers to employment migration and ΔE refers to change in employment. The possibilities are as follows: (a) one more job attracts one more employed migrant, or $\partial M/\partial E = 1.0$; (b) another job attracts no migrants, or $\partial M/\partial E = 0$; and (c) another job attracts some fraction of a migrant (or, say, 100 jobs attract between 1 and 99 migrants), or $0 < \partial M/\partial E < 1.0$. This last case reflects Muth’s finding that, for example, 100 jobs would attract 67 employed migrants. This is the most likely case. In case b, local residents take all of the *incremental jobs*, as could be the case for less-skilled jobs such as might be available at McDonalds. On the contrary, in case a, where migrants fill all the incremental jobs, the jobs may be highly specialized, such as airplane mechanics. Little research has been done on the migrant-attractive power of different types (occupations) of jobs.

Although the most common finding is the one-to-one relationship, depending upon the specific region, other findings are evident for US regions (Greenwood and Hunt 1984). Thus, some *crowding out* appears to occur, but it is not a universal phenomenon. Even with respect to US immigrants, some studies deny the existence

of such a crowding-out relationship. Butcher and Card (1991) argue that this general conclusion is limited to New York, Los Angeles, and Miami. Based on their use of CPS data for the 1980s, they conclude that for 21 other cities, “native immigration flows during the 1980s were positively correlated with inflows of recent immigrants” (1991, p. 294). Similarly, Kritz and Gurak (2001) find little support for the hypothesis that native men migrate away from states with heavy immigrant concentrations over the 1985–1990 period.

1.6 Conclusions

Early studies acknowledged the importance of economic opportunities as a key determinant of migration, but due to lack of data reflecting such opportunities, these studies provided little empirical support for the hypothesis. A strong focus on rural-to-urban migration was evident in very early migration research, and the general assumption presumably was that economic opportunities in cities were sufficiently better than in rural areas to generate a strong flow of migrants from one type of area to the other. D.S. Thomas’s (1938) effort in the 1930s to summarize and synthesize the migration literature is a good example of this lack of data. Although she mentions the importance of the business cycle in determining the volume and age composition of migration, she never specifically addresses what she might have referred to, but did not, as “income differentials” and none of the many studies she cites introduce a measure of income or wages in an analysis of migration.

The first study that formally introduced a measure of economic opportunity was conducted in the late 1930s and used an unemployment measure to study intercounty migration in Britain. Beginning in the 1950s, as publicly provided aggregate income measures (such as median and mean income for states and more narrowly defined local areas) became more commonly available, such measures were introduced into migration models, which would have been judged severely lacking in their absence. Studies from this period are reviewed in Greenwood (1975a, 1985). Although it is fair to argue that these studies did not always find strong support for the hypothesis that income or wage differences were among the most important determinants of migration, on balance such measures did hold up reasonably well to empirical scrutiny.

Several recent studies have identified “crowding out” as a reason for internal US migration. This phenomenon relates to one group absorbing local jobs and thereby displacing others from their positions, and thus causing the displaced individuals to migrate from the area. Most frequently, new immigrants are seen as crowding-out natives, but the same relationship has been observed in the past as immigrants discouraged native out-migration from the South to the North, and during the Depression, rural-to-urban migrants crowded urban dwellers from their cities of residence.

As microdata became more widely available during the 1980s and beyond, later studies incorporated individual and household income data to allow the further and deeper study of the importance of income in the analysis of migration. For example, now spousal incomes are available that allow the study of family migration.

Thus, the empirical implementation of measures of economic opportunities in migration models was highly dependent upon the development of various measures of economic well-being, at first from the census and later from various special surveys. Without question, economic opportunities are now central to virtually any model reflecting human migration. Moreover, among economic opportunity measures, the availability of jobs stands out as the single most consistent variable to which migrants respond.

Abstract

Over long periods of human history, labor market equilibrium involved movements from low-wage areas to high-wage areas, a form of arbitrage under the implicit view that wage differentials corresponded to utility differentials. This “labor economics” view is likely to be viable as long as movement and information costs are high, and under this view, the movements would be expected to cause wage convergence over space. In recent decades, beginning as early as the 1960s in the United States, both the out-of-pocket and psychological costs of movement have plummeted with advances in transportation and communication technology and innovation. In addition, these same advances have enabled individual households and firms to have vastly improved information about potential benefits of locating in a host of potential locations. These observations, along with recent failures to observe convergence in wage rates, suggest that an alternative view – assuming a utility equilibrium over space – might better predict and explain the labor market equilibrium. This “urban/regional economics” view takes wages and rents as being compensatory for varying levels of

household and firm amenities. In this view, whether the spatial equilibrium in labor markets involves convergence or divergence becomes quite a complicated issue. This chapter explores a number of the complexities, hinting at a broad range of potentially fruitful future research.

2.1 Introduction

People have been moving from location to location for millennia. Such moves were prompted by a myriad of motivations, ranging from famine, war, and religious persecution to the present concern with spatial equilibrium in labor markets. With primitive transportation technology, moves – particularly moves covering long distances – were very costly. In some cases, such as slavery, the moves were involuntary, while in other cases the moves, while voluntary, involved indentured or redemptioner servitude as a means of paying the high costs of passage. Chiswick and Hatton (2002) review the determinants and consequences of intercontinental migration over four centuries, with an emphasis on the colonial and postcolonial period. Rosenbloom (2002) provides an excellent review of the development of labor markets in the USA in a primarily cliometric framework. Both of the preceding provide a more general background for this chapter, but the central purpose here is to explore the role of migration (i) as a response to labor market variables and (ii) as a cause of change in labor market variables.

We shall see that the labor economics literature's traditional view of spatial equilibrium in labor markets has clear implications about the role of migration along these two dimensions. As emphasized in the early work of Borts and Stein (1964), (urban) regions with high capital to labor ratios would be expected to have higher wages than (rural) regions with low capital to labor ratios, leading to the expectation that labor flows would be from the latter to the former. These theoretical observations suggest that migration occurs as a response to arbitrageable variations in wage rates, a form of human capital investment. Examining the migration choice in detail, Sjaastad (1962) argues that migration would be expected to occur when the present value of the benefits of a move exceeds present value of the costs of that move. As we shall see in Sect. 2.2, under this approach the benefits of a move have been taken to be the higher wages obtainable in a potential destination.

That is, higher wages in a location are presumed to correspond to higher utility levels in that location. The long-run spatial equilibrium in this view of migration would be one of *convergence* in wage levels over space. Thus, (i) migrants respond to higher wages in a location with in-migration to that location, and (ii) the resulting in-migration reduces the divergence in wage levels over space.

A newer approach derives its insights much more explicitly from the urban/regional economics literature, rather than the labor economics literature briefly described above. The early theory of this more general approach is developed in Graves and Linneman (1979), with an early empirical quasi-dynamic application of the comparative-static theory in Graves (1979). The theory did not receive widespread attention until the now-classic contribution by Roback (1982) and the

supporting empirical work by Blomquist, Berger, and Hoehn (1988). In this approach, wages are only one of many things, notably rents and natural and man-made amenity levels, which vary over space. Roback explores the implications of assuming that spatial equilibrium is in existence, examining the nature of that equilibrium, an equilibrium in which utility levels and firm profitability are presumed equal everywhere. In this view, as we shall see in Sect. 2.3 below, wages and rents are expected to offset variations in amenities; hence, there is no longer an expectation of wage convergence, although it will become apparent that rent changes over time complicate an understanding of this prediction. That is, if rents tend, in the long run, to capture the full value of amenities (both household and firm amenities), then one would expect wage convergence to occur. The motivations for convergence will be seen, however, to be markedly different in the two approaches in terms of understanding the nature of the spatial labor market.

2.2 The Traditional Labor Economics View of Spatial Labor Markets

To tersely characterize the labor economics approach to migration, let utility be a function of goods consumption, as is implicit in the most basic texts in economics:

$$U = U(X) \tag{2.1}$$

where X is a vector of goods consumed, with U increasing in each element of X (any “bad” is redefined as a “good,” e.g., pollution becomes pollution abatement). Equation (2.1) is maximized subject to the usual budget constraint:

$$\begin{aligned} \text{Max } U &= U(X) \\ \text{s.t. } Y &= PX \end{aligned} \tag{2.2}$$

where P is the vector of prices corresponding to each element of the goods vector and Y is income of the decision-maker. This utility function, *increasing* in its arguments, can be written as an “indirect” utility function, V :

$$\text{Max } V = V(P, Y) \tag{2.3}$$

where V is *decreasing* in P and *increasing* in Y . Taking labor supply to be fixed, for simplicity (and to make some comparisons in the next section), the i th migrant’s location decision among the j locations becomes:

$$\text{Max } V_{ij} = V(P_{ij}, Y_{ij}) - C_{ij} \tag{2.4}$$

where migrant i faces prices, specific to his/her consumption bundle, which vary over space, and faces incomes, specific to his/her human capital, which also vary over space. The C_{ij} term measures the monetary and psychological costs of moving to location j , where this cost, too, is specific to migrant i (i.e., age, wage rate, distance to location j , affinity to friends or relatives, and the like can vary among migrants causing the costs of movement to vary).

In this simple model, potential migrants would not move if the cost of moving from their initial location, j_0 , exceeded the gain from moving to any alternative location $j \neq 0$. If a move occurs, it would be to the location with the highest net benefit of movement, j^* . In an even more simplified world with all goods being tradable at negligible transportation costs, prices would not vary and potential migrants would move to the locations with highest net income ($Y_j - C_j$).

The preceding simple model predicts that movement would generally occur from low-wage to high-wage areas, and aggregating to the local labor market level, the movement would tend to lead toward wage convergence. Low-wage locations would lose labor supply as households moved away, causing wages to rise; high-wage locations would experience increases in labor supply, causing wages to fall, a generalization of Borts and Stein's characterization of rural to urban labor flows. A more detailed discussion of how well this model predicts relative to its alternative in [Sect. 2.3](#) comes later; for present purposes, it is sufficient to note that non-convergence, or implausibly slow convergence, is frequently observed. To the extent that there has been convergence, it has slowed or reversed beginning in the 1980s. Moreover, in areas with high levels of *net* immigration, there are also high levels of out-migration which would seem difficult to reconcile with the simple model of this section.

2.3 An Urban/Regional View of Spatial Labor Markets

In light of the observation that convergence appears to be occurring either not at all or at a pace which is implausibly slow, might there be an alternative way of looking at labor markets that is consistent with this observation? Roback (1982) provides an alternative view of labor market functioning that relies on assumed equilibrium in utility levels over space. The underlying notion is quite simple – just as there is no such thing as a “fast lane” on a freeway during rush hour – there is no such thing as a “nice place” to live vis-à-vis other places. Movement would be expected to occur to approximately equate speed in each lane, in the first case, and in the latter case, movement would be expected to occur to make all locations approximately equally desirable. Movement to the “nice” place should continue to occur until either high housing prices or low wages make that place no nicer than elsewhere. The details of the argument are, however, not quite this simple (see Taylor 2008 for the formal equations for this model corresponding to those for the disequilibrium model of [Sect. 2.2](#)). Our treatment here will be more intuitive, driven by words.

Fig. 2.1 Wage (W) and rent (R) expectations under various amenity assumptions

	Good for Firms	Neutral for Firms	Bad for Firms
Good for Households	$R > R_o$ $W?$	$R > R_o$ $W < W_o$	$R?$ $W < W_o$
Neutral for Households	$R > R_o$ $W > W_o$	(Base Case) $R = R_o$ $W = W_o$	$R < R_o$ $W < W_o$
Bad for Households	$R?$ $W > W_o$	$R < R_o$ $W > W_o$	$R < R_o$ $W?$

Locations offer amenities, which may be either natural or man made, that affect utility in the case of households (e.g., desirable weather, scenic views, restaurant diversity and quality) and affect production functions in the case of firms (e.g., deep-water ports, access to mine mouth, right to work laws). Considering these cases separately, if a location is unusually desirable to households, they would be expected to enter driving up housing demand and increasing the supply of labor. Hence, in equilibrium, a nice location should have higher housing costs (property values or rents) and lower wages. Conversely, an undesirable location would be expected, in equilibrium, to have some mix of lower housing costs and higher wages.

Turning to firm amenities, desirable locations would lead to firm in-migration, and that movement would be expected to increase demand for land (directly for industrial sites and indirectly for new employee housing) and increase the demand for labor. Hence, a desirable firm location, relative to others, would be expected to have – other things equal – higher housing prices (property values and rents) and higher wages. Similarly, locations that are undesirable to firms would be characterized by lower housing prices and wages.

Temporarily assuming homogeneity for simplicity, where all households possess the same utility functions and all firms possess the same production functions, all locations will have amenity bundles that would be, on net, reliably characterized as in Fig. 2.1.

Note that in the table, the “base-case” location (neither good nor bad for either firms or households) is seen in the center cell, where the rent is R_o and the wage is W_o . The wage and rent combination in this cell may be thought of as representing an “average” location. All other cases represent locations with amenity bundles that are either good or bad for one or both of households and firms relative to this average location. The cases merit consideration in more detail.

If a location is both good for firms and good for households, this location will clearly become quite large with much higher than average rents since both firms and households will want to move in (e.g., San Francisco Bay area). The impact on

wages will, in general, be ambiguous since the influx of households would lower wages, while the influx of firms would raise wages. This ambiguity is reflected in the $W?$ symbol of cell 1, Fig. 2.1 – without more information on the relative importance of the amenity to firms versus households, it is not possible to know what wages will be like compared to ordinary (base-case) locations. Conversely, in the bottom right cell, a location that is undesirable for both firms and households will have unambiguously lower rents but wages that may be higher or lower than W_0 , depending on relative undesirability.

A location that is bad for households and good for firms (lower left cell in Fig. 2.1) will have unambiguously higher wages in equilibrium (smaller supply of labor and larger demand for labor reinforce each other in raising wages). The impact on rents, $R?$, is now ambiguous, since without further information about the relative magnitude of the (dis)amenity, we do not know whether the location will be larger or smaller than average. Conversely, in the upper right cell, if a location is bad for firms and good for households, it will have unambiguously lower wages, with an ambiguous effect on rents, because the relative importance of the (dis)amenity is not known without further information from empirical investigations.

A confusion that persists in the general population, and to a lesser extent among economists, is the role of “cost of living” in labor market equilibrium. In the case of a location that is very desirable to households and neutral to firms, the higher rents are not a higher “cost” of living but rather a higher “benefit” of living, just one that we, perhaps unfortunately, have to pay for. A nice location vis-à-vis an undesirable location is exactly analogous to comparing a new BMW to a 1980s GMC K-car – you pay more for the former, but you get more. Note however that when an amenity is neutral for households but desirable for firms, the higher rents *do* reflect a higher “cost of living.” However, in equilibrium, that higher cost of living must be compensated for by higher wages – households can be no worse off financially in such locations in equilibrium, because such amenity-neutral locations would otherwise be less desirable than alternatives.

From this point on, it is assumed that disequilibrium view of labor economics in Sect. 2.2 is no longer an appropriate way to view spatial labor market equilibrium (see Partridge 2010 for a recent gathering of corroborative evidence). As discussed at the outset, it is likely that arbitrageable variation in real utility was the dominant cause of labor market flows when costs of movement were high and when information about the benefits of movement was costly, if available at all, as with transcontinental moves for many centuries. Costs of movement have fallen dramatically, especially relative to income growth in the United States (e.g., Interstate Highway System, more widely available and reliable automobiles, falling airfares, and long-distance phone rates to maintain psychological and other connections). Rapid advances in information technology (e.g., television beginning in the 1950s, ubiquitous by the 1960s, internet) have resulted in Americans in all locations knowing a great deal about the general nature of many if not most potential destinations. Additionally, as made clear by Roback, it is now apparent that the labor markets and the land markets cannot be considered separately, since an

amenity will generally be capitalized into both markets, something completely ignored in the labor market arbitrage model.

Two early empirical findings helped initiate the shift from the labor market disequilibrium approach. Graves (1979), using data from the 1960s, found net migration was occurring to locations with *lower* incomes, not to locations with higher incomes. Only when climate amenities were introduced into the regression did the income variable take on its “proper” sign; clearly if all amenities could be held constant in an estimating equation, more income would have to be preferred to less. Moreover, in the context of the labor market disequilibrium approach, higher rents would represent higher “costs of living,” hence would, *ceteris paribus*, be expected to lead to lower real incomes – one should expect movement, holding nominal income constant, away from high-rent locations. Yet exactly the opposite was seen to be occurring in Graves (1983), where migrants were moving *toward* high-rent locations, holding income constant. These two results strongly support a model in which the rising national income of earlier years led to greater demands for desirable locations, driving down wages and driving up rents, and in the 1960s, with income continuing to rise, migration continued to the desirable locations, despite the lower wages and higher rents observed in such locations.

Finally, note too that, as with the case of the “fast lane” on the freeway, it does not necessarily take many movers to yield an equilibrium in which real utility is approximately equal across space. This is not to argue that there are no longer *any* variations in utility over space, but rather that the dominant observed pattern is one of equilibrium (as discussed in Mueser and Graves 1995, shocks to employment continue to occur, but they are more intertemporally and spatially random than are the systematic amenity influences). To a large extent, the importance of demand-side influences relative to supply-side influences depends on the time perspective of interest: for near-term interests, the demand-side approach becomes more relevant (see Greenwood and Hunt 1989), while for longer-term interests, the supply-side approach becomes more relevant (as with the early supply-side approach of Borts and Stein, though that was driven by excess labor in agriculture rather than amenities).

2.4 Spatial Labor Market Equilibrium in the Urban/Regional View with Suggestions for Future Research

Taking the equilibrium view, the central observation to make is that there is no compelling reason to expect wage convergence. Indeed, since wage differentials are compensatory for amenity differentials, one might expect wage *divergence* over time, if desirable locations are also normal or superior, as might be expected. That is, as first discussed in Graves 1979, rising income nationwide will increase the demand for many things such as restaurant meals, clothing, automobiles, and the like – but while those goods can be incremented in situ, increased demand for lower humidity or more sunshine requires migration toward areas offering these non-tradable goods. Thus, one might expect that the ongoing migration from

undesirable (high-wage) locations to desirable (low-wage) locations would lead to a growing wage gap over time, not a narrowing gap as would be expected in the disequilibrium view.

On the other hand, rents might capture increasing percentages of the value of a location's amenities over time, as nice places become larger. This is particularly likely if, as will occur with an aging population, an increasing percentage of households have no members in the labor force – such households would be expected to move to locations where amenities are capitalized largely in wages, since they do not have to pay that compensation (see Graves and Waldman 1991). In the process of moving, these households will increase the share of amenity compensation occurring in land markets, at least to some extent. Moreover, if there are endogenous disamenities that are functions of city size (e.g., pollution or congestion), nice places might become less nice – the compensation for say good climate may go not entirely into wages and rents but also into offsetting endogenous “bads.” Hence, at the level of theory, it is unclear whether wage differentials over space would be expected to converge or diverge over time, when exogenous variables (e.g., national income growth and increasing average age) affecting the demand for locations change in magnitude.

However, dropping the assumptions made earlier that households have identical preferences and firms have identical production functions allows a fairly wide range of predictions regarding the spatial labor market equilibrium.

First, as already mentioned, an aging population with fewer labor force members will result in a higher percentage of households not in the labor force. The movement of these households to desirable locations with their amenity values largely capitalized into labor markets will drive up rents, reducing the percentage of the amenity value capitalized into lower wages. Similarly, such households leaving the undesirable locations will lower rents, decreasing the wage compensation necessary to equilibrate utility over space; hence, the mere fact that a population is aging results in wage convergence, a prediction that, as far as I know, has not been made before despite it being a fairly clear implication of the model.

More generally, the rich (high skilled and well educated) will outbid the poor (low skilled and poorly educated) for the desirable areas, much as they outbid them for BMWs, while the poor will outbid the rich for the undesirable areas, much as they outbid them for a 1980s K-cars. However, the rich in the desirable areas will demand the services of the poor. Since the rents will be determined by the rich buyers, the poor will be unwilling to work in the nice locations unless they receive wage compensation. The nature of the compensation will depend on how close desirable and undesirable areas are to one another. If they are quite close (e.g., as in some parts of Los Angeles), the necessary wage compensation will be the commuting cost of the poor. If there are no undesirable locations near to the desirable area, the necessary wage compensation will be the difference between value of the amenity to the rich and to the poor, adjusted for differential lot sizes for the two groups (a “stand-alone” topic we shall return to). In terms of the spatial labor market equilibrium, the wages of the poor will be *higher* in the desirable location – to those not carefully considering the situation, it might be inferred that the

desirable location to the rich is actually *undesirable* to the poor. This is another example of the tricky interaction between wage and rent compensation in the equilibrium urban/regional approach when heterogeneity of preferences is allowed.

In addition to aging and income, another exogenous variable with potentially important – yet unexplored – implications for the wage-rent hedonic analyses is the presence and number of children in a household. The effects of children are clear within an urban area – young married couples tend to centrally locate (to minimize average commute times and take advantage of central amenities such as restaurant and cultural diversity) until their children reach school age, at which point most move to the suburbs to obtain larger lot sizes, better education, and lower crime rates.

These intra-metro effects are likely to exist over a broader array of spatial locations, with larger families moving to metropolitan areas with lower housing prices vis-à-vis childless or small families. Those movements will have had impacts on the equilibrium wage compensation in the USA since the trend in average family size has been markedly downward from the 1950s, with 3.37 persons per household, to the present 2.6 persons per household (<http://www.infoplease.com/ipa/A0884238.html>). If the growing numbers of childless and small family households prefer high-amenity and more central locations, such locations will become more costly in land markets. Whether this leads to a lower or higher amount of amenity capitalization in labor markets depends on whether such families have a higher or lower number of labor force participants and housing density. If, as was the historical case, bigger families are likely to have fewer labor force participants as one spouse stays home to take care of the children, an influx of childless and small families might lower wage rates, leading to increasing divergence in wages over space.

The preceding examples of individual traits that vary among households (income, age, and number of children) are traits that are widespread in the population. This would lead to the expectation that, in equilibrium, utility will be equilibrated over space. That is, there will be no “spatial consumer surplus.” Essentially, at a full hedonic equilibrium, households could flip a coin to decide where to live, because compensation for variation in amenities would result in equal utility in all locations.

For some traits, however, it may well be that the number of households possessing a strong demand for a particular amenity is smaller than the number of locations offering that amenity. In this case, individual households can obtain spatial consumer surplus, being better off – possibly much better off – in some locations than in others. A disabled person, for example, might get far greater than average benefit from access to public transit, but the number of disabled individuals might be quite small relative to the number of locations offering that access. A passionate mountain climber might well obtain greater than normal satisfaction from occupying a town near climbing opportunities than do other occupants of that town. To the extent that unusual preferences relative to the opportunities available are important, amenities will be undervalued in land and labor markets by the hedonic method. It is quite likely that those in the “upper tails” of the demands for a wide variety of amenities might be paying less than their willingness to pay for the

levels consumed. The true value of the amenity, for example, public transit, is the sum of the observed willingness to pay plus any *unobserved* consumer surplus. Similarly, those in the “lower tails” of demands may receive more compensation than necessary for bads, also resulting in spatial surplus – if, for example, there is a high probability of death in a high-risk location, rents will be very low; one who does not care much about such risks achieves spatial consumer surplus by locating in such areas.

A long-standing interest in labor economics is the return to education. At first blush, it would seem that amenity compensation in labor markets would result in an *understatement* of the returns to education. Since the more highly educated would have higher lifetime expected incomes, regardless of location, one would surmise that they would want to locate in the more desirable locations, but since the desirable locations offer lower wages, *ceteris paribus*, the highly educated would *appear* to get a lower financial return from their education, since they would be taking part of that return in the form of amenity consumption. It turns out, surprisingly, that this is not the case (see Graves et al. (1999a) for more detailed discussion and a graphical treatment). The reason is that, in the actual array of locations in the USA, desirable locations for households are even *more desirable* to firms. Consider the upper left cell in Fig. 2.1, where it was shown that locations desirable to both firms and households will be large with high rents, while the impact on wages is ambiguous, depending on relative desirability which is an empirical issue. In the data of Blomquist, Berger, and Hoehn (and very likely most other more recent empirical studies), the locations that were desirable to households were even more desirable to firms; hence, while the greater supply of labor leads to wage reduction, the demand for labor is greater yet, leading on net to higher wages in such areas. Hence, earnings functions that aim to estimate the return to education *overstate* the benefits of education in analyses ignoring amenities (for a somewhat different approach yielding the same conclusion, see Dahl 2002).

Another long-standing issue in the labor economics literature is the magnitude of the return to unionization. Unions have, as a historical fact, been concentrated in the Northeast and upper Midwest. As noted in Graves, Arthur, and Sexton (1999a), all studies of unionization fail to control for amenities. In one of their specifications, fully one-half of the presumed benefits of unionization were seen to be related to the fact that unions were stronger in areas of less desirable amenities, particularly climate – unions are getting “credit” for what is really compensation for a bad weather. A detailed analysis at a more disaggregated level would be better able to separate the relative importance of amenities and unionization.

Interestingly, amenities are actually substantially more important than they appear in existing empirical studies, because these studies ignore fringe benefits due to limited data. It turns out that fringe benefits are spatially varying in ways that reinforce observed wage compensation for amenities (see Graves et al. 1999b). Fringe benefits are substantially higher in the Midwest and Northeast than they are in the South and West, perhaps in part because of structural differences in the nature of occupations among the regions. Hence, the higher wages that are paid in the

former regions to compensate for undesirable climates would be higher yet, were full compensation employed rather than just wage compensation. Similarly, the desirable South and West regions have both lower wages and lower levels of fringe benefits. If foreign and other competition is causing the fringe benefits to decline, as appears to be the case in the Northeast and Midwest, this would lead to wage *divergence* as the necessary compensation would cause wages to rise as fringe benefits fall in equilibrium.

As mentioned earlier, some authors have regarded the ratio of net migration to the gross flows as a measure of “migration efficiency.” In the context of the labor market disequilibrium approach, this notion makes a fair amount of sense – it would seem inefficient to have large numbers of people moving both in and out, when net in-migration is occurring. If people are moving in because wages are higher in a location, it would seem odd (“inefficient”) that many people are also moving out. Yet, an empirical regularity is that when net in-migration is large to a location, so are the flows of out-migration. In the urban/regional equilibrium view, this empirical regularity is actually to be expected. As individuals move in to, for example, desirable locations, they drive up rents and lower wages (and also increase endogenous levels of disamenities), which in turn results in others leaving, as an optimal reaction to these changes, not as a matter of “inefficiency.” Some will cash out of their houses as their property values increase resulting in a nonoptimally large share of wealth in housing. Others will leave as the property comes to be worth less to them than to the newcomers. And still others will leave because congestion and air pollution are of particular importance to them. Finally, some will leave because their wages are lower in ways that the amenity level no longer compensates for.

Another issue in the urban/regional approach, which has implications for spatial equilibrium in the labor market, is the appropriate capitalization rate to use when converting rents into property values or vice versa. Linneman (1980) and Linneman and Voith (1991) argue that to consider either rents or property values separately in a hedonic valuation function results in selectivity bias; hence, they should be considered together. However, doing so raises the question of how to merge rent data with property value data. In the earlier paper, Linneman found that a 3 % capitalization rate was appropriate to convert property values into rental flow equivalents for 1973 Chicago data. In the later study, a capitalization rate (varying with traits of the household head) was argued to be 10 % for 1982 data from Philadelphia.

For analyses within any particular housing market, it seems important to correctly merge the data to avoid selectivity bias present in using either property values or rents separately. If, however, a study is being conducted using data at a national or large regional level (to, e.g., estimate the value of a greater variety of amenity bundles), there are additional concerns. In areas expected to grow (in either size or value due to growing demand for the amenities offered), property values will be high relative to *current* rents, because those rents are expected to be increasing – there is the expectation of two forms of return to housing in growing areas, rents collected currently and growth in property value over time as the rental stream gets larger. Conversely, in areas expected to lose population, rents will be expected to

fall in the future, so current property values will be low relative to current rents, since a fall in values is expected. These results are required to have housing investment profitability be the same in both growing and declining markets.

To get a sense of the disparity in rent/value ratios, using 2009 census data, the entire state of Colorado had a median housing value of \$234,100 and a median monthly rental housing cost of \$835, for a rent/value ratio of .00356, or .04272, multiplying by 12 to annualize this ratio, for easier intuition and to compare returns to other assets. The state of Michigan had median housing value of \$147,500 and a median monthly rental housing cost of \$709, an annualized rent/value ratio of .05772. There is, perhaps not surprisingly, great variation of these numbers within states, and that variation is consistent with the arguments made here. For example, Aspen City (\$860,000, \$1,319,.01836) and Boulder City (\$464,200, \$998,.0258) have very low annualized rent/value ratios relative to Colorado as a whole, while Birmingham City (\$388,800, \$1,145,.03528) and Ann Arbor (\$244,300, \$950,.04668) also have lower numbers than averages for Michigan.

What are the implications of the preceding for the spatial labor market equilibrium? For locations that are expected to either grow in size or that possess superior amenities that are expected to be valued more in the future, using a single capitalization rate results in hedonic analyses that are biased. The US average annualized rent/value ratio is .05292 (\$185,400, \$817), while Hawaii's rent/value ratio is .02808 (\$521,500, \$1,221), and Oklahoma's rent/value ratio is .07452 (\$98,800, \$614) – these are the current annual returns (2.8 % and 7.5 %) necessary to have housing investments be equally profitable in both locations, allowing for expectations of growth and decline in rental returns, respectively. The percentage owner occupied in Hawaii is 58.1 % compared to Oklahoma's 67.9 % and a national average of 66.9 %. If the national capitalization rate were applied to Hawaii, imputed rents would be \$2,300/month, when actual rents were only \$1,221. Averaging the numbers with a weighting of 58.1 % on the former would imply a weighted hedonic rent-equivalent value of \$1,848, rather than the actual rental rate of \$1,221; for Oklahoma, using the national capitalization rate would result in a weighted hedonic rent-equivalent value of \$493, far below the actual \$614 rents actually being paid. Hence, using a single capitalization rate in a national hedonic study will bias *upward* the rents estimated for nice locations and will bias *downward* the rents estimated in more undesirable locations – if, on the other hand, rents were capitalized up to property values with a constant national capitalization rate, property values would be biased *downward* in nice places and biased *upward* in less nice places.

Assuming that property values are converted to rents, and under strong homogeneity assumptions that rental housing and owner-occupied housing are equivalent, as are renters and owners, then labor would “look” from the hedonic housing models to require less compensation in nice places (since more of the niceness appears to be going into rents than is actually the case) and to require more compensation in the undesirable places because less disamenity appears to be capitalized into rents in those locations. In light of the difficulties raised here, along with the likelihood that rental housing and owner housing are different as

are renters and owners, it would seem that an argument could be made for conducting separate analyses for each group, resulting in different amenity values for each group. Obtaining the “true” amenity value of a location, then, might merely be a matter of weighting the values obtained in the separate analyses by the percentages of people in each group, which would vary by location.

Closely related to the preceding difficulty with hedonic models is the ubiquitous assumption in the theory of a constant lot size and a constant dollop of work effort (the 40-h week), each normalized to unity. This would not seem, at first thought, to be a great difficulty at the empirical level since the labor hedonic data could be restricted to full-time workers and the housing hedonic could include lot size as an explanatory variable. However, both the quantity supplied (e.g., perhaps fewer hours at lower wage rates in nice places) and the supply of labor (e.g., shifting if leisure is a complement or a substitute with amenities) are likely to vary in what are currently unknown ways with wage variation due to variation in amenities. Moreover, any particular wage level can occur with either high rents (if a location is high in either household amenities or firm amenities or both) or low rents (if a location is undesirable to either or both) – and one would generally expect that housing prices would not be independent of work effort, apart from simple Cobb-Douglas utility characterizations. If leisure is complementary with amenities, the supply of labor will be lower in nice places (wages higher) and higher in undesirable locations (wages lower). The assumption of a fixed amount of labor in all locations will then bias downward the apparent value of amenities under complementarity. Moreover, if desirable locations are also superior, the assumption of a constant amount of work effort over space will, then, result in a bias that will, over time, look like more convergence is going on than actually is.

In addition, how to handle lot size is complicated. Consider an amenity bundle, common in practice, which is comprised of amenities whose consumption is independent of lot size – for example, access to the central business district in the standard urban model or access to a wide variety of other amenities, such as nearness to an ocean or the breathing of air of various quality levels. In such situations, one would expect substitution of capital for land to occur (e.g., high-rise buildings as one approaches the CBD radially). How much is being paid for the amenity in this case depends critically on lot size – if one buys twice the average lot size, one is paying twice as much as others for the amenity. This implies that merely holding lot size constant in the rent hedonic is insufficient; to obtain marginal prices, an interaction term between lot size and the various amenities must be introduced.

If actual lot sizes get smaller in high-amenity locations, as would generally be expected, the assumption that lot sizes are constant leads to a bias that underestimates the amenity values. And, if smaller lot sizes, *ceteris paribus*, are less desirable than larger lot sizes, again as expected, the nice places are a little less nice for this reason; hence, wages in nice areas would be biased *upward* by the constant lot size assumption, while wages would be biased *downward* in the less desirable areas where lot sizes would be larger than average. Thus, there appears to be greater convergence in wages than there truly is, just because of the assumption of constant lot size.

The standard models also assume competitive land and labor markets. As but one important case where this assumption is not valid, consider the California Coastal Commission that regulates building construction in coastal California. Were it not for the stringent zoning of this commission, it is very likely that virtually the entire coastline of California would look like Collins Blvd in South Beach, Miami, with high-rises lining the ocean and extending inward. This might result in a much larger percentage of the US population living in California. The “value of ocean access” would be seen to be vastly higher in such a world, aggregating over the many consumers. This is not necessarily to argue that the zoning is inefficient as it is possible, though I suspect highly unlikely that nonuse values of all Americans might exceed the use values of the many millions of residents who would occupy those buildings. The scenic views from the Pacific Coast Highway certainly have value, to Californians and visitors alike, but those values are not being captured by property value studies, since the properties that “would” be there in a free-market setting are prohibited by the Coastal Commission. The large-lot zoning requirements effectively restrict ocean access to the very rich (e.g., as in Malibu) who are willing to pay a great deal for ocean access with the less rich who would like to acquire ocean access along with potentially much smaller lot sizes being effectively excluded by CCC zoning laws.

Taxation at the federal, state, and local levels also modifies the competitive outcome. Progressive federal taxes will tend to encourage movement toward locations in which amenities are capitalized into lower wages, since a lower percentage tax on true income can be obtained in such locations. To the extent that state income taxes paid are not closely related to services received, they too will distort the location decision, the empirical question being how are state income tax levels related to amenities available by state? Variation in property taxes similarly will distort location decisions, with interesting effects depending on the correlation between amenity levels and property tax rates. Even varying sales taxes over space will have impacts since local non-tradable goods will be less expensive in locations in which amenities are more capitalized into wages. All of such tax effects have been little studied as far as I know yet could yield important insights – for example, if rents are high for firm productivity reasons, a high property tax will be compensated for in equilibrium with higher wages, but if rents are high due to household amenities, the higher property taxes would just be another portion of the price paid for amenities in land markets, resulting in higher wages than would otherwise be the case.

The hedonic method implicitly assumes that all amenities associated with a location are accurately perceived by households and firms. This is not controversial for amenities whose benefits are sensed by our five senses (e.g., view premiums, the sound of the ocean, smells of various sorts, the feel of warmth on the skin, the diversity of tastes available in locations with many fine restaurants). However, there are amenities whose benefits are unlikely to be fully captured by the senses. Environmental improvements, for example, might be partially perceived by the senses, but complex health effects, the magnitude of which experts in the field argue about, are unlikely to be perceived accurately if at all. In such cases, the hedonic

method is very likely to undervalue the amenity, with property values too low and wage rates too high in the clean locations.

Some effects might even be quite misperceived. For example, acid-polluted lakes offer much greater water visibility than do non-acid-polluted lakes – cleaning up such lakes might lead property values to fall around them, if people think that being able to see deeper in the lake is an important trait. Nearness to hazardous waste dumps has a very large negative effect on property values (and perhaps wages, to the extent that wage variation occurs within labor markets, as seen in Blomquist, Berger, and Hoehn), even when knowledgeable experts assert that there can be no local effects associated with the dump. Individuals receive more radiation leaning against a granite wall in Grand Central Station than they would receive leaning against the outside wall of a nuclear reactor, yet thousands do the former every day that would be horrified to contemplate the latter.

What is one to make of these examples? In the case of amenity benefits that are not fully perceived, an argument could be made for adding benefits from health effects models (e.g., number of asthma attacks averted times the willingness to pay for an averted asthma attack, number of lives saved times \$7 million dollars, the current value of a statistical life saved being employed by the EPA) to those from hedonic models. However, this is likely to involve some double counting as households might infer that smelly air is unhealthy air. Also, if an individual “feels” damaged by a hazardous waste dump or a nuclear reactor, then is that not a *real* damage? If that individual gets an ulcer from worry, it is still an ulcer. One might argue that public authorities should attempt to educate households about the true risks of damage they face from various sources, since households are notoriously bad at assessing such risks. On the other hand, the dread associated with some risks (e.g., cancer, terrorist attack) may truly be greater than that associated with other risks with similar “outcomes” (e.g., dying in a car crash), and willingness to pay to avoid the first group of risks may be genuinely much greater than WTP for the latter risks.

It should be noted that the array of amenity levels among locations is not independent of either technology or public policy. The creation of the interstate highway system in the 1950s, the 1960s, and continuing into the present has hastened the decline of the Rustbelt and the expansion of the Sunbelt. However, the latter expansion would have been much smaller were it not for the invention and widespread innovation of air conditioning in the South and Southwest. Uniform national environmental standards (e.g., the requirement that all cars be equipped with catalytic convertors) have the practical effect of causing movement to the areas that most benefit from such policies – Los Angeles, with frequent stagnant air conditions, benefits more from such policies than does Chicago. What these examples imply is that one cannot run a hedonic equation at one point in time and apply the results to time periods far before or far after that study.

In certain relatively rare cases, the nature of the underlying preferences for an amenity matters greatly to its valuation. Normally, economists do not care at all “why” households desire the goods they desire, it not mattering whether one person wants a refrigerator to keep beer cold, while another wants a refrigerator for fresh

produce or ice cubes. In either case, the estimation of the price, cross-price, and income elasticities of interest to the economists is unaffected. Even in situations in which economists think about the underlying motives (as with the medium of exchange, asset, and precautionary motives for holding money), the estimations and conclusions are unaffected by those thoughts. For environmental goods, however, the nature of the preferences matters in a way not widely known, as suggested by the California Coastal Commission discussion above.

Environmental economists typically talk about (i) use values, (ii) option to use values, (iii) bequest motives, and (iv) preservation/existence values. Unlike the case of the refrigerator, these values frequently “clash,” in the sense that some households want to use an amenity directly, while others would like to preserve the amenity in its unused state. Are the demands for nonuse of the California coastline as large as or larger than the use values? Is Central Park in New York City more valuable as a park than the billions, perhaps trillions, of dollars it would be worth if developed? Is it better or worse to allow snowmobiles in Yellowstone Park in the winter when their noise and pollution disturbs the wildlife at a time when other stresses on the animals are at their annual peak? These are difficult questions, yet decisions have to be made; the decision to do nothing is itself a decision with costs and benefits. The decisions in these clashing cases are difficult largely because there is great controversy about the methods of ascertaining nonuse value vis-à-vis the methods employed – one of which is the hedonic method discussed here – to get estimates of use values. The takeaway message, though, is that the nonuse value of the amenity, from society’s perspective, *might* be larger than the benefits of using the amenity, the latter being measured by the higher property values and lower wage rates associated with using the amenity.

The discussion of this section has involved many topics related to the spatial labor market equilibrium. Many of these topics are either not discussed at all in the existing literature or the discussions are, as here, unduly preliminary to obtain solid policy-relevant conclusions. It is to be hoped, however, that the research initiatives sketched in this section will lead to more substantive contributions in the years to come.

2.5 Conclusions

In this chapter, two quite contrasting views of the nature of spatial labor markets have been examined. The notion that variation in wage rates represents variation in utility levels was appealing when costs of movement were high and when information about the nature of alternative locations was low. Those assumptions are increasingly irrelevant to observed movement patterns, and the bulk of this chapter took a polar opposite approach – assuming that variations in wages (and rents) occur as compensation for variation in amenities over space. In this latter view, expectations about wage convergence become quite ambiguous, depending on a wide variety of factors, many touched on in the previous section. It is argued here that the urban/regional view of the spatial labor market equilibrium is of

growing relative importance in the understanding of labor markets in the United States, and this is likely to be the case in the rest of the world in the years to come. Future research efforts pursuing in more detail the somewhat speculative assertions made throughout this chapter are likely to have important payoffs in terms of advancing our knowledge of labor markets and how those interact with land markets and amenity variables.

Abstract

This chapter reviews labor supply, demand, and equilibrium topics with the goal of showing how they determine labor market area (LMA) outcomes across geographic space. Labor supply curves are based on utility-maximizing choices between working and leisure, subject to a budget constraint, while labor demand curves are derived from the firm's production function assuming profit-maximizing behavior. The challenges of defining and empirically delimiting LMAs are examined from historical perspectives and using statistical clustering analysis, with commuting data serving as a key tool. A key distinction is drawn between functional versus homogenous regionalization problems, and a number

of suitable statistical approaches are reviewed. Current models used to study differences in earnings across labor markets as well as the effects of boom and bust cycles are also discussed. An empirical technique is presented for decomposing employment change within a community into four key labor market concepts: commuting, unemployment, labor force participation, and migration.

3.1 Introduction

The highest average wages earned in any US county in 2009 (\$90,500 in New York, NY) were nearly nine times higher than the lowest wages (\$11,400, in Worth County, Missouri) (Bureau of Economic Analysis, Regional Economic Information System). Across the NUTS 1 (Nomenclature of Territorial Units for Statistics) regions of the EU, average gross annual earnings in industry and services in 2006 ranged from EUR 72,038 in UKI London, compared with only EUR 2,397 in BGS Severna/Iztochna Bulgaria (Eurostat, `earns_ser06_26`). Understanding the reasons for these vast discrepancies across regional labor markets is a central objective of this chapter. More specifically, this chapter presents theory and models used by economists and regional scientists to analyze and understand spatially varying labor market variables including labor supply and demand, wages and productivity, and employment or unemployment, along with changes in these variables over time. The discrepancy in wages across US counties and EU regions provides a first important indication that labor markets do not simply equilibrate wages over space as might be expected, for example, in the case of the price of apples net of transport costs. With perfect knowledge and foresight and *all else equal* including the distribution of worker skills, labor (or firms) would migrate in response to wage differentials until the price of labor was the same in different locations. Instead, persistent wage differentials and variation in unemployment rates over space suggest that rigidities and other factors play important roles in the labor market that are worth studying. Of course, the average quality of labor as measured by skills also varies across labor markets, but this raises the question of why some markets attract higher shares of skilled labor than others.

This chapter is organized as follows. After reviewing basic microeconomic labor theory including labor force participation and discussing how labor market areas have been defined in the literature, applied models that have been used to study wage differences across labor market areas are examined. Chief among these are models of the returns to education and recent studies that examine differences in labor productivity due to spatial agglomeration and clustering. The economics of agglomeration has become a well-established area within regional science and labor economics, but it is receiving renewed attention with growing concerns about wage inequality (e.g., Goetz et al. 2011) and, as the world becomes more urbanized, with some cities attracting more economic growth than others (e.g., Glaeser 2008, 2011).

Although their role in determining local labor market outcomes is not explicitly discussed here, it is important to note that institutions such as labor unions

also matter. To the extent that unionized workers have higher earnings and more generous benefits, labor bargaining associations can produce different outcomes in local labor markets for equivalent labor efforts. When the Boeing aircraft company announced in 2011 that it would manufacture some of its new 787 Dreamliners in South Carolina rather than the State of Washington, it was accused of union “busting” and retaliation against unionized workers at the Seattle plant by paying lower wages to nonunionized laborers in the South.

Important labor topics including unemployment, migration, commuting, spatial mismatch, and job search are discussed in other chapters within this volume, as is spatial equilibrium in labor and housing markets. Nevertheless, this chapter briefly ties these topics together empirically in Sect. 3.4 on labor market models, where localized economic booms and busts are also discussed. The next section starts by outlining the basic neoclassical model of a labor market.

3.2 Labor Market Theory

To understand regional or spatial variations in basic employment measures, we start with the microeconomic determinants of labor supply and demand in an *aspatial* context. Using this framework, the rich and interesting causes of different labor market outcomes can be studied along with potential implications for policy and further research. This section builds on Cahuc and Zylberberg (2004), who do not discuss local, spatial, or regional labor markets or list these topics in their index. In fact, standard micro- and macroeconomics textbooks ignore or abstract from the effect of space altogether, and this is also true in the area of labor economics.

3.2.1 Labor Supply

A worker’s decision to supply labor to the job market is the result of an optimal choice between earning income (y), which enables consumption (c), and leisure (l) time. In the basic model, the individual worker faces a time constraint of 24 h a day, exogenous income ($y_g \geq 0$), which could be an inheritance or a spouse’s earnings, and wage rate w . The only decision to be made is how much leisure time to take given the wage rate, and this is given by the tangency between the worker’s indifference curve (u) and budget constraint ($c - wh - y_g \leq 0$) that is determined by income. After subtracting hours of leisure time from the 24 total hours available, we are left with the number of hours worked (h) at the given wage rate (w), which provides earned income.

This decision problem is shown graphically in Fig. 3.1 where total income is measured in the upper panel along the vertical axis and leisure time is recorded along the horizontal axis. Also shown are the utility curves ($u_1 > u_0$) that trace out the worker’s points of indifference between leisure (or working) and income. These curves have the usual properties of being convex to the origin, to reflect a diminishing marginal rate of substitution between leisure and income

Fig. 3.1 Derivation of the labor supply curve for an individual worker

(or consumption), and they are continuous and twice differentiable. The budget constraint is shown as the unlabelled straight line, which has been shifted vertically by the amount of exogenous income (y_g) and has a slope given by the wage rate:

$$y = y_g + w_0h(= c) \tag{3.1}$$

where $h = (24-l)$ so that $dh/dl = -1$. For each additional hour of work or leisure foregone, income rises by w_0 (or w_1). Hence, the opportunity cost of an hour of leisure is w_0 .

An initial equilibrium (optimum) may be given at point a which provides the highest possible utility given wages of w_0 ; here, the worker consumes l_0 units of leisure and y_0 worth of goods while supplying h_0 h of labor. As the wage rate rises from w_0 to w_1 , the worker reduces the amount of leisure time taken and works more hours. This new optimal point is b , and it is determined by the tangency between the higher indifference curve u_1 and the new budget line reflecting the higher wage. The clockwise rotation in the budget constraint brought about by the higher wage relaxes the income constraint and allows the worker to reach a higher level of utility.

The lower panel of Fig. 3.1 shows the number of hours worked versus wages earned (with the x -axis inverted, i.e., increasing hours worked are measured from right to left). The individual worker's labor supply curve is given by the line Oef . The graph shows an area in which the supply curve is backward bending: Wages can eventually rise so high as to lead to a reduction in hours worked. In other words, when the marginal utility of income falls below the marginal utility of leisure, then leisure is chosen over work. Of course, this assumes that workers can choose the actual number of hours worked each day, which in many cases is unrealistic. The lower panel in Fig. 3.1 shows another important concept, that of the reservation wage $w_r \geq 0$, which is the wage level below which a worker chooses not to supply his or her labor, resulting in nonparticipation. As we will see later, this wage has important implications for who benefits from different kinds of local development projects, among other outcomes. In fact, the worker's problem consists of two different parts: first, whether or not to work and, second, how much labor to supply, conditional on having decided to work. If $w < w_r$, then the worker will not supply any labor, preferring instead to consume at a corner solution on the indifference curve labeled u_r in the upper panel of Fig. 3.1. An increase in wages in a local labor market may therefore induce workers not only to supply more hours but also to cause more people to work, that is, to enter the workforce.

We can state the worker's problem formally as that of maximizing the utility of consumption (or income) and leisure subject to the budget constraint:

$$\max u(c, l)$$

$$\text{subject to } c \leq wh + y_g$$

Note that there is another implicit constraint involved, in that $h + l \leq 24$ h. Using a Lagrangian multiplier and the shadow price of leisure in the complementary slackness condition, this optimization problem is solved for an interior solution (i.e., $h > 0$) by differentiating with respect to h and equating the result with zero. This yields

$$\partial u / \partial l = w(\partial u / \partial c)$$

The individual reaches an optimum when the contribution of the last unit of leisure to utility equals the value of the last unit of consumption, multiplied by the wage rate. In other words, the wage rate at the optimum equals the ratio of the marginal utility of leisure to the marginal utility of consumption, which can be simplified to $w = (\partial c/\partial l)$. In Fig. 3.1, this means that we have reached a point of tangency between the budget constraint and the indifference curve; here, the marginal rate of substitution of leisure for consumption is equal to the wage rate. For example, this is illustrated by point a along indifference curve u_0 .

We can also show the decomposition of a wage change into income and substitution effects familiar from consumer theory. To do this, assume again that the worker has exogenous income in addition to wage earnings, so that as before, $y = wh + y_g$, and $h = h(w, y_g)$. Using the fact that $l = 24 - h$, we in this case can write that

$$\partial l/\partial w = (\partial l/\partial w)|_U + l(\partial l/\partial y) \quad (3.2)$$

Here, the effect of wages on leisure (or its inverse, hours worked) is decomposed into a substitution effect in which utility is held constant (i.e., we are moving along the indifference curve, u_1 , which gives the compensated, Hicksian labor supply) and a pure income effect (i.e., the budget constraint is shifted to the left by Δw , yielding the uncompensated, Marshallian labor supply which accounts for the income changes associated with the wage increase). In Fig. 3.1, the substitution effect occurs as a movement along u_0 from point a to b' . To get this point, we basically take away the income gained during the wage increase so as to keep the worker on the same indifference curve. This provides the (labor for leisure) substitution effect, which is always negative because at the higher wage the worker finds it worthwhile to work *more*. Subsequently, the income is restored which allows the consumer to reach the higher indifference curve (u_1), and this is the income effect. Now that the worker is better off, he or she can afford to work fewer hours, enjoying more leisure.

So long as leisure increases with income, it is a normal good. When the income effect exceeds the substitution effect, however, the labor supply curve can bend backward; in Fig. 3.1, point b could be located to the right of point a . Indeed, since at least the middle of the last century, men have been working fewer hours and participated less in labor markets, while women have entered the workforce in increasing numbers and they are also working more hours. To the extent that workers in different regions of a nation, that is, in different labor markets, make these trade-offs in different ways, it is already clear that labor supply varies over space and so will labor market outcomes.

As one interesting implication, Cahuc and Zylberberg (2004: 13) show that the reservation wage (w_r) satisfies the following equality:

$$u[y_g + w_r(24 - l_c), l_c] = u(y_g, 24) \quad (3.3)$$

Here, l_c is the constrained number of hours that the individual must work, in a take it or leave it full-time job situation. For example, this may be a mandatory 8-h workday, when in fact an individual may prefer to work only 6 h, which would

Table 3.1 Labor force participation rate (φ), November 2011, selected states, seasonally adjusted

Lowest-ranked states	Rate	Highest-ranked states	Rate
West Virginia	53.0	Vermont	70.8
Alabama	58.4	South Dakota	70.8
Louisiana	59.1	Minnesota	71.6
Michigan	59.8	Nebraska	71.8
New Mexico	60.0	North Dakota	73.2

Source: US Department of Labor, Bureau of Labor Statistics, Local Area Unemployment Statistics, December 20, 2011; estimates are based on population aged 16 years and older

allow him or her to reach a higher indifference curve. The worker is indifferent – or at the tipping point – between not working (living off exogenous income and consuming the maximum amount of leisure) and working the required amount of time. This is an important point, because a slight change in the wage will cause the individual to drop out of the workforce, causing nonparticipation.

Next, by summing the individual labor supplies (number of hours worked by each individual i), we can calculate the aggregate labor supply, $N_F = \sum h_i$, for a nation as well as for individual regions or labor market areas, as defined below. The labor force participation rate out of the total population (POP) is defined as $\varphi = LF/POP$, where the labor force $LF = N_F + N_U$ is comprised of the number of employed (N_F) and unemployed (N_U) workers. This also means that $v = N_U/LF$ is the unemployment rate, to be determined below. Note that the labor force participation rate is the number of individuals who are either working or unemployed and actively looking for work, as a share of working age individuals (usually 16–65 years of age or simply 16 and over) in the population. Table 3.1 shows the five states with the highest and lowest levels of φ . The high rate of labor force participation in North Dakota, which is going through an economic boom related to oil exploration in this period, is noteworthy, as is the very low rate in West Virginia.

There also is a relatively systematic relationship between the labor force participation and unemployment rates. Figure 3.2 shows a pronounced negative association between φ and v : About one-half of the variation in the participation rate across state labor market areas is associated with variation in unemployment. The labor market of North Dakota has both the lowest rates for v and the highest rate for φ , suggesting that the high local earnings associated with the oil boom and the resulting low local unemployment are drawing large shares of workers into the labor force.

The size of the labor force at any moment in time and in any given labor market area depends on the wage rate and, more specifically, the reservation wage w_r . To see this, consider a cumulative distribution function, $cdf(\cdot)$, also shown in Fig. 3.3, which represents the distribution of reservation wages within the population; for example, this may be a standard normal distribution. Then, it is true that $cdf(w)$ measures the share of working age population for whom $w_r < w$, or the participation rate, and $POPcdf(w) = LF$. Furthermore, note that $\partial LF/\partial w > 0$ because the cdf is an increasing function. These relationships are graphed in Fig. 3.3.

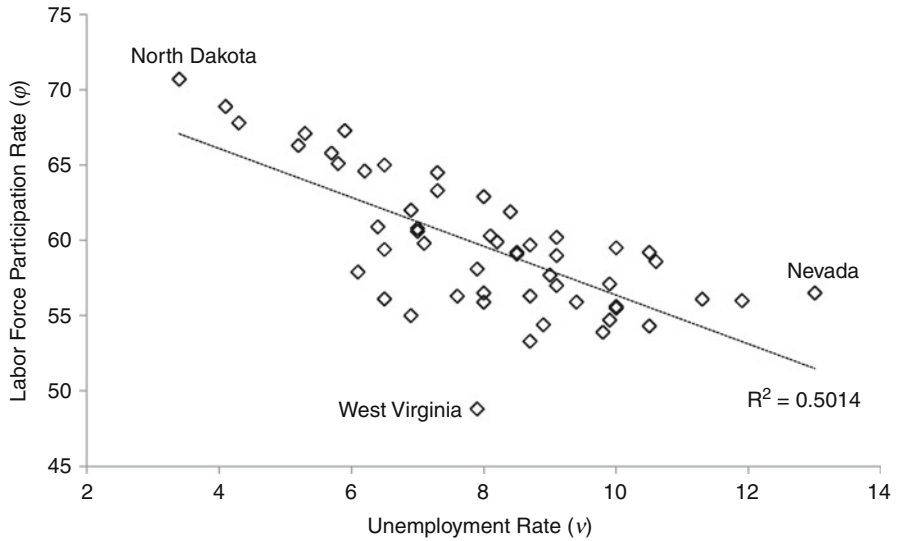

Fig. 3.2 Relationship between ϕ and v in state labor market areas, November 2011 (Data Source: Local Area Unemployment Statistics, BLS, January 2012)

Fig. 3.3 Cumulative distribution function for wages

There is one other important group of workers relevant especially in regional and national labor market analyses, and that is the number of discouraged workers – those who have given up the search for work. These workers’ reservation wages would be covered in the local market, but their employment prospects are so weak that they have given up the search for work and are no longer counted as being part of the LF (see also ► [Chap. 4, “Job Search Theory”](#) in this volume). It is important to consider these individuals in local analyses because they may jump back into the labor market if there are new jobs. In turn, this may lead to a short-run increase in unemployment rates, if a (new) factory starts to (re)hire workers locally. The aggregate number of discouraged workers in the USA was estimated to be

around one million in January 2012 (Bureau of Labor Statistics), and it can therefore not be ignored by policymakers. The share of discouraged workers in the labor force also varies over space, that is, by labor market area.

So far, we cannot say anything about unemployment because that depends also on labor demand. We return to this important concept briefly after discussing labor demand; a more thorough treatment can be found in ► [Chap. 7, “Regional Employment and Unemployment.”](#) Here, the subject of job search is important as it relates to nonparticipation as well as the phenomenon of discouraged workers.

In the conventional (aspatial) textbook treatment of labor supply, other topics that are covered here include labor supply elasticities (with those of men being higher than those of women), human capital and the role of education in determining worker outcomes, and the returns to education. A number of models have been developed to study these topics, and empirical research has been carried out on varying returns to education across labor markets. We have also glossed over other important rigidities in the labor market, such as the transaction costs involved in finding work as well as working, including the need for a wardrobe and transportation, and in the decision to work in more than one job (i.e., multiple jobholding).

3.2.2 Labor Demand

Like other inputs, labor (n) is a factor of production for the firm and as such is subject to a derived demand. The production function $q = q(n, k)$, where k is a fixed capital input, is assumed to be strictly increasing and concave, so that the marginal product increases ($q' > 0$) at a diminishing rate ($q'' < 0$) over the relevant range. Assuming that labor, at wage w , and capital, at rental cost r , are the only inputs, the firm maximizes the following profit function with respect to the variable input, n :

$$\max_n \pi = pq(n) - wn - rk \quad (3.4)$$

Since $dk = 0$ in the short run, this yields $\partial\pi/\partial n = 0 = p\partial q/\partial n - w$ or $mpp_n = w/p$.

The firm's demand for labor depends on a number of factors, including the marginal productivity of inputs (i.e., the curvature of the production function), and on relative prices of factors as well as output, which in turn depend on the firm's market power. Graphically, the demand for labor is that segment of the marginal physical product (mpp) curve that lies in stage II of the static neoclassical production function, which is essentially a cubic function with an inflection point and a turning point (i.e., $q = a + bn + cn^2 + dn^3$, where $a \geq 0$, $c > 0$, and $d < 0$). Stage II is the area between the inflection point, or maximum mpp , and the point of maximum production, where $mpp = 0$.

[Figure 3.4](#) depicts the relationship between the firm's revenue, or its output (q) scaled by the price of the output (p_q), and the amount of labor (n) used in production. The relevant decision range for the firm is the area between maximum

Fig. 3.4 Derivation of the firm's demand for labor

mpp (or mvp) and $mvp = 0$. As the cost of labor, or marginal factor cost $mfc = w$, rises and falls, the firm determines the amount of labor hired by the intersection point between the curves, that is, $mvp = w$, thus tracing out the conditional labor demand schedule, which is unambiguously downward sloping (because $\partial p_q q / \partial n < 0$). Hence, $n_1 < n_0$ since $w_1 > w_0$. If there is another factor of production, such as capital, then the degree to which labor demand is adjusted in response to wage changes depends also on the elasticity of substitution between the two factors.

One other variable important for determining labor demand is the output price, p_q . This price may vary across labor markets, for the same good, and different firms may also have varying degrees of market power locally, allowing them to set prices. To examine this effect, we start with the inverse demand function facing the firm, $p = p(q)$ with elasticity $\xi = qp'(q)/p(q) < 0$, which we also assume for the sake of simplicity to be constant.

The constant ξ has a few convenient properties, including that $\xi = 0$ under perfect competition, that is, when the firm takes market prices as given. When this condition no longer holds, that is, $\xi < 0$, the firm has some power to set prices by changing output levels. The larger is $|\xi|$, the greater is the firm's market power. Of course, ξ also depends on the actions of other firms, but if a particular chain has driven competitors out of local markets, that, too, would increase its market power in those markets. Finally, using the notation from Fig. 3.4 and the profit-maximizing equilibrium condition that $mfc = mvp$, we can show that (see also Cahuc and Zylberberg 2004: 175)

$$mpp_n = \rho(w/p_q) \tag{3.5}$$

where $\rho \equiv (1+\xi)^{-1}$ is a markup factor determined by the firm's market power. The firm's profits are maximized when mpp_n equals the markup factor ρ times the real wage paid by the firm. In the absence of market power, the elasticity is zero and the markup $\rho = 1$. A similar result is obtained by examining the cost of production, where it can be shown that at the profit maximum the marginal cost of production $c'(n)$ is multiplied by the markup factor: $p_q = \xi c'(n)$. And, under perfect competition ($\xi = 1$), the good is priced at precisely the marginal cost.

3.2.3 Labor Market Equilibrium

At last we turn to combining labor supply and labor demand factors to arrive at equilibrium in the labor market. Usually the topics of aggregate labor supply and demand in a nation are covered within macroeconomics and involve other variables such as aggregate production and demand and prices and inflation as well as fiscal and monetary policy instruments for stimulating the economy. As already noted, the subject of regional or local labor markets is usually not covered in economics textbooks, including Cahuc and Zylberberg (2004), although studies do exist of labor markets in different countries, including those making up the European Union.

Given a downward-sloping labor demand curve and an upward-sloping labor supply curve in wage-labor space, equilibrium wages and employment levels are determined at the point of intersection. This is shown as wages w_e and aggregate employment N_F in Fig. 3.5. In practice, there is always at least some unemployment in the economy, which in the graphic is shown as the (vertical) distance between the labor supply curve and the vertical line denoting the labor force (LF), which represents maximum feasible employment. Thus, at any given wage, we have that $N_U = LF - N_F$ or the number of unemployed people who would be willing to work if they could find a job. The supply curve asymptotically approaches the line LF showing that as wages rise, more and more workers see their reservation wage exceeded and wish to work, until the maximum is reached.

In this model, wages will rise, along with employment levels, in response to a demand shock. For example, a new firm may locate in a local labor market or the price of a natural resource may rise in response to changing world market conditions. In the static case, the unemployment rate would drop as wages rise, in some cases sharply, such as in response to booming commodity prices (e.g., oil, gold). In a dynamic labor market, however, the local labor force itself is not fixed. Instead, word about new employment opportunities will spread, and the local labor supply will expand. We can in fact expect three distinct adjustments or labor responses: First, previously discouraged workers return to the labor market, thus contributing to a larger LF (e.g., at LF' in Fig. 3.5). Second, more workers may find it worthwhile to commute into the region from a different labor market. And, third, new migrants may arrive in the local labor market from elsewhere in the nation. How these relative numbers get sorted out has important implications for how the benefits of the new employment opportunities are distributed among local residents of the labor market and others. Note that this question about distributional effects would not be relevant at the national level.

So far, we have assumed that individual firms are price takers in the local labor markets within which they operate. In other words, they pay the same amount per unit of labor as other firms, and their individual hiring and firing decisions have no influence on local wages. While this is certainly a reasonable assumption for national markets (with possible exceptions of highly skilled occupation such as basketball players), an analysis of local labor markets opens up interesting new possibilities and questions. In particular, it is plausible that a single large employer such as a big-box

Fig. 3.5 Equilibrium wage and employment determination

Fig. 3.6 Labor monopsony showing deadweight loss to society

retailer or mine operator is the only major local employer, who in that case does influence wages with its hiring decisions. In particular, starting from the initial competitive position, this employer would have to start paying higher wages to attract workers. In practice, this means that the firm faces an upward-sloping average labor (or factor) cost curve, rather than a horizontal line at the market wage, which would represent a perfectly elastic labor supply to the firm (i.e., the perfectly competitive case). The average labor supply curve (afc_n) can only slope upward if the marginal labor supply (mfc_n) curve lies above it, as is shown in Fig. 3.6.

The profit-maximizing monopsonist chooses to hire labor up to the point where the marginal factor cost is equal to the marginal value product; in other words, at the optimum the cost of the last unit of labor is equal to the contribution to profits of that unit. In Fig. 3.6, this occurs at level of employment N_m , which is clearly below the competitive level of N_F . At this point, it is also clear that $w_m < w_e$, so that the monopsonist both pays less and hires fewer workers than the firm facing competition from rivals. The deadweight loss to society from this outcome is given by triangle abc in Fig. 3.6. This area shows the additional gain to society from hiring more workers and expanding output ($\int_{\Delta N} mvp_n$ where $\Delta N = N_F - N_m$) compared to the additional cost to society of employing these labor resources ($\int_{\Delta N} S_N$) which would prevail under perfect competition.

The existence of monopoly situations may not be far-fetched if we are studying local labor markets (Edwards 2007). For example, transportation costs may pose insurmountable barriers in certain remote regions, including those within Appalachia in the USA, thereby limiting the labor response or supply elasticity. Also, Bonanno and Lopez (2012) found that Wal-Mart's power to set prices in labor markets may be greater in rural areas and in the Southern USA, where the company has operated for more years than anywhere in the world. Another barrier may arise in the form of entry costs into a market in which a particular firm dominates the hiring activity, thus limiting competition. This could relate to a labor skill that is so specialized as to not be useful in other fields. We will return to this in Sect. 3.4 in the context of examining the benefits of agglomeration.

3.3 Defining Labor Market Areas

In practice, the concept of local or regional labor market areas is difficult to define precisely. Even nations that on the surface have clearly delineated labor markets experience flows of migrant workers across their borders, which raises the question of how far labor market areas extend. On the other hand, workers in so-called integrated labor market areas such as the EU also face barriers including those related to languages and potential cultural differences. Thus, even at the national level, it is not always obvious where a labor market area (LMA) begins and ends.

Within nations, the answers are not much clearer. Researchers have used administrative boundaries ranging from multistate regions to states, statistical metropolitan areas, and individual counties to implicitly or explicitly define LMAs, for example. Yet labor markets also exist within larger cities within single counties, and they can extend internationally. Others function only at certain times of the year – for example, those for seasonal workers such as migrant farm labor – and there are specific definitions of labor market areas for certain occupations that do not exist for others. For example, lawyers need to pass bar exams in the state(s) in which they wish to practice, and medical doctors can receive special benefits by locating in so-called areas of physician shortages, usually in rural regions.

In any regional analysis that seeks to group “basic spatial units” into meaningful regions, such as LMAs, it is important to distinguish between homogeneity versus functionality of the regions (Hoover and Giarratani 1984, Chap. 9). The underlying rationale is that “regions” should consist of spatial units that are more homogenous within than across regions. An example of a homogenous region is the former US manufacturing belt or the wheat-growing area of the Northern Great Plains. These regions would be affected in similar ways by policy changes, such as interest rate policies that influence the foreign exchange value of the dollar or new labor market policies that alter unionization laws. Alternatively, regions may exhibit higher or lower degrees of integration with respect to functions such as cross-border commuting, trade, and telecommunication flows. For example, Metropolitan Statistical Areas are characterized by spatial subunits (counties) that are linked by commuting or newspaper circulation patterns, that is, economic functions; usually, these

involve a central node in the form of a business district and outlying or peripheral bedroom communities. At the end of [Sect. 3.3.2](#), the implications of distinguishing between functional and homogenous regions for the analytical methods used are presented.

3.3.1 Historical Efforts

US government agencies and researchers have sought to define regional labor markets as far back as the 1940s. The War Manpower Commission “defined a labor market as the widest area within which employees with fixed addresses would accept employment,” while the War Labor Board “defined a labor market area as one in which the wage structures and levels in an industry were fairly uniform” (Minnesota University Employment Stabilization Research Institute 1948, p.1; this section draws heavily on Goetz 1999). A related definition holds that workers are part of the same labor market area if they can change their jobs without moving their residence. Later, Smart (1974, 255) pointed out:

[i]t is perhaps surprising that systematic criteria for defining labour market areas have not been more extensively developed. The main obstacle has probably lain in the fluid and heterogeneous character of work movements. The jobs to which workers travel at any moment do not necessarily represent their optimum (achievable) preferences, or those of their employers in recruiting labour, particularly if there are imperfections in the labour market resulting from deficiencies in information. Labour economists . . . have shown that the operation of market forces is often extremely imperfect, as seen, for example, in the ranges of earnings which may be found for similar occupations in the same area.

Other variables that have been used to delineate labor markets conceptually include the extent of competition faced from other firms. Horan and Tolbert (1984: 10) define LMAs as “geographic areas within which transactions between buyers and sellers of labor are situated and occur on a regular basis,” or “the area bounded by the commuting radius around a district of concentrated employment opportunities.” Thus, at the core of any geographic boundary to an LMA are the notions of place of residence and place of work and the friction or transaction costs of moving between them. Geographic or economic distance – in terms of travel time and costs of gathering market information – is important.

Commuting is central to defining LMAs because it is inherently spatial, involving the physical separation of place of work and of residence, and it also relates to matching labor supply and demand. Along with population size, commuting is essential in the definition of Metropolitan Statistical Areas (MSAs), where counties are considered part of an urban (metro) core if a certain share of their residents works in the core. Klaassen and Drewe (1973, 21) proposed that regional and local labor markets can be distinguished as follows:

The most significant criterion on which to draw a distinction between local and regional labour markets is distance – physical, or even better economic (using travel costs and intervening economic opportunities) and social distance (communication barriers and travel time).

Although many studies have been conducted using various administrative boundaries to delimit labor market areas by default, including state and county borders, the most prominent work uses various aggregations of counties based on commuter flows to arrive at formal LMAs. The Bureau of Economic Analysis (BEA) draws on central place theory to delineate economic areas (EAs) that “represent the relevant regional markets for labor, products, and information. They are mainly determined by labor commuting patterns that delineate local labor markets. . .” (Johnson and Kort 2004: 68). These authors start with metro- or micropolitan areas that represent the main nodes or centers of economic activity and then use an iterative procedure to sort counties into Component Economic Areas (CEAs) using commuter flows and data on newspaper circulation, in situations where the commuting data are insufficient to arrive at a classification. The final EA has to be (p. 71) “a region of sufficient size to support regional statistical analyses, and each economic area is a labor market that is independent of other labor markets.” Using the 2000 county-to-county commuter flow data, Johnson and Kort (2004) arrive at 344 CEAs, of which 177 are either not large enough (e.g., <50,000 employed residents or <10 counties and <100,000 employed residents) or have too many out-commuters (>8 %) to qualify as an EA or both. These are subsequently merged with CEAs that qualify as economic areas to arrive at a total of 179 BEA EAs, with maximum inter-EA commuting of $\leq 4\%$. This number is up from 172 EAs that were obtained using the 1990 commuter flows. As an example from Europe, Casado-Diaz (2000) uses travel-to-work data from the 1991 census in Spain to delineate local labor market areas, including those that are specific to different industries and occupations.

3.3.2 Cluster-Based Analysis

A different approach to identifying LMAs is taken in Tolbert and Sizer (1996; for updates see the URL under Fig. 3.7), who argue that the BEA’s focus on large urban centers and its hinterlands inadequately captures labor markets in rural areas. They also start with the commuter flow data from the census and create a frequency matrix capturing the flows between two counties. Entry a_{ij} is the number of commuters from i into j divided by the smaller of the two resident labor forces of the counties; by convention, elements of the main diagonal are set to 0. The authors use PROC CLUSTER within SAS, which uses dissimilarity between elements rather than similarity. For this reason, Tolbert and Sizer (p. 12) transform their data using $d_{ij} = d_{ji} = (1 - a_{ij})$, which represent distance coefficients. Thus, the smaller the value of d_{ij} , the closer the distance and the greater the similarity between two counties in terms of the commuting relationship. In this procedure, the goal is for counties that belong to a commuting zone to be more similar than those that do not belong; in other words, the aim is for homogeneity within groups and heterogeneity across groups.

The hierarchical clustering algorithm starts by placing each unit (in this case county) into its own category and then merges counties starting with the pair

Fig. 3.7 Map of US labor market areas (Source: <http://www.ers.usda.gov/briefing/rurality/lmacz/> Accessed 3 January 2012)

exhibiting the greatest similarity or commuting strength. This procedure continues iteratively until all counties have been merged into a single cluster. The history of the merging procedure is recorded in a dendrogram, which resembles a tree and shows the average distance between clusters on the vertical axis and records the different counties on the horizontal axis. The length or depth of the branches of the tree measures the strength of the connection between two or more counties. The only remaining question then is where to choose the cutoff point that determines whether or not a set of counties is in the final cluster. If two or more clusters are sufficiently different or distinct from one another, then they are separated into two different groups.

From this analysis, Tolbert and Sizer generate 741 distinct commuting zones for the USA, based on the 1990 commuting data, compared with 709 using the 2000 data. These CZs are subsequently aggregated into 394 LMAs using the population threshold criterion of $\geq 100,000$ persons, which is substantially more than the number obtained by the BEA and in part reflects the greater sensitivity to inclusion of rural areas. [Figure 3.7](#) shows the map of LMAs developed by Tolbert and Sizer for the USA. Readers familiar with the US county geography will see that these areas appear very different from the typical county-level maps. Indeed, it is difficult to even pick out the state outlines from this figure, because most LMAs straddle state lines. As an artifact of the population settlement history and natural geography of the county, the geographically relatively large LMAs in the western part stand out compared to those in the eastern portion.

It is important to note a key limitation of this analysis, namely, that it does not allow the overlapping of counties across LMAs or cross-commuting across the areas. In other words, the hierarchical procedure allocates counties in such a manner that counties cannot belong to multiple LMAs simultaneously, and the method does not accommodate cross-commuting behavior. Isserman et al. (1986: 544) point out that “overlapping regionalization schemes make modeling far more complex because of the need to assure consistency in the treatment of the areas included in more than one region.” Recent work, which is beyond the scope of the overview that can be presented here, draws on advances in the science of networks to address some of these issues by accommodating both hierarchy and overlap of counties within LMAs. This new work also aims to address issues that are arising in the context of megacities and megaregions, including how they are most appropriately delineated.

The LMAs described here are based on a functional rather than a homogenous regionalization, and it must be noted that the clustering procedures described are not necessarily the best techniques available. Fischer et al. (1993) instead apply the intramax and iterative proportional fitting procedures (IPFP) to telecommunications data in Austria, arguing that these methods have the advantage of not requiring contiguity among spatial units. Using these methods, the authors find (p. 225) “. . . important differences in terms of both the data transformation and the grouping techniques used” and suggest that these methods may be better suited to modeling flows of data, commuters, or goods and services across spatial lines, that is, for functional delimitations of regions. These methods employ more refined procedures for creating standardized network matrices (than, e.g., those used in Tolbert and Sizer 1996) that are then used in grouping the spatial units into regions. The intramax procedure compares expected and observed flows to gauge the interactions among spatial units, while the IPFP involves iterative convergence in the matrix standardization to an equilibrium criterion; this procedure is available in SAS as PROC IPFPHC.

In another paper exploring less restrictive clustering procedures, Baumann et al. (1983) describe a method for functional regionalization that (p. 54) “neither assumes symmetry in the daily commuting relationship between the basic spatial units nor requires a priori assumptions about the relative importance of each basic spatial unit.” The contribution of this paper lies in showing that how regions are defined and identified in labor market analyses can affect both the parameters of estimated regression models and how the models perform statistically. More specifically, analysts need to choose (p. 58) both the optimal number k of labor market regions, in the first step, and how best to aggregate these regions in the second step; these are known as the scale and aggregation problems, respectively. Interestingly, because there also is no contiguity constraint in the IPFP approach adopted, “. . . the result [in terms of LMA identified] may sometimes be a functional regional typology and not a functional regionalization” (p. 61). These authors conclude that the defining of regions is complementary to econometric estimation, and both procedures should be considered jointly. This is an area warranting additional research.

Finally, Barkley et al. (1995) examine how much spatial association in the form of spread and backwash effects exists within labor market areas that include various definitions of Functional Economic Areas (FEAs). The authors argue that “[i]f there is little revealed dependence or association [within an economic area], then the integrated functional region concept is of limited value in the analysis of hinterland development problems” (Barkley et al. 1995: 298). Presumably, if the association is high, on the other hand, then the LMAs are useful analytical tools. Barkley et al. (1995) calculate the local and global Moran’s I and the Getis-Ord G statistic for population and income changes within eight FEAs to arrive at two central conclusions. First, they find that linkages between the core and periphery varied in a statistically significant manner both across and within their chosen LMAs. Second, spatial economic linkages to the urban core area tended to favor those hinterland areas that were closest to the core. Thus, with current definitions, relationships within FEAs (and thus LMAs) tend to be robust for counties closer to the urban core and less so for more remote rural counties. In turn, this suggests that spatial socioeconomic analyses should take into consideration counties’ position in the spatial rural–urban hierarchy, in addition to considering FEAs.

3.4 Labor Market Area Analyses

Having outlined theoretical concepts related to spatial or regional labor markets and methods for defining them empirically, we are now ready to review applications in the form of models that have been developed by researchers. The first section examines models used to explain differences in labor earnings across LMAs, while the second considers economic models of boom and bust.

3.4.1 Explaining Differences in Labor Earnings

One of the active areas of research that seeks to explain earning differences across LMAs builds on Mincer (1974) – style earning equations of the following sort:

$$\ln w_i = \alpha_0 + \alpha_1 edu_i + \alpha_2 exp_i + \beta X_i + \varepsilon_i \quad (3.6)$$

where w_i is a measure of average earnings in labor market area i , edu_i is average education (usually in years) of the population, exp_i is years of on-the-job or similar experience, X_i is a vector of other individual characteristics that affect earnings, and ε_i is a random error term. While some recent studies are conducted at the level of individuals, others have been conducted at the level of labor market areas, such as the US states or rural versus urban areas, including cities (e.g., Goetz and Rupasingha 2004; Moretti 2010). Studies have found, for example, that returns to education in rural labor markets are lower than commensurate returns in urban areas. In particular, a one percentage point increase in educated adults in rural areas leads to only about a one-third of the comparable increase in earnings of more urban areas.

While this literature describes the issue, it does not fully explain why this happens; partial explanations focus on job access elsewhere by, for example, statistically interacting the educational attainment variable with interstate highway access, which reduces travel cost to a distant job, possibly in an urban core area. In some ways, this literature is a precursor to studies that focus on understanding how agglomeration economies can lead to higher labor productivity and earnings in more densely settled places. This subject is discussed next.

The fact that labor (and firm) productivity is higher in more densely settled areas, or labor markets, has been established going at least as far back as Marshall (1890). Such agglomeration economies result from better sharing, matching, and learning that occur when businesses are located near one another (Rosenthal and Strange 2004; Puga 2010). Although these three forces may apply to inputs generally, they are especially powerful in the case of labor. For example, greater intensity of economic activity allows for greater specialization in production as well as in learning highly specialized skills, and the knowledge that there are numerous sources of demand for a particular skill makes it easier for a worker to justify the cost and risk associated with investing in such a skill. Note also in terms of the earlier discussion related to monopsony or oligopsony labor hiring power of firms that this means a lower likelihood of firms extracting rents from workers. Puga (2010: 213) further notes that “concentrations of employment iron out idiosyncratic shocks and facilitate the transfer of labor from low to high productivity establishments.” The so-called “thick” labor markets, finally, also facilitate searches and improve matches between employers and workers, making mismatches in terms of skill requirements less likely.

3.4.2 Models of Spatial Adjustment: Booms and Busts

One area of research in which local labor market modeling is especially important is in so-called boom and bust studies, which often revolve around natural resource-based exogenous price shocks but which are also relevant to understanding the local economic effects of government investments and industrial recruitment. Current oil and natural gas drilling activity in the Marcellus (e.g., Pennsylvania) and Bakken (e.g., North Dakota) Shales, for example, has brought about profound local economic adjustments that are best studied in the context of labor markets. In North Dakota, the attraction of new population via in-migration has been so phenomenal that the state’s population recorded an all-time high in the 2010 census, after experiencing decades of out-migration. Earlier booms and busts during the 1970s energy crisis related to coal in Appalachia have also been studied using labor market models.

Often these kinds of studies are interested in finding out how a boom in one sector (e.g., natural resources or manufacturing, when a plant is recruited from elsewhere) impacts other sectors within the same local labor market area. For example, if a state provides subsidies to recruit a manufacturer, existing firms may see their local labor costs bid up as the demand for labor increases, especially if there are no labor supply adjustments – for example, through in-migration or

changes in labor force participation. Likewise, in an economic bust, the impact on local wages will depend on the degree to which the local labor market adjusts to the decline, for example, through out-migration or early retirement of workers from the labor force.

A general model used to study the effect of a commodity- or government investment-related boom and bust on key local labor market variables is the following (Black et al. 2005):

$$\Delta \ln(Y_{ist}) = \sum_{j=1}^3 \beta_j (T_i P_{jt}) + (\mathbf{State}_s \mathbf{Year}_t) \zeta + \varepsilon_{ist} \quad (3.7)$$

where $\Delta \ln(Y_{ist}) = \ln(Y_{ist}) - \ln(Y_{ist-1})$ is the first difference in the dependent variable, Y_{ist} , which may be jobs, wages, or total earnings; i indexes a county, s a state, and t is the year; β_j and ζ are coefficients to be estimated, where $j = \{1, 2, 3\}$ for a boom, peak, and bust, respectively (the peak occurs between the boom and the bust period); $T_i = 1$ when county i is in the treatment group and 0 otherwise; $P_1 = 1$ during the boom period and zero otherwise and analogously for the peak and bust; \mathbf{State}_s is a vector of the states included in the analysis; \mathbf{Year}_t is a vector of the years covering the boom-peak-bust period; and ε_{ist} is an error term indexed for each county, state, and year.

The product $\mathbf{State}_s \mathbf{Year}_t$ holds constant those factors that vary at the state level over time (a state-time fixed effect). Here, the county is the basic labor market area (unit), and it is nested within the larger state context, with different policies and institutions. Note also that this setup incorporates a counterfactual comparison of treated with nontreatment counties and that the coefficients β_1 , β_2 , and β_3 “measure the difference in average growth between the treatment and comparison counties during the boom, peak and bust, respectively” (Black et al. 2005: 457).

The analysis can be extended to examine spillover effects from the basic (usually tradeables) to the nonbasic (local goods) sectors within each local labor market area (i.e., county). This is done using the same equation as above but including earnings and employment changes for the non-mining sector only as the dependent variables, and it allows a comparison of growth in these variables in the treated versus non-treated counties to assess any spillovers. In addition, the non-mining sector can be further decomposed into separate sectors such as services, retailing, construction, and manufacturing to study impacts in greater detail. Lastly, the above analysis can be adapted to examine the effects of booms and busts on wages, poverty rates and levels, and population migration (see Black et al. 2005 for details).

A number of important local labor market concepts, including commuting, unemployment, labor force participation, and migration, can be jointly studied at the county level using the following identity which is due to Partridge et al. (2009):

$$N_F = (N_F/N_R)(N_R/LF)(LF/POP)POP \quad (3.8)$$

This equation is an identity as appropriate canceling of terms will reveal, and with the exception of N_R , each of these variables has been defined previously.

The term N_R measures employment by place (county) of residence as opposed to place of work. In the USA, the labor force is counted both by the Bureau of Labor Statistics at the place or county of residence and by the Bureau of Economic Analysis at the place or county of employment, through firm-level surveys. This makes it possible to create a crude *commuting* measure in that $N_F/N_R > 1$ characterizes a situation of average net in-commuting into the county, while a reversal of the inequality corresponds to net out-commuting.

Next, the term N_R/LF captures the employment rate by place or county of residence of the worker, where both of these are measured, or one minus the *unemployment rate*, $(1 - v) = (1 - N_U/LF)$. The *labor force participation rate*, or $\varphi = LF/POP$, was described earlier, while changes in population (*POP*) will occur in response to *migration*. This can be seen clearly once we log-differentiate the above equation, which allows us to study the effect of adjusting each of these four key components on employment at the firm (note also that $\Delta \ln X \approx \Delta X/X$). This gives us the rate of change in each of the component variables, as follows:

$$\begin{aligned} \Delta N_F/N_F &= (\Delta N_F/N_F - \Delta N_R/N_R) + (\Delta N_R/N_R - \Delta LF/LF) \\ &\quad + (\Delta LF/LF - \Delta POP/POP) + \Delta POP/POP \end{aligned} \quad (3.9)$$

which is change in (net commuting + [1–unemployment rate] + labor force participation + net migration), where we have abstracted from births and deaths, which are the other major demographic components that lead to population change. Thus, we have decomposed, for a given local labor market, the key components that lead to adjustment in firm-level employment in response to a particular economic shock. The effects of each of these components can in turn be estimated from county-level data, using the following relationships (Partridge et al. 2009: 15):

Commuting: $(\Delta N_F/N_F - \Delta N_R/N_R) = \beta_{COM} \Delta N_F/N_F$

Employment rate: $(\Delta N_R/N_R - \Delta LF/LF) = \beta_{ER} \Delta N_F/N_F$

Labor force participation: $(\Delta LF/LF - \Delta POP/POP) = \beta_{LFP} \Delta N_F/N_F$

Migration: $\Delta POP/POP = \beta_{MIG} \Delta N_F/N_F$

where each change equation in addition features a specific county fixed effect, a fixed time effect, and a conventional residual error term. Because $\sum \beta = 1$, the estimated regression parameters can be used to calculate the share of new labor supplies coming from changes in each of the four sources identified.

This kind of study also confirms the importance of considering different geographic scales in studying LMAs, and it reveals that longer time lags produce different results because they allow more adjustments to occur between labor markets. Sensitivity to adjustments across LMAs in turn is important for fully assessing the distributional impacts of local and regional economic development projects.

3.5 Conclusions

Even though LMAs are not treated explicitly in standard micro- or macroeconomic textbooks and defining them remains an ongoing challenge, this chapter has

provided a sense of the importance and merits of considering different labor markets over space and their individual characteristics, as well as the adjustments that inevitably occur within and between them over time. Although researchers have developed detailed LMA models and insights into how they operate, more work is needed to classify these markets and to understand how they are affected by federal policy as well as other exogenous shocks in a dynamic setting. With growing apprehension about income inequality in the USA especially, regional labor market analyses promise to generate a better understanding of the causes and consequences of such economic disparities. The questions surrounding local market power, supply adjustments, short- and long-term boom-bust effects, and the causes and consequences of agglomeration economies, especially with respect to labor and learning spillovers, also remain as important research topics. Finally, considerable promise lies in applying emerging insights from network science to better formulate and delineate LMAs and associated megacities and megaregions. This is an area of research that will likely receive much attention in the future.

Abstract

This chapter summarizes the main developments in job search theory ever since its inception in the 1970s. After describing the assumptions and formulation of the basic model, the chapter moves onto analyzing how the original framework has been extended by removing some of the initial limitations. A separate section is then devoted to the matching function theory which represents one of the main developments of job search theory in more recent years and whose importance has been recognized by the award of the 2010 Nobel Prize in economics. The last section attempts to reconcile job search and migration theory by introducing the role of space and describing the main contributions on these topics by regional economists.

4.1 Introduction

With two thirds of national incomes coming, on average, from labor, it is not surprising that labor economists have devoted so much effort in modeling job search decisions. Although the share of labor income in more developed countries has decreased in recent years, labor still represents the main means of support of most households. Hence, choosing the “right” job is one of the most important lifetime decisions individuals have to make.

Job search theory became popular in the 1970s as an alternative to the “standard” *neoclassical labor supply theory*. The neoclassical framework, based on the assumption of perfect information, did not allow for unemployment where individuals *actively* sought work but were unable to find it. Individual agents only had two options, either being employed or being inactive (i.e., not part of the labor force). However, evidence showed that unemployment and its duration were not negligible. This led a group of scholars to formulate an alternative theory able to account for unemployment, which became known as “job search theory.” The main premise of job search models is that looking for a job is a dynamic sequential process and that individuals have to decide when to stop this process under conditions of uncertainty and imperfect information. Frictional unemployment is a natural outcome of this process.

Ever since the 1970s, job search theory has been refined and extended in several directions and countless contributions have been published on the topic. While most of these contributions are interesting and provide new insights into the labor search process, the development of a “matching function” stands out as being possibly the most fundamental development in job search theory since its inception. The importance of this latest development was recognized by awarding the 2010 Nobel Prize to Peter Diamond, Dale Mortensen, and Christopher Pissarides, whose work formed the basis of such development.

This chapter tries to survey the key features of the job search theory while facing some constraints. Firstly, the literature on job search theory is so vast that only the milestones can be presented. Secondly, job search models involve a high degree of mathematical sophistication, which goes beyond the scope of this chapter. In presenting the models, the mathematical formulation is streamlined to a minimum while preserving the main insights of each model. The economic meaning and intuition behind the mathematical formulation is also provided.

The organization of the chapter is chronological going from the initial contributions in the 1970s to the more recent contributions (also known as the Diamond-Mortensen-Pissarides model) for which the 2010 Nobel Prize was awarded. The last section before the conclusions will introduce the role of migration into job search theory and will present some contributions developed specifically in the regional economics field.

4.2 The Standard Job Search Model

4.2.1 Basic Formulation

Although the origin of job search theory is normally attributed to the two seminal articles by McCall (1970) and Mortensen (1970), two papers by Stigler (1961, 1962) questioned the perfect information assumption of the neoclassical theory and laid some of the foundations of what was then developed in the 1970s.

Both in Stigler's model and in the basic job search model, the individual has more than one earning opportunities available and has to select the "best" one. However, the "strategy" to select the best job is different. In Stigler's model, the main decision an individual has to make is how many jobs to sample before deciding which one is the "best." Sampling an extra job has an associated "search" marginal cost c over a given time period, and the decision variable is the sample size n representing the number of firms a job seeker will consider in their search. The neoclassical assumption of perfect information is a special case where the cost c equals zero.

In job search models, the decision process is sequential. There is no "optimal" sample size because the jobs are randomly sampled one at a time and the individual stops when an acceptable job becomes available. Hence, the number of jobs sampled depends on their sequence and the sample size itself is a random variable (Mortensen 1986). The basic job search model is simply an "optimal stopping rule" problem which can be described as follows.

Each job seeker receives n wage offers $- w_1, w_2, \dots, w_n$ - per period of length h spent searching for a job. The best offer in each period is equal to

$$w = \max \{w_1, w_2, \dots, w_n\} \quad (4.1)$$

Wages associated with future job offers are distributed according to a probability distribution $f(w)$. The job seeker's aim is to maximize net benefits (future stream of income minus search costs).

In its simplest form, the job search model is based on the following assumptions:

- (i) Time is continuous; t denotes the time periods, each of length h .
- (ii) Although wages associated with future job offers are unknown to the seeker, the probability distribution $f(w)$ is known and it is constant over time.
- (iii) The search cost per unit of time is c .
- (iv) Once the seeker *accepts* a job offer, this leads to *permanent employment* at a fixed per-period wage, w .
- (v) The discount rate is r .
- (vi) Individuals have infinite lifetimes.
- (vii) The seeker receives one job offer per period.
- (viii) If the job is *rejected*, it *cannot be recalled*.
- (ix) The seeker is unemployed.

Based on these assumptions, the basic model can be formalized as follows.

$W(w)$ is an unspecified functional relationship representing the future stream of income associated with a per-period wage equal to w . The present value of the lifetime wealth, at time t , is

$$V_t = -ch + e^{-rh}W(w) \quad (4.2a)$$

if the individual accepts the job offer at time t or

$$V_t = -ch + e^{-rh}E(V_{t+1}) \quad (4.2b)$$

if the individual rejects the job offer at time t and continues the search at time $t+1$.

The best strategy is one which maximizes V_t or, in other words,

$$V_t = -ch + e^{-rh}E\{\max[W(w), V_{t+1}]\} \quad (4.3)$$

where $E\{\cdot\}$ denotes the expectation operator. Remember that, by assumption, the cost of search, c , is constant over time, the wage distribution is constant over time, and the individual has an infinite lifetime. We know that

$$V_t = V_{t+1} = V \quad (4.4)$$

And so it follows that

$$V = -ch + e^{-rh}E\{\max(W(w), V)\} = -ch + e^{-rh}E\{\max(W(w) - V, 0)\} \quad (4.5)$$

In the continuous time version of the model with infinite time horizon, this formula simplifies to

$$rV = -c + E\left\{\max\left(\frac{w}{r} - V, 0\right)\right\} \quad (4.6)$$

An individual would accept the job offer if $w/r > V$ and reject it if $w/r < V$. The value which separates acceptable and unacceptable job offers, $w^* = rV$, is called reservation wage.

It can be shown that, in the simplest case in which we assume the individual has just one job offer per period, the reservation wage equals

$$w^* = -c + \frac{1}{r} \int_{w^*}^{\infty} (w - w^*)f(w)dw \quad (4.7)$$

The economic interpretation of Eq. (4.7) is intuitive. It says that the marginal cost of continuing searching, given by the opportunity cost w^* and the cost of search c , is equal to the expected marginal return from continuing the search process, which is given by the second term on the right-hand side of Eq. (4.7).

4.2.2 Extensions

Violation of Assumption (v): Finite Lifetime (Gronau 1971)

One of the assumptions of the basic job search model, presented in the previous section, is that individuals have infinite lifetime. The violation of this condition is analyzed in Gronau (1971). His contribution shows that if individuals have a finite number of periods, the reservation wage does not level out to an equilibrium level but rather decreases over time as we approach the end of the period.

Violation of Assumption (vi): The Seeker Receives a Different Number of Offers in Each Period

The best way of modeling the variation in the arrival rate of offers is to assume that they follow a Poisson distribution. Following Mortensen (1986), we can define the probability distribution, $q(n)$, of the number of job offers received, n , in each period of time as a Poisson distribution with parameter λ :

$$q(n) = e^{-\lambda} \frac{\lambda^n}{n!} \quad (4.8)$$

And Eq. (4.7) will simply become

$$w^* = -c + \frac{\lambda}{r} \int_{w^*}^{\infty} (w - w^*) f(w) dw \quad (4.9)$$

where λ is the offer arrival rate which is inversely related the expected length of time between job offers.

Violation of Assumption (vii): Allowing Recall

In the basic model where most of the parameters are unchanging over time, allowing recall does not make any difference. A job offer, which is rejected today, will be rejected also in the future, as the parameters upon which the individuals are basing their decision are the same. However, in some more sophisticated versions of the model, recall might make a difference in the reservation wage expression.

Violation of Assumption (viii): On-the-Job Search (Burdett 1978)

One of the most criticized assumptions of the basic search model is that only unemployed individuals search for jobs. In his contribution Burdett develops a model which removes this constraint by allowing workers to look for another job while employed. In his model, employed workers have to decide their job search “intensity” by allocating their time to three alternative uses: working, enjoying leisure, and seeking another job. The search intensity decision is modeled by allowing the costs of search, c , and the arrival rate of offers, λ , to be both a function of search intensity, s . Hence, the reservation wage expression is modified as follows:

$$w^* = -c(s) + \frac{\lambda(s)}{r} \int_{w^*}^{\infty} (w - w^*) f(w) dw \quad (4.10)$$

Both the cost of search and the number of job offers received are increasing in s . The optimal search intensity declines with the wage earned which also implies that an employed individual has a lower optimal search intensity than somebody who is unemployed. If the wage earned is high enough, the employed worker will not search ($s = 0$). In other words, on-the-job search is always associated with a “bad” job position. The Burdett model offers an alternative explanation to why more experienced workers have generally higher salaries. The traditional wisdom – based on the human capital theory – is that productivity increases with experience. While that is generally true, the Burdett model also highlights that older workers – having been in the labor market for longer – are also more likely to have found a better job offer. The Burdett model also assumes implicitly that some nonwage characteristics of the job become known to the worker only after having started working. Moreover, as Blau (1992) points out, spending some time on the job might be beneficial to remove the *stigma* associated with being unemployed. A final point is that while quits are not allowed in the basic standard job search model, now they are a possibility (*violation of assumption (iii)*). Although we do not enter into the details of his work, Wilde (1979) provides a good discussion of job quits and nonwage job characteristics.

Violation of Assumption (i): Unknown Wage Distribution (Rothschild 1974)

The most fundamental assumption of the standard job search models is that the distribution of wages is known to the seekers and constant over time. Many have criticized this assumption. High (1983) points out that relaxing this assumption makes the job search models more realistic. The first contribution to study the problem of unknown distributions is Rothschild (1974). Although his example was related to prices and not wages, the same principles apply to wage distributions. With unknown wage distributions an optimal single reservation wage does not exist. This is because seekers learn about the distribution as they progress with their search and hence they change their reservation wage based on the new information collected. Rothschild formalized it in the following way. Suppose search is without recall, eliciting each time an element (price or wage in our case) of the finite set:

$$P = \{p_1, p_2, \dots, p_n\} \quad (4.11)$$

Suppose also that the number of times each price (or wage) has been observed is summarized by

$$N = \{N_1, N_2, \dots, N_n\} \quad (4.12)$$

Let us define $\rho = \frac{1}{\sum_{i=1}^n N_i}$ and $\mu_i = \rho N_i$ with $i = 1, \dots, n$ so that (μ, ρ) contains all the information accumulated by an individual where μ is the content of the information and ρ is its precision. $\lambda(\mu, \rho)$ is a probability distribution which represents the seeker’s beliefs based on what he has already observed. Based on this probability distribution, an individual would expect to observe a price (wage)

p_i with odds $\frac{\lambda_i(\mu, \rho)}{1 - \lambda_i(\mu, \rho)}$. Every time a new price (wage) p_i is observed, the new information is assimilated into the model according to the following function:

$$h_i(\mu, \rho) = \left(\frac{\mu_1}{\rho + 1} + \dots + \frac{\mu_n}{\rho + 1}; \frac{\rho}{\rho + 1} \right) \quad (4.13)$$

The optimal strategy is defined – as normal in this kind of dynamic models – by induction. Applying the Rothschild model to wages rather than prices, we can define the expected wage if the seeker is only allowed to search once as

$$V_1(\mu, \rho) = \sum_{i=1}^n \lambda_i(\mu, \rho) w_i \quad (4.14)$$

and the expected wage if the individual is allowed to search T times as

$$V_T(\mu, \rho) = \sum_{i=1}^n \lambda_i(\mu, \rho) \max\{w_i, V_{T-1}[h_i(\mu, \rho)] - c\} \quad (4.15)$$

The value of the extra information converges over time $V_T(\mu, \rho) \leq V_{T-1}(\mu, \rho)$ so that

$$\lim_{T \rightarrow \infty} V_T(\mu, \rho) = V(\mu, \rho) \quad (4.16)$$

The optimal stopping rule is based on a comparison between the actual wage offer received and the expected wage offer minus the costs of search. An individual has to stop searching when a wage offer satisfying this condition is received:

$$w_i \geq V_{T-1}[h_i(\mu, \rho)] - c \quad (4.17)$$

Empirical papers using unknown wage distributions often rely on experimental methods to test the behavior of individuals. One good example is Cox and Oaxaca (2000), which also provides a review of previous experimental empirical contributions on this issue.

4.3 The Matching Function

The early job search models are one-sided models where the main problem is to find an optimal stopping rule for individuals looking for a job. In this sense, these models are supply-side oriented. The work by Peter Diamond (1982a, b), Dale Mortensen (1970, 1986), and Christopher Pissarides (1979, 1984, 2000) – who were awarded the 2010 Nobel Prize for economics – changed this logic allowing job seekers and firms to interact in a framework that became known as “matching theory.”

Matching theory is based on a “matching function” whose simplest form is

$$M = m(U, V) \quad (4.18)$$

where $m(\cdot)$ is an unspecified functional relationship, U is the number of unemployed workers looking for job, V is the number of vacancies advertised by firms, and M is the number of matches between the two sets. The matching function is a kind of a black box and it is assumed to have constant returns to scale so that – on average – an unemployed worker finds a job in a unit period length with probability

$$\frac{m(U, V)}{U} = m(1, \theta) \equiv \alpha(\theta) \quad (4.19)$$

and a vacancy is filled with probability

$$\frac{m(U, V)}{V} = \frac{m(U, V)}{U} \frac{U}{V} \equiv \frac{\alpha(\theta)}{\theta} \quad (4.20)$$

The parameter $\theta = \frac{V}{U}$ is a measure of “labor market tightness.” Every time there is a “match” between a vacancy and a job seeker, a surplus is formed (relative to the situation in which they remained “unmatched”). This surplus is split through a Nash bargaining process. The Nash bargaining process is a very well-known concept in game theory and it refers to the work of John Nash (1953) for which he received the Nobel Prize in economics in 1994. The Nash bargaining process is a way to formalize the interaction of individuals using a simple two-player game. Each player contracts with the other on the basis of their preferences as described by their utility functions. A good description of the concept can be found Osborne and Rubinstein (1994). A high value of θ means that it is easy for a job seeker to find a new job. This means that the job seekers are in a relatively strong position compared to the firms offering the jobs and can therefore negotiate to get a higher share of the surplus generated by the match.

In its simplest version, the model assumes that both firms and workers are homogeneous, each firm consists of a single job, and there is a unit measure of workers. Workers move from unemployment to employment at an endogenous rate $\alpha(\theta)$ and in the opposite direction at an exogenous rate λ . The expected lifetime utilities, given a discount rate r , of being unemployed and employed – U and N respectively – are

$$rU = z + \alpha(\theta)(N - U) \quad (4.21)$$

where z is an instantaneous return, e.g., from home production, and

$$rN = w + \lambda(U - N) \quad (4.22)$$

Similarly, the firm hires at an endogenous rate $\alpha(\theta)/\theta$ and loses workers at an exogenous rate λ . The expected profits associated with the vacancy being not filled and filled – V and J , respectively – are

$$rV = -c + \frac{\alpha(\theta)}{\theta}(J - V) \quad (4.23)$$

where c is the cost incurred while the vacancy is unfilled, and

$$rJ = (y - w) + \lambda(V - J) \quad (4.24)$$

and $(y - w)$ is the surplus generated to the firm with income y while the worker is employed at a wage w . In equilibrium $V = 0$, so after solving for V in Eq. (4.24) and substituting into Eq. (4.23), the following can be derived:

$$\frac{\alpha(\theta)}{\theta} = \frac{r + \lambda}{y - w} c \quad (4.25)$$

Equation (4.25) describes the relationship between “market tightness” and wage. When the wage is higher, a firm is less willing to post vacancies (lower θ). However, to find the steady-state values of (θ, w) , we need a second condition to be combined with Eq. (4.25). This comes from the observation that the surplus to be divided between the worker and the firm when a match is realized is the worker surplus plus the firm surplus:

$$\frac{w - rU}{r + \lambda} + \frac{y - w}{r + \lambda} = \frac{y - rU}{r + \lambda} \quad (4.26)$$

Assuming the worker gets a β proportion of this surplus, we arrive at a second relationship between θ and w

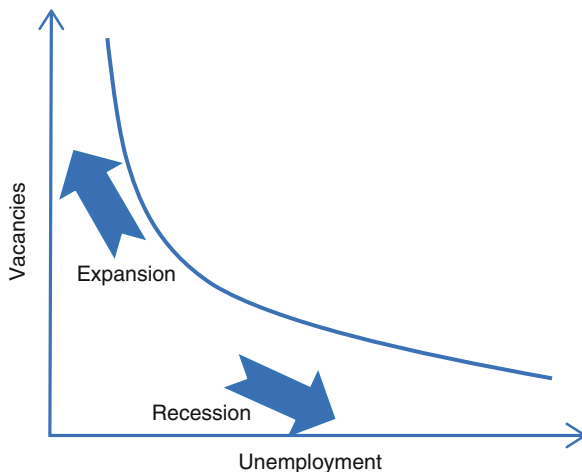

$$w = \beta y + (1 - \beta) \frac{(r + \lambda)z + \alpha(\theta)w}{r + \lambda + \alpha(\theta)} \quad (4.27)$$

Solving the system given by Eqs. (4.23) and (4.25) gives us the steady-state conditions for θ and w .

This basic matching model, which has also been called by the Diamond-Mortensen-Pissarides (or DMP) model has been extended in several ways. Two very detailed reviews of the matching function approach and its extensions are given by Petrongolo and Pissarides (2001) and Albrecht (2011). Petrongolo and Pissarides (2001) in particular review how the empirical contributions have tried to operationalize the matching function model. They classify the empirical studies into four categories:

1. Contributions which rely on the estimation on a Beveridge curve
2. Contributions which estimate aggregate matching functions
3. Contributions which estimate matching functions for local labor markets
4. Contributions which focus on estimating hazard functions for unemployed workers

The Beveridge curve is the equilibrium relationship between vacancy rate and unemployment rate. In a perfectly functioning (neoclassical) labor market, there would be no unemployed individuals looking for jobs nor vacancies to be filled,

Fig. 4.1 Beveridge curve

but – as pointed out by the job search theory – frictions are a reality and the Beveridge curve is a representation of this. Estimated Beveridge curves slope downward and we observe movements along the curve toward the right in a recession (where fewer vacancies are posted and more individuals are unemployed) and toward the left when an economy is booming (Fig. 4.1).

The Beveridge curve (Blanchard and Diamond 1989) is consistent with the expectations of the matching theory and hence provides indirect support for it. However, the majority of studies seeking support for the DMP model rely on the direct estimation of aggregate matching functions. As for production functions, a functional form needs to be chosen for matching functions. The majority of studies use a log-linear specification for the matching function with constant returns to scale, although some other specifications have also been tested. Petrongolo and Pissarides (2001) list 17 empirical studies which try to estimate aggregate matching functions, and they conclude by stating that plausible values for the unemployment elasticity range from 0.5 to 0.7.

Comparing the estimates for local labor market matching functions is considerably more complicated as the studies vary greatly in terms of countries studied and the level of aggregation. In their extensive review, Petrongolo and Pissarides (2001) also list 11 sectoral matching function studies covering a range of countries including the UK, the USA, the Netherlands, the Czech Republic, and Slovakia. They conclude that, although there is a great variety in the periods analyzed, the level of aggregation used, and the variables used in the matching functions, these studies do not contradict the main findings of the more aggregate studies.

Finally, contributions on individual hazard rates are microeconomic in nature and stress mainly the effect of individual characteristics on matching probabilities. One of the advantages of these studies is that they try to distinguish between the variables influencing the probability of *receiving* a job offer and those influencing the probability of *accepting* a job offer once received. Age, education, and

experience have all been proved to greatly influence the likelihood of receiving offers, while the cost of search, the unemployment income, and the overall perceived distribution of wages affect the individual reservation wage and hence the willingness to accept a job offer.

4.4 Job Search and Migration

For regional economists, there is one element missing in job search theory and that is *location*. Migration might improve the chances of finding a good match or might be the result of having found a good match elsewhere. In applying the job search theory to migration, a fundamental distinction needs to be introduced: whether the migration is part of the search (ex ante) or a consequence of the job search process (ex post). Molho (1986), in his review, labels these two as “speculative” and “contracted” types of migration. Speculative migration is “*undertaken in the hope of finding a suitable opportunity at the point of destination*” and contracted migration is “*undertaken after having already secured such an opportunity*” (Molho 1986 p. 402).

Several authors considered the case of speculative migration. Rogerson (1982), for instance, included in his job search model spatial variables such as the distribution of wages for each region and a matrix of costs related to distances. McCall and McCall (1987) presented a sophisticated model in which they also assumed that migration must precede job search. Their model is based on a “multiarmed bandit methodology” combined with the theory of belated information. The multiarmed bandit methodology takes its name from a traditional slot machine (one-armed bandit), and it is used in statistics to describe sequential optimization processes. Multiarmed bandit models are usually applied to problems where an agent is trying to simultaneously acquire new knowledge and maximize his/her utility based on the existing knowledge already acquired. Some of their findings are that regions with large wage variability attract migrants, while regions with large nonpecuniary returns are more likely to have high rates of both in- and out-migration.

Other authors tackled the problem of contracted migration. Gordon and Vickerman (1982), for instance, focus specifically on this issue and build a general model in which the probability that an individual z will migrate from origin a to destination b , at time t , is decomposed as follows:

$$P_t(m_{ab}^z) = P_t(s_a^z)P_t(o_b^z|s_a^z)P_t(d_b^z|o_b^z)P_t(1 - R_a^z|d_b^z) \quad (4.28)$$

$P_t(m_{ab}^z)$ is the probability that individual z will migrate ($m = 1$ if migrating; zero otherwise) from location a to a location b at time t ; $P_t(s_b^z)$ is the probability that individual z located in a is searching ($s = 1$ if searching; zero otherwise) for a job at time t ; $P_t(o_b^z|s_a^z)$ is the probability that individual z receives a job opportunity ($o = 1$ if receiving an opportunity; zero otherwise) in b conditional to the probability of being in search; $P_t(d_b^z|o_b^z)$ is the probability that the z individual accepts ($d = 1$ if the individual accepts; zero otherwise) the opportunity that was given; and finally

$P_t(R_a^z)$ is the probability that individual z residing in a has already received an acceptable opportunity at time t ($R = 1$ if the individual already an acceptable opportunity; zero otherwise). These probability functions are not defined explicitly in Gordon and Vickerman (1982).

More recently Basker (2003) tried to reconcile speculative and contracted migration by proposing a model in which the question of whether migration is part of the job search or a consequence is endogenously determined by the model itself. In Basker's model an individual z , looking for a job, has three possible options: (a) search locally, (b) search globally (i.e., also outside the region of domicile) from home, and (c) search globally by moving preemptively. The optimal strategy is based on the maximization of individual utility. Each of the three search options has an associated utility function – U_L , U_G , and U_M , respectively – which depends upon several parameters: the value of the reservation wage, the relative favorableness of the local market, the probability of finding a job globally, the costs of search, and the cost of migrating (for a full specification of the utility functions and the model setup, see Basker 2003, pp. 4–5). Local search is assumed to be costless, but is less likely to yield a job (especially a high-paying one). If the local market conditions are really bad, all but the lowest skilled choose the last strategy: migrating to search for a job elsewhere. As the favorableness of the local labor market increases, the probability of speculative migration decreases and more high-skilled workers turn toward contracted migration (i.e., a global search without migrating first). Eventually, very favorable local labor markets mean that everyone adopts the “search locally” strategy.

Jackman and Savouri (1992) is an interesting contribution that combines the matching function approach with migration. Migration is defined in their model as a way to solve a spatial mismatch. In Jackman and Savouri's words, migration is a “*special case of job-matching in which a job-seeker in region a is matched to a job in region b* ” (p. 1434) and therefore depends on the number of unemployed people (U) in the origin region a and the job vacancies (V) in the destination region b . This is different from the traditional matching function approach where a match does not necessarily imply a geographical movement. A match can indeed happen in the area where the worker lives and/or has been working previously. The concept is formalized by defining a generic “hiring function” – whose functional form is not specified – as in Eq. (4.29):

$$H_{ab} = H(U_a, V_b) \quad (4.29)$$

with $\partial H_{ab}/\partial U_a > 0$ and $\partial H_{ab}/\partial V_b > 0$.

The model is quite innovative because it considers regional level variables (at UK Government Office Regions level, which is comparable to the European NUTS1 level) rather than individual characteristics, but the motivation for the need of such a model is rather weak. Jackman and Savouri (1992), indeed, begin by stressing that their model represents an alternative to the traditional *human capital migration model* (Sjaastad 1962), which fails to explain the direction of interregional flows in a recession. According to the human capital migration theory,

migration can be seen as an investment in the human agent, which has costs and renders returns. A person will decide to migrate when the net present value of a migration investment is positive. Let us suppose that a potential migrant wants to move from region a to region b . He/she will migrate only if the net present value (NPV) of his expected returns in region b (destination) is greater than that in region a (origin) minus the cost associated with relocation (C_{ab}), i.e., $NPV_b > NPV_a - C_{ab}$.

Jackman and Savouri argue that, since regional differences are highest in a recession, the human capital model forecasts that more people would move from poorer to richer regions, but the evidence shows that actual migration flows tend to “*rise in times of prosperity and fall in a recession*” (p. 1433) when they are most needed to restore balance to the system. The hiring function approach provides an explanation to these perverse migration flows by assuming that the number of engagements falls in a recession.

Although the authors are correct in pointing out that the human capital migration model, as such, is inadequate to explain the actual patterns of migration flows observed during recession, the human capital framework can easily be adapted to fit these facts. The human capital approach is neoclassical in essence so the decision to migrate depends exclusively on the comparison of future net benefits associated with the decision to move (Sjaastad 1962). The probability of finding a job is set equal to one and is unaffected by macroeconomic conditions. The addition of a probability function depending on the status of the economy could solve the inadequateness of the human capital migration model to explain lower migration flows in a recession without the need of a completely new alternative model. Especially in the case where the person is actually employed in the region of origin (enjoying a certain future income stream even though it may be low), there is less incentive to move because the probability of finding a job elsewhere is lower.

The reasons for the negative relationship between increased regional gaps in recession and lower probability of finding a job by migrating includes the Jackman and Savouri (1992) argument that employers react to crisis by reducing recruitment and therefore jobs become more difficult to find. As a result, the role of information costs also needs to be considered. Information costs increase when jobs become more sparsely distributed throughout the territory. Moreover, since people perceive that there is a crisis, their reservation wages normally go down. Jobs with lower wages may be more easily available locally and this in turn reduces the chances of having to make a migratory move. Properly defining the function for probability could then reconcile the job search and human capital theories of migration.

Despite the fact that the human capital and job search theories are often regarded as competing, they reach similar conclusions regarding migration. First of all, they both predict that individuals with higher human capital are more likely to migrate. In the case of the human capital theory, this is due to the fact that individuals have to be compensated for their investment in education, and in the case of job search, they need to be compensated for their higher reservation wage. However, one difference needs to be emphasized. In the human capital theory, the migration propensity of each single individual increases with education, while in the traditional job search

theory, on average, higher-human-capital individuals are more mobile than lower-human-capital individuals, but this does not necessarily hold true for every single individual. Indeed, whether or not an individual migrates is related to the location of the *first* acceptable job (i.e., the job that meets the reservation wage). Jobs are randomly distributed over space and the process is sequential (one offer at a time), so it *may* be that some individuals are lucky enough to find an acceptable offer close to their current location. However, higher-reservation-wage jobs are expected to be more sparsely distributed in space so that, on average, higher-human-capital (and therefore higher-reservation-wage) individuals have to move further.

4.5 Conclusions

The aim of this chapter was to present the main ideas behind job search theory and its importance in the field of economics. Job search theory, though microeconomic in nature, contributed to explain macroeconomic phenomena such as frictional unemployment, which could not be explained by the traditional neoclassical theory. Since its inception, there have been many extensions to the model. For example, on the theoretical front, the heterogeneity of individuals has been emphasized, while other contributions focused on “family” job search, in which the decision regarding a job is not taken by an individual but rather by the whole household. On the empirical side, the availability of better data – both individual and aggregate – provided the basis to test some of the propositions of the models. In recent years, many empirical contributions employed experimental methods to better understand individual behavior in the labor market. While this chapter only scratched the surface of job search theory, it hopefully provided the basic notions for further study.

Abstract

In the monocentric model, commuting is viewed as a burden whose cost shapes the spatial structure of cities to a considerable extent. This view has been challenged by the finding that actual commuting patterns are far from efficient. However, this “wasteful” commuting is better interpreted as an indication of labor market frictions that are traded off against commuting frictions than as a neglect of commuting costs. Urban sprawl results from the decreasing importance of physical space that was the consequence of the automobile and is fundamentally consistent with the basic insights of the monocentric model. Large and diversified urban labor markets flourish when space restrictions are relaxed because this facilitates the matching of jobs and workers along other dimensions. Having a large mortgage puts more stress on this allocation mechanism.

5.1 Introduction

Before the industrial revolution, most people lived where they worked. New production techniques and – later – increasing welfare resulted in the spatial separation of the residential and work locations. Commutes provide the connection between the housing and labor markets. The home-work trip is generally considered as a burden: spatial separation causes friction that can only be overcome by accepting transport costs. This view on commuting has long been dominant in the thinking of urban economists. However, commuting also offers some flexibility: one can change job while staying in the same house and vice versa. In dense urban areas, all kinds of jobs are available at reasonable commutes. This second view on commuting has become more prominent in the more recent literature. It does not necessarily contradict the first one: a worker may dislike commuting while at the same time appreciating the job opportunities that a large metropolitan labor market offers. In this chapter, both points of view will be discussed.

In the next section we start with a discussion of the monocentric model that gives a central role to commuting costs in its explanation of the spatial structure of cities. [Section 5.3](#) provides a discussion of the challenge that the discovery of “wasteful” commuting implied for the established view and the answer provided by search theory. [Section 5.4](#) deals with the decrease in commuting cost that was associated with the automobile which had, in accordance with the main insights of the monocentric model, an enormous impact on spatial urban structure. In [Sect. 5.5](#), the advantages of density for matching heterogeneous workers and jobs are discussed, as well as the interaction between agglomeration effects – which tend to favor monofunctional areas – and commuting disutility, which tends to favor mixed land use. [Section 5.5](#) continues with a review of the discussion about Oswald’s thesis which says that homeownership has negative effects on labor market performance and argues that the distinction between outright and leveraged owners is of crucial importance here. [Section 5.6](#) concludes.

5.2 The Monocentric Model

The monocentric model, developed by Alonso, Muth, and Mills, studies the housing market that emerges around an employment center. It thus investigates the connection between a very simple labor market – where identical workers are employed at the same location and earn the same wage – and a somewhat more elaborate housing market, where houses differ in quality as well as in the distance to the employment center. Housing requires land, and land is available in limited quantity around the employment center. Workers prefer to reside close to their work location, but the limited supply of land makes it impossible for all to realize this desire. Commuting provides the possibility to separate the residential and work locations, but workers dislike it. Equilibrium therefore requires that workers with a long commute are somehow compensated. This works via the housing market: cheap housing

compensates for long commutes and allows all households to reach the same utility level, even though their circumstances are quite different.

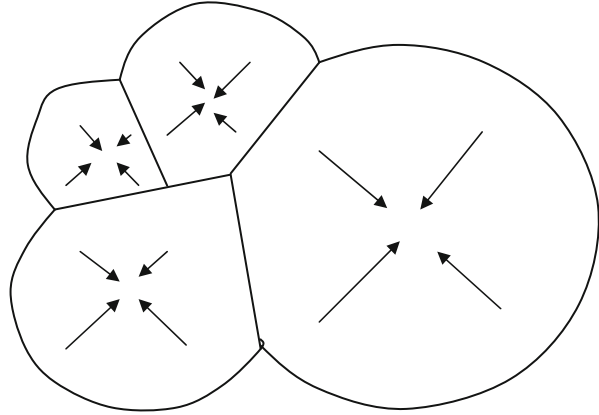

It is useful to go a little bit into the formalities of the model since this clarifies the fundamental role of commuting cost in the model. Households have preferences over housing h and other consumption c that can be summarized in a utility function $u(c, h)$. The budget constraint says that total expenditure on housing and commuting must be equal to net income, defined as the difference between the wage w and the commuting cost. The latter is equal to the product of the distance x to the employment center and commuting cost per unit of distance t . The unit price for housing p is allowed to vary with distance to the center. The budget constraint can thus be written as $c + p(x)h = w - tx$. Note that the unit price for other consumption has been normalized to 1. Maximization of utility subject to the budget constraint leads to the indirect utility function that gives the maximum utility the consumer is able to reach at given location, housing price, and net income: $u = v(w - tx, p(x))$. The equilibrium condition requires indirect utility to be independent of the location; hence, $\partial v / \partial x = 0$. This implies the well-known Muth condition

$$\frac{\partial p}{\partial x} = - \frac{t}{h(p(x), \bar{u})} \quad (5.1)$$

The left-hand side is the slope of the house price function, while the right-hand side equals minus the ratio of the transport cost per unit of distance and the Hicksian demand function for housing. \bar{u} denotes the equilibrium value of utility. The Muth condition determines how the house price changes with distance to the employment center. The house price determines, jointly with the equilibrium level of utility, the demand for housing at each location in the city. If one introduces housing construction in the model, then the housing price determines the density of housing – the size of houses and of gardens close to the city edge but also building height close to the employment center – as well as the population density and the price of land at all locations. In short, virtually every aspect of the housing market in the monocentric city is determined to a considerable extent by the Muth condition in which the commuting cost per unit occupies a central place. It is therefore no exaggeration to say that commuting is a crucial element in this model which can entirely be regarded as focusing on the relationship between the housing and labor market in a simplified setting.

In the monocentric model the edge of the city is determined by the point where the bid rent – the highest rent that is compatible with reaching the equilibrium level of utility – for residential land equals the price of agricultural land. In a city with homogeneous workers, the bid rent equals the housing price function, whose slope is determined by the Muth condition. It is not difficult to show that the size of the city – measured by the distance from the employment center to the edge – increases when transport costs decrease. This simple comparative static result can be related to the phenomenon of urban sprawl, and it demonstrates once again that the Muth condition, with its central role for commuting cost, does a very good job in predicting empirical regularities.

Fig. 5.1 Figure shows four employment centers of different sizes surrounded by disjoint recruitment areas. Wages differ between the centers. In each recruitment area the logic of the monocentric model holds. The *arrows* indicate the direction of the commutes

Although the model is called monocentric and has often been criticized for being so, it is useful to note that it has no difficulty with the existence of multiple employment centers. If we stick to the assumption of identical workers and allow them to be mobile between the various centers, the logic of the model implies that there will be residential areas around every center from where workers commute exclusively to that center, as is illustrated in Fig. 5.1. The equilibrium condition that all workers must reach the same utility level determines the maximum bids of workers in a particular center for each possible residential location. The worker that offers the highest bid “wins” the residential location, and in this way, recruitment areas emerge for each employment center.

5.3 “Wasteful” Commuting

The central position of the commuting cost in the monocentric model makes clear why Hamilton’s (1982) finding, that actual commuting patterns appear to be closer to those resulting from random matching than to an efficient allocation of workers to jobs, was a cause of real concern among urban economists. Hamilton developed a variant of the monocentric model in which some employment is located outside the center. The labor market is competitive, and the wage of the decentralized jobs must therefore be such that any worker who is employed there must be indifferent between this job and one in the CBD. This is a strong condition: it implies that workers accept only decentralized jobs that are located on the straight line between their home and the CBD. All commutes are therefore in the direction of the CBD, although not all of them end there. Armed with this result, Hamilton could show that this commuting pattern is efficient in the sense that it minimizes the total commuting distance traveled by the workers in the city.

This prediction of the extended model could be tested by comparing the actual total commuting distance with the minimum. It was of course not a complete surprise that the actual situation differed from the efficient one. However, the difference was so large that Hamilton’s results called into question the logic

of the monocentric model: crisscross commuting seemed incompatible with a strong impact of transportation costs on urban structure. Briefly, most commuting appeared to be wasteful instead of efficient.

A few years later, White (1988) pointed out that Hamilton had ignored the existence of multiple employment centers with their own recruitment areas. The decentralized employment in Hamilton's model differs from the multicentered city with several employment centers, each with their own recruitment area that we briefly discussed at the end of the previous section. In such a city, Hamilton's equilibrium condition does not hold: commutes are not all directed to one particular center. White (1988) presented alternative figures about commuting across boundaries of zones within urban areas that suggested that actual commuting patterns were much closer to the efficient lower bound than was implied by Hamilton's results (see also Hamilton 1989). Again a few years later, Small and Song (1992) confirmed this finding but also showed that within zones there was a considerable amount of "excess" commuting, a term preferred by these authors to Hamilton's adjective. This normatively neutral qualification was probably related to the observation that the assumptions underlying Hamilton's conclusions were quite strong. Real world urban labor markets are characterized more by substantial heterogeneity of both jobs and workers than by the extreme homogeneity that is the standard assumption in the monocentric model. Housing is also an extremely heterogeneous commodity. In addition, it is durable and transformations are costly. These properties make it unlikely that actual urban labor markets will be able to come close to the efficiency boundary by swapping jobs or houses between workers whenever that leads to shorter commutes to both parties involved. The presence of two worker households adds to these problems.

However, these considerations do not answer the question whether the actual commuting patterns could be reconciled with the logic of the monocentric model that attributes a large role to commuting costs. It turns out that a somewhat different view on the labor market can do just this. In the course of the 1970s, search models became quite popular in (nonspatial) labor economics. These models stressed the information problems that occur when workers looking for a(nother) job have to find employers with a suitable vacancy and vice versa. See ► [Chap. 4, "Job Search Theory"](#) for a discussion of spatial application of search theory. A spatial version of the standard model of job search developed in this literature runs as follows. Consider an unemployed worker located at x , who is searching for a job. We do not model his or her search activities explicitly, but only the result: job offers arrive now and then. Formally, we assume that there is a constant arrival rate λ that equals the expected number of job offers per period. The jobs offered are identical, except for the net income associated with them. Such differences in net income may result from an identical wage paid in a number of employment centers located at different distances from the searcher's residential location. Alternatively, one may think of a city with decentralized employment à la Hamilton where jobs are located either in the center or elsewhere in the city and the offered wage depends on the location of the job. To keep the model reasonably general, we assume a given distribution of net wages y that will not be specified further at this moment. A job offer is a random

draw from this distribution. Each time a job offer arrives, the searcher has to decide if she accepts it. Acceptance implies the end of the search process and employment in the job for the remainder of her life. Refusal implies that the search process continues, which usually implies the possibility of a better job offer in the (near) future. As long as the search process continues, the worker receives an unemployment benefit b . This benefit must also be interpreted as a net amount of money, as it seems likely that the searcher has to travel in order to locate vacancies. We take the housing consumption h of the searcher as given and assume that there is no saving or income from other sources. That means that instantaneous utility equals $u(b - p(x)h, h)$ as long as the searcher remains unemployed and $u(y - p(x)h, h)$ when a job with net wage y is accepted.

It seems likely that the optimal search strategy is such that if a job with net wage y will be accepted, also all jobs with a higher net wage will be accepted. Unless all job offers are accepted, this must imply the existence of a lowest acceptable wage. Moreover, as long as the arrival rate, the job offer distribution, and the unemployment rate remain unchanged, there seems to be no reason why this critical net wage should change over time. Formal analysis confirms these conjectures and proves that the solution of the dynamic optimization problem has the so-called reservation wage property: there is a critical net wage y^{res} , and the searcher accepts the first offer that implies at least this net wage.

This standard model is consistent with a potentially large amount of apparently wasteful commuting. To see this, consider the situation in which job offers originate from a finite number of unemployment centers indexed $n=1, \dots, N$. (We will not discuss the case in which employment is distributed continuously over space as is, for instance, the case in Hamilton's monocentric model with decentralized employment. The implications are entirely similar). Let φ_n be the probability that a wage offer originates from center n and w_n the wage offered there. The following expression holds: $u(y^{res} - p(x)h, h) = \frac{\rho u(b - p(x)h, h) + \lambda \sum_{n \in A} \varphi_n u(y_n - t d_{xn} - p(x)h, h)}{\rho + \lambda \sum_{n \in A} \varphi_n}$

In this equation, ρ denotes the rate of discount and A the optimal acceptance set, that is, the set of employment centers for which the net wage exceeds the reservation wage. That is, $n \in A$ if $y_n - t d_{xn} > y^{res}$. The distance d_{xn} is the distance between the searcher's residential location and employment center n .

The left-hand side of the equation gives the utility reached by the searcher when the net wage equals the reservation wage y^{res} . The right-hand side shows that it equals a weighted average of the instantaneous utility that is experienced as long as the searcher has not accepted a job offer and the instantaneous utilities that may be experienced after acceptance of a job offer. The appendix provides a simple algorithm for the computation of the reservation wage. It implies that the searcher will only accept job offers from the most attractive employment centers. If the acceptance set has only one element, we are in a situation with exclusive recruitment areas for each employment center. It is not difficult to verify that such a situation will be reached when $\lambda \rightarrow \infty$. Then the searcher can be selective without having to suffer an increase in unemployment duration, and she will accept only job offers that imply the highest possible net wage. When $\lambda \rightarrow 0$, the opportunity cost

of rejecting a job offer becomes very large, and the searcher will accept all job offers that imply a net wage that exceeds the unemployment benefit. The arrival rate thus indicates how far (or how close) the labor market is from the frictionless situation assumed in the conventional monocentric model.

It is interesting to consider the special situation in which identical wages are offered in each center. The reservation wage strategy is then equivalent to a strategy that uses a critical commuting distance: the first offered job that has an implied commute shorter than the critical value will be accepted. In the more general case, when offered wages can vary over centers, long commutes can be compensated by higher wages. Note that the number of acceptable centers can be large, and in special cases with low arrival rates of job offers, the whole set of employment centers in an urban area may be acceptable. If that happens, the worker can commute to any employment center, and his or her behavior is in fact determined by random matching. It is possible that all workers in the urban area are in this position, and in this case the commuting flows are indeed determined by random matching of workers to jobs, the situation that was close to Hamilton's empirical findings.

Does this imply that the connection between the housing market and the labor market that plays such an important role in the monocentric model breaks down? Not at all. To see why this is the case, consider the expression $\sum_{n \in A} \varphi_n u(y_n - t d_{xn} - p(x)h, h)$ which is a weighted sum of the instantaneous utilities that will be experienced after acceptance of a job. It depends on the implied commuting distances from x to the acceptable employment centers and on the price of housing at x . If the searcher would move to a residential location that has better accessibility to employment centers, his lifetime utility would increase, even if the set of acceptable centers would remain unchanged, unless the price of housing would go up. This effect would be reinforced if the searcher becomes more choosy after the movement and changes her acceptance set. Clearly, accessibility to the relevant employment centers is relevant in the present model. Note that this is also the case in the situation in which job offers from all employment centers are accepted (see Rouwendal 1998).

This shows that in a city in which new inhabitants enter the city unemployed and have to choose a residential location, they will prefer those that provide good accessibility to employment centers. Since space is limited, the usual bidding process will then lead to a spatial structure with a trade-off between job accessibility and house prices that is in many respects similar to that of the traditional model. All the conventional predictions about the rent gradient, the density of housing, etc., still follow, even though the workers can now be cross commuting over large parts of or even the entire urban area. One interesting difference is that locations in between employment centers may have reasonably good accessibility to all the centers, without being very close to any of them. The search model predicts that such locations can be very desirable, whereas the traditional theory regards them as inferior to locations in the close proximity of a single center.

The model assumes that households choose a residential location once and for all. Since the model assumes that workers stick to a job forever after it has been accepted, it may be argued that workers have an incentive to move as close as

possible to the job they have accepted. However, this incentive is weakened if we introduce the possibility that workers can lose their job and become unemployed again. It can be shown that little changes in the model developed above when we do so. Sticking to a residential location that has once been chosen may be a good strategy when there are substantial moving costs. Empirically, there is little impact of a change in employment status on the residential location, which suggests that the assumption of a fixed residential location does little harm.

Empirical research based on the search model has also confirmed that workers attach considerable weight to commuting costs when accepting a job. See Van den Berg and Gorter (1997), Rouwendal (1999), and Van Ommeren, Van den Berg, and Gorter (2000). Interestingly, these studies have also shown that a worker's sensitivity to commuting costs depends on household characteristics. A repeated finding is that women attach a greater weight to commuting distance than men and that this is especially the case when young children are present in the household. Allocation of tasks within the household thus appears to interact with labor supply.

The search model introduced above helps to explain the phenomenon of wasteful commuting, but there is certainly also a role to play for heterogeneity on labor supply and demand. This will be further discussed in [Sect. 5.5](#) below. For the moment it is useful to think of the urban labor market as a set of disjoint segments. Workers from one segment cannot be employed in jobs that belong to another segment, and jobs from one segment cannot be filled by workers from any other segment. Within each segment, a search model like the one presented above is valid. In this model, wasteful commuting results from immobility between sectors as well as from search frictions within sectors. If jobs requiring different types of workers are present in the same firms, employers will in general prefer central locations (in the CBD), but there may still exist differences between the worker types that lead to sorting behavior. The slopes of the bid rent curves are now determined not only by commuting costs and housing consumption but also by the frequency and duration of unemployment. This tends to sort workers with a bad labor market position to locations with relatively bad job accessibility.

This mechanism is quite different from Kain's spatial mismatch hypothesis, which is discussed in detail ► [Chap. 6, "Spatial Mismatch, Poverty, and Vulnerable Populations"](#), although it results in a similar correlation between job accessibility and labor market position. According to Kain (1968), black workers who were often located in ghetto's close to the CBD were disproportionately disadvantaged by the shift of manufacturing industries to peripheral areas, since housing market discrimination hampered their ability to adjust to the new situation by moving closer to the manufacturing jobs. This may well have been true, but it is clear that in general there is a potentially important endogeneity problem involved. Recent research has tried to isolate the effect of living at a location with bad accessibility to jobs by taking advantage of natural experiments. One example is Andersson et al. (2011) who use mass layoff to compare the subsequent unemployment durations of workers at different locations, finding a significant but relatively small effect. Another is Phillips (2011), who reports about a field experiment in which the transport costs of a random subsample of unemployed persons living at remote

suburbs were lowered while using the other part of the sample as a control group. He finds significantly smaller unemployment durations for the treatment group, although the ultimate impact on the share that found a new job was close to zero. It appears therefore that the effects of living at locations with relatively bad geographical accessibility to employment per se are limited, as is implied by the equilibrium interpretation of location choices. The empirical evidence suggests that the structural unemployment among specific groups, like low-educated blacks in many US cities, is not primarily due to their residential locations that do not offer good accessibility to jobs.

5.4 Transport Modes, Sorting, and Urban Sprawl

If it is true that commuting costs are an important determinant of urban structure and that apparently wasteful commuting does not change the essence of this thesis, then one expects that changes in commuting costs will have important consequences for the interaction between labor and housing markets. In this section, we consider various aspects of this issue.

We start with the relationship between income and location choice. Although income does not appear explicitly in the Muth condition, it is not difficult to see how it changes when income increases. There are two effects. First, housing is a normal good, so its consumption increases with income. This also implies that – all else equal – Hicksian demand for housing will be higher for households with a higher income. Second, travel time is an important determinant of the commuting cost, and its value is closely related to income. The first effect tends to make the bid rent curve flatter, while the second tends to make it steeper. It is well known that, in the monocentric city setting, heterogeneous households sort in such a way that the group with the steepest bid rent curve will locate closest to the center. These are the households with the highest incomes if housing is a luxury good, while they are the households with the lowest incomes if housing is a necessity. Since most studies of housing demand find an income elasticity of the demand for housing that is well below 1, the latter situation seems relevant. This suggests that urban economists are again in trouble: empirically the high incomes were the first to suburbanize, and poor households are overrepresented in the city centers. Wheaton (1977) who was one of the first to point this out suggested that the explanation must be found in the durability of housing, which causes old, low-quality housing to be present in the oldest parts of the cities, which are usually close to the employment centers.

However, a closer look at the way new, faster transport modes are introduced in cities reveals a somewhat different insight that was put forward first in LeRoy and Sonstelie (1983). A good example is the early types of public transport, streetcars, that were introduced in a time when most people had to walk to work, keeping the cities small and dense. The introduction of public transport meant that one could move faster, although only by buying a ticket. The relatively well-paid workers have the highest value of time and therefore also the highest willingness to pay for the new transport mode. For these workers the switch to the new transport mode

meant a decrease in the full cost of commuting. This made their bid rents curves flatter, while those of the workers who still walked to work remained unchanged. The logic of the monocentric model thus suggests that the rich who switched to the new transport mode became the group located at the largest distance from the center. It has been documented by Gin and Sonstelie (1992) that this was exactly what happened in nineteenth -century Philadelphia when the streetcar was introduced. Similar stories could be told for many cities where in the nineteenth and early twentieth century, the construction of public transport – commuter –lines that extended to the borders of the existing cities resulted in residential development in the vicinity that was especially used by relatively well-paid workers. This explanation emphasizes that the introduction of a new transport mode flattens the bid rent curve of those who use it while keeping the bid rent curve of the others unchanged. This differential impact on the bid rent curves is the reason why the impact of the introduction of the faster transport mode differs from what is suggested by an analysis of its general impact in the right-hand side of the Muth condition. Ultimately, when the new transport mode is used by almost everyone, this general impact dominates. However, that can take a long time, and the durability of housing may of course contribute to the prolongation of the initial transitory effects.

This history repeated itself when the car was introduced in the early twentieth century. The car is remarkably faster than any previously existing type of public transport and has the important advantage that it could bring one to practically every place as long as good roads are available. That its introduction has had substantial effects on city structure is therefore completely in line with the analysis of the monocentric model. The analysis of the impact of a fast transport mode discussed above suggests that the rich will move out earliest, and that is exactly what happened. Glaeser and Kahn (2003) argue extensively that the automobile is the most important driver of urban sprawl. They emphasize that the increase in average commuting distances that is associated with this phenomenon does not imply an increase in commuting times and indeed that the latter are often shorter for car drivers than for public transport users. Although physical distance has increased, travel time distances rose much less and may even fall. The automobile relaxes the tight connection between the residential and work locations, but it did not change the fundamental forces emphasized by the monocentric model. Commutes remain the essential connections between home and work they have always been since the physical separation of the two that was a main consequence of the industrial revolution.

Two important points remain. First, the analysis suggests that the rich will return to the central city when all workers can afford a car. When the new transport mode becomes available to all, all bid rents curves are flatter and the same relative positions become relevant again, suggesting that the rich will be closer to employment centers than the poor. This may well be related to the surprising revitalization of many inner cities that took place since the 1980s. The “consumer city” that receives much attention in recent work in urban economics may have much to do with it.

Second, the decrease in transport cost that was associated with the car (and the truck) has had enormous consequences for the consumption of land and the size of cities.

It is not to be expected that this development will also be reversed. Only if real transport costs will increase substantially can we expect significantly denser urban areas. Recent analyses of the land use controls also strongly suggest that such measures keep density close to city centers at artificially low levels, thereby contributing to longer commutes and perhaps less well-functioning labor markets in urban areas.

5.5 Density, Diversity, and Agglomeration

The monocentric model takes the location and size of employment centers as given and concentrates on the location of workers around them. The employment centers may be located at points that have particular natural advantages, but there are also endogenous forces at work. Marshall (1890) famously pointed out that specialization of employment centers in particular types of tasks, related, for instance, to a particular type of manufacturing industry, may result in concentration of workers with the complementary skills around these centers. This may cause an agglomeration effect as workers with the specific skills are attracted to the city because it offers them better opportunities to find a job, whereas firms with the specific tasks are attracted to the city because it offers them a better chance to fill their vacancies.

This line of reasoning may be related to our job search analysis by relaxing the assumption that jobs and workers are completely homogeneous. At the end of [Sect. 5.3](#), a brief discussion of a labor market with a number of different segments was provided. In reality, the various segments are seldom completely disjoint, as was assumed there. The heterogeneity in workers and jobs then adds to the difficulties in labor market allocation that were discussed in that section. If jobs differ in tasks to be performed and the suitability of a worker to fill these tasks, vacancies can only be offered to workers whose skills are reasonably close to those required by a particular job, and the wage offer is also likely to depend on the quality of the match. It follows that the heterogeneity of jobs and workers increases search costs. One possibility to mitigate this effect is to let cities or employment centers specialize in particular tasks and skills. The spatial separation of workers and jobs tends to make the labor market more homogeneous, and this facilitates the functioning of the labor market.

To see how this works, return to the model with disjoint segments of the end of [Sect. 5.3](#) and assume now that each segment is located in a different city. For each segment the search model discussed is relevant. For the specialization to have any effect, the specialized cities must offer better possibilities for finding a suitable match than diversified cities of equal size. The mechanism that generates contacts between workers with vacancies and job searchers can be the same in both cities. It may work, for instance, by randomly drawing a vacancy and a job seeker. The probability that such a randomly generated contact implies a reasonable match between skills and tasks is higher in the specialized city than in the diversified one. The result will be a higher arrival rate of job offers for searchers in the diversified city and shorter durations of unemployment and vacancies.

An impact of density on the generation of contacts between labor supply and demand seems quite plausible. In a larger labor market that is geographically concentrated in a small area, it is easier to get into contact with the other side of the market. However, this conjecture is at variance with conventional labor market models in which the contact-generating function has constant returns to scale; see, for instance, Pissarides (2000). Since in such models only the ratio between the number of job searchers and the number of vacancies is important and the same ratio can result from low and high densities, a specialization effect is absent in such models. This constant return to scale property of the matching function implies a congestion effect that seems more plausible in a homogeneous market than in a diversified one. Although the existing empirical evidence, reviewed in Petrongolo and Pissarides (2001), is generally favorable to constant returns to scale specifications, it should be noted that research has not really been focused on the roles of heterogeneity and density.

The diversity of large urban labor markets should be expected to be especially important for the upper end of the skills and tasks distributions where the market is thin and geographical specialization is difficult to realize. A large and diversified labor market then offers firms as well as workers the opportunity to find a reasonable fit between required and available skills. Teulings and Gautier (2004) and Gautier and Teulings (2009) provide an extensive discussion of a search model with increasing returns to scale in the matching function in which cities have particular advantages in terms of labor market allocation. Interestingly, they argue that it is not just physical density, jobs, or workers per squared kilometer but also the integration of geographical locations into a single labor market area that matters. In Gautier and Teulings (2003), they develop an empirical index, denoted as γ , for this aspect that can be estimated as

$$\gamma_n = \frac{\sum_{m=1}^N (s_{nm} - x_m)^2}{1 - \sum_{m=1}^N x_m^2}, \quad n = 1, \dots, N \quad (5.2)$$

The index refers to a (metropolitan) region in which employment and workers are distributed over N areas. In the equation, s_{nm} is the share of the workers in area n that reside in area m , while x_m is the share of houses in the region as a whole (all N areas together) located in m . A lower value of γ_n indicates that the urban area is denser in the sense of being more connected to the areas in the proximity. The index reaches its minimum value, 0, when $s_{nm} = x_m$ for all m . In that situation, the share of workers in n who live in m is equal to the overall share of workers in the city who live in m , which implies that distance does not play a role in attracting workers to area n . This is exactly the apparently random matching of jobs to workers that Hamilton (1982) interpreted as the opposite of efficient commuting. Clearly, the commuting pattern that is extremely inefficient in the context of a perfectly homogeneous labor market is extremely attractive in the context of a labor market with heterogeneity and search frictions. Intuitively, the reason is that the market is better able to reach a good match between skills and tasks when spatial frictions are absent.

In their empirical work, Gautier and Teulings (2003) find a strong negative correlation between their index γ and the log hourly wage, even after the effect of workers or jobs per square km has been taken into account.

Glaeser (1999) argues that one of the advantages of an urban labor markets is that one can switch from one job to another without having to move house. By accepting some inefficiency in commuting, one saves transaction costs in the housing market. Costa and Kahn (2000) have argued that couples of highly educated workers benefit especially from urban labor markets since their often specialized skills make it hard to find a suitable match with available jobs at a reasonable commute in other areas. They show that such couples are indeed strongly overrepresented in large metropolitan areas and argue that this is caused by the dense and diversified demand for labor at these places. Similar concentration effects have been found in other countries, for instance, for the Netherlands. In joint work with Willemijn Wejschede, it was shown that commutes of couples are hardly longer than those of single workers in otherwise comparable households, a finding that should probably be attributed to spatial sorting effects. A strategic choice of the residential location within an urban area, which is of course facilitated by their higher income, allows two earner households to keep their commutes limited, their collocation problem notwithstanding.

The discussion thus far has argued that specialization as well as diversity might benefit the functioning of the labor market in cities. There is evidence that both types of agglomeration effects are exploited in reality. For instance, Duranton and Puga (2001) develop a model that explains the empirically documented tendency of many industries to locate in a diversified environment in early stages of their life cycle and in a specialized environment after standardization of their product occurs in a later stage. Although their model does not analyze labor market frictions explicitly, the discussion above fits in the picture they draw. The discussion so far suggests that, at least in diversified cities, a better match between skills and tasks can be realized at the cost of some apparently wasteful commuting. However, a tractable model that deals with the spatial aspects as well as with the match between tasks and skills does not seem to be available.

One should realize that labor market matching is not the only agglomeration force that is active in urban areas. Production externalities tend to have clustering effects on firms, and although the CBD is often treated as a single point in monocentric models, larger concentrations of firms imply in reality longer commutes for their workers. This trade-off is investigated in Lucas and Rossi-Hansberg (2002) who relax the assumption of a given employment center in a setting that is otherwise very close to that of the monocentric model. They attempt to explain the location of workers and jobs in a circular area that is initially completely homogeneous. Two forces are at work. First, workers become more productive when their employment location is close to that of other workers. This agglomeration effect is modeled as a “potential” effect on productivity, and it stimulates clustering of firms. Firms produce a commodity that is sold at the world market without transport costs and at a given price. This means that firms have no preference for locations apart from those that result from the agglomeration forces and the wage they have to pay

to attract workers. Second, workers dislike commuting. This is the force that is also present in the conventional monocentric model. All workers are identical and the labor market is assumed to be perfect. The land market is also perfect and rents are determined by the highest bid.

In this setup it is possible that all firms and workers are spread homogeneously over space. Each worker then lives next door to his job, so there is no commuting. However, firms located close to the border of the city then benefit less from proximity to other workers than those located in the center of the circle. Firms will therefore tend to concentrate in the center, but this means that at least some workers have to commute. Concentration of firms implies higher productivity, and therefore higher wages can be offered. But the workers who earn these higher wages can use them to bid more for residential land in the proximity of their employment location, thus counteracting the tendency to agglomeration. The final result of the interaction depends on the relative size of the agglomeration effects and the workers' dislike of commuting. If agglomeration effects are strong, a conventional monocentric city results with all employment concentrated in the center. If commuting costs are more important, other configurations may arise. Lucas and Rossi-Hansberg show, for instance, that it is possible that the city center is a residential area. The inhabitants work in firms located in a ring surrounding the center. These authors also show the possibility of mixed zones in which workers and firms are located next to each other.

The results of Lucas and Rossi-Hansberg (2002) are intriguing since they suggest a rich pattern of spatial equilibria is possible once we relax the assumption of a fixed location and size of employment centers. Although formally their results are restricted to a situation in which space is circular, something similar will probably hold in more general settings. For instance, it is possible that the configuration shown in Fig. 5.1 is consistent with an extended model in which there can also be agricultural land. Recent empirical work, carried out jointly with Hans Koster, confirms the importance of agglomeration as well as dislike of commuting on land prices as determining factors of urban land rents, although other forces, like the presence of consumer amenities and negative externalities imposed by firms on households, should also be taken into account to complete the picture.

5.6 Owning, Renting, and Unemployment

Oswald (1996) has put forward the thesis that there is a causal effect of homeownership on unemployment. According to his analysis, a 10 % increase in the ownership rate increases long-term unemployment by 2 %. Although his paper has long remained unpublished, it was soon referenced in an influential article by Nickell and Layard (1999), and the thesis received a lot of interest. A possible background of a causal effect is the much lower residential mobility of homeowners. If owners would be less willing than renters to accept a job outside their residential area after becoming unemployed, a higher rate of homeownership could indeed push up long-term unemployment rates. Munch et al. (2006) have investigated this hypothesis on the basis of Danish micro data. The theoretical

framework they use is a search model in which job offers can originate from the searcher's region of residence as well as from elsewhere in the country. The first type of job offers can be accepted without moving house, whereas acceptance of the second requires moving to a different region. According to the model, homeowners, who have higher costs of residential mobility, are more reluctant in accepting job offers from other regions than renters. However, their model suggests that they are more willing to accept job offers from the local labor market by setting a lower reservation wage. This effect was confirmed by the empirical analysis, which showed a substantially higher outflow of owners into jobs located in their region of residence. Oswald's thesis was therefore rejected, and this conclusion has been replicated in work for the UK and the Netherlands. These studies find that residential mobility related to accepting a job after a period of unemployment of renters as well as owners is so low that it is questionable whether it can have a significant impact on unemployment rates.

The differences in acceptance of jobs without moving are much more important, and apart from the lower reservation wages that are suggested by the standard search model, they could also be explained by a more intense search effort of owners or differences in the acceptance of long commutes. It is indeed well known that owners have on average longer commutes than renters. However all these explanations fail to make comprehensible the higher overall exit rate from unemployment among homeowners as was pointed out by Van Vuuren (2008). The reason is that the greater effort of owners to find a job on the local labor market is induced by their higher mobility cost, and in economic models such compensating reactions are typically partial. This implies that they predict that overall unemployment spells of homeowners must still be longer than those of renters, whereas the data show the opposite.

Flatau et al. (2003) have found partial confirmation for Oswald's thesis in Australian data: outright owners have longer unemployment spells than otherwise comparable renters. However, they also find that highly leveraged homeowners have shorter unemployment spells and since their number is larger, the net impact of homeownership on unemployment is still negative as in Munch et al. (2006). Recent work, carried out in collaboration with Yuval Kantor and Peter Nijkamp, shows that these findings can be rationalized by a standard search model in which searchers are risk averse if the mortgage payments are larger than the rents and confirmed the strong effects of mortgage payments and also rent subsidies on labor market behavior. In earlier work with Peter Nijkamp, this was shown to be the case for many Dutch households. We also found that highly leveraged homeowners accept long commutes more frequently than others.

The significance of these findings is that they suggest a closer relationship between labor and housing markets than the spatial connection via commutes – however important that is – suggests. In countries with mortgage interest deductibility, many homeowners are highly leveraged, and if this improves their labor market functioning significantly, this should be taken into account when evaluating this measure. At a more general level, Decreuse and Van Ypersele (2011) have recently argued that there is empirically a close connection between housing market regulation and job protection measures.

5.7 Conclusions

This chapter discussed some aspects of the relations between labor and housing markets while focusing on the role of space. Although transportation costs have decreased enormously and information and communication technologies that facilitate cheap and fast interaction between people at different locations have become widely available, the face-to-face interactions with colleagues and clients and suppliers of intermediaries and inputs that often take place at employment locations remain important. Commutes therefore still provide a necessary link between housing and labor market, and there seems to be no reason to expect this to be different in the future although the details of the relationship may change.

This chapter has been limited in the choice of the topics and the literature that is referenced. Although it makes no claim for complete coverage, it hopes to have addressed a number of relevant issues (see Rouwendal and Nijkamp (2004) for an alternative survey). The reader is referred to the other chapters in this *handbook* for discussion of related issues, and the literature that has been cited here contains many references to other papers that help the interested reader to find the relevant literature on topics that could not be addressed here.

Appendix Computation of the Reservation Wage

To see how the equilibrium can be found, start with the simple situation in which there is only one employment center ($N=1$). When the wage offered there is high enough to let the net income at the searcher's residential location exceed the unemployment benefit, the reservation wage will be lower than the net wage offered, and the searcher will always accept a job offer. When there are two or more employment centers, the optimal acceptance set can be determined by the following simple procedure: determine the subset of employment centers whose job offers imply a net wage at x that is at least equal to the unemployment benefit. If it is nonempty, start with an acceptance set that contains only the employment center that offers the highest net wage at x and compute a preliminary reservation wage from the above equation using this acceptance set. Compare this reservation wage with the highest net wage offered by a center that is not yet in the acceptance set. If this wage is higher than the preliminary reservation wage, add this center to the acceptance set. Recompute the reservation wage and repeat this procedure until no employment center fulfills the entrance condition or no employment centers with a net wage at x exceeding the unemployment benefit is left.

Abstract

Spatial mismatch relates the unemployment and poverty of vulnerable population groups to their remoteness from job opportunities. Although the intuition initially applied to African Americans in US inner cities, spatial mismatch has a broader validity beyond the sole US context. In light of a detailed presentation of the mechanisms at work, we present the main results from various empirical tests of the spatial mismatch theory. Since key aspects of that theory remain to be tested, we also discuss methodological approaches and provide guidance for further research. We derive lessons for policy implications and comment on the appropriateness of related urban policies.

6.1 Introduction

Spatial mismatch is a topic and a theory that relates unemployment and poverty to the structure of cities. It covers a variety of situations according to which the residents of poor neighborhoods are adversely affected by their physical disconnection from places where jobs are located. The focus is thus essentially on large urban areas where such disconnections are likely to be found. Having emerged in the 1960s in the context of racially segregated US cities, the initial intuition quickly became a key topic in urban economics and remained one for more than half a century. Its relevance is now apparent in several other contexts, including for cities of European countries and sprawling metropolitan areas in Asia, Africa, and Latin America.

The spatial mismatch hypothesis was originally formulated by economist John Kain with an initial and exclusive focus on the African American poor in inner cities. The genesis of the hypothesis is rooted in the history of US cities, where, as early as in the 1940s, urban jobs that were initially concentrated in city centers had begun to decentralize to more peripheral locations. This movement went along with the rapid expansion of middle- and upper-class residential suburbs almost exclusively populated by white households. At the same time, the bulk of African Americans were maintaining their residences in city centers, a situation which the author of the spatial mismatch hypothesis attributed to housing market discrimination against blacks that prevented them from suburbanizing to the same extent as whites. The combination of these two trends caused the emergence of the typical US city structure where blacks live far away from the job offers corresponding to their skill levels and that they could apply to. Kain (1968) was the first to hypothesize that the disconnection between places of residence and places of employment could be a key contributor to the high unemployment, low wages, and poverty in the black ghettos of central cities.

A very abundant literature followed Kain's seminal paper for more than four decades and variants were expressed. One noticeable change in focus was the role of race in the "workings" of spatial mismatch. By assuming residential segregation against blacks, the initial spatial mismatch hypothesis clearly put race on the agenda but limited its role to a factor explaining residential immobility. It thus presented race only as a cause of spatial mismatch. After two decades of empirical work, however, whether blacks were really disconnected from or affected by distance to job opportunities became the center of a controversy as a study on Chicago concluded to the opposite and suggested that *race* rather than *space* was in fact the main determinant of the bad labor market outcomes of blacks in inner cities (Ellwood 1986). Following this study, whether spatial mismatch was a relevant explanation of black labor market outcomes polarized the debate for several years in spite of an increasing number of sources documenting the physical disconnection of blacks from jobs (and likely from job opportunities) and although subsequent empirical papers, including on Chicago, were finding that spatial mismatch did play a key role in black unemployment. The opposition between the race and space arguments then gradually disappeared from the literature.

Most contributions to the literature on spatial mismatch are empirical papers that try to assess a link between the disconnection from jobs and bad labor market outcomes (see Ihlanfeldt and Sjoquist 1998 and Gobillon et al. 2007 for extensive surveys). In this literature, the main challenge throughout has been to establish causality and to isolate the contribution of spatial mismatch to labor market outcomes from other spatial and nonspatial explanatory factors. Although some authors have looked at the effect on wages and labor market participation, most papers focus on unemployment so that it is probably not exaggerated to present spatial mismatch as mainly a spatial theory of unemployment. Surprisingly, however – and this is probably one of the few examples in the history of economic theory – it is only starting in the late 1990s, this is to say *after* the publication of many empirical papers on the topic, that the theoretical works on spatial mismatch began to emerge. The publication of spatial mismatch models gave the initial hypothesis the status of a fully fledged theory rather than being just an intuition. These models typically shed light on (a) the *causes* of spatial mismatch, i.e., on why blacks in US cities live in areas that are physically distant from jobs – and in some cases proposing alternative explanations to housing market discrimination – and on (b) the *consequences* of spatial mismatch, shedding light on several competing mechanisms to explain how physical disconnection from jobs can affect the labor market outcomes of black workers. These models provided an analytical framework to think about spatial mismatch. By formalizing the diversity of potential mechanisms, they also provided a sound basis to derive the policy implications associated with the different mechanisms. Models of spatial mismatch also helped clarify several of the drawbacks and misunderstandings regarding the scope and interpretation of related empirical work. These models for instance provided interesting insights on what the counterfactual of spatial mismatch should be and implications for empirical tests: Should one compare the outcomes of black and white subgroups exposed to different levels of disconnection from jobs? Or should the test focus instead on an estimation of what the outcomes of black inner-city unemployment would be under a less intense disconnection from jobs? Theory also helped discard a number of inadequate tests, for instance, the idea that short commutes provide an interpretable indication regarding the level of spatial mismatch (as short commutes may indicate both neighborhood proximity to or remoteness from jobs if the only jobs that remain accessible are the local ones). Spatial mismatch models also paved the way for refined empirical tests of specific spatial mismatch mechanisms.

Over the past decade, new directions in the spatial mismatch literature have also emerged.

Some authors have argued that race and space, rather than being alternative explanations of black unemployment, may *combine* to explain the harmful effects of spatial mismatch. The interaction between race and space may probably reflect several mechanisms, not all of which are clearly spelled out at present. One underlying assumption is that blacks are not affected by distance to jobs in the same way as whites. Another underlying assumption is that proximity to particular types of low-skill jobs may matter. The reason why this should be the case is the subject of recent research and illustrates the tendency of the literature to move

toward the elicitation and exploration of finer and subtler mechanisms. Some works have also focused on other minority groups (e.g., Hispanics and Asians in US cities) as well as on women. These studies raise interesting research questions on whether and why different groups could be differently affected by spatial mismatch. Are some groups simply less exposed to spatial mismatch or to the effects of spatial mismatch? In other words, do some groups reside closer to jobs or are they simply less affected by distance from job opportunities all things else equal? Are there particular mechanisms that are more relevant for some groups than for others – and why should this be the case? The gender approach to spatial mismatch also raises challenging questions as the location choices of women may be more constrained than those of men and given other gender specificities with regard to more complex commuting patterns, labor market participation, or time schedules (which may also depend on the life cycle of individuals, with activities such as picking up children from school being specific to relatively young individuals). There is also an increasing number of attempts to study spatial mismatch in non-US contexts, especially in European cities (which exhibit spatial structures that differ markedly from US cities) and in developing countries where lack of control over rapid urbanization often results in severe urban sprawl.

Finally, the various analyses of spatial mismatch lead to a diversity of policy implications. Depending on the context and mechanisms potentially at play, policy makers may consider options as diverse as the adoption and implementation of antidiscriminatory laws, the facilitation of residential mobility, neighborhood regeneration policies (in particular through the setup of enterprise zones designed to attract jobs), the development or subsidization of public and private transport, or the spatial dissemination of information on jobs.

In what follows, we present the main theory, empirics, and policy issues surrounding spatial mismatch.

6.2 The Theory of Spatial Mismatch

“Understanding” spatial mismatch requires a focus not only on the labor market mechanisms leading to unemployment, low wages, and poverty but also on what causes ethnic minorities to be physically disconnected from jobs in the first place. Several complementary explanations that can be replaced in a historical perspective have been put forward. They revolve around the (re)location of firms to the suburbs and the reasons why blacks did not move closer to suburban jobs.

The structure of US cities has evolved over the second half of the twentieth century with the emergence of faster and cheaper means of transport for people and goods. A large fraction of middle- and upper-class white workers were able to move to the suburbs to consume more land and build larger houses, as they could commute to inner-city jobs by tramway, train, bus, and, for many, by car. Lower transport costs (resulting from innovations in transportation) also allowed manufacturing firms to relocate to the suburbs to avoid high land prices in the central business district. While many white workers relocated closer to their jobs to

incur shorter commutes while able to increase their housing consumption, the vast majority of blacks did not follow.

When US cities began to decentralize, relocating to the suburbs was an option that was mainly attractive for manufacturing firms as they usually needed a fair amount of land to operate and land was cheaper in the suburbs. The usual agglomeration forces highlighted by economic geography were also at play. As suburban manufacturing activity grew, it fostered the location of firms producing intermediary inputs so as to facilitate the input–output linkage. Services firms providing services to other firms as well as to workers (e.g., convenience services for local households) also followed. More generally, the creation and relocation of firms was also facilitated by the existence of the labor pool consisting of workers located in newly created residential areas. Some firms were attracted to the suburbs by the prospect of benefiting from newly adopted innovations, while others were driven away from city centers because the intensive use of private vehicles had caused congestion problems and because the relocation of firms employing low-skilled labor out of popular neighborhoods had increased the level of unemployment, poverty, and consequently criminality in inner cities. Even firms which had chosen to remain centralized later tended to relocate when criminality reached a tipping point. This “flight from blight” further reinforced the cumulative process of suburbanization.

The explanation initially provided by Kain for blacks not relocating to the suburbs was that blacks faced racial discrimination in the housing market, causing the residential separation of blacks from whites and, indirectly, from suburban jobs. Housing discrimination was indeed certainly a powerful force that shaped US cities in the 1960s when the intuition of spatial mismatch theory emerged and has remained an important driver of segregation. The prevalence of housing discrimination in US cities was unambiguously demonstrated through controlled experiments that assessed the lower number of houses shown by real estate agents to black clients in comparison to the number of houses shown to white clients with similar socioeconomic background (see Yinger 1986). Other studies stressed that discriminatory practices may in fact occur at different stages of the residential mobility process, including during house hunting, borrowing (for those acquiring a home), and rental lease agreement or contract settlement. Mortgage and credit institutions in particular could be applying stricter lending criteria to minorities, constraining their location choices and making their suburbanization more difficult (Ross and Yinger 2002). Interestingly, there can be various motivations underpinning these discriminatory practices, ranging from sheer prejudice (which includes so-called customer discrimination by real estate agents who believe that selling houses to blacks will make the neighborhood less attractive to future white customers) to statistical discrimination from lenders (whereby minority members are expected to have a higher default rate on average).

It is important to understand that although housing market discrimination was initially presented as a key element of the spatial mismatch hypothesis, it is not needed at all to account for the physical disconnection of minorities from jobs. In fact, spatial mismatch can also occur under free location choices according to a variety of mechanisms. In standard land use models in urban economics,

households compete for land, and spatial sorting according to income is a spontaneous equilibrium outcome: As heterogeneous income groups make different trade-offs between proximity to job centers and housing consumption (land being endogenously cheaper further away from places of employment), this may cause the poor – and for historical reasons the minority groups – to live further away from jobs. Separation from jobs may also occur because of the spatial sorting of households in homogenous jurisdictions: As whites and blacks may have different preferences for public goods, they could end up segregating themselves from one another by voting with their feet. This can result in blacks living in inner cities while whites reside in the suburbs where many entry-level jobs are located. Finally, some authors have also put forward (and empirically assessed) the preferences of ethnic groups to live together. This encompasses both mechanisms of white flight (whites seceding from mixed neighborhoods) as well as ethnic clustering of minorities who may want to live together (Ihlanfeldt and Scafidi 2002), even at a distance from jobs.

A number of policies and regulations may also have voluntarily or involuntarily contributed to the disconnection of minorities from jobs. This includes the implementation of most housing projects in city centers (where minorities already live) and in places where land prices are cheaper and that are thus likely to be distant from jobs (Kain 1992). Local zoning regulations in the suburbs may also impose stringent minimum requirements for dwellings as in particular minimum lot sizes, with the implicit objective to prevent an inflow of poorer households to these areas by making housing too expensive for them (Squires 1996). For fear of crime, residents in suburban areas often oppose public transport extensions linking poor areas to their neighborhoods of residence. This further contributes to isolating inner-city minorities from suburban jobs.

There are at least five theoretical mechanisms that can make the distance to job opportunities harmful, especially for ethnic minorities (see Gobillon et al. 2007 for a full description of the corresponding models).

Mechanism 1. The first mechanism relies on *commuting costs* associated with job offers. When a worker receives an offer for a job located far from his place of residence, he anticipates that he will have to incur daily commuting costs if he accepts the offer. These costs can be important enough to outweigh the benefits from even a well-paid suburban job, in which case the worker will turn down the offer. He may prefer to remain unemployed or occupy a lower-wage job which is located closer to his place of residence. This mechanism is particularly relevant for ethnic groups which are not wealthy enough to purchase a car and to pay for its insurance and maintenance and who thus have no other choice than to rely on inefficient public transport.

Mechanism 2. Distance to jobs can also be harmful to workers because it decreases their *job search efficiency*. When searching for a job, a worker may have very little information on which places have suitable job offers and may end up looking for a job in the wrong locations. For low-skill services jobs in particular, the recruiting methods of employers are often local (e.g., ads in local newspapers and “wanted” signs), which may further reduce the information that applicants have on distant job offers.

Mechanism 3. Another mechanism revolves around the idea that *job search costs* can be large and may deter workers from looking for a job in places that are distant from their residence. Job seekers may restrict their search to their neighborhood or its vicinity even if job opportunities in those places are scarce. This is particularly true for workers who do not have a car and depend on inefficient public transports to search for a job in distant places.

Mechanism 4. Workers who reside in areas that are far from job centers and where housing is more affordable may have less incentive to actively look for a job. As a consequence, they may not exert much *job search effort*. Since their housing expenses are lower, they can afford to remain unemployed for a longer period of time than households living in less affordable areas that are closer to jobs. On the contrary, unemployed workers living in areas where rents are expensive may feel more pressured to intensively search for a job in order to avoid having to move out.

Mechanism 5. Finally, employers may consider that long commutes deteriorate the *productivity of workers* and may decide not to hire workers who reside too far from the workplace. The reason why productivity may be deteriorated by distance is that distant workers are more likely to be late or tired. This is particularly true for workers located in poor suburbs that do not have a car and use unreliable mass transit.

Several comments can be made about these mechanisms. Interestingly, the consequences of spatial mismatch do not percolate through mechanisms that directly involve ethnicity but rather through the residential location of ethnic minorities within metropolitan areas. In fact, these general mechanisms may in theory apply to any worker who is distant from job opportunities, irrespective of ethnicity. Of course, it does not mean that race does not play a role at all as discussed in the previous subsection on the causes of spatial mismatch. In fact, race can and does play a key role in several respects. First, spatial mismatch can add up to other mechanisms that prevent the employment of minorities in the suburbs such as customer discrimination in fast food restaurants (see Ihlanfeldt and Young 1996) and more generally in suburban services jobs that require contact between clients and employees. The idea here is that, when filling those jobs, employers discriminate against minorities to satisfy the racial preferences of their customers. In this context, residential segregation leads to labor market discrimination (although it should be noted that this involves more the *disconnection* between the neighborhoods than the *distance* between the neighborhoods). This in turn shuts off the access of many suburban jobs to black applicants. Second, spatial mismatch may be all the more relevant in situations of ethnic discrimination in the labor market. The idea is that when minorities are discriminated against, they become more dependent on physical proximity to job opportunities to find jobs (Selod and Zenou 2006). It is also noticeable that these spatial mismatch mechanisms can play at different stages of the job match process and involve both the workers' perspective (for the first four mechanisms) and the firms' perspective (for the fifth mechanism). Finally, even though the spatial mismatch theory focuses on the effect of distance and not on the effect of other neighborhood or group characteristics on labor market outcomes, the

above five mechanisms can also indirectly be amplified by local or group interactions. For example, distance to jobs can have a direct negative effect on workers employment through either one of the five above mechanism, but also indirectly through a feedback process involving localized social network. When most individuals in a location are harmed by distance and are more likely to be unemployed, the local social network is of bad quality, implying that neighbors cannot be used as referrals to potential employers.

6.3 The Empirical Tests of Spatial Mismatch

During the first decades during which the spatial mismatch literature unfolded, most empirical studies aimed to provide some *general test* of the spatial mismatch theory for US cities by assessing whether differences in labor market outcomes between blacks and whites could be related to differences in physical disconnection from jobs. Although establishing causality was usually not done properly, more convincing empirical tests have been proposed over time. Three main strategies have emerged:

- (a) The first strategy is to *instrument the disconnection from jobs with specific local variables* related to local development or industrial composition. This makes it possible to consider only exogenous sources of variations in disconnection from jobs to measure its effect on labor market outcomes. Adopting this strategy, Weinberg (2000) for instance studies the effect of the relative centralization of blacks compared to whites on the black-white employment differential for young workers in large US metropolitan areas. The centralization of blacks is instrumented with historical features of the housing stock and past black centralization. It is found after instrumentation that the larger centralization of blacks relative to whites accounts for around half of the black-white employment differential. Alternatively, Weinberg (2004) focuses on the effect of job decentralization on the black-white employment differential and instruments job decentralization with the city industry composition. Job decentralization is shown to have a negative effect on the employment of blacks relative to whites.
- (b) Secondly, *natural or controlled experiments* can also help address the reverse causality issue (i.e., the fact that it could be the adverse labor market outcomes that cause minority workers to live far from jobs). The idea is to find a subpopulation of workers whose place of residence was determined irrespectively of proximity to job locations. Several papers restrict their analysis to young adults residing with their parents as they have not chosen their location. However, this approach is imperfect as the unobserved characteristics of these young adults may be correlated with those of their parents and therefore be related to residential location. Alternatively, some housing policy measures may in fact render the location of a targeted subpopulation exogenous. To our knowledge, no such experiment has been studied in the USA but some European countries provide a relatively adequate background. In France, for instance, one may choose to restrict the analysis to workers in the housing

public sector considering that applicants cannot choose the precise location of their dwelling which is attributed by public authorities. However, this remains an imperfect strategy given that, in practice, applicants are given the option to decline housing offers and wait for more suitable ones, at least in the beginning of the process. This obviously makes room for some degree of residential choice as a function of local job availability. In Sweden, the spatial allocation process of political refugees in the 1990s provides an interesting and robust framework to study spatial mismatch (Aslund et al. 2010). In the Swedish context, political refugees were indeed dispatched throughout the territory based only on their observed characteristics in applications. This was done without any interaction with public officers, thus making it possible to evaluate the causal effect of job density in the refugees' areas of residence on employment. In the paper, the econometric specifications take into account the observable characteristics that are reported in applications so as to neutralize the possible effect of sorting across space. The results support the role of the disconnection from jobs on employment.

- (c) A third and last approach consists in conducting a *sensitivity analysis* by simulating the extent to which the location choice may be endogenous (Harding 2003; Dujardin et al. 2008). This makes it possible to deal with the endogeneity bias in studies that try to relate the unemployment status of an individual to a neighborhood dummy (which can capture distance from jobs). There is an endogeneity bias if some unobserved individual characteristics affect both the unemployment status and the location dummy. One way to overcome this issue is to simultaneously model the location choice and find an exclusion restriction to identify the effect of location on unemployment. This exclusion restriction consists in having one individual variable explaining the location but having no direct effect on unemployment. However, such an exclusion restriction is hard to find. This problem can be overcome in a sensitivity analysis where one can arbitrarily fix the correlation between the residuals of the unemployment and location equations to a given level and reestimate the model. The results are considered to be robust if the estimated effect of residence on unemployment remains significant for all plausible values of the correlation between residuals.

A few other empirical works have tried to *test some of the five specific mechanisms* whereby distance to job opportunities can affect the labor market outcomes of minorities.

The most famous empirical study is a test of Mechanism 1 above which addresses the role of changing commuting costs following the relocation of a Detroit firm from the city center to a white suburb (Zax and Kain 1996). Whereas whites tended to move closer to the new firm location, it was less often the case of black employees, possibly because of housing discrimination. Following the relocation, the increase in African Americans' commuting distance also induced many of them to quit their job.

Other papers tried to assess the importance of search costs and of lack of information on job opportunities on the bad labor market outcomes of blacks (Mechanisms 2 and 3), although it is usually not possible to distinguish clearly

between the two explanations. For instance, Holzer and Reaser (2000) investigate the application of blacks and whites to jobs in the suburbs using a survey on several metropolitan areas. They find that less-educated black workers apply less frequently for jobs in the suburbs than in the central cities. Evidence provided by Stoll (1999) further shows that increasing blacks' access to cars or decreasing their average distance to search areas would lead them to conduct a more extensive geographical job search.

To our knowledge, Mechanisms 4 and 5 remain largely unexplored by the empirical literature.

Several authors have started investigating whether spatial mismatch could also be of concern for other subgroups of the US urban population. Raphael and Stoll (2001) for instance show that spatial mismatch also contributes to the unemployment of Hispanics and Asians but to a lesser extent than for African Americans. Differences in the vulnerability of the different groups to spatial mismatch point to possible variations across ethnic groups in the level of housing discrimination, in residential location, in access to private and public transports, and in skills (with low-skilled workers more likely to be affected by spatial mismatch). The literature however has not explored the underlying mechanisms so that more detailed studies will be necessary to validate these potential explanations.

While most studies focus on males, recent developments in the spatial mismatch literature have also begun investigating the gender relevance of the theory. Emphasis is put on the residential and workplace location choices of women in multi-person households (which can be tied to those of males or constrained by the presence of children) and on the complexity of the commuting patterns of women which may involve trips to various places such as schools and shops (Blumenberg 2004). This adds complexity to Mechanism 1 above as it is the whole itinerary that is now taken into account in the search and acceptance of job offers, especially for single mothers without cars. To carry out further the analysis, future research could be devoted to studying female spatial mismatch taking into account intra-family decisions (possibly at different stages of the life cycle) and complex itineraries using detailed data on transport patterns.

An important opening of the spatial mismatch literature over the last decade has been to test its validity in several cities outside the USA. Although the historical context and spatial settings in these cities are very different from the USA, this does not preclude a test of the mechanisms. In Europe for instance, urban spatial structure is somehow inverted: Many low-skill jobs tend to be located in relatively central parts of the cities, whereas minorities are residentially concentrated in some relatively peripheral areas. Evidence for these cities, however, is mixed. Among the supportive papers, we already mentioned Aslund et al. (2010) which shows that, in Sweden, the job densities in the places where political refugees are exogenously assigned play a significant positive role on their employment. In greater London, Fieldhouse (1999) finds that employment is correlated with job density for a few ethnic groups, namely, the Pakistani and the Bangladeshi. For Madrid and Barcelona, Matas et al. (2010) show that low job accessibility in public transport negatively affects employment probability. For Paris and Brussels, papers show

that the spatial mismatch hypothesis is not really an issue. Gobillon et al. (2011) find that job density within 45 min by public or private transport is not correlated with finding a job for unemployed workers. Surprisingly, Dujardin et al. (2008) even find a positive correlation between job density and the probability of unemployment. In fact, the evidence in these papers points to vulnerable groups not being largely disconnected from jobs and to segregation effects (in terms of nationality or skill) that are believed to be more problematic than spatial mismatch.

Besides the USA and Europe, there are also many indications of vulnerable groups being physically disconnected from jobs in many other regions of the world, in Latin America, Africa, and Asia (see for instance Sang et al. 2011 on China). In South Africa, this is evidenced by very long and costly commutes. In Johannesburg for instance, the average commute is around 80 min one way, and a national household survey shows that commuters in the poorest income bracket spend about 35 % of their earnings on commuting. Unfortunately and probably due to lack of adequate data, very few studies exist on the effect of physical disconnection to jobs on labor market outcomes in developing countries. South African cities stand as an exception where research suggests a negative impact of distance to jobs on the employment of township residents (Rospabé and Selod 2006).

6.4 Local Policies to Reduce Poverty

After five decades of investigations, the abundant literature on spatial mismatch has shed convincing light on both the causes and consequences of spatial mismatch. Evidence of market failures in both housing and labor markets provides a justification for policy intervention. To categorize the diversity of policy responses in the US case, Ilhanfeldt and Sjoquist (1998) have come up with a useful typology: moving people closer to jobs (desegregation strategy), moving jobs closer to workers (inner-city development strategy), and making it easier for workers to get to existing jobs (strategy of promoting mobility and disseminating information on jobs).

Moving people to jobs is a straightforward recommendation in contexts of constrained mobility. A simple way to address housing, mortgage, and credit markets discrimination is to enforce antidiscrimination policies through the legal system.

Existing public policies could also be modified to facilitate the access of minorities to suburban neighborhoods. In particular, public dwellings could be constructed in predominantly white suburbs with greater job densities. But the policy could prove inefficient in the long run as whites and jobs may respond to the influx of minorities by deciding to move out of these suburbs. The policy would then result in the creation of new deprived neighborhoods out of city centers that may not necessarily be better connected to jobs. Other policy measures could consist in suppressing or forbidding zoning regulations that impose minimum lot sizes in suburbs. This would not necessarily be sufficient though if the constraint is not binding, with developers still targeting rich populations in priority by constructing only large high-quality dwellings.

Another option is to subsidize residential mobility through the granting of rental vouchers (as, e.g., in the Gautreaux program in Chicago 1976–1990 and the Moving to Opportunity program in Baltimore, Chicago, Boston, Los Angeles, and New York 1994–1999). Originally, these experimental programs were meant to facilitate the moving of households out of poor and segregated areas. In particular, a condition to benefit from vouchers in the Moving to Opportunity program was to relocate to a low-poverty neighborhood. However, there has been no assessment of whether these programs helped households get closer to jobs. Whether or not this happened, an assessment of the Moving to Opportunity program shows that it did not lead to a significant improvement of labor market outcomes (Katz et al. 2001). If a similar program were meant to reduce the physical disconnection to jobs, it would need to grant vouchers to households under the condition that they relocate closer to jobs, and the efficiency of such a program would still have to be evaluated. Even if an experimental program had desirable effects at a small scale, it would be difficult to scale it up and a scaled-up policy would probably not be as successful given a general equilibrium effect whereby vouchers could simply end up being capitalized in the housing prices of neighborhoods located close to jobs.

Moving jobs to people has been pursued in a multiplicity of contexts. Inspired from export processing zones, enterprise zones are meant to attract firms in distressed and low job density areas through the provision of fiscal incentives. A key issue is whether jobs in the attracted firms substitute for other local jobs or if the policy is not just displacing jobs between neighboring areas. The effect of the policy may also be limited if local unemployed workers do not have the required skills or if the targeted residential areas simply do not have sufficient space for office development. It transpires from the literature that the evidence on the efficiency of such policies is rather mixed. One drawback of the related studies is that they often focus on the number of firms and gross employment creation rather than on the local level of employment and local poverty in the targeted areas. Nevertheless, there is some evidence in the US case of a significant decrease in unemployment and poverty related to the introduction of the federal Empowerment Zone program. For France, the introduction of the French enterprise zone program has been shown to have only a small positive effect on finding a job for unemployed workers located in the Paris region. Maybe the creation of jobs adapted to workers' skills could be encouraged by providing tax incentives only to firms in some specific activity branches or for specific jobs. This kind of targeting is usually not implemented in the existing enterprise zone programs. Other place-based policies designed to attract firms include measures to decrease criminality as it can affect firm productivity through vandalism and violence of which employees may be victims. Other policies also include investments in transport infrastructures such as connections to highways that can decrease the transport cost of goods.

Improving connections between people and jobs may seem easier than the above-mentioned options. Improving transport will decrease commuting and search costs and increase the search efficiency and productivity of workers (Mechanisms 1, 2, 3, and 5). This can be achieved through improvements in public transport (adding train and subway stations, increasing transport frequency, or subsidizing fares).

In the USA and other places, this would effectively target minorities who tend to have a lower access to cars and use public transit. However, the extension of the public rail network from the city center to the suburbs may be hindered by the opposition of suburbanites by fear of displacement of criminality. Moreover, public transport improvements may also have some drawbacks: The creation of a new station is likely to cause a local increase in housing prices which could in turn induce renters to move away to further locations. It is also hard to improve connections throughout the city for trains and tramways as it could require massive investments. Adding bus stations and increasing bus frequencies should be less costly, but buses are affected by traffic jams. A better access to private transport could also be achieved with the provision of vouchers to purchase motor vehicles. However, increasing the access to private transport should increase the overall traffic and congestion. Moreover, improved accessibility may paradoxically provide little incentive for poor households to move to better locations and may consequently reinforce segregation.

Beyond transport policies, facilitating the circulation of information flows between firm and workers can also help overcome the information hurdles associated with physical distance. Disseminating the information on the spatial distribution of job openings can greatly help job seekers apply to right places. Improving the flow of information can be achieved by creating local employment agencies in poor neighborhoods where they are missing and by better targeting the informational needs of unemployed workers regarding job offers. In particular, local employment centers could organize meetings with suburban businesses to give an opportunity to unemployed workers to meet with potential employers face to face (Ihlanfeldt and Sjoquist 1998).

6.5 Conclusions

Since the end of the 1960s, a large literature has focused on the contribution of spatial mismatch to the bad labor market outcomes of ethnic minorities. The importance of this contribution can be assessed in contrast to alternative explanations. With the benefit of hindsight, we derive three principal lessons from our review.

First, spatial mismatch refers to mechanisms that can apply in many different contexts and it should not be considered as a topic that may be valid only to explain the poverty of African Americans in US inner cities. There are many indications (and in some cases scientifically determined evidence) that vulnerable populations in the USA and elsewhere are affected by similar problems of disconnection between places of residence and places of employment.

Second, although spatial mismatch is a spatial theory of local unemployment, it should be clear that other spatial mechanisms may also contribute to poor labor market outcomes in poor areas. As a matter of fact, residential segregation constitutes a competing spatial explanation to the unemployment of ethnic minorities through a variety of mechanisms (e.g., the existence of local peer effects on

employability, deteriorated information networks on jobs, and discriminating employers using neighborhood composition to infer information and employability). In the current state of research, it is not clear however whether it is spatial mismatch or segregation that contributes the most. In some contexts, only one or the other may play a role. In other contexts, they probably combine and amplify one another. What is established however is that spatial factors largely contribute to and are probably among the main factors explaining economic and social outcomes and in particular local poverty.

Third, there are also important nonspatial factors at play (e.g., sheer labor market discrimination or skill bias) that can explain the unemployment of vulnerable groups. A direct implication is that policies addressing such nonspatial factors may also have an effect by locally alleviating unemployment. Another implication is that place-based policies will, of course, not suffice to solve the unemployment problems of ethnic minorities. In this context, an important challenge for policy makers is probably to find the right policy mix that is needed between spatial and nonspatial policies.

Acknowledgments We would like to thank all our respective coauthors on our work on spatial mismatch for the many interesting discussions that helped us better understand the topic. Readers may find additional insights on the topic by reading the chapters on ► [Chap. 3, “Labor Market Theory and Models,”](#) ► [Chap. 4, “Job Search Theory,”](#) and ► [Chap. 5, “Commuting, Housing, and Labor Markets,”](#) in the present edition of the Handbook of Regional Science. Abstract

A prominent theme in the socioeconomic and regional science literature has been the topic of unemployment. We focus on *regional unemployment* and put forward candidate series of explanations for it using a basic model of labor supply and demand. The persistence of regional unemployment differentials points to inefficiencies in labor markets that in the long run could affect aggregate unemployment rates. Both a lack of labor demand and a constraint of labor supply increase regional unemployment. We finally discuss people- and place-based policies which aim to reduce high unemployment rates.

7.1 Introduction

Unemployment is a social, political, and economic plague that affects modern economies. It generally reduces national economic growth, increases inflation, favors the inequality of income distribution, and also carries important *human consequences*. People decide to be employed not only to earn income for living but also, to a certain extent, for nonpecuniary reasons. Individuals want to work to enjoy the feeling of doing something productive, of being needed, of reaching a certain social status, etc. Though unemployment increases leisure, the value of this may thus be wholly offset by the feeling of rejection, and the new status could have profound effects on both the mental and physical health of individuals. Further, from a labor market perspective, there is a risk that the unemployed lose some of the skills or human capital previously possessed, making it increasingly difficult for them to find employment in the future. Employers also tend to assume that those who have been out of the labor market for a long period are not as qualified or reliable as those who have been working more recently. This may result in a number of dissatisfied individuals that remain unproductive, which could ultimately decide to permanently leave the labor market, thereby affecting an economy's growth potential.

Unemployment rates vary considerably across regions. The persistency of regional unemployment differentials is a symptom of inefficiencies in labor market adjustments that in the long run could affect aggregate unemployment and total output. Understanding the determinants of spatial variation in unemployment is crucial for adopting the appropriate policy instruments able to reduce these disparities and limit the adverse effects of unemployment in economically depressed regions.

This chapter provides a review of the theoretical and empirical literature on regional employment and unemployment. In [Sect. 7.2](#) we discuss the causes of spatial differences in regional unemployment rates. [Section 7.3](#) sketches a simple model of supply and demand of labor. [Section 7.4](#) examines how a lack of labor demand and productivity shortfalls may limit regional employment. [Section 7.5](#) considers the effect of industry composition on unemployment disparities. [Section 7.6](#) analyzes how labor supply is constrained by human capital and skills,

demographic features, and a lack of mobility that limits movements to expanding regions. Section 7.7 discusses the effects of unemployment social insurance and place-based policies. The final section concludes.

7.2 The Determinants of Regional Disparities in Unemployment Rates

The nature and persistence of regional unemployment differentials have attracted growing scholarly attention since the late 1960s (see, for instance, Thirlwall 1966), giving rise to a large number of potential explanations for the existence of such disparities. These may be broadly ascribed to three categories: (i) “*labor supply*” factors, such as the composition of regional labor force in terms of age, gender, and ethnicity, or the average level of education attainment and skills possessed by individuals (these features affect the regional labor force participation behavior and workers decisions to migrate in search of better work opportunities); (ii) “*labor demand*” factors, which point at differences between goods markets as determinants of an uneven labor demand (within this type of explanation, all factors affecting location decisions by firms, such as the different regional specialization patterns or the economic influence played by surrounding, geographically contiguous regions, are also included); and (iii) “the *flexibility of wages*,” which may be reduced, for instance, by the existence of minimum wages or union activity. If labor markets were efficient, the adjusting forces of labor and capital mobility and changes in relative prices would eventually eliminate unemployment differentials between regions. On the other hand, while internal migration may act as an adjustment mechanism to reduce general unemployment dispersion, it also varies considerably across regions due to the existence of mobility barriers which may limit movements to expanding regions. The decision to move is indeed complex and affected by multiple factors such as personal attributes, cultural reasons, individual labor market situations, the high costs involved with moving, or the generosity of unemployment insurance.

From a theoretical perspective, two competing explanations account for the existence of unemployment differentials between regions (Marston 1985). The first one is that there is an equilibrium relationship of unemployment rates across areas. Workers migrate in search of better work opportunities until there is no further incentive to move because they feel somehow compensated (e.g., by local amenities and land endowments). Each region tends to its own *equilibrium unemployment* rate and the existence of persistent unemployment disparities between regions simply reflects the underlying preference of workers for some areas. Contrary to the equilibrium view, the *disequilibrium explanation* assumes that labor flows slowly between areas because of severe economic and social barriers restricting mobility, which generate persistent unemployment rate differentials between regions. The equilibrium interpretation has received empirical support from Marston (1985) – who finds that high unemployment rate areas are those with high wages, high unemployment insurance, and attractive amenities – and Partridge and Rickman (1997).

Over the years, the empirical relevance of the relative importance of these explanations has been scarce. This is probably because the equilibrium and disequilibrium views on long-term regional disparities are not mutually exclusive and a model allowing the conterminous testing of both theories is considered a near impossible task (Pehkonen and Tervo 1998). By contrast, the analysis has been more oriented toward identifying which determinants of the spatial variation in unemployment rates have been more important.

7.3 A Simple Model Based on Supply and Demand

In order to provide a framework for the analysis of the labor market, this paragraph sketches a basic *model of supply and demand* (Johnson and Layard 1986) that defines the equilibrium long-run unemployment rate at which the system would settle down if prices and wages were correctly foreseen. In this model (depicted in Fig. 7.1), at given real wage and labor force, only a fraction of the labor force (L) wants to work. If the market clears, unemployment is simply leisure, voluntarily chosen.

7.3.1 Labor Demand

Firms have the following aggregate production function with constant returns to scale:

$$Y = F(N, K) = Nf(k) \quad f' > 0, f'' < 0 \quad (7.1)$$

where Y is output, N is employment (= LE , size of employed labor force), K is capital, and $k = K/N$. The marginal productivity condition is

$$W = F_N(LE, K) \quad (7.2)$$

In the short run, capital is given (\bar{K}) so that labor is the only factor. Firms demand as much labor as it is necessary to equate the marginal productivity of labor to the real wage and the demand curve is downward sloping.

In the long run, if the real interest rate is fixed, the marginal productivity condition under constant returns to scale is:

$$W = f(k) - kf'(k) \quad (7.3)$$

and

$$r = f'(k) \quad (7.4)$$

If r is given, the demand price for labor depends on Eqs. (7.3) and (7.4).

Fig. 7.1 Supply and demand model of unemployment, market-clearing

7.3.2 Labor Supply

On the supply side, we assume that individuals differ in their taste for work, with some individuals becoming permanently unemployed and others remaining permanently employed. The supply of labor is determined within the context of an individual's work-leisure choice. Utility (U) depends on consumption (C) and hours of work (H). Individuals can choose between working a given number of hours per week (\bar{H}) and receiving a wage W , or not working at all ($H = 0$) without income ($Y = Y_0$). The i th person utility is given by:

$$U_i = U_i(C_i, H_i) \quad (7.5)$$

She is indifferent between working or not (i.e., unemployment) at a reservation wage W_i^* , so that:

$$U_i(W_i^*, \bar{H}) = U_i(Y_0, 0) \quad (7.6)$$

The individual maximizes utility given his budget constraint. The resulting supply decision will depend on his real wage (W) and other parameters of his budget constraint (Z):

$$E = E(W, Z) \quad (7.7)$$

where E is the employment rate, which is one minus the unemployment rate. The attractiveness of entering the labor market may depend on various factors such as, for instance, the tax system, the generosity, and the duration of unemployment benefits. For a given Z , the supply curve is a positive function of real wages and is

upward sloping (starting from the lowest W^*). In the absence of taxes and benefits, the equilibrium unemployment rate results from the intersection of the demand and supply curves and is equal to one minus the employment rate.

7.4 Changes in Labor Demand and Productivity

From a Keynesian perspective, *labor demand* is mainly constrained by the level of aggregate demand (the demand for labor is in fact considered a “derived demand”) and unemployment is a direct result of demand deficiencies in the product market. A reduction in demand for the region’s goods and services causes an inward shift of the labor demand curve that, in presence of sticky real wages, reduces the number of people actually employed while maintaining the number of those that wish to work. Basically, workers become (involuntarily) unemployed if the demand for firms’ output is not enough to induce employers to take on all the labor actually available for employment.

Shifts in regional labor demand may be caused by persistent *productivity changes*, which can vary across regions depending upon multiple factors, such as their industrial composition, investments in technology, or endowments of human and physical capital. When productivity decreases, labor demand may contract because wages cannot decrease (they are sticky), causing involuntary unemployment. A productivity slowdown may increase unemployment via two mechanisms acting on wages’ inertia: (a) workers’ wage aspirations do not readily adjust downward and (b) unions push for sudden higher wages.

7.5 Changes in Industry Composition

From the discussion above, it could be expected that the different *industrial mix* of regional economies is a crucial factor affecting labor demand and, hence, unemployment. The available empirical evidence is however controversial. There are some studies that consider the industrial composition a major explanation for divergent unemployment rates across areas. McGee (1985), for instance, argues that regions with a larger proportion of the labor force in industries with high (low) unemployment rates are considered more likely to have higher (lower) unemployment rates than the national average. Other research suggests instead that spatial differences in industrial composition account for little, if any, of the variation in unemployment rates across regions (Cheshire 1973; Taylor and Bradley 1983; Martin 1997). Martin (1997), for instance, finds that the same industry experiences different unemployment rates in different regions, with a strong tendency for unemployment to become equalized between industries within each area (because high unemployment industries exert a negative spillover effect on other industries in the area). Taylor and Bradley (1997) suggest that the effect of industry mix on unemployment disparities varies not only between regions but also between sectors. They find that Italian regions with a high proportion of workers in the

manufacturing sector tend to have lower unemployment rates, while having a high proportion of workers in the agricultural sector is particularly disadvantageous. The opposite is true for the UK, where the regions more heavily dependent on agriculture are those that have lower unemployment rates. High dependence on market services in UK regions is in turn correlated to substantially lower unemployment rates. On the whole, the observed heterogeneity in results suggests that large differences in employment performance among regions may not be explained exclusively in terms of disparities in industry composition. They probably depend also from other characteristics, such as the extent of innovative activity, the profitability of plants and firms, the degree of accessibility to product and factor markets, and the effects of agglomeration (dis)economies.

7.6 Labor Supply Constraints

7.6.1 Human Capital and Skills

The supply of labor depends on investments in *human capital* and *skills* attained by workers, which influence labor market attachment of the labor force. The different composition of regional population in terms of these factors, combined with a global skill-biased demand shift, may partly account for spatial variations in unemployment rates across regions.

The level of educational attainment within a region is one potential indicator of the stock of regional human capital and is a proxy for skills and matching success in local labor markets. Higher levels of education tend to be positively related to labor force participation rates and negatively related to unemployment rates (McGee 1985; Partridge and Rickman 1997). Employment rates of less-educated people are also much lower than those of the more educated. Less-educated people have a limited access to the labor market and are unlikely to find work even if there is an increase in labor demand, because they do not possess the skills, or are in some way unsuitable, for the jobs on offer. To give an example, the unemployment rate in the Euro area in 2007 was 9.3 % for those with lower secondary education, 6.4 % for those with upper secondary education, and 4.1 % for those with tertiary education.

In general, *unskilled* people have much higher *unemployment rates* than those with skills, which tend to be more selective and also demonstrate a preference for employed search. The *vulnerability of low skilled* may depend on different factors (Metcalf 1975): (i) they lack information; (ii) skilled workers have more firm-specific training and (in case of recession) employers tend to hoard skilled labor or, at least, decide to lay off the unskilled workers first; and (iii) they cannot compete with skilled workers for many jobs, while skilled workers are also able to perform unskilled jobs. In addition, due to new technologies and international competition, many countries have experienced a dramatic change in the structure of employment in recent years. This has shifted production/demand requirements toward workers with higher qualifications and higher skill levels, leading to a collapse of demand

for the unskilled. Consequently, regions hosting a high proportion of low-skilled workers may have seen their unemployment rates rise (Overman and Puga 2002).

Different migration patterns characterize individuals with different levels of educational attainments and abilities as the better educated, more skilled, and adaptable workers tend to be also the most geographically mobile (see, e.g., Courchene 1970; Pissarides and Wadsworth 1989; Martin 1997; Partridge and Rickman 1997). There are a number of potential explanations for such *self-selecting migration*: (i) skilled professional workers are more able to meet the costs of moving and also have better chances to receive assistance from employers to meet these costs; (ii) individuals with a higher level of human capital are more likely to migrate to obtain higher returns; (iii) low-skilled people may rely more on friends and families for support (e.g., transportation or child care), making it risky for them to move; and (iv) the psychological reluctance to moving may be lower for well-educated workers, especially if they pursued advanced studies away from their homes.

As suggested by Martin (1997), labor migration of the most educated-skilled-adaptable workers may perpetuate regional unemployment differentials by transforming temporary regional labor demand problems (or an unfavorable industrial composition) into long-term, region-specific, labor supply problems. The skills and benefits associated with enterprising workers may be lost to a region, and its skill base and work culture can become cumulatively less viable and less productive, which in turn may militate against employment growth and hence any substantial reduction in unemployment (Martin 1997: 246).

We want to stress that an increase in employment is not directly translated in a decrease of unemployment because the relationship is not one-to-one. Employment growth at the regional level may not reduce the regional unemployment rate because in-migrants may absorb all the new jobs leaving unemployment unaffected (Partridge and Rickman 1997). As suggested by Blanchard and Katz (1992), “trends in employment do not lead to trends in unemployment” (p. 29).

7.6.2 Demographic Factors

The labor supply is constrained by *demographic factors* like *age*, *gender*, and *ethnicity*, which influence the number of people available and willing to participate in paid employment. Changes in demographic features of labor supply may have considerable consequences for the wage structure and unemployment rates of sub-groups of workers. Assuming flexible wages and unchanged labor demand, an increase (decrease) in the relative supply of a specific type of worker results in a lower (higher) wage relative to other types of workers. If, however, employers do not regard workers from various groups as good substitutes for one another and wage rigidities occur (at least in the short run), this may result in a mismatch between unemployed workers and available jobs (i.e., an increase of structural unemployment). On the whole, when some demographic groups register above-average unemployment rates, the aggregate unemployment rate increases (because

the overall rate is a weighted average of the rates of all groups). Regional differences in (un)employment may therefore be driven by regional differences in the composition of the labor supply and participation trends.

7.6.2.1 Age and Gender Differences

If we look at the characteristics of the different demographic groups, on average *young people* are more likely to be unemployed than older people; they enter/exit the labor force more often than adult men and exhibit weaker job and labor force attachment (McGee 1985). This is possibly explained by the fact that they lack skills and experience with respect to older workers. In most countries, they also work in different sectors from adults with a tendency to find more occupations in the retail, hotel, and restaurant industries rather than in education, utilities, or the public administration. Their successful transition into the working world varies considerably by education attainment in every country, with higher unemployment rates for those with the least education. Similarly, the labor market participation of the elderly tends to be very low. On the whole, however, the empirical literature suggests that regions with an older population register lower unemployment rates, while the opposite occurs when there is a large proportion of young labor force.

Turning to *gender differences*, women have often a limited access to the labor market, though there are cross-national differences. In the European Union, for instance, participation and *employment rates* are substantially higher for males than for females in all age groups. The causes of gender inequality in the European labor market are quite complex, with a variety of political, administrative, and legislative responses implicated. *Women* have more responsibilities for caregiving and household tasks than their male partners. Many women, particularly those who are heads of households with young children, have a tendency either unemployed or limited in their employment opportunities for reasons that include inflexible working conditions and arrangements, inadequate sharing of family responsibility, and a lack of sufficient services such as child care. Many women stop working altogether after their having their first child, while others return to the labor market as part-time workers or when their child or children are of school age (Rodríguez-Pose 2002: 80). The cultural barriers, including the persistence of informal networks from which women are excluded, also prevent them from achieving equal participation in the labor market. The effect of women's individual characteristics which shape their access to the labor market may depend on the sociopolitical structure, such as the male-dominated hierarchy of the political economy and the existing ideologies on gender. According to Barnes et al. (2005: 171), gender inequalities at the regional level reveal the predominance of women in part-time work, women's underrepresentation in sectors such as engineering. Rodríguez-Pose (2002) argues that there is an age and gender divide in atypical employment forms, because the number of women working part-time is higher than that of men, whose part-time employment is concentrated among the young and the over 55s, while self-employment is basically a male phenomenon. People with lower skills are being relegated to these forms of employment and condemned to lower salaries. The concern is whether the differences in access to work for different age groups and the

gender divide in employment can be justified by intergroup differences in worker attributes or whether these differences are the result of employment discrimination and unfair access to work.

7.6.3 Barriers to Labor Mobility

The elasticity of labor supply largely depends upon the geographical mobility of labor: the more readily labor can transfer between regions, the more elastic the supply curve. When mobility increases, geographical mismatches in labor supply and demand are more easily accommodated, and consequently unemployment may be low. Conversely, a more immobile work force may result in higher structural unemployment due to an insufficient supply of labor.

A wide array of individual considerations may affect mobility decisions of workers by making them more attached to their place of residence. These include, for instance, the anxiety of relocation; the unwillingness of people to leave their social, cultural, and family ties (i.e., psychic costs); a lack of information about jobs in other areas; or the pecuniary costs involved with moving (e.g., costs of selling a house). On the whole, mobility propensity is largely influenced by personal characteristics of movers (e.g., age, education, expectations), but in general workers decide to migrate if the expected utility of moving is higher than the expected utility of staying, net of migration costs. Human capital theory in particular sees mobility as an investment decision in which monetary and psychic costs are undertaken in an initial period in order to obtain returns over a longer period of time. The choice of migrating is based upon the net present value of the costs and benefits of such an investment (Becker 1962).

Housing market prices and tenure choices are frequently cited as an obstacle to geographical labor mobility. The empirical evidence shows that high relative price houses may prevent labor market adjustment by discouraging net migration to a region. Potential movers may in fact find that the housing price differential is too large an obstacle to overcome. Moreover, mobility patterns are strongly affected by housing tenure choices. Those living in rented public-sector housing (i.e., council houses) are less likely to move regions than other types of tenants, while owner-occupiers are less mobile than private-sector renters (Hughes and McCormick 1987).

There are a number of possible reasons for the relative immobility of council tenants. One is that public renters wishing to migrate are expected to rely upon council house exchange/transfers, but it is possible that the number of households seeking to enter and leave an area may be unequal (Hughes and McCormick 1987). Another explanation lies in the allocation procedure of properties, which often gives high weight to residence in the local authority, thereby increasing the difficulty of moving into equivalent subsidized houses in a different area.

On the other hand, the reduced mobility of home owners relative to private renters largely depends from the high search and transaction costs involved with buying and selling a house (e.g., transaction taxes, such as capital gain taxes and ad

valorem taxes which are proportional to the house value) which makes them more location bounded. Consequently, as transaction costs are spread over a longer period, most households decide to buy a house the longer the expected length of stay in a dwelling. For the same reason, mortgage holders are more likely to make a long-term locational commitment and are the least mobile group, especially when the mortgage interest rates are high.

The mobility constraints imposed by council housing and home ownership hinder the propensity of individuals living in these types of tenancies to move from regions experiencing a decline in labor demand to expanding regions. Based on this finding, Oswald (1997) suggests that home ownership represents a major barrier to smoothly operating labor markets, which increases *unemployment disparities* between regions. Numerous authors have tested this prediction with different regional data and most aggregate analysis confirms a positive relationship between owner occupation and unemployment (e.g., Partridge and Rickman 1997). At the microlevel (controlling for different characteristics of individuals or households), the evidence is however less favorable to *Oswald's hypothesis*. Homeowners have not only lower unemployment probabilities but also higher wages and shorter spells of unemployment than renters (Coulson and Fisher 2002). With respect to council housing, the literature confirms a positive correlation between the regional unemployment rate (or the probability to be unemployed) and the proportion of households in the public housing sector (Taylor and Bradley 1983; McCormick 1983).

7.7 Policy Constraints

7.7.1 Social Insurance

Public *unemployment insurance* (UI) is a social institution meant to provide temporary financial assistance to workers who are displaced from their job. Despite operating beneficial redistributive effects on those suffering an income loss, thereby reducing intrapersonal income disparities, the unemployment insurance adversely affects labor market behavior. In those cases where unemployment benefits are generous, they may contribute to raise the unemployment equilibrium and to reduce the speed of labor market adjustment after an exogenous shock. They may also reduce the rate at which displaced workers become employed in other sectors. In particular, four features of the unemployment benefit system influence equilibrium unemployment: the level of benefits, the maximum duration of entitlement, the coverage of the system, and the strictness with which the system is operated.

Since the early 1970s, a large number of studies have investigated the effect of unemployment insurance on unemployment level and duration. The main predictions for the *effects of UI* are mainly derived from job search theory, which provide rigorous and detailed analysis of rational individual behavior during unemployment. The standard result from search theory is that unemployment benefits are expected to raise beneficiaries' reservation wages, thereby reducing their search

efforts and their willingness to accept job offers. Workers have perceptions of the wage distribution and voluntarily decide to remain unemployed when current wages are lower than their reservation wage, increasing optimal search time. Reducing the opportunity cost of rejecting a job and prolonging the unemployment spells, UI (among other factors) may inhibit geographical mobility by favoring a stronger geographical attachment. This argument is consistent with the typical negative correlation between mobility rates and the generosity of UI in Europe and the United States: Europe is characterized by high UI and low mobility, while the USA features low UI and high mobility.

Research seems to confirm that the more generous unemployment benefits, the longer the unemployment spells and the higher overall unemployment rate (see, e.g., Moffitt and Nicholson 1982; Marston 1985). Over the period 1984–1997, for instance, Partridge (2001) shows that a one standard deviation rise in average provincial UI in Canada increased the unemployment rate by about 1.3 points.

Regional differences in unemployment insurance payments are in particular suspected to “short-circuit” the market forces that would naturally induce migration from low- to high-income areas (Shaw 1986). Assuming that migration decisions depend exclusively on earned incomes or labor productivities in any location, regional differences in the amount of *unemployment insurance* benefits would have no direct *effect on migration*. Workers would tend to move toward regions where they could earn a higher income. However, as they compensate covered workers for a large fraction of the income lost for being unemployed, UI benefits affect the expected income of individuals in the areas where they live (Fields 1979). The result is that higher benefits may subsidize residence in regionally depressed regions by adversely influencing potential migrants’ decisions, therefore prolonging unemployment and contributing to maintain inequality in unemployment rates among regions. Nonetheless, the effect of UI depends in general on the design features of the unemployment benefit system (in terms of eligibility conditions, level and duration of benefits) and the availability of effective active labor market policies that stimulate job search but do not create obstacles to mobility (OECD 2005).

Empirical research has documented that UI has had an adverse effect on Canadian interregional migration patterns. Courchene (1970), for instance, demonstrates that the generosity of unemployment insurance payments in Canada, relative to the USA, had a significant negative effect on out-migration in Canadian provinces over the period 1952–1967. Similarly, Winer and Gauthier (1982) report that out-migration from the high unemployment Atlantic provinces has been inhibited by increases in UI benefits in the Atlantic region and stimulated by increases in UI support in other regions. The evidence for other countries is weaker. For the United States, Fields (1979) finds that the amount and availability of UI benefits have had some effect on the geographic mobility of labor, but these effects are not very large. Goss and Paul (1990) show that UI compensation decreases the migration likelihood only for those who are involuntarily unemployed, while the opposite occurs for the voluntarily unemployed. For Europe, Tatsiramos (2009) observes that receiving benefits is not associated with lower mobility, but the effects might

vary depending on the institutional characteristics and incentive structure of the UI system of each country. In countries with relatively generous benefits (Denmark, France, and, to some extent, Spain), recipients of UI are more likely to move compared to non-recipients, while in countries that provide less generous benefits (UK), or generous but with a relatively weak incentive structure (Germany), recipients do not differ significantly on their likelihood to move.

7.7.2 Place-Based Policies That Limit Mobility

Differences in (un)employment rates across regions may also arise in reaction of “place-based” policies aimed at helping economically disadvantaged areas/communities, which may alter the adjustment of regional labor markets. These policies take the form of subsidies, grants, or tax incentives to local economic development of specific areas.

An example of *regional spatial policies* with a particular emphasis on worklessness is the *enterprise zones*. These programs were initially developed in the UK in the early 1980s to induce property development as well as industrial and commercial investment in selected areas by removing/reducing certain fiscal burden (mainly local taxes and taxes on capital investment), simplifying administrative procedures and reforming certain statutory controls like planning regulations (OECD 2005). Similar policies have been adopted in other European countries and the USA, which also launched an Empowerment Zone program with similar purposes. Although intuitively appealing, evaluation of enterprise and empowerment zones is rather controversial in terms of social outcomes and it is questioned whether the attained benefits in terms of job growth are sufficient to balance their costs (Glaeser and Gottlieb 2008).

Despite having always been politically popular, economists have traditionally expressed little support for place-based policies in the employment realm, fearing they would alter economic behavior by sending incorrect signals about where to live and to work. Opponents to place-based policies claim that these create *spatial distortions* that limit the tendency of the poor to exit declining areas for localities that offer better employment opportunities (Glaeser and Gottlieb 2008). This is especially the case for low-skilled people, which risk remaining trapped in places with a limited future. In general, standard models of spatial equilibrium are against place-based policies, suggesting that subsidies to poor places are anyhow offset by higher prices and arguing that their primary real effect can be just to redistribute jobs to economically unproductive areas (Glaeser and Gottlieb 2008).

7.8 Conclusions

Researchers across a wide range of fields, policy makers, and large segments of the public believe that unemployment has important social, political, and economic consequences, especially for those regional economies subject to persistently high

levels of joblessness. High regional unemployment means that regional economies not only are leaving talent and skills untapped – thus reducing regional economic growth and development – but may also lead to social unrest, as well as to greater misery and hopelessness for those affected (Begg et al. 2008). It is widely known that putting demand and supply together, we can determine equilibrium prices and quantities in different factor markets, i.e., labor, capital, and land. Each firm simultaneously decides how much output to supply and how many factors to demand. The demand and supply curves are inextricably interlinked. But are these markets always in equilibrium? Are there regional disparities in factor markets and in their returns? In this chapter, we have discussed the regional labor supply and demand and the determinants of regional disparities in unemployment rates. Each regional market tends to clear at the equilibrium wage and employment level that equates supply and demand. However, it may not be possible to take labor market equilibrium for granted. The possible explanations for insufficient regional wage flexibility to maintain the labor market in equilibrium are related to shifts in labor demand and in labor supply. A lack of labor demand, productivity shortfalls, and a different industrial composition may limit regional employment. Similarly, labor supply, constrained by human capital and skills, demographic features (e.g., age, gender, and ethnicity), and a lack of mobility, may limit migration flows to expanding regions and increase regional unemployment. Both shifts in labor demand and shifts in labor supply, which interact and are not mutually exclusive, cause differentials in regional unemployment, making these differentials symptoms of inefficiencies in labor market adjustments.

Understanding the causes of high unemployment in particular areas and the nature of observed regional disparities in unemployment rates is an important step toward identifying the appropriate policy response. In the voluminous literature on this subject, two strands of thoughts and policies stand out: people-based policies and place-based policies. The first camp assumes geographical mobility which leads to a more even geographical distribution of employment and to the convergence of areas with low employment levels, while the second camp assumes that geographical context really matters and focuses on the issue of knowledge in labor policy intervention (Barca et al. 2012). On the one hand, people-based policies may generate shifts either in labor demand or in labor supply. For example, differences in the rate of unemployment may result from the weakness of the monopoly power of trade unions; grants that allow redundant workers to retrain in relevant skills; various government measures introduced to help school-leavers develop skills and job experience for the first time; special measures to encourage the long-term unemployed back into the labor force, which are policies aimed at the supply of labor; or through investment subsidies, tax breaks, and decrease of interest rates, which are policies aimed at the demand for labor (Begg et al. 2008). On the other hand, differences in unemployment rates may arise in reaction to place-based policies aimed at helping economically disadvantaged regions through subsidies, grants, or tax incentives. Hence, both people- and place-based policies could address high unemployment levels and high spatial disparities in unemployment rates, and it is not entirely clear which

type of policies will, in the long run, have more beneficial effects in tackling the local unemployment problems which have become so pervasive across many parts of the world.

Abstract

This chapter presents a comprehensive review of the fundamental concepts regarding real estate and housing markets. It aims firstly to provide an overview of the specific features of real property in general and housing in particular that make property a unique and multidimensional “good.” Building upon that, the chapter presents the key analytical tools extensively used in the relevant literature to capture the functioning of the real estate market as a set of interconnected markets, namely, the user (or space) market, the capital (or investment) market,

and the development market. In this context, property development is examined as a process serving to reconcile long-run demand and supply imbalances generated in the user and investor markets. With regard to the housing market, after an overview of the key determinants of housing demand and supply, this chapter places its focus on the link between housing and the macroeconomy. Finally, the chapter explores the role of financial internationalization in the operation of real property markets and housing in particular, in the context of an increasingly globalized economy.

8.1 Introduction

In economic theory, land is ascribed a very important role as one of the main factors of production. However, real property and the operation of real estate markets have been relatively understudied in mainstream economics, despite the fact that its operation has important implications, not just for the efficiency of individual firms but also for the economy in aggregate. The value of new construction of buildings, either private or public, represents a significant component of the annual gross domestic product (GDP) in most countries. The value of existing buildings is the largest part of a nation's stock of wealth and represents one of the most important assets in the balance sheets of most firms. As such, the analysis of the built environment has increasingly become an important part of the curriculum in urban economics and in subdisciplines of housing and real estate economics, as well as related disciplines such as economic geography and political science.

A common perception is that real estate economics study the business and institutional dimension of property markets, whereas housing economics is primarily focused on public policy (e.g., for a more detailed analysis of the different approaches, see Arnott and McMillen 2006, pp. 142–144). This chapter attempts to present aspects from both these approaches and offers a comprehensive review of the basic concepts regarding real estate and housing markets.

8.2 What Exactly Is Real Estate?

Real estate analysis usually focuses on a specific type of property – for instance, housing or commercial properties. Actually, such an empirical analysis has a spatial dimension, that is, housing markets in a specific town or area. Property types are usually classified, for analytical and practical reasons, as housing and commercial properties; the latter category is in turn broken down to retail properties, hotels, offices, and industrial properties. Sometimes logistics is added as a separate subcategory of commercial properties; moreover, vacant land is also part of real estate. Investors in advanced real estate markets belong to two major categories: individual investors and institutional investors. Most textbooks analyze the economic behavior of the latter category, “not because there aren't sizable individual investors engaged in real estate investing, but because they often team up with

institutions, which have the capital and set most of the ground rules for the investment program” (McMahan 2006, p. 59). The major institutional investors are life insurance companies, real estate investment trusts (usually referred as REITs), pension funds, open-end (they are called open-end funds because investors can periodically withdraw) and closed-end funds, and individual and institutional foreign investors.

Why is there a need for a separate treatment of built property from economics and other disciplines, when there is a vast body of existing literature regarding other types of goods? The answer is that real estate property in general, and housing in particular, has some distinctive features that make it unique.

Real estate property has primarily a *physical dimension*, as it involves a physical asset. At the same time, it has a *legal dimension* which refers to the property rights on the physical asset. In fact, what is traded in the property market is not the physical units of land and buildings but rather the legal rights or interests which exist over them. An important characteristic of this “physical” aspect of real estate which separates property from many other types of goods is its *durability*. The stock of real property constructed at any point in time lasts for many years, and its value can depreciate and/or become obsolete. The problem of property depreciation and obsolescence creates the need for maintenance which adds extra costs. It has to be noted that the depreciation or obsolescence of real estate property has to be construed in its economic and not “physical” meaning. It is possible that the “physical life” of a building may be longer than its “economic life” if nobody wants to use it either for housing or commercial use. Durability also implies that the supply for real estate property is considered “inelastic” – as property stock cannot easily be increased, at least in the short and medium run; as Baum (2009) observes, it is even more difficult to vary downward.

Another characteristic of real estate property is that it is highly *illiquid*. This is another way of saying that it is (very) costly to trade real estate property, as it involves direct cost such as taxes, legal fees, valuation fees, brokers’ fees, and indirect costs. This latter category of costs is of great significance, as it includes the “information costs” regarding property, the risk associated with the property transaction, and other transaction costs (e.g., for a more extensive analysis of these costs, see Baum 2009).

Due to the aforementioned characteristics of heterogeneity, spatial fixity, high transaction costs, and asymmetric information among the market “players,” it has often been argued that the real estate market is inefficient. The concept of what “efficiency” actually means for such a complex market as real estate has been inadequately theorized in the relevant literature. However, the judgment of inefficiency arises by reference to an “ideal” concept of efficiency, one which assumes a perfectly competitive market in equilibrium, characterized by a homogeneous product and rational, perfectly informed actors. The relevant research literature has primarily focused on the issue of *information efficiency* in the real estate market, not only in terms of how easy it is for participants to access all the potentially available knowledge before entering the market but also with regard to whether all relevant information is effectively capitalized into market prices.

Institutional approaches to the issue have “relaxed” the strict notion of efficiency and have offered a more pragmatic conceptualization, in which the degree of efficiency of the market in question is evaluated in comparison to its best potential (rather than absolute optimum) outcome. These approaches take into consideration the institutional environment with all the constraints that it imposes on the efficient operation of individual markets (see Evans (2004) for a detailed account of the issue of efficiency in real estate).

Due to availability of a wide variety of capital sources for both direct and indirect investment, the real estate market is increasingly becoming more “liquid” and less costly to trade and manage. Yet there remain significant “inefficiencies” in real estate, in both its user (or space) market and its investment market. High vacancy rates in commercial property, continuous fluctuations, and divergence across spatial submarkets, all of which are characteristics of real estate, are far from an economist’s vision of a perfect market.

8.3 Developers and the Development Process

Real estate developers can be classified into three categories. The first category is private-sector developers, which is the typical kind of developers. Another category is not-for-profit developers; they typically complete projects such as schools and hospitals. A third category, akin to the not-for-profit one, is public-sector developers. Private-sector developers charge development fees in order to cover their administrative costs and living expenses; they additionally earn reversionary profits on the sales of developed properties. Not-for-profit developers also earn developer’s fees, but they do not get any reversionary profits. This is also the case for public-sector developers; this category of developers is working in special markets, such as hospitals, schools, and governments buildings (Peca 2009).

Developers of all kinds have as their potential tasks to estimate future demand for the specific project in hand, and to calculate the costs, to obtain the necessary planning permissions, to find the necessary financial resources for the completion of the development project, to complete the construction phase, and to manage the constructed property (the developer can sell part of the property). A detailed description of these tasks can be found in Harvey and Jowsey (2004).

McDonald and McMillen (2006) define the stages of land development as follows: the first stage (initial contact by land broker) includes the site inspection, a preliminary market study and cost estimates, and an option contract with land owner; the second stage (option period) includes soil studies and engineering, feasibility appraisal and design strategy, finance plans, etc.; in the third stage (development period), the land is purchased, and loans have been secured; in the fourth stage (sales period), developers implement marketing programs, design controls, and facility management.

One potential breakdown of the development process is greenfield development, brownfield development, and greyfield development. The first category refers to development that takes place in “empty space,” for instance, farmland or forests.

Brownfield development is construction activity typically occurring in urban areas facing environmental degradation, for instance, in defunct industrial plants. The last category (which is rather controversial as a term) refers to cases in which existing “underutilized” buildings are improved (“redeveloped”).

Developers engage in one or more activities (or phases) of the development process. The development process is broken down to the site acquisition, cost planning, market planning, financial leasing, project timing and scheduling, property management, approval of the plan, architecture design, engineering design, and actual construction. Other suggested development “phases” in the relevant literature include concept and initial consideration, site appraisal and feasibility study, detailed design and evaluation, contract and construction, and marketing, management, and disposal (see Ratcliffe et al. 2004). What becomes evident from the complex process of development is that a real estate project involves a great array of professions, organized by the “developer” (for a more extensive analysis, see Peca 2009).

8.4 A Property and Asset Market Model

The most celebrated model of real estate markets is DiPasquale and Wheaton (1996). A similar model was presented by Fisher (1992). It is the staple model in advanced undergraduate and postgraduate courses in urban economics and real estate markets and in popular textbooks and papers alike (e.g., Achour-Fischer 1999; Geltner et al. 2007). Their model is elegant in its simplicity because it introduces two basic markets for real estate property: the market for “use” of built stock (“Property Market: Rent Determination,” in the model’s parlance) and the market of property as an asset (called “Asset Market: Valuation”). This analytical “device” connects these two different “functions” of real estate property and has a pedagogical significance of its own; nonetheless, it has the power to describe the “dynamics.” Yet Colwell (2002, p. 24) argued that the initial model reveals very little about short-run adjustments of real estate and construction markets in the context of a “comparative static analysis” (also see DiPasquale and Wheaton 1996, p. 11).

We present an abridged version of the DiPasquale and Wheaton model (D-W model). The focus on this model is due to its explanatory potential for the basic mechanics of real estate and construction markets, and secondly because some of its most important points go amiss while trying to grasp the complexities within a real economy. Of all the different aspects of the real estate markets assessed in the model, this section concentrates on the structure of the various markets, their interconnection, and on the repercussions an exogenous change would have on these markets. The model comprises four separate diagrams combined in one, thus forming a “cross”-type diagram, which allows to study the way in which changes in one market may affect others, as well as the feedback mechanisms built in the model.

The first market analyzed is that of “use” of built space. The fact that it is always the first to be analyzed does not imply that it is more significant than the other markets. Indeed, the most important feature of this model is the “interaction” of the

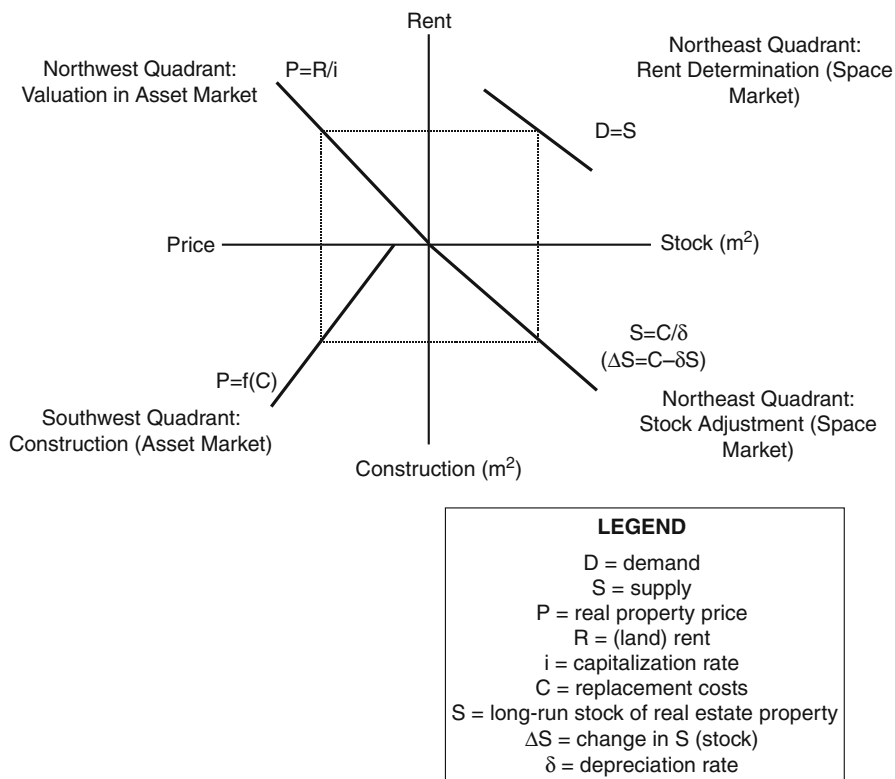

Fig. 8.1 The DiPasquale and Wheaton model of property and asset markets

markets. The diagram of this property market presents the physical stock of built property described as a vertical inelastic supply curve (the “quantity” of this supply and demand diagram, usually expressed in square feet or meters) on the horizontal axis, and on the vertical one the “rent” determined by space use (the “price” in the diagram); thus, at the point of equilibrium, supply equals demand. Demand is a function of the level of rent and the state of the general economy (DiPasquale and Wheaton 1996, p. 8). In some books, the four different quadrants which constitute the “cross” diagram are called northeast, northwest, southwest, and southeast, respectively, following an anticlockwise turn (this convention is followed here). Thus, the “property market for use” is the northeast of Fig. 8.1.

The second, northwest, part of Fig. 8.1 describes the valuation of property in asset markets; here, current rent is related to real property prices (needless to say that in this northwest part of the diagram, the horizontal axis, which is the price of real estate property, increases from right to left). The important question is how rent is “transformed” (related) to prices; this happens via the simple equation $P = R/i$, where P is real property price, R is (land) rent, and i a capitalization rate. This equation begs the next question which is exactly what a capitalization rate is.

The previous equation can be rearranged to $i = R/P$, but, again, this is rather tautological.

Capitalization rate is exogenously determined by a number of factors, such as forecasts about the demand and supply of space markets (e.g., Geltner et al. 2007, p. 24). Note that the capitalization rate is not the nominal interest rate, as it can be construed as a real rate of risk (Colwell 2002, p. 26). If the line in this quadrant is closer to (or further from) the rent axis, that is, this line is “steeper” (“flatter”), it then follows that a given level of rent will be “translated” to “lower” (“higher”) prices for property. A number of factors can make this line “steeper,” for instance, an increase in long-term real interest rates (or the inflation rate), an increase in taxes on real estate property, or greater perceived risk for real estate. To summarize, a “steeper” line in this quadrant is a graphic expression of an increase of the capitalization rate; such an increase will lower real estate prices.

The third part of the diagram, that is, the southwest quadrant, is the one describing the operation of the construction – the development industry. The line in this quadrant is the short-run supply curve of the construction industry. Here, the construction investment is gross, as it contains both the new investment on built space and the replacement of depreciated buildings. The construction line is a short-run curve, which in this diagram does not emanate from the intersection of axes as it is supposed that a minimum level of price is needed in order to have construction activity. This activity is linked with the equation $P = f(C)$, where P is real property price and C are the replacement costs. Factors that increase the construction cost will shift the line away from the construction level axis; such factors are, among others, an increase of short-run interest rates, stricter building or zoning regulations, etc. Colwell has argued that it is possible to reduce the range of prices over which there is no construction activity (Colwell 2002, p. 27). However, such an alteration would compromise the look of the diagram. Geltner et al. have observed that the slope of the construction line depicted in this quadrant represents long-run costs in the supply of the built space (Geltner et al. 2007, p. 27).

The last market of the diagram is that of the southeast quadrant, which represents the way in which the flow of new construction is converted into property stock. This relationship is described by the equation $S = C/\delta$, where S is the long-run stock of real estate property, C are replacement costs, and δ is the depreciation rate. Depreciation in this context means that older buildings are “either abandoned and demolished or converted to other uses” (Geltner et al. 2007, p. 27). The slope of the line in this quadrant represents the “speed” of depreciation process, that is, a steeper line represents faster depreciation. Note that in some cases this line can look as one half of a single line, if the other half is the line of the northwest quadrant. Of course, this is not the case, as the two lines are completely different.

It is argued above that this diagram can be used to show fluctuations and long-run equilibrium in real estate markets. Due to space limitations, only one exogenous change in the system is presented – a demand shift in the northeast quadrant; the interested reader can explore more exogenous changes in the three basic references of this section, that is, Colwell (2002), DiPasquale and Wheaton (1996), and Geltner et al. (2007). This case is presented in Fig. 8.2. The inner box depicts the initial state of

Fig. 8.2 The DiPasquale and Wheaton model: The effect of demand growth on property and asset markets

equilibrium and the outer box the new equilibrium achieved after the exogenous shock that is the increase of the demand for the use of built space. What is missing is the “path” of the adjustment process between the initial and the new equilibrium.

Figure 8.3 illustrates the adjustment process (this diagram is originally presented in Colwell 2002; a more extensive analysis is offered there). The demand for built space use shifts toward the right, and in the new temporary equilibrium, the supply is still the same (as there is not enough time for supply to adjust), and the rent is higher. This leads to an increase of property price in the northwest quadrant and, in turn, in an increase of the gross property construction in the southwest quadrant. This translates as an increase of the real property stock, via the southeast quadrant. As a result, in the northeast quadrant, there will be a shift of the supply curve to the right, which will eventually result in a decreased property rent. This process will continue until there is equilibrium in all four markets. An interested reader can find an altered D-W model in Colwell (2002), where the vertical supply line of northeast quadrant has been replaced by a long-run supply curve with negative slope.

Fig. 8.3 The DiPasquale and Wheaton model: The adjustment process after demand growth

(In this case, there is an extensive presentation of the adjustment process toward the new long-run equilibrium). This equilibrium is presented in Fig. 8.2.

In the D-W model, real estate property, in its “asset incarnation” (i.e., in the northwest quadrant), is compared to alternative investment options, such as bonds and securities. One of the real estate characteristics is its “lumpiness” (Baum 2009), as property comes in large and uneven sizes, meaning that it cannot be diversified in the way other kinds of assets can. Thus, the creation of a portfolio based on real estate property can be rather challenging.

The overview of the complex characteristics of real estate markets shows that it is important to incorporate in any analysis both built space for “use” and real estate property as an asset. Formal analytical models make evident that real estate markets reach a state of equilibrium after a prolonged process; they also show that one of the most important dimensions of built property analysis is real estate finance. Real estate finance globally links the local and specific markets of real estate properties. This trend intensified in the second half of the twentieth century with increasing internationalization of the estate markets.

8.5 The “Internationalization” of Property and Asset Markets

The DiPasquale and Wheaton model presented above analyzes the interconnection between the different markets related to real estate property. It also shows, however, that one of the most important dimensions of the analysis is real estate finance. Modern real estate markets are based on underlying physical assets, which are the basis of a whole financial structure. One crucial difference that separates real estate market from other markets, for example, manufacturing, is that large real estate investors can own directly the underlying physical assets. How then is it possible for small investors to own these physical assets that are worth large sums? The answer is the use of liquid-traded property vehicles. These vehicles include real estate investment trusts (REITs), which own directly real estate property. Since they have access to capital, they can also build additional properties (Block 2006, p. 8). Other ways small investors can own physical assets include other unlisted funds, property derivatives, and mortgage-backed securities (Baum 2009).

It is argued earlier on that real estate markets have essentially a local “nature.” In one sense, the seller of a particular property is a monopolist, as that property is the only one in the specific floor, at the specific side, at the specific street. There is, however, the argument that there is an increasing internationalization/globalization of the real estate markets (e.g., Seabrooke et al. 2004). This trend has started, or at least intensified, in the second half of the twentieth century – when the confluence of several historical events, economic processes, and technological changes transformed the financial markets crucially linked to real estate investment and construction activity.

The seed for this “internationalization” of financial markets was sowed with the breakdown of the Bretton Woods agreement and the shift to floating exchange rates in the early 1970s. This led to the increase of the use of existing financial products and the creation of new ones. This “internationalization” hinged on the existence of new technologies such as computers, and sophisticated telecommunications, which make possible the (instantaneous in most cases) international transfer of vast amounts of money, ending to a large degree in the real estate markets. The question, however, is where these vast amounts were coming from. The brief answer is that there were several sources of global capital accumulation in the last 50 years (see Goldberg (2004) for more details). The oil crises of the 1970s and the trade surpluses of the oil-producing countries created the “petrodollar” markets. Other countries, for instance, Japan in the 1980s and recently China, had also accumulated huge amounts of capital resulting from trade surpluses; the economic growth of Asia led to groups such as the Southeast Chinese to amass a lot of capital. In Europe, the process toward a single economic market and the European Union has also had a deep impact on the real estate markets (Nicholls 2004 offers an extensive analysis). In the last decades, differences in exchange rates between the dollar and other currencies have created a flow of capital mostly from Europe to the United States. The overall conclusion of these fundamental changes in the real estate markets is that at one level, they keep their local characteristics, but at another level, associated with the financial (asset) “nature” of property markets, real estate is increasingly “internationalized.”

8.6 The Housing Market

Housing constitutes a major sector in national economies, and therefore, the way housing markets function is closely interlinked with many elements of the macroeconomy. The functioning of housing markets can be explored through the standard tools of supply and demand analysis; however, housing, like all real estate, is a multidimensional commodity with inherent complexities and distinctive characteristics. This means that the analysis of housing markets needs to take into account these complexities.

First of all, like all the other forms of property, housing is a *heterogeneous* good. Each house is made up of a bundle of characteristics – both structural (number of rooms, garden size, presence of a garage, etc.) and location specific (proximity to a park, coastal or mountain location, proximity to schools, etc.). These characteristics affect how much people are willing to pay for a particular housing unit (for a detailed account of how the heterogeneous nature of housing is captured and theorized in house price models, please refer to ► [Chap. 9, “Housing Choice, Residential Mobility, and Hedonic Approaches”](#) in this handbook).

Secondly, housing is spatially fixed. In terms of the analysis of the housing markets, this characteristic gives rise to two analytical issues:

- (a) Since housing cannot move, households need to move to homes. This means that the availability or absence of appropriate housing in a location will influence location decisions of households and therefore generate mobility. This is one way in which housing is linked with the macroeconomy and the labor market in particular. Moreover, the spatial fixity of housing is the reason why housing development gives rise to major planning debates, as there can be mismatches between demand and supply of housing in different locations.
- (b) The housing market is not an “aggregate entity” but a series of interconnected location-specific submarkets: these can be international, regional, or urban. Analyses at these different spatial scales give rise to different analytical and policy issues. For instance, while the study of international housing markets focuses primarily on the global interaction of housing markets, the study of regional housing markets highlights regional differences and views housing markets as one factor reflecting (as well as explaining) regional growth variations. In the case of urban housing markets, the focus is on intraurban location decisions of households, spatial segregation, and social exclusion in the housing market. A key difference between international/national housing market analysis and regional/urban analysis is that in the former cases, the spatial dimension is absent.

Finally, like all the other forms of property, housing is a *durable* good. Housing stock lasts for many years (60–100 years), which implies that the existing stock is quite substantial in relation to the flow of newly constructed housing. Most importantly, the characteristic of durability automatically implies that other than a “user function,” housing has an investment aspect as well. Therefore, when looking at the motives for holding residential property, analyses should consider and distinguish between demand for housing for consumption (occupation) and demand for housing

for investment purposes. However, housing other than a durable “consumer” good and an investment good is also a *social good*: governments are committed to provide decent accommodation to disadvantaged parts of the population. Housing subsidies and tax incentives exist in order to make housing more affordable. These can be argued to generate distortions in the functioning of the market and the price of housing.

All these complex characteristics of housing, combined with the aforementioned high transaction costs that generally apply to the property market (legal fees, estate agent fees, search costs), constitute sources of inefficiency in the functioning of the housing market. Traditional neoclassical space/access models do not take into account these complexities. As MacLennan and Tu (1996) note: “*Although the insights of the standard neo-classical model are very important, it is clear that economic phenomena such as mis-information, commodity variety, space, time and the nature of the market itself are all victims of the abstraction process*” (p. 388). In these models, housing is approached as a one-dimensional homogeneous product, and the focus lies predominantly on the relationship of housing with the wider urban structure rather than on the operation of housing markets. In these models, the price of housing is demand determined, as supply of housing seems to respond “unproblematically” to changes in demand conditions. As such, these models do not take into account factors that affect the supply of housing, such as future expectations for house price changes, changes in construction costs, time lags, uncertainty, and speculation in the land and housing markets.

8.6.1 Demand, Supply, and House Price Determination

One of the building blocks of housing economics is the assumption that in the short-run, housing supply is inelastic. Factors such as uncertainty, monopolistic ownership, high transaction costs of property changing hands, and, most importantly, the time new housing takes to be constructed imply that short-run supply is measured in terms of just the existing housing stock, which is assumed to remain unchanged. Therefore, in the short run, house prices are assumed to be dependent only on changes in housing demand.

The factors that determine housing demand (H^d) can be expressed as

$$H^d = f(\underbrace{Y, PH, PC, r, Cr, W, T}_{\text{Short Run Determinants}}, \underbrace{\text{Pop, HR, MG}}_{\text{Long Run Determinants}}) \quad (8.1)$$

where Y denotes income, PH house price, PC price of other goods, r mortgage interest rates, Cr credit availability, W wealth, T housing taxation, Pop population size, HR headship rates, and MG migration.

Housing demand in the longer run is determined by (a) natural population growth and (b) population growth due to migration and (c) changes in headship rates. Fluctuations in real incomes and interest rates are considered the most

important determinants of housing demand especially in the short run. As a result, they constitute key causes of house price fluctuations. However, the extent to which house prices “respond” to changes in real incomes depends on the income elasticity of housing demand. Different studies have provided different estimates of income elasticities, ranging from values of as high as two to close to zero. Observed differences in income elasticities can result from the use of different measures of income: for instance, income elasticities are higher when permanent (predicted) income rather than current income. Moreover, the use of aggregate rather than individual data would inflate observed income elasticities. For instance, Mayo (1981) suggests that most US estimates find income elasticities greater than one when aggregate data are used and below one when individual data are used. Finally, income elasticities will vary significantly for rental as opposed to owner-occupied housing (Meen 2001). The estimation of income elasticities is a core issue in housing studies, as it plays an important role with respect to both urban structures and housing policies. Indicatively, Meen (2001) highlights the importance of the study of income elasticities, by pointing out that estimated income elasticity greater than one might imply that income increases would lead households to relocate away from the city center to the suburbs.

In the long run, housing supply is responsive to changes in demand for housing. New housing development takes place in the longer run, and the housing supply curve is no longer inelastic due to the addition of newly constructed units in the existing housing stock.

Housing supply (H^S) at any period can therefore be expressed as

$$H^S = (1 - \delta)H^S_{-1} + Q \quad (8.2)$$

where H^S_{-1} denotes the existing housing stock (stock “inherited” from previous period), δ depreciation rate, and Q new housing construction.

This expression shows that the total housing stock for a city/metropolitan area at a specific point in time equals to housing constructed in (“inherited” from) previous periods, after taking into account the rate of depreciation, plus the new supply of housing due to construction in the current period. In turn, this new supply Q , which affects H^S in the longer run, can be expressed as a function of

$$Q = h(PH, CC, r) \quad (8.3)$$

where CC denotes construction costs including the cost of land for development.

New housing construction is negatively affected by increases in interest rates and construction costs, whereas it is positively related to changes in house prices. The sensitivity of housing construction to interest rate changes illustrates how monetary policy can have an effect on housing construction cycles. In the long run, housing supply is considered to be more responsive to changes in house prices and therefore not perfectly inelastic. Excessive price decreases or increases experienced in the short run will “ease,” and, in the long run, prices will move in line with construction costs.

Differences in house prices in different locations (as well as variations in price among different housing types) will reflect consumer preferences. Willingness to pay sends “signals” to the market and will affect the price the construction industry is prepared to pay for acquiring land for housing developments of certain types and in certain locations.

8.6.2 The Effect of Planning Controls on the Housing Market

The responsiveness of housing supply is affected by the availability of developable land, which in turn depends on the land use regulations in place. Studies of the European (including the UK) and US housing markets demonstrate a strong positive correlation between the level of strictness of land use regulations, low house supply elasticities, and house prices. Land use and planning policies can impose restrictions on land availability and new construction and affect – directly and indirectly – the profitability of land developed for housing purposes. Moreover, such policies change the spatial benefits of particular locations through infrastructure provision. Monk et al. (1991) offer a systematic approach of the complex relationship between planning and the ways it can affect land and house prices. He describes that an effective planning system directly affects the supply of land made available for housing not only by restricting the total quantity of land for development but also by restricting the location of the land that is made available. This pattern restricts the way in which land is developed and determines the timing of development. Moreover, the existence of housing submarkets and the heterogeneity of housing as a complex good means that development constraints in one location cannot be “counterbalanced” by increased availability of land for housing development in another location. The degree of substitutability of house types and locations will determine whether constraints applying for a certain type or location will affect another.

Development control and planning regulations do not only affect the supply of housing and the amount of land put forward for housing development purposes; they can also affect housing demand: negatively by the imposition of costs and by long delays or uncertainties associated with obtaining planning permissions, and positively by setting environmental and design guidelines that will affect potential buyers’ willingness to pay for housing and consequently increase the value of housing as an investment good. In this latter case, planning restrictions are viewed as a mechanism that can correct negative externalities such as overcrowding and incompatible land uses (nevertheless, density controls could be considered to have negative effect for those households demanding small plots at high densities, such as low-income households).

8.6.3 Other Types of Intervention in the Housing Market

Other than planning restrictions, housing markets in most countries feature various degrees of government involvement, which can take several forms, from direct

subsidies (housing allowances, public housing) and fiscal interventions (taxation, mortgage incentives) to market regulations such as rent controls or tenure protection legislation (For an example of the complexities of modelling housing choice in the context of regulated urban housing markets, see Aufhauser et al. (1986)). The reasons for an active role by the government are multifaceted; one reason for government intervention is the well-documented inefficient functioning of the housing market which makes government action necessary in order to achieve Pareto efficiency; moreover, there is a “welfare” aspect based on the premise that housing is a necessary good and society ought to provide housing if an individual cannot afford it; therefore, supporting housing consumption and investment serves as a mechanism to redistribute income and wealth. However, what needs to be noted here is that relevant research suggests that, while housing market regulation such as public housing provision is undoubtedly a means to alleviate affordability problems, it can be far from unproblematic, due to its high supply costs, as well as due to the fact that can often exacerbate (or even be the cause of) socioeconomic segregation.

Whitehead (1999) notes that housing policy has been approached – and analyzed – very differently in the European and American literature. Traditionally, in the American literature, local and national governments are seen as actors that can influence private investment in housing through housing taxation, rent controls, subsidies, and zoning. These forms of regulation are largely local policies and, as such, can be evaluated through cross area comparisons. In Europe, on the other hand, housing regulation is approached by the relevant literature mainly in relation to welfare and social policy. Supply subsidies and rent controls are primarily decided at the national level while often mediated by local governments. Consequently, such policies apply either at a national level or across population groups/households.

8.6.4 Housing Market and the Macroeconomy

Housing constitutes a major sector in national economies and represents the largest share of household assets. As a result, changes in house prices will have an effect on many aspects of national and regional economies and, most importantly, incomes, consumption, and the labor market.

There is the argument that one of the most important aspects of housing is its connection to the welfare state; this line of reasoning originates in the work of Kemeny (1980) and Castles (1998). Schwartz and Seabrooke (2009) have provided a classification of western countries according to the characteristics of their housing markets. One category refers to the countries in which the housing market is highly commodified. These countries have, according to Schwartz and Seabrooke’s (2009) terminology, a *liberal market* in which houses are treated as assets, and where there are high owner-occupation rates and high property tax revenues, and where mortgages as percentage of GDP are high. These markets are more integrated in the global financial system. Another type is *corporatist markets*, which have lower

owner-occupation rates, but high percent of mortgages versus GDP. In both of these housing market categories, there is strong market stratification. The *statist-developmental* category refers to countries in which housing is regarded as a social right. Here, the owner-occupation rate is relatively low, as are also mortgages as percentage of GDP. In this category of countries, property tax revenues are low. There is, finally, the *familial* category in which housing is a familial social good. It is characterized by high owner-occupation rates and low percentage of mortgage on GDP (see Schwartz and Seabrooke's (2009) extensive description).

These differences across western countries imply that the housing market will affect, and will be affected by, the overall economy in different ways. In countries with a liberal economic system, it is expected that households which invested in residential property would accumulate wealth over their life cycle. These households would prefer (and, thus, vote for) lower taxation and lower interest rates. In these societies, pensions, *ceteris paribus*, would be expected to be low and houses to be a substitute for retirement income (for a detailed analysis, see Schwartz and Seabrooke 2009).

The strong links of the housing market and the macroeconomy and its effects on both aggregate demand and supply have been widely discussed (Meen 2003; Case et al. 2005). The relevant literature specifically focuses on the effects of changes in house prices on consumer expenditure (Muellbauer 1990; Holmes 1993; Parkinson et al. 2009), the links between the housing and the labor market (Cameron and Muellbauer 1998; Cannari et al. 2000; Engelhardt 2003; Henley 1998), and the analysis of housing booms and busts in the context of increasingly globalizing economies. The following sections look at these issues in turn.

8.6.4.1 House Prices and Consumer Expenditure

The relationship between house prices and consumer spending is not only a causal one: factors such as changes in interest rates, or people's expectations about future incomes, affect both the demand for consumer goods and services and the demand for housing and therefore have an effect on house prices. Especially with regard to future expected income, empirical evidence suggests that this affects the behavior both of homeowners and renters and therefore plays a significant role in the co-movement of consumer spending and house prices. However, theoretical and empirical research in the field also discusses the causal relationship as well, as house price fluctuations are expected to contribute to fluctuations in consumer spending. There are various ways in which this link can be explained.

The degree of credit market liberalization plays a big role in the way house price growth affects growth in consumer spending, since it leads to house price increases being translated into increased borrowing for consumption purposes. The expansion of mortgage markets in recent years has strengthened the linkages between house prices and consumption. Moreover, the liberalization of credit markets has increased the sensitivity of housing markets (and consumption) to interest rate changes. Housing as an asset can be made more "liquid," either through equity release schemes or through remortgaging. Credit products that are secured against

the value of a house allow consumers to access the equity that their house “contains” without having to sell it.

In the context of the UK housing market, Muellbauer (1990) examines this causal relationship between house price growth and excessive growth in consumer expenditure in the UK. In a similar context, Holmes (1993) discusses the phenomenon of equity withdrawal (the borrowing on mortgage more than it is required to finance the purchase of a house) in the UK and provides evidence of the positive impacts from equity withdrawal on the average propensity to consume. Boelhouwer (2000) reports similar findings for the case of the Netherlands, where the dramatic increase of house prices in the 1990s led to a high rise in consumer spending, partly financed by the overvaluation of the Dutch homes. Again, in the Dutch case, credit market liberalization and the opportunity of commercial banks to expand their offer of mortgages led to increase borrowing, of which only a small part went to the purchase of new homes. Parkinson et al. (2009) examine comparatively the phenomenon of mortgage equity withdrawal in the cases of Britain and Australia, concluding that equity borrowing “*is not just about using housing wealth as routinely as an ATM; rather housing wealth is funding some substantial ‘one-off’ or sustained expenditures*” (p. 385). Their research suggests that in the recent financial crisis, housing wealth took more of an insurance role (a safety net) rather than a pure consumption one, where households used it to meet expenditure demands associated with job loss, childcare, and general welfare.

In the case of the USA, macroeconomic studies find evidence that there is an important relationship between the wealth effect associated with housing and the propensity to consume. Indicatively, the study of Case et al. (2005) uses a panel of quarterly data for US states and a panel of annual observations on 14 developed countries to find a large and significant effect of housing wealth upon household consumption – while at the same time evidence on the wealth effect of financial assets seems weak.

8.6.4.2 The Effect of Housing on the Labor Market

Households seldom make employment decisions independently from housing decisions. The functioning of local and national housing markets will affect labor mobility through house price levels and housing tenure structure. High relative house prices in a region can be a factor that discourages in-migration (net of amenities), and relative house prices can have an effect on choosing where to migrate. Moreover, as banks and mortgage lenders allocate mortgages based on loan-to-house value and loan-to-income ratios, first-time buyers interested in buying property in more prosperous regions could face cash-flow problems if mortgage rates increase, while, conversely, residents in richer regions could be in an advantaged position of being able to use their equity in order to reduce borrowing or to move up the property ladder by moving to other regions (Cameron and Muellbauer 1998).

Tenure structures in the housing market are also related to labor mobility. The relevant literature suggests that even though in more recent years, local authority tenants have become more mobile, they are still the least mobile, followed by owner occupiers, whereas private tenants have the highest levels of mobility.

Even though mobility between regions can be the result of reasons irrelevant to employment choice, there is strong international evidence to support the link between the housing market and labor mobility. Indicatively, in the case of the UK, Henley (1998) finds evidence to suggest that negative equity in the early 1990s impaired households to sell their property and move and therefore reduced their ability to find a better job match elsewhere. Labor immobility leading to inability to match vacancies and consequently causing labor market inefficiencies is also noted in Cameron and Muellbauer (1998) who also find that, as levels of owner-occupation rose in the UK, the influence of relative house prices on net migration rates has also risen. In the case of Italy, Cannari et al. (2000) use market price data at a provincial level to examine whether the housing market played a role in the decline in internal migration between 1965 and 1995. They provide evidence to suggest that differences in the cost of housing between the north and the south of Italy have restrained migration flows and are an important factor in explaining falling patterns of labor mobility.

8.6.4.3 Housing Markets in the Global Economy

In recent years, the integration of increasingly deregulated international financial markets and the general business cycle linkages has led to the co-movement in house prices across countries globally. Strong similarities in house price fluctuations across different countries are not a characteristic of just the recent house price boom: studies of house price data for the period 1970–1992 from OECD countries show that house price dynamics are interdependent, even though there is no evidence supporting the existence of an international house price cycle (Englund and Ioannides 1997). In more recent years, the degree of international housing market *synchronization* has been widely researched (Kim and Renaud 2009). Even though individual countries might exhibit differences in levels of house price growth, there are significant ties between housing markets of big European countries and the USA. Studies have indicated significant correlations between real house price trends between the USA and the EU, with EU countries following US house price trends with an approximate 2-year time lag.

The recent economic crisis and the international slump in housing markets starting in 2007 have stimulated further research of the interdependences of international housing markets. The housing market has played a key role in the economic boom of recent years, as well as and the subsequent downturn. This can be explained by the fact that, as housing and housing-related spending (for renovation, maintenance, as well as furniture and appliance purchases) “pull” large amounts of capital, they allow high levels of equity extraction, which can generate large amounts of household debt. The aforementioned increasing liberalization of housing markets, with the confluence of the persistent (and unsustainable) increase of house prices and low interest rates, encouraged less affluent homebuyers to enter the US housing market, triggering the subprime mortgage crisis. Banks and mortgage lenders sold mortgage derivatives (“packaged” mortgages) to institutional buyers, the value of which soon “crashed” as some households started defaulting on their mortgage payments. The consequence of uncontrolled mortgage

lending and loan distribution was disastrous not only for major US financial institutions but for institutions worldwide, some of which had to be either bailed out by their national governments or were taken over by other financial institutions (for a more extensive analysis of the main reasons for the collapse of the housing market, as well as of the role of new “exotic” financial products in the crisis, see Schwartz 2009).

In recent years, comparative studies on international house price trends have also looked at the issue of housing affordability. Apart from the destabilizing effect that the recent international house price boom has had on national economies, it also raised major concerns with regard to housing affordability (measured as the house price to earnings ratio). On the one hand, factors mentioned earlier, such as low interest rates and favorable borrowing and mortgage conditions designed to enhance affordability to potential homebuyers by reducing monthly payments, made the housing market more “accessible” to lower income and younger households (first-time buyers). However, in most countries, wages and household incomes of middle- and low-income households did not rise proportionately to rising house prices, leading to ownership affordability problems. Kim and Renaud (2009) review relevant studies for different countries (France, Spain, New Zealand, Australia) which provide evidence to suggest that low interest rates and the subsequent rise in house prices caused declines in homeownership rates.

8.7 Concluding Remarks

The analytical intricacies arising from specific features of real property in general and housing in particular make the study of the operation of the real estate market a complex task. This chapter has touched upon these complexities and has highlighted the multidimensional nature of the property market as a set of interconnected markets – the user market, the investment market, and the development market, all of which are invariably linked to the macroeconomy.

On the one hand, demand for commercial property is derived directly from economic activity; land and property are very important inputs in the production process. As a result, in most developed economies, the decline in manufacturing and the growth of the service sector were reflected in decreased demand for industrial property and increased demand for retail and office space. In fact, more recently, the fast pace of globalization in information and communications technology (ICT) and the emergence of a plethora of dot.com firms in the 1990s (all of which were seen as the foundations of a new so-called “weightless” economy), gave rise to a debate as to whether the role of real estate as an asset in the production process would weaken. This raised the following question: will demand for real estate decline, as information technology starts substituting real estate in production functions? Evidence suggests that the relevant debate of the “death of real estate” has been largely exaggerated. Naturally, developments in ICT have brought significant changes in business processes, which have affected traditional sectors and have caused radical changes in all sectors of commercial real estate (for an extensive analysis, see Dixon et al. 2005).

However, real estate space is increasingly adapting, leading to the emergence of new types of real estate, and the reconfiguration of existing real estate spaces that take into account changes in customer and service provider relationships.

With regard to the housing market, this chapter has underlined its strong interaction with the macroeconomy and in particular with household incomes, consumer spending, wage formation, unemployment, and migration. Construction of housing (and commercial property alike) is highly dependent on monetary policies through the effects of interest rate fluctuations on construction costs. The effects of the recent housing boom and subsequent bust have been a clear illustration of this interconnectedness, in the context of an increasingly globalized economy and in times of financial liberalization and internationalization.

Abstract

This chapter explores the literature on residential mobility and house price hedonics. Residential mobility studies the decision of economic agents to move or not and, if they move, their choice of new residence. Topics covered in this chapter include the theory behind the move-or-stay decision, modeling intra- and interregional moves, empirically validated determinants of moving, and macro- and microlevel studies on mobility. Next, house price hedonics explain the price of a house as the sum of all the things that give a house value, from structural characteristics like the number of full bathrooms to public services and neighborhood characteristics that the house experiences. The chapter discusses the theory behind hedonics, applications of the technique, and empirical approaches to identify hedonic house price studies and second-stage hedonic regressions of the demand and supply of characteristics that give a house its value.

9.1 Introduction

Everyone moves at some point in their life, and if they are lucky, they move into a dwelling. This chapter takes up the topics of residential mobility and house price hedonics: the movement of people from one dwelling to another and the factors that influence the price of the dwelling they move into.

The first part of this chapter covers residential mobility. First, the theoretical underpinnings of residential mobility are covered: why do people move? Life cycle models, cost-benefit models, and neighborhood change models are discussed. The chapter then discusses attempts to model moves within a region and between different regions. The factors influencing moves are explored, including the role of job changes, social capital, public policy, climate, and differences in the mobility of men and women. It includes a look at macrolevel and microlevel studies. The chapter finishes with a discussion of whether jobs follow people or if people follow jobs.

The second part of the chapter covers house price hedonics. First, the theoretical framework of the hedonic method is discussed. The issue of estimating a second-stage demand or supply regression from the first-stage hedonic is then explored, with particular attention to identifying the second stage from the first. The various applications of the hedonic method are discussed: (i) capitalization of taxes and public services into house price, (ii) quantifying the relative importance of non-market goods to house prices, (iii) constructing hedonic price indexes, (iv) evaluating policy alternatives, (v) applications to real estate finance, and (vi) testing for market segmentation. The discussion of hedonics concludes with an exploration of a handful of ways researchers have tried to identify hedonic parameters, including instrumental variables, spatial econometrics, the borders approach, and the mixed index approach. The final part of the chapter offers concluding thoughts and directions for future research.

9.2 Residential Mobility

Residential mobility studies the decision of economic agents to move or not and, if they move, their choice of new residence. Residential mobility is a key driver of economic development. By means of agglomeration economies, residents make a city more productive the larger a city becomes. The forced relocation of peasants to large urban areas in the early years of the Soviet Union was an attempt to create the conditions for a revolution of the proletariat described by Marx but was also an attempt to kick-start economic development. The migration of rural poor to urban areas of China has been a driver and consequence of the economic development of China's cities in our day.

Most of the literature in regional science on residential mobility takes an existing urban setting as its starting point. Winstanley, Thorns, and Perkins (2002) provide

a valuable background for the literature, noting that mobility of households within an urban area was traditionally considered a negative phenomenon because it interfered with social networks and moves were often provoked by deteriorating housing stock or neighborhoods or by adverse health events in a family. When Rossi (1955) challenged this view, a new literature was born on the premise that it is perfectly normal for a household to change locations over time. As people marry, have children, age, and experience other *household-formation events* like divorce and retirement, their housing needs change and they move to meet these new needs. These needs include house-specific needs like extra bedrooms but also encompass the need for schools, shopping, leisure and employment opportunities, and proximity to family and friends.

Winstanley, Thorns, and Perkins (2002) divide the literature on residential mobility into three strands: *life cycle models*, cost-benefit models, and *neighborhood change models*. From a regional science point of view, all models can be reduced to cost-benefit models if the costs and benefits are defined appropriately. Recent work by Rabe and Taylor (2010) illustrates the linkage between life cycle models and neighborhood change models, finding that life cycle events may be associated with a move to a better neighborhood (having a baby) or a worse one (a single person moving out of a parent's basement or a husband's unemployment).

Brueckner (2011) provides a useful overview of residential mobility using Tiebout (1956) sorting within a single urban area as a starting point. Tiebout sorting says that under certain conditions, households vote with their feet to end up in a municipality whose levels of public services exactly match consumer preferences, without the community changing its public service level.

In theory, with a head tax, an urban area consists of a collection of municipalities with internally homogeneous public service level demand. If income levels drive public service demand, municipalities are stratified by income. In the real world, *Tiebout sorting* is imperfect: there are a limited number of municipalities to choose from, so sorting is restricted to the "closest" match, leaving internally heterogeneous communities. Urban areas characterized by city-county governments are especially restricted in opportunities for Tiebout sorting, while there are better opportunities for sorting in large urban areas with many municipalities.

But even in a theoretical world with unlimited potential for Tiebout sorting, *economies of scale* provide a limit to the number of municipalities that will form. In the presence of important economies of scale, a minimum number of residents are required to lower the average cost of public service provision to a level competitive with its neighbors. That is, even if community A provides exactly the level of public service desired by a household, the household may choose community B if the cost of public service provision, and therefore taxes, is significantly lower than A, while the level of public service provision is sufficiently close to the most-preferred level. Scale economies may occur at different population levels for different services, which may result in a municipality

providing its own police services but cooperating with other municipalities for schooling services.

If higher income levels equate to higher preference for public service levels, a rich municipality chooses a high public service provision with a high head tax. But if models allow preferences to deviate from income levels, lower-income individuals may wish to sort into a high-service municipality. A sufficiently high head tax may be enough to discourage high-preference poor people from entering the rich municipality. Whether because of income levels, a prohibitive head tax, or both, a poor community forms with a low head tax and a low level of public service.

Property taxes finance a large share of local public services in the USA, and to the extent that they do, it allows more internal heterogeneity within a municipality. All else equal, a poor person would like to consume the larger amount of public service. But the taxes required are too high under a head tax. If a property tax replaces the head tax and the poor person can find a small house in the rich municipality, the poor person can pay a small property tax and still enjoy the large amount of public service.

The influx of poor residents into a rich municipality will have fiscal consequences for the rich residents. Because the poor residents pay less for the service, the municipality may run a fiscal deficit on these residents, a deficit that must be made up for by rich residents if the most-preferred level of public services is to be maintained. In response, rich residents may choose to engage in fiscal zoning, so that new construction pays for the cost of the public services provided to the new residence.

The literature long held that job changes primarily affect moves between urban areas but that households do not generally move within an urban area in response to a change in jobs. However, Clark and Davies-Withers (1999) show that, in fact, a person who takes a new job in the same urban area as the old job is 2.4 times more likely to find a new residence than people who experience no change in job. Such *intra-urban moves* are more likely for young households, single-earner households, and renters; in contrast, older households, dual-income households, and homeowners are more likely to commute to their new job from their current residence.

Apart from mobility within an urban area, households also may move from one urban area to another. Such long-distance moves to new labor markets are often spurred on by changes in employment opportunities, including households moving after retirement (Clark and van Lierop 1986). Changes in human capital are often cited as a cause of *interregional migration*.

While changes in employment opportunities are important to mobility, recent research explores reasons why such moves do not always happen. For instance, Kan (2007) explores the role of social capital in the decision to move, finding evidence that the more social ties a household has in an area, the less likely it is to move to a new location within the same labor market and that social ties make a move to a new labor market even more unlikely.

The issue of household mobility, be it intraurban or interregional, involves three decisions: (1) whether to move, (2) where to move, and (3) what to move into.

These decisions may be viewed as sequential as in a nested framework (e.g., Fischer and Aufhauser, 1988) or as a simultaneous set of decisions. The decision of whether to move has been modeled as *housing dissatisfaction* (e.g., Hanushek and Quigley, 1978). Before Hanushek and Quigley, most research on residential mobility was descriptive. Hanushek and Quigley motivate their work by noting that moving is a dynamic response to a household's changed circumstances. The decision to move depends not only on housing demand but also on search costs, the transaction costs of moving, and the distribution of house prices available to a prospective mover. Hanushek and Quigley model the decision to move as a probit function where the dependent variable is the difference between a household's housing consumption and its desired housing consumption in the next period, divided by its desired housing consumption in the next period. They use a data set of renters from Phoenix and Pittsburgh who were interviewed initially, then one year later, then a year later again. Housing demand is estimated by an ordinary least squares model that regresses monthly rent on income, wealth, age, household size, household education level, race, and whether the apartment has a refrigerator, air conditioner, or stove. The percentage difference between housing consumption expenditures and predicted housing consumption expenditures is Hanushek and Quigley's measure of disequilibrium. The decision to move is modeled as a function of demographic characteristics like age, income, race, and household size. The authors extend their model to a multinomial probit case of whether a household searches and moves, searches for new housing without moving, and does not search for new housing. Hanushek and Quigley's model is readily extended from housing dissatisfaction to neighborhood dissatisfaction, providing a link between housing dissatisfaction and neighborhood change models.

More recent research on household mobility has focused on the role of public policy. California's Proposition 13 prohibits reassessment of the base-year value of a property except in the case of new construction or a change in ownership. The law provides incentive for residents to stay in their current dwelling. Recent work by Ferreira (2010) estimates the impact on household mobility by analyzing recent amendments to Proposition 13 that allow residents over 55 years of age to sell their house and still transfer the tax savings to a new house. Ferreira finds that 55-year-old homeowners are 25 % more likely to move than comparable 54-year-olds.

A wide variety of approaches to modeling mobility have been used in the literature, as discussed by Clark and Van Lierop (1986). These include linear programming models, gravity models, discrete choice, and behavioral models. The methods are described below, and readers may refer to Clark and Van Lierop (1986) for specific examples of research using each method.

Perhaps the oldest approach to modeling residential location is the linear programming model, which is the counterpart to the Alonso location model. In the linear programming model, households choose a market basket of non-housing goods to maximize the ability of the household to spend on housing. The outcome of choosing the optimal basket results in the household choosing the optimal housing location, optimal in the Pareto sense that no household can relocate to

increase its expenditures on rent without displacing another household, thus reducing the other household's expenditures on rent.

Gravity models were sometimes used to model residential location instead of linear programming models. *Gravity models* are derived from Newton's law of gravity and are also known as distance decay models, *spatial interaction models*, and *origin-destination flow models*. These models describe the attraction between two objects, in this case people in one location and their attraction to another location. It is common in the residential mobility literature to parameterize spatial interaction models with a log-linear functional form to look at the aggregate movement of households between areas. These log-linear models regress the number of moves between two areas as a function of explanatory variables such as the net migration from each area, the control variables, the distance between each area, and the distribution of flows between areas. Shortcomings of these models, particularly their failure to consider spatial dependence, are discussed in LeSage and Fischer (2010).

The micro counterpart to the log-linear spatial interaction models is the use of discrete choice models, pioneered by Hanushek and Quigley (1978). Even today, most research follows this methodology. Households receive utility from choosing a dwelling, and the utility they receive affects the probability that they will select the dwelling. The discrete choice framework is used to model the move-or-stay decision, the rent or own decision, as well as the decision to select a new place of residence from a variety of locations. The discrete choice framework is also used in more complex procedures like sequential choices of move versus stay, then choice of a specific neighborhood from a finite option set, then a choice of a specific dwelling within the neighborhood.

Behavioral models of residential mobility examine a household's level stress, disequilibrium, or, as in Hanushek and Quigley (1978), dissatisfaction with housing consumption (discussed earlier in this chapter). Much attention has been given to the search process involved in relocation. Often, such models contain a stopping parameter that guides when a household finalizes its decision, such as when the expected gap between the expected utility resulting from additional search and the highest utility available is small enough. *Search models* have incorporated preferences over housing consumption and neighborhood consumption, as well as incorporating the preferences of single-earner households, dual-earner households, and the preferences of households with children that allow the children's preferences to enter into the decision calculus.

Perhaps due to data constraints, many of the early studies on residential mobility were macro-oriented, dealing with the moves of an aggregated number of people between geographic areas like urban areas, census tracts, or municipalities. The increased availability of data has led to the micro approach – the examination of the residential mobility decisions of a single household – gathering the lion's share of attention in the literature. Nevertheless, recent research reviewed by Dieleman (2001) has rediscovered the macro side of the equation, uncovering new factors important for mobility between geographic areas. *Turnover rates of the housing stock* and housing prices vary across regions and across time. The renewal of the

housing stock allows for more potential choice of housing by area residents, while low housing prices make home ownership more affordable to young people and household formation by young people into renter-occupied dwellings more feasible. Household mobility is twice as prevalent in the American South as in the American Northwest. Research suggests that moves are more common where the local economy is stronger: such areas are marked by increased construction of new dwellings and an influx of young workers. Endogenous growth in the number of young workers also plays a role, as Southerners are more likely to raise children and Northwesterners are more likely to raise dogs. Differences in public policy might also help explain variations between regions in mobility, with the urban growth boundaries of Portland providing a marked contrast with the urban sprawl of Atlanta and the regulatory difficulty of constructing new dwellings in California contrasted with the relative lack of zoning laws in Texas. Internationally, such differences help explain the relative lack of housing stock turnover and household formation in Europe. There is some truth to the joke of the Italian man who proudly proclaims, “Before I was 35, I lived with my mother; now that I’m over 35, my *mother* lives with *me*.” Variation in *housing prices* tends to persist over time, although there are places where the variation in house prices over time is greater, such as the coastal regions of the USA, which experience boom and bust cycles to a greater degree than inland cities. Higher house prices are found in larger urban areas, more rapidly growing urban areas, and areas where construction costs – including regulatory approval costs – are higher. Direct government intervention in the housing market also affects the price of housing, such as rent controls, government construction of low-income dwellings, urban growth boundaries and development taxes, and government treatment of renting versus owning.

Mobility is a subject with many aspects to be investigated: renting versus owning, within versus interurban mobility, and mobility by education, marital status, child status, racial composition, and more. Perhaps surprisingly, little research has investigated the *mobility of women* relative to men. The field commonly assumed that women were less mobile than men without engaging in much empirical research to confirm or refute the supposition. Faggian, McCann, and Sheppard (2007) find evidence that women in the UK are more mobile than men. They point out that previous research on the issue almost entirely ignores the role of human capital in the relative migration of men and women. Faggian, McCann, and Sheppard study a sample of UK university graduates. They follow these individuals from their homes to university and from university to place of first employment. After controlling for human capital and regional economic conditions, they find women are more interregionally mobile than men, arguing that this increased mobility represents attempts by women to overcome gender bias in the labor market. Faggian, McCann, and Sheppard also find that racial minorities, older individuals, unemployment in the individual’s hometown, and distance of the individual’s hometown to London reduce mobility of the four types of migrants studied, relative to nonmigrants. They use multinomial logit, dichotomous logit, and conditional logit regression approaches.

In recent decades, the role of climate in attracting new residents has drawn a lot of research attention. The population shift from New England and the Midwest in the USA to the “Sunbelt” areas of the South and West is attributed in large part to climate. Rappaport (2007) challenges the claim that the invention of air conditioning is responsible for the shift, finding increased population not only in areas with warmer winters but also in areas with cooler, less humid summers. Rappaport also notes that the shift to nice weather is driven not just by elderly retirees but also is happening at almost the same rate by working-age people. Rappaport details the literature on *climate and residential mobility*, pointing out that the traditional approach is the *compensating differential approach*: estimating the wages that workers forego to live in places with a better climate. But Rappaport notes that there are several important drawbacks to the compensating wage differential approach used by previous studies. One such problem is that the level of detailed observations required is only available for places with over 100,000 people. This population requirement introduces sample selection bias because data is only available from places where a lot of people have already chosen to live. A second problem is the inability to properly control for individual-specific and house-specific characteristics. This is particularly a problem because high-income individuals may choose to live in areas with a high quality of life, so that the unobserved characteristics of these individuals are likely positively correlated with quality of life variables, including climate. Given the limitations of the compensating differential approach, Rappaport instead studies climate’s role in changes in quality of life and productivity. Weather’s contribution to changes in quality of life and changes in productivity has occurred for four reasons: (i) the decline of agricultural employment has made weather less important for agricultural productivity, (ii) air conditioning and improved heating technology have made extreme temperatures more bearable, (iii) rising incomes have increased the consumption of good weather, and (iv) the utility value of weather has increased because of the rise in the number of affluent retirees. His approach is unable to distinguish between the quality of life and the productivity effects of climate, and the approach cannot quantify the size of the effects, but it avoids the problems of the compensating differential approach and opens up a new angle of attack with which to research a long-standing issue. Rappaport uses county-level data, which provides a large number of observations and full coverage of the USA, avoiding the sample selection problem of using urban area-level data. The annual growth rate of population density is regressed as a function of average January high temperature, average July high temperature, precipitation, and other controls. Population growth is found to be statistically significantly related to high temperatures in January and July in most regressions.

Like Rappaport (2007), Partridge and Rickman (2003) also investigate a long-standing issue with a new approach. For decades, regional scientists have investigated whether *jobs follow people or people follow jobs*. The lack of finality in the issue stems from the fact that both job growth and population growth are endogenous, leading multiple researchers to call this a “chicken and egg” problem. Job growth draws new residents, while an influx of new residents creates new jobs.

Early attempts to identify the direction of causality employed simultaneously estimating employment and migration equations using instrumental variables, but such an approach suffers from the difficulty of finding appropriate instruments. It also fails to estimate short-run versus long-run responses. *Vector autoregression (VAR) models* have been used more recently to try to disentangle the job-people question, but previous attempts have fallen short in various ways. Some VAR studies assumed that all contemporaneous employment innovations were labor-demand shocks. Other VAR studies fail to include relevant equations in their models, such as migration equations or wage equations, making it impossible to disentangle labor demand and supply. Instead, Partridge and Rickman use a structural VAR model that incorporates a labor market model. The labor market model is used to create long-run identifying restrictions for the structural VAR model. Partridge and Rickman also distinguish between *labor-supply and labor-demand shocks* noting that wages respond in opposite directions to each type of shock. Finally, Partridge and Rickman decompose labor-supply shocks into those due to new residents and original residents. They use data from the 48 contiguous United States from 1969 to 1998, finding labor-demand shocks account for about 46 % of the variance in employment forecasts. Migration (labor-supply) shocks account for about 33 % of the variance, and internal labor-supply shocks the remaining 21 %. So while people seem to follow jobs more than jobs follow people (46 % vs. 33 %), when you sum the 33 % from migration and 21 % from internal labor-supply shocks, it is clear that the role of supply is as important as that of labor demand. Partridge and Rickman's model suggests that Sunbelt states are more influenced by migration shocks, and Rustbelt, Farm Belt, and Energy states are more influenced by labor-demand shocks.

9.3 House Price Hedonics

House price hedonic regressions attempt to break the price of a house into each aspect of the house that gives it value, from structural characteristics like house size to neighborhood characteristics like crime rates and to public finance characteristics like tax rates. Adding up the price of all the things that give a house its value will tell you the market value of the house. But a house is a bundle of services, each providing value but few being easily added onto or subtracted from a house. That is, while it may be possible to find the market value of adding another full bathroom to a house by getting a quote from a contractor, it is not as easy to take the same house and purchase an extra unit of air quality or public safety for it. The house price hedonic estimation is a way to use statistics to estimate the value that an extra unit of public safety would provide toward a house.

Residential mobility is linked to house price hedonics through many channels. As households *Tiebout sort* into an urban area, their demand for specific housing characteristics will be reflected in house price through the relative supply of that attribute in the area. If houses with high-quality public schools are in short supply relative to demand, households will have to pay a premium to live in such houses.

Housing turnover affects residential mobility, but the lack of new housing will tend to push the price of newer houses up, especially in the face of supply restrictions like development taxes and urban growth boundaries. And while residential mobility is likely to be less pronounced in urban areas with low *population growth rates*, the level of house prices is likely to be lower in such areas as well.

Although its use goes back to the early 1900s, the modern era of house price hedonics began when Sherwin Rosen (1974) detailed the theoretical underpinnings of the method. Rosen notes that the number of rooms in a house provides value to the house, but a house is a bundle of attributes, including the number of rooms. If we let z be the amount of housing consumed, then $z = (z_1, z_2, z_3, \dots, z_n)$ lets the amount of housing consumed be a function of the n characteristics of the house, so that summing z_1 through z_n yields the amount of housing consumption. These quantities can be converted to prices p so that $p(z) = p(z_1, z_2, z_3, \dots, z_n)$: the price of a house $p(z)$ is a function of the price of its attributes.

Buyers and sellers come together in the market to determine the price of the attributes of a house, the end result of which determines the selling price of the house. Consumers have a budget constraint in which their incomes are exhausted on purchases of housing attributes and a numeraire good. Consumers maximize utility over housing attributes and the numeraire good subject to a budget constraint. The first-order conditions of the constrained maximization equate the marginal rate of substitution for house characteristic z_i to p_i , the marginal price of characteristic z_i . And because the house is a bundle of characteristics that cannot be easily bought and sold separately on the market, each p_i is an *implicit price*, not an explicit price.

Consumers bid for housing attributes given a fixed level of income and utility. A bid is the marginal rate of substitution between a housing attribute z_i and money, which shows the consumer's reservation demand price for an additional unit of z_i . Next, $p(z)$, the minimum price a consumer must pay in the market for various quantities of z_i , is graphed along with consumers' bid functions, and tangencies show the optimal consumption of an attribute by a consumer.

Rosen next considers *producers of housing*, which are assumed to operate in a perfectly competitive environment. Producers maximize profits by producing additional housing attributes until marginal cost equals marginal revenue. A producer's offer function shows the unit prices a producer will accept for various house designs, given a fixed level of profits. Producers maximize their offer prices subject to the price they can get in the market, $p(z)$. Rosen graphs a producer's offer function for characteristic z_i along with the price $p(z)$ obtainable in the market, and tangencies between these curves reveal the optimal amount of characteristic z_i the firm should offer, given the optimal quantity of other housing characteristics.

Rosen next puts consumers' bids together with producers' offers, and tangencies denote a joint envelope all along $p(z)$, the implicit price function of characteristic z_i . Rosen notes that $p(z)$ may be nonlinear: the price of a characteristic may change as more of it is consumed.

Rosen's work would have been influential enough if he had stopped there, but Rosen goes on to describe how the supply and demand for *implicit house price*

hedonic characteristics may be estimated. Step 1: regress $p(z)$ as a function of all z_i . This is the house price hedonic. Step 2: compute the marginal implicit prices $\partial p(z)/\partial z_i = p_i(z)$ for each buyer and seller, evaluated at the actual quantities consumed. Step 3: use the marginal implicit prices endogenously in a system of supply and demand for characteristics, being careful to include some exogenous shift characteristics in each equation. Step 4: estimate supply and demand simultaneously, making sure both supply and demand equations are identified from each other.

Later, James Brown and Harvey Rosen (1982) claimed the need to modify Sherwin Rosen's method of estimating a second-stage supply and demand system for hedonic attributes. They point out that while Sherwin Rosen was careful to identify the supply curve from the demand curve and vice versa, neither the supply nor the demand is identified from the initial house price hedonic in Step 1 above. All the information from the house price hedonic is embedded in the marginal implicit prices included in the second-stage supply and demand regressions, so that attribute prices are not independent of errors in the second stage.

Because of the difficulties in *identifying the demand for a hedonic attribute* like air quality from the underlying house price hedonic, most researchers stop at estimating a first-stage hedonic regression. However, there have been suggestions for how to identify second-stage supply and demand equations from the first-stage hedonic. The first, and the most frequently applied, is Brown and Rosen's (1982) suggestion to segment the housing market.

Market segmentation is the identification strategy taken by Brasington and Hite (2005). Brasington and Hite regress the natural log of house prices on twenty-two explanatory variables, including the focus variable, DISTANCE TO HAZARD, representing the distance from each house to the nearest environmental hazard. They run separate first-stage hedonic regressions for the six largest urban areas in Ohio, using a *spatial Durbin model* to help control for the influence of omitted variables. They use the parameter estimate of DISTANCE TO HAZARD to calculate the marginal implicit price of *environmental quality* for each of the 44,255 houses in the sample, although values are averaged at the census block group level (5,051 census block groups). The implicit prices for the six urban areas are based on six different parameter estimates of DISTANCE TO HAZARD, but all implicit prices in the sample are pooled to estimate a single second-stage demand curve for environmental quality. The implicit prices are treated endogenously using instrumental variables. Brasington and Hite find a small, statistically significant relationship between house prices and environmental quality in five of the six urban areas. They estimate the demand for environmental quality using two-stage least squares, limited information maximum likelihood, a fixed effect model, and a spatial Durbin model. There seems to be no relationship between environmental quality and lot size in the spatial regression. However, house size seems to be a substitute for environmental quality, and school quality and environmental quality seem to be complements.

Other than Brown and Rosen's (1982) market segmentation by geography, researchers have used or promoted identification of demand and supply from

first-stage hedonics by segmentation by time, functional form assumptions, and instrumental variables approaches. Of particular note is a paper by Cheshire and Sheppard (1998), who use a spatial lag of the two nearest houses as an instrument for implicit prices. Cheshire and Sheppard obtain similar results for their instrumented and so-called underidentified demand system, suggesting that while identification of demand from initial hedonic regressions is theoretically important, it does not affect regression results much. Also of note are Ekeland, Heckman, and Nesheim (2002), which claim that Rosen (1974) was right. Specifically, they claim that when all the information in the hedonic model is exploited, second-stage demand equations are identified from the first-stage hedonic even in single markets and without having to impose an arbitrary functional form assumption. The problem with second-stage models is that the hedonic model is generically nonlinear, and it is only when people use a linearization that identification problems arise. They show theoretically that a normal linear quadratic model achieves identification, but they do not actually estimate such a model.

Far more common than two-stage demand models are models that simply apply the first-stage hedonic house price regression to various problems of interest to regional scientists. These applications fall into at least six categories: (i) capitalization of taxes and public services, (ii) quantifying the relative importance of non-market goods to house prices, (iii) constructing hedonic price indexes, (iv) evaluating policy alternatives, (v) applications to real estate finance, and (vi) testing for market segmentation.

One of the first *applications of the hedonic method* to regional science was to investigate the capitalization of taxes and public services into constant-quality house prices. The idea of capitalization of taxes, for example, is that, holding public services and everything else constant, low taxes provide value to a house. Low taxes provide value to a house in the current period, the next period, and all successive periods for the life of the house (or land) subject to a discount rate. The sum of this discounted stream of value boosts house price above what it otherwise would be, so that low taxes are “capitalized” into constant-quality house price. Oates (1969) is the most-cited paper in the field of public finance capitalization, although Orr (1968) preceded that article or was at least contemporaneous. Oates found capitalization of both property taxes and school spending and claimed that it proved Tiebout (1956) was right. But the interpretation of *capitalization* has a large literature of its own. Several papers claim that capitalization should not occur in theory and that Tiebout’s paper itself would not predict capitalization. Other papers say that capitalization does exist and that its existence is a result either of a scarcity of desirable public service/tax combinations, local governments using more resources than necessary to produce public services, or local governments spending too much or too little on public services. Another paper says that both major views of capitalization are right: it should occur and should not occur simultaneously, depending on whether the house is in an area of high or low housing supply elasticity. See Brasington (2002) for a detailed discussion and empirical exploration of this issue.

The house price hedonic has been used extensively to quantify the relative importance of *non-market goods*. The difficulty for economists and regional scientists in studying nonmarket goods is that there is no observable market price. Some researchers estimate the market price by contingent value surveys or estimating travel cost models; others exploit the housing market. If air quality imparts value to a house, it should be possible to see how much value it imparts to a house by regressing house price as a function of house characteristics, neighborhood characteristics, and air quality. The partial derivative of house price with respect to air quality yields its marginal implicit price, from which a marginal willingness to pay can be calculated. Other nonmarket goods whose value has been estimated by house price hedonic regressions include public school quality, crime rates, and proximity to lakes, parks, hospitals, churches, shopping malls, and airports.

Hedonic price indexes are used to track how the price of a typical house changes over time. The house price hedonic is first estimated. A researcher then plugs in the sample means of the explanatory variables which, together with the parameter estimates for each variable, yield the typical house's estimated price in the base year (index = 100). The regression is run again for new time periods, with researchers plugging in the *old* sample means for the explanatory variables and using the new parameter estimates to come up with a new value for the index. There are different ways to construct hedonic price indexes. Gatzlaff and Ling (1994) compare indexes constructed from traditional hedonics based on sale price, hedonics based on assessed value, and the repeat sales method. The repeat sales method follows the sale price of the same houses over time. In theory, it provides an unbiased price index because, unlike the traditional house price hedonic, there are no unobserved characteristics to bias the price – as long as the quality of the house remains constant between sales. The criticisms typically levied against the *repeat sales method* are that (i) it suffers from sample selection bias, as certain starter homes and undesirable homes may sell more often than other houses; (ii) that the same houses may have been remodeled between sales, so that researchers are not really comparing the same house over time; and (iii) that the repeat sales method wastes a tremendous amount of data, because only a small subset of houses sell more than once over a small time period. These and other criticisms of the repeat sales model are detailed by Haurin and Hendershott (1991). Gatzlaff and Ling get around these criticisms by having information about houses that did not sell during the time period, using the entire set of houses for the city of Miami between 1971 and 1991, and controlling for houses that have been substantially remodeled between sales. Gatzlaff and Ling find that all methods provide precise measurements of house price indexes, both in levels and in changes between years, although there was more noise in quarterly price changes. It is especially noteworthy that indexes based on assessed value were similar to those based on actual sale prices, because assessed property value data is much easier and cheaper to obtain than sale price data.

The house price hedonic can be used to *evaluate policy alternatives*. This can be done in a cross-sectional study or a study measuring changes over time. For a cross-sectional study, a researcher pools data from a group of houses that does

not have policy x and a group that does. A dummy variable for policy x is included in the regression, and a statistically significant parameter estimate for the dummy variable tells whether the policy has a positive, negative, or no effect on house prices. Care must be taken to control for every possible influence, so that omitted variables are not driving the dummy variable's parameter estimate. The same procedure can be done across time, with the sample containing house sales before and after the policy change and the dummy variable reflecting sales after the policy change.

There are numerous applications of the house price hedonic to real estate. Researchers have used the technique to estimate the discount or premium for having an unusual house for the neighborhood, a motivated seller discount, differences in sale price for houses transacting with a real estate broker or for-sale-by-owner, and the effect on price of selling by way of a sheriff's auction or bank sale.

As mentioned before, the two-stage hedonic demand technique described by Rosen (1974) is most often conducted by using segmented housing markets in the first-stage regression. Another use of the hedonic technique is to test for *market segmentation*. A different house price hedonic regression is run for every area suspected of being a distinct housing market. If the parameter estimates are significantly different from each other, the houses are deemed to come from segmented markets; that is, each market is subject to a different set of supply and demand conditions.

While hundreds of house price hedonic studies have been conducted, the *identification issue* – whether we believe the parameter estimates are accurate – is an issue that continues to dog the hedonic approach. In response, a variety of estimation techniques have been used. These include ordinary least squares, two-stage least squares, other instrumental variable techniques, spatial regression approaches, the borders approach, and the mixed index approach. Traditionally, ordinary least squares has been used to estimate house price hedonics. One example is Hoehn, Berger, and Blomquist (1987), which deserves special note in this chapter. This paper uses the hedonic method not only to estimate a house price equation but also to estimate a wage equation, an additional application of the hedonic technique. Furthermore, it helps bridge the gap between the hedonic and residential mobility literatures by including a considerable number of quality of life controls including numerous measures of pollution, climate, and other urban amenities.

Subsequent research recognized the drawbacks of ordinary least squares for hedonic regressions. An early adopter of instrumentation is Voith (1991), who simultaneously runs wage and rent regressions using two-stage least squares. Instrumentation is necessary, Voith says, because wages and rents are simultaneously determined. Another attempt to identify house price hedonics using instrumental variables is found in Epple and Sieg (1999).

Although not a statistical method, another approach to identifying parameter estimates from hedonic models is to exploit borders. The technique was pioneered by Gill (1983) and was all but forgotten until the late 1990s, since which time it has become more popular than ever (although Gill's paper is rarely credited).

The idea is to examine houses that are similar in all respects but one: the houses on one side of a border have characteristic x , and those on the other side of the border have characteristic y . The border could be a school district boundary, as in Gill (1983), or it could be a state line, county line, tax abatement zone boundary, or any other boundary of interest to researchers. Gill picks areas with similar housing that have less than 10 % of blacks in neighborhood schools. Some areas are within the Columbus (Ohio) City School District; others are in suburban school districts. Suddenly in 1978, a school busing plan was approved that mandated all city schools to have between 20.9 % and 50.9 % black students. Suburban schools were exempt from busing. Gill finds evidence of increased demand for suburban houses, especially those with four or more bedrooms, when the courts first ordered city schools to desegregate.

Despite the current popularity of the *borders approach* to identifying house price hedonics, LaCombe (2004) shows that the use of spatial statistics is better. Note that while spatial statistics is not a technique in itself, it is an approach that incorporates spatial dependence in a variety of regression techniques. LaCombe takes counties that border each side of a state. He studies whether state-level differences in AFDC and food stamp usage is associated with a different prevalence of female-headed households and labor force participation levels by women. LaCombe uses both the borders approach and *spatial statistics*. While the borders approach shows no relationship between AFDC and food stamps on the percentage of female-headed households, the spatial statistical models show a positive, statistically significant relationship, a finding more consistent with theory and previous studies. LaCombe argues that the driver of this result is the presence of spatial dependence: the idea that observations nearby in space are similar to each other but that observations farther away from each other are less similar. The same Brasington and Hite (2005) paper described above for two-stage hedonic demand uses spatial econometrics to address spatial dependence. The specific procedure used in Brasington and Hite is the *spatial Durbin model*. Brasington and Hite describe the intuition behind how their spatial Durbin model incorporates the influence of *omitted variables*, thus helping to identify a house price hedonic (p. 63):

while a lagged dependent variable in time series regressions relies on observations nearby in time, the spatial lag relies on a linear combination of house values nearby in space. Unmeasured influences help determine the value of neighboring houses and, as explained earlier, the value of neighboring houses is related to the value of our own house. So our own house value is affected by the unmeasured influences of neighboring observations. And the unmeasured influences of neighboring houses are similar to the unmeasured influences for our house because our neighbors are close: the same things that affect our neighbors should affect us, too.

More formal and detailed discussions of spatial models and omitted variable bias are given in Fischer and Getis (2010) and LeSage and Pace (2010; ► [Chap. 77, “Interpreting Spatial Econometric Models”](#)). There are many models within spatial econometrics and spatial statistics that can incorporate the influence of spatial dependence. These include the spatial autoregressive model, the general

spatial model, the geographically weighted regression, and the spatial Durbin model. Certain models incorporate the influence of omitted variables; others do not. Spatial routines are available in Matlab at www.spatial-econometrics.com and www.spatial-statistics.com and also with S+, Spatial Stata, PySAL, STARS, Open GeoDa, GeoR, and GeoDa Space, most of which are free.

A final technique to identify hedonics comes from an idea of Bowden (1992), operationalized by Brasington and Hite (2008). In their introduction, Brasington and Hite (2008) discuss the shortcomings of the borders approach, instrumental variables approach, panel data approaches, and spatial statistical approaches. They then discuss Bowden's observation that Tiebout sorting leads to endogeneity of house price hedonic variables and that even including buyer characteristics as explanatory variables is insufficient to identify the hedonic. What is needed, Bowden says, is a *mixed index model*. This mixed index model consists of a system of equations estimated simultaneously. This system contains a house price hedonic with explanatory variables for house characteristics and buyer characteristics (Brasington and Hite add neighborhood characteristics to Bowden's list). The system of equations also contains equations with dependent variables representing endogenous explanatory variables from the house price hedonic. Brasington and Hite implement Bowden's mixed index model for the first time. The endogenous variables they choose from the house price hedonic are the homeowner's income, commute time, and air pollution in the homeowner's census block group. These endogenous variables are regressed as a function of additional homeowner characteristics, house characteristics, and neighborhood characteristics. Brasington and Hite find that the mixed index model yields predicted house prices that are statistically significantly different from a traditional ordinary least squares regression and from a traditional regression that adds buyer characteristics. They find the magnitude of the *capitalization of environmental quality* differs a lot when using the mixed index model, and they find the mixed index model has the most accurate policy predictions with the lowest prediction variance and the most favorable skewness and kurtosis performance. The major drawback for implementing the mixed index model is that data on the characteristics of the buyers of each house is rarely available. Furthermore, even the most thoughtful exclusion restrictions in the system of equations are somewhat arbitrary. Still, the favorable statistical properties may make the mixed index model an attractive choice when data on individual *buyer characteristics* becomes more widely available.

9.4 Conclusions

This chapter has examined the state of the literature on residential mobility and house price hedonics. It has discussed the theoretical framework of the literature, looked at the empirical approaches to test theory, and briefly discussed the factors influencing mobility and house prices.

While the theory behind the second-stage demand regressions stemming from house price hedonics continues to receive some attention, the theory behind residential mobility and first-stage house price hedonics seems relatively stable. Rather, it is the empirical side of the story that has received much more exploration in recent decades.

The residential mobility literature has advanced far in testing the determinants of mobility, but less energy has been invested in the empirical techniques used. While traditional probits and the like are appropriate and certain studies like Partridge and Rickman (2003) have applied structural vector autoregression to traditional questions, there is room to apply newer econometric approaches to investigate long-standing issues in the literature. For example, in a discipline in which space plays such a prominent role, there is a notable lack of research applying spatial statistics and econometrics to the residential mobility literature (Fischer and Getis, 2010). There is also room to investigate other determinants of mobility that have been understudied. For instance, what is the impact of having a city-county government on in-migration and out-migration? Is moving more or less common than in urban areas with a large number of highly fragmented political jurisdictions?

Concerning the house price hedonic literature, there has been some advance in regression technique, with several approaches available to help identify parameter estimates in first- and second-stage hedonic regressions. What is needed is more research like Lacombe (2004) to *compare the different techniques* to see which offer the best combination of desirable estimation qualities like unbiasedness and efficiency. The hedonic literature is a major beneficiary of renewed interest in *housing prices* as much of the developed world suffers through a post-bubble *housing bust*. Some of this renewed literature could investigate additional hedonic determinants of rises and falls in housing prices, including the role of climate and views of lakes and oceans and the role of the industries a city specializes in – the hedonic counterpart to Rappaport (2007) and Partridge and Rickman (2003).

Both the residential mobility and the house price hedonic literatures could benefit from a comprehensive data set that would put the Nurses' Health Study and the Panel Study of Income Dynamics to shame. Such a data set would need to cover an entire continent to account for mobility of subjects. It would need to enroll a large number of subjects. All the purchases of these subjects would need to be tracked, as well as the sales of durable goods. The residences and workplaces of these subjects throughout their lifetimes would be recorded, as would health, fertility, and income data. And detailed information about the subjects' residences and neighborhoods would be collected, as well as certain information about the subjects' relatives. The information about relatives would be useful for constructing instrumental variables for endogenous variables. Data on education, religious practice, criminal records, and misbehavior in school would also be useful. Data collected on such persons over the course of a lifetime would prove a research gold mine, if confidentiality could be maintained.

Abstract

This chapter provides an overview of the literature on neoclassical growth, starting with the simple Solow-Swan model and highlighting the main components of the neoclassical growth process. It considers the assumptions, predictions, and limitations of the Solow-Swan model and discusses several extensions that address some of these limitations and, in particular, those that are unrealistic for a regional growth setting. Several more complex models are presented and

discussed, including a model that allows for exogenous technological progress, one that includes a broader definition of capital to also encompass human capital, and one that relaxes the assumption of a closed economy. Finally, the chapter considers a more complex model of neoclassical growth, the Ramsey-Cass-Koopmans model, which incorporates consumer behavior and allows for an endogenously determined savings rate.

10.1 Introduction

The publication of two seminal papers by Robert Solow, “A Contribution to the Theory of Economic Growth” in 1956 and “Technical Change and the Aggregate Production Function” in 1957, revolutionized the study of macroeconomics and started a major new research area in economic theory (Boianovsky and Hoover 2009). The neoclassical models, so-called because of their assumption of a neoclassical production function with constant returns to scale, remained the standard in growth theory until the 1980s, when new modeling techniques led to a second revolution in the field, and the advent of endogenous growth theory. However, to this day, the neoclassical models of growth retain considerable interest in the field due to their simplicity and empirical explanatory power.

This chapter provides an overview of the neoclassical models of growth, starting with the simple Solow-Swan model with exogenous savings. The model has important implications for the ultimate causes of growth and the transitional dynamics of an economy towards its long-run equilibrium or steady state. Next, the chapter discusses three important extensions of the Solow-Swan model with particular relevance to regional economies: an extension to incorporate exogenous technological progress, a version of the model that allows for physical and human capital, and an extension that relaxes the assumption of a closed economy, with no factor mobility. Finally, we will consider the Ramsey-Cass-Koopmans model, a neoclassical model that allows for endogenous savings, further relaxing the assumptions of the Solow-Swan model. The approach taken throughout the chapter is to present the models using both mathematical equations and diagrams, and the reader is directed to sources of further reading for more extensive details and discussions of other versions of the models.

The remainder of the chapter is organized as follows: [Sect. 10.2](#) discusses the main characteristics of neoclassical growth models and presents the simple Solow-Swan model. [Section 10.3](#) highlights several important extensions of the original model and discusses their strengths and limitations. [Section 10.4](#) presents the more complex Ramsey-Cass-Koopmans model. [Section 10.5](#) concludes.

10.2 The Solow-Swan Model

The Solow-Swan model is named after two influential papers on economic growth published independently by Solow (1956) and Swan (1956). It is based on three

equations: a neoclassical production function, a capital accumulation equation, and a labor supply function. We discuss the three equations and their properties in turn.

10.2.1 Neoclassical Production Function

The key to understanding neoclassical growth models is the feature that sets them apart from other streams of the growth literature: the neoclassical production function. To see why, consider the production function $Y = F(K, L)$, where Y is output, K is capital, and L is labor. The function is said to be neoclassical if a number of properties hold.

First, the function must exhibit constant returns to scale, also known as homogeneity of degree one. This property holds if when increasing all inputs by a factor λ the result is an increase in output by the same factor. For instance, a business running a factory might build a second factory and operate it using the same amount of capital and labor as the first. If the production process is based on constant returns to scale technology, this will result in a doubling of the output. Formally, this assumption can be stated as

$$F(\lambda K, \lambda L) = \lambda F(K, L) \quad (10.1)$$

Second, there must be positive and diminishing returns to all inputs. This holds if adding an additional unit of each input to the production process results in a positive increase in output, but the increase becomes smaller as more of the input is added, while holding all other inputs constant. Formally we have

$$\begin{aligned} \frac{\partial F}{\partial K} > 0, & \quad \frac{\partial^2 F}{\partial K^2} < 0 \\ \frac{\partial F}{\partial L} > 0, & \quad \frac{\partial^2 F}{\partial L^2} < 0 \end{aligned} \quad (10.2)$$

Finally, two sets of technical conditions must hold. The so-called Inada conditions state that the marginal product of capital will approach infinity as the labor input tends to zero and approach zero as the labor input tends to infinity (and vice versa for labor). In addition, both inputs must be *essential*, that is, a strictly positive amount of each input is needed to produce a unit of output (Barro and Sala-i-Martin 2004; Acemoglu 2009).

The above conditions define the neoclassical production function. Because the focus of growth is generally on per-capita values (such as GDP per capita), the production function is often expressed in per-capita terms. Since the neoclassical production function is subject to constant returns to scale, we can divide all the variables by the same scaling factor $\lambda = 1/L$ to give

$$Y/L = F(K/L, L/L) = F(K/L, 1) \quad (10.3)$$

We can express all the variables in their *per-capita* terms, also known as in *intensive form*, to give

$$y = f(k) \quad (10.4)$$

where y is output per capita and k is an input capital per capita. Since the Solow-Swan model is a model of the macroeconomy, the output is a composite variable, generally taken to mean total output in the economy. In practical terms, this is often operationalized using gross domestic product (GDP) in the case of countries or gross value added (GVA) in the case of regions. Writing the neoclassical production function out in intensive form also highlights one of its most important properties, which is the absence of scale effects. Production in large countries or regions is not affected by the size of the market, but rather is determined by the amount of physical capital that is available to each worker.

Another important aspect of this production function concerns the marginal products of the factors of production. These are given by the derivatives of Eq. (10.4) with respect to capital and labor:

$$\begin{aligned} \frac{\partial F}{\partial K} &= f'(k) \\ \frac{\partial F}{\partial L} &= f(k) - kf'(k) \end{aligned} \quad (10.5)$$

In a perfectly competitive economy, the factors of production are each paid their marginal product. In other words, firms will hire labor until the marginal product of labor is equal to the wage rate w and will rent capital until the marginal product of capital is equal to the rental price R .

A commonly used production function is the Cobb-Douglas function, given by

$$Y = K^\alpha L^{1-\alpha} \quad (10.6)$$

where α is a constant such that $0 < \alpha < 1$. Expressing the function in intensive form gives

$$y = k^\alpha \quad (10.7)$$

The Cobb-Douglas production function satisfies all the properties of neoclassical production functions as discussed above and also has an additional desirable property, which is that the factor income shares, or the proportions of output that accrue to each factor of production, are constant and equal α for capital and $(1 - \alpha)$ for labor. Formally,

$$\begin{aligned} R &= \frac{\partial F}{\partial K} = \alpha \frac{Y}{K} \\ w &= \frac{\partial F}{\partial L} = (1 - \alpha) \frac{Y}{L} \end{aligned} \quad (10.8)$$

It is easy to verify that the payments to the factors of production exhaust total output since

$$wL + RK = \alpha Y + (1 - \alpha)Y = Y \quad (10.9)$$

10.2.2 Capital Accumulation Equation

The second equation of the Solow-Swan model describes changes in the capital stock over time. In the discussion that follows, we will make use of *dot* notation to denote time derivatives, so that $\partial K / \partial t = \dot{K}$, and similarly for other variables. The change of the capital stock, K , over time is given by

$$\dot{K} = sF(K, L) - \delta K \quad (10.10)$$

where s is the savings rate (which is equal to the investment rate) and δ is the capital depreciation rate or the rate at which the existing capital stock becomes obsolete. The model thus assumes that all of the income that is not consumed (and is therefore *saved*) is invested in new capital stock. Equation (10.10) can also be expressed in intensive form, by using the relationship $k = K/L$, taking logs and differentiating with respect to time to give a relationship between growth rates:

$$\frac{\dot{k}}{k} = \frac{\dot{K}}{K} - \frac{\dot{L}}{L} \quad (10.11)$$

Dividing Eq. (10.10) by K and substituting into Eq. (10.11) give

$$\frac{\dot{k}}{k} = \frac{sF(K, L)}{K} - \delta - \frac{\dot{L}}{L} \quad (10.12)$$

and multiplying both sides by $k = K/L$ and rearranging give

$$\dot{k} = sf(k) - \left(\delta + \frac{\dot{L}}{L}\right)k \quad (10.13)$$

The final component of the model is the so far undefined labor force growth rate, given by \dot{L}/L , which is the final equation of the model.

10.2.3 Labor Supply Function

The Solow-Swan model in its simplest form assumes a constant labor force growth rate, so that

$$L = L_0 e^{nt} \Rightarrow \frac{\dot{L}}{L} = n \quad (10.14)$$

Fig. 10.1 The Solow Diagram

where L_0 is the initial supply of labor and n is the labor force growth rate. The model thus assumes that the labor force changes at a constant rate, given by the exogenous n . Substituting the expression for the growth rate of the labor force Eq. (10.14) into Eq. (10.13) gives the capital accumulation equation in intensive form:

$$\dot{k} = sf(k) - (\delta + n)k \quad (10.15)$$

10.2.4 Solow Diagram and Dynamics of the Model

Equation (10.15) is the fundamental differential equation of the model and describes the evolution of the capital stock as a function of capital per worker k and a set of constant factors. The term $(\delta + n)$ can be thought of as the effective depreciation rate of the capital-labor ratio. In other words, the capital stock per worker declines in part because of depreciation (which makes a fraction of existing capital obsolete) and in part because of the labor force growth rate.

The workings of the model can be shown most effectively on a phase diagram, an innovative method introduced by Solow (1956), and which is now known as the *Solow diagram* (see Fig. 10.1). The diagram shows the neoclassical production-function $f(k)$ and the two components of the capital accumulation equation given by Eq. (10.15). The curve $sf(k)$ shows the amount of investment in capital per worker and has the same shape as the production function but is scaled down by a factor s . The line $(\delta + n)k$ shows the effective depreciation in capital per worker.

In order to analyze the predictions of the model, we first consider the long-run or *steady state* behavior and then discuss the short-run dynamics. In the long run, the model predicts that an economy will reach a steady state where all the variables are either constant or growing at a constant, steady rate. The steady state occurs when the capital stock per worker is constant, so that $\dot{k} = 0$. As can be seen from Eq. (10.15), this is only possible when the level of investment per worker just

Fig. 10.2 The Impact of a Higher Savings Rate

equals the effective depreciation of capital per worker, given by the point where the curves $sf(k)$ and $(\delta + n)k$ meet. At this point, the steady state capital stock is equal to k^* in Fig. 10.1. To see why this is a steady state, consider an economy that initially has a lower capital stock per worker, such as k_0 . At this point, the investment in new capital stock per worker $sf(k)$ is greater than the effective depreciation per worker $(\delta + n)k$ so that the capital stock per worker is growing and will continue to grow until the steady state is reached. Similarly, if the economy is at a point to the right of k^* , effective depreciation exceeds new investment, and the capital stock per worker falls until the steady state is reached. Note that in the steady state, the capital stock per worker is constant, while the level of the capital stock K grows at the constant rate of labor growth n . Similarly, output per worker $y^* = f(k^*)$ and consumption per worker $c^* = (1 - s)f(k^*)$ are constant, while output Y and consumption C grow at the constant rate n .

The Solow diagram can also be used to study the effects of a change in one of the fundamental factors of the model, for instance, the savings rate s . As shown on Fig. 10.2, an increase in the savings rate from s_1 to s_2 results in an upward shift of the $sf(k)$ curve and, as a result, a higher steady state level of capital per worker k_2^* . However, the effect of this increase on growth is only temporary. The economy initially grows as the level of capital per worker increases, but as the new steady state is reached, capital and output per worker cease to grow and become constant, while the new levels of capital and output grow steadily at the rate of the labor force growth n . To summarize, an economy with a higher rate of saving will achieve a higher level of output per worker but will, once the steady state is reached, grow at the same rate as an economy with a lower savings rate.

The equation for the growth rate of capital per worker can be seen by dividing the capital accumulation equation given by Eq. (10.15) by k :

$$\frac{\dot{k}}{k} = \frac{sf(k)}{k} - (\delta + n) \quad (10.16)$$

Fig. 10.3 Neoclassical Convergence

The implications of the dynamics of the growth rate of capital can also be seen diagrammatically by drawing two curves corresponding to the two components of Eq. (10.16), shown on Fig. 10.3. The growth rate of capital per worker is zero in the steady state, when the two curves intersect and capital per worker is equal to k^* . At other values of k , the growth rate is given by the gap between the two curves, so the furthest an economy is from its steady state, the fastest it grows toward it. In other words, an economy grows asymptotically toward its steady state. The reason for this result is the assumption of diminishing returns to capital of the neoclassical production function; when k is relatively low, the average product of capital is high, and hence, the gross investment per unit of capital $sf(k)/k$ is high, while the effective rate of depreciation stays constant. The growth rate is positive if the level of capital per worker is lower than the steady state and negative if the current level is higher than the steady state.

This last result has important implications for the comparative study of growth rates across countries or regions. Specifically, as long as two economies have the same production function and the same savings, labor force growth, and capital depreciation rates, they will converge to the same steady state. Differences in growth rates will only be observed if the two economies are at different stages in this convergence process, for instance, because one economy is less developed than the other and has a smaller initial value of k . As shown on Fig. 10.3, the less developing economy has a lower level of capital per worker, denoted k_0^{dev} , while the more industrialized economy initially has k_0^{ind} . While both economies are converging to the same steady state k^* , the developing economy will temporarily have a faster rate of growth, while it *catches up* to the capital per-worker level of the industrialized economy.

The speed of convergence of a country to its steady state is thus a measure of how fast the growth rate declines as the capital stock increases or formally

$$\beta = - \frac{\partial(\dot{k}/k)}{\partial \log k} \quad (10.17)$$

where β is the speed of convergence. A large empirical literature exists to estimate the speed of convergence, typically in a cross section of countries or regions. Note that, as discussed above, the concept of convergence only applies to economies converging to their own steady states, unless all countries or regions that are included in the analysis have the same production function, savings, population growth, and capital depreciation rates. This is more likely to be the case for regions within the same country or countries that are relatively similar (e.g., the OECD economies), although population growth rates and the level of technology can sometimes vary markedly across regions within one country. Many empirical studies control for differences in these factors by including them in a multivariate regression context.

The simple Solow-Swan model discussed up until now abstracts from reality in several important ways. First, it does not allow for technological progress and assumes that the same combinations of capital and labor will always result in the same amount of output. Second, it assumes that all units of labor are equally productive, regardless of their level of skill. The model thus abstracts from education and training. Finally, and importantly, in the context of regions, the model assumes a closed economy, that is, there are no exports, and capital and labor are assumed immobile. We next discuss several extensions of the Solow-Swan model to incorporate these factors. Note that we have so far abstracted from markets and the behavior of individual households and firms. We will discuss these micro-foundations of the model in more detail in [Sect. 10.4](#). However, it is worth mentioning at this point that the results of the simple Solow-Swan model can also be shown to hold in a framework that explicitly incorporates markets for labor and financial assets (see Barro and Sala-i-Martin 2004, pp. 31–33 for details).

10.3 Extensions of the Solow-Swan Model

10.3.1 Technological Progress

Introducing exogenous technological progress into the Solow-Swan model is fairly straightforward. The first step is to include the level of technology in the neoclassical production function. This can take several forms, depending on whether we define the technology as a process that allows production of the same amount of output with less capital input (capital-saving technology) and less labor input (labor-saving technology) or a process that does not save relatively more of either input (neutral or unbiased technological progress). The definition of the latter also varies. For the purposes of the Solow-Swan model, we assume a *Harrod neutral* or *labor-augmenting* technology, which is necessary to ensure that the model has a steady state (see Barro and Sala-i-Martin 2004, pp. 52–53 for a discussion). Our production function now takes the form

$$Y = F(K, AL) \tag{10.18}$$

where A is the level of labor-augmenting technology, which raises output in the same way as an increase in the stock of labor. We therefore refer to AL as the *effective units of labor* used in production. A distinguishing characteristic of the neoclassical models is that technological progress is assumed to be exogenous, so that

$$A = A_0 e^{gt} \Rightarrow \frac{\dot{A}}{A} = g \quad (10.19)$$

where g is the exogenous growth rate of technology and A_0 is the initial level of technology. The capital accumulation in Eq. (10.10) still holds, but we construct a new *state variable* $\tilde{k} = K/AL$, defined as *capital per effective unit of labor*, and which is constant in the steady state. Taking logs and differentiating with respect to time, we obtain

$$\frac{\dot{\tilde{k}}}{\tilde{k}} = \frac{\dot{K}}{K} - \frac{\dot{A}}{A} - \frac{\dot{L}}{L} \quad (10.20)$$

Substituting Eqs. (10.10), (10.14), and (10.19) into Eq. (10.20) gives

$$\frac{\dot{\tilde{k}}}{\tilde{k}} = \frac{sF(K, AL)}{K} - \delta - g - n \quad (10.21)$$

and rearranging Eq. (10.21) gives

$$\dot{\tilde{k}} = \frac{sF(K, AL)}{AL} - (\delta + g + n)\tilde{k} \quad (10.22)$$

The production function can be also be expressed in terms of effective units of labor, so that $\tilde{y} = f(\tilde{k})$. Substituting into Eq. (10.22) gives the capital accumulation equation for the Solow-Swan model, in terms of effective units of labor:

$$\dot{\tilde{k}} = sf(\tilde{k}) - (\delta + g + n)\tilde{k} \quad (10.23)$$

To derive the steady state of the model, we now proceed as before. The steady state occurs when the capital per effective unit of labor is constant or $\dot{\tilde{k}} = 0$. This occurs when

$$sf(\tilde{k}) = (\delta + g + n)\tilde{k} \quad (10.24)$$

that is, when the gross investment per unit of effective labor is just equal to the reduction in capital per unit of effective labor due to the effective depreciation rate that now includes technological progress. In the long run, therefore, capital and output *per unit of effective labor* are constant, capital and output *per worker* grow at the constant rate of technological progress g , and capital and output grow at the constant rate $(n + g)$. As with the simple model discussed above, the short-run

growth rate in capital per worker (and therefore in output per worker) is greater the further a country or region is from its steady state. During transition, the growth rate in output per worker is therefore greater than the rate of technological progress, declining asymptotically until reaching the constant growth rate g in the steady state.

The speed of convergence of an economy toward its own steady state was defined in Eq. (10.17) as the proportional decrease in the growth rate of the state variable as the capital stock declines. To see how it varies with the variables of the augmented model, we first assume that the economy has a Cobb-Douglas production function with labor-augmenting technology given by

$$Y = F(K, AL) = K^\alpha (AL)^{1-\alpha} \quad (10.25)$$

or $y = \tilde{k}^\alpha$ in augmented form, where α is a constant such that $0 < \alpha < 1$. By dividing Eq. (10.23) by \tilde{k} , we obtain the growth rate of capital per unit of effective labor:

$$\frac{\dot{\tilde{k}}}{\tilde{k}} = \frac{sf(\tilde{k})}{\tilde{k}} - (\delta + g + n) \quad (10.26)$$

In the Cobb-Douglas case, this is given by

$$\frac{\dot{\tilde{k}}}{\tilde{k}} = \frac{s\tilde{k}^\alpha}{\tilde{k}} - (\delta + g + n) = s\tilde{k}^{-(1-\alpha)} - (\delta + g + n) \quad (10.27)$$

We can rewrite the expression for the growth rate of \tilde{k} given in Eq. (10.27) as a function of $\log(\tilde{k})$

$$\frac{\dot{\tilde{k}}}{\tilde{k}} = se^{-(1-\alpha)\log(\tilde{k})} - (\delta + g + n) \quad (10.28)$$

and differentiate with respect to $\log(\tilde{k})$ to give an expression for the speed of convergence β , as defined in Eq. (10.17)

$$\beta = -\frac{\partial(\dot{\tilde{k}}/\tilde{k})}{\partial \log \tilde{k}} = (1 - \alpha)s\tilde{k}^{-(1-\alpha)} \quad (10.29)$$

At the steady state, $s\tilde{k}^{-(1-\alpha)} = (\delta + g + n)$, as shown by Eq. (10.27). Therefore, in the neighborhood of the steady state, the speed of convergence is given by

$$\beta^* = (1 - \alpha)(\delta + g + n) \quad (10.30)$$

The model therefore predicts that the rate of long-run per-capita output growth is equal across all countries or regions, since it is given by the exogenous rate of technological progress. Because technological progress is determined outside the

model (or, in other words, is not explained by the model), the model is silent on the ultimate causes of long-run growth. This shortcoming, in particular, has resulted in a large new stream of literature, known as *endogenous growth* or *new growth*, that has sought to explain the origins of technological progress.

10.3.2 Human Capital

A second major limitation of the simple Solow-Swan model is its abstraction from education and skills, although these variables clearly differ across countries (and regions). It is therefore no surprise that an extension of the Solow-Swan model to incorporate human capital came about for empirical reasons, as it became apparent that the original model failed to accurately explain differences in growth rates and, in particular, to adequately explain the speed of convergence given in Eq. (10.30).

For instance, Barro and Sala-i-Martin (2004) use benchmark values for the United States economy of $\delta = 0.05$ per year, $g = 0.02$ per year, and $n = 0.01$ per year. The value for the growth rate of technology corresponds to the long-run growth rate of GDP in the United States, while the values for the capital depreciation and labor force growth rate are long-run averages. They also assume a value of the capital share of income of $\alpha = 1/3$, in line with previous studies. Using these values, the predicted speed of convergence is $\beta^* = 0.053$ or 5.3 % per year, which is much larger than the observed average speed of convergence of around 2 % per year. Such a low value would be consistent with a higher capital share of income of the order of $\alpha = 0.75$.

One way to resolve this discrepancy is to allow for both human and physical capital in the model, thus leading to a higher capital share in income. We use an augmented version of the Cobb-Douglas production function given in Eq. (10.25):

$$Y = K^\alpha H^\eta (AL)^{1-\alpha-\eta} \quad (10.31)$$

where H is human capital, L is raw labor, and α and η are constants such that $0 < \alpha < 1$ and $0 < \eta < 1$. We again express the model in terms of units of effective labor by dividing all variables by AL . Output per unit of effective labor is now given by

$$\tilde{y} = f(\tilde{k}, \tilde{h}) = \tilde{k}^\alpha \tilde{h}^\eta \quad (10.32)$$

We assume, as before, that households consume a constant share of their income, with the remainder saved and invested in capital. We further make the simplifying assumption that both physical and human capital depreciate at the same rate of δ . The capital accumulation equation is then given by

$$\dot{\tilde{k}} + \dot{\tilde{h}} = sf(\tilde{k}, \tilde{h}) - (\delta + g + n)(\tilde{k} + \tilde{h}) \quad (10.33)$$

and substituting expression (10.32) into (10.33) gives

$$\dot{\tilde{k}} + \dot{\tilde{h}} = s\tilde{k}^\alpha\tilde{h}^\eta - (\delta + g + n)(\tilde{k} + \tilde{h}) \quad (10.34)$$

Households will invest in the form of capital that gives the highest rate of return, if investment in both forms of capital is positive. In equilibrium, the marginal products of physical and human capital must therefore be equal:

$$\alpha\frac{\tilde{y}}{\tilde{k}} - \delta = \eta\frac{\tilde{y}}{\tilde{h}} - \delta \quad (10.35)$$

Rearranging, we obtain a relationship between physical and human capital:

$$\tilde{h} = \frac{\eta}{\alpha}\tilde{k} \quad (10.36)$$

and substituting Eq. (10.35) into the capital accumulation equation given by Eq. (10.33) results in

$$\dot{\tilde{k}} = s\phi k^{\alpha+\eta} - (\delta + g + n)\tilde{k} \quad (10.37)$$

where $\phi = (\eta^\eta\alpha^{1-\eta})/(\alpha + \eta)$ is a constant. Following the same procedure used in Eqs. (10.26)–(10.30), we arrive at a new expression for the speed of convergence in the neighborhood of the steady state:

$$\beta^* = (1 - \alpha - \eta)(\delta + g + n) \quad (10.38)$$

Given a reasonable estimate of the human capital share of $\eta = 0.4$ and the other estimates discussed above, we obtain an estimated speed of convergence of $\beta^* = 0.21$ or 2.1 % per year, a result that is in line with much of the empirical literature.

The model presented above is a slight variation of the approach followed by Mankiw et al. (1992) in a seminal paper. The authors estimate a model with two capital accumulation equations, one for physical and one for human capital, with the rates of investment in the two types of capital being determined independently of each other. The expression for the speed of convergence obtained by Mankiw et al. (1992) is the same as that given by Eq. (10.38), and the authors find strong support for the predictions of the neoclassical model. In particular, their estimated speed of convergence is close to 2 %, particularly if the sample is restricted to similar countries such as the OECD economies (see Abreu et al. 2005, for an extended discussion). It is also worth noting that recent approaches to modeling regional growth build on the Solow model, with or without human capital, and extend it in new ways, such as by incorporating technology spillovers across countries (Ertur and Koch 2007) or regions (Fischer 2011).

10.3.3 Migration

The assumption of a closed economy, implying that the factors of production are immobile across economies, is particularly unrealistic if the model is applied to regions (rather than countries). We are therefore interested in extensions of the neoclassical approach that relax the assumptions of labor and capital mobility. In this section, we consider a version of the Solow-Swan model that allows for migration and is based on a model developed in Barro and Sala-i-Martin (2004).

We allow for the movement of labor but not capital or goods, that is, we assume there is no trade or capital mobility that is independent of migration. We do, however, assume that migrants carry capital as they move, most of which is in the form of human capital. In what follows, we do not distinguish between physical and human capital, but denote by κ the total quantity of broad capital carried by each migrant. The net flow of migrants is given by M , which is equal to in-migration minus out-migration, and the net migration rate is given by M/L . The overall growth in the domestic labor force is therefore given by

$$\frac{\dot{L}}{L} = n + m \quad (10.39)$$

Since migrants bring κM units of capital into the domestic economy, the capital accumulation equation is now given by

$$\dot{K} = sF(K, AL) - \delta K + \kappa M \quad (10.40)$$

where we have assumed that technological progress is labor augmenting, as in Eq. (10.18). As before, we use Eq. (10.40) and the relationship between growth rates given in Eq. (10.20) to obtain the growth rate of capital per effective worker \tilde{k} :

$$\frac{\dot{\tilde{k}}}{\tilde{k}} = \frac{sf(\tilde{k})}{\tilde{k}} - (\delta + g + n) - m \left(1 - \frac{\tilde{\kappa}}{\tilde{k}} \right) \quad (10.41)$$

where $\tilde{\kappa} = \kappa e^{-gt}$ is the capital per effective immigrant. In the Solow-Swan model with technological progress, discussed in Sect. 10.3.1, capital per unit of effective labor depreciates due to the growth of effective labor $g + n$ and due to capital depreciation rate δ . Once we add migration to the model, there is an additional element; capital per unit of effective labor also depreciates due to migration, because migrants increase the domestic labor supply and typically have lower levels of capital than domestic workers, that is, $\tilde{\kappa} < \tilde{k}$.

We next make several assumptions about the factors included in the final term of Eq. (10.41). First, we assume that the capital per effective immigrant $\tilde{\kappa}$ is approximately constant over time, since either (a) there is in-migration, and if the typical origin country is close to its steady state, then $\tilde{\kappa} < \tilde{k}$ is independent of \tilde{k} , or (b) there is out-migration, so $\tilde{\kappa}$ is the capital per effective worker for each emigrant and $\tilde{\kappa} < \tilde{k}$ is likely to be fairly constant.

Fig. 10.4 The Solow-Swan Model with Migration

Second, we assume that there is a positive relationship between the net migration rate m and the capital per unit of effective labor \tilde{k} . This is because a higher \tilde{k} implies a higher domestic wage rate and therefore a more attractive prospect for potential migrants. The relationship between m and \tilde{k} is affected by exogenous factors such as the wage rate or standard of living in the origin countries or regions, the costs of migration, and the volume of migration.

We are now ready to analyze the conditions of the steady state and the dynamics of the model. We define the last term of the capital accumulation in Eq. (10.41) as

$$\xi(\tilde{k}) = m(\tilde{k}) \left(1 - \frac{\tilde{k}}{k} \right) \tag{10.42}$$

where m is now a function of \tilde{k} . Substituting Eq. (10.42) into the expression for the growth rate of capital per unit of effective worker Eq. (10.41) gives

$$\frac{\dot{\tilde{k}}}{\tilde{k}} = \frac{sf(\tilde{k})}{\tilde{k}} - [\delta + g + n + \xi(\tilde{k})] \tag{10.43}$$

It can be shown (see Barro and Sala-i-Martin 2004, p. 387, for details) that the derivative of $\xi(\tilde{k})$ with respect to \tilde{k} is positive whether the net migration rate is positive or negative. It follows that an increase in \tilde{k} raises the effective capital depreciation rate $\delta + g + n + \xi(\tilde{k})$, in contrast with previous versions of the Solow-Swan model discussed above, where this term was independent of \tilde{k} .

The implications of this can be seen on a diagram of the growth dynamics of \tilde{k} . Figure 10.4 shows the growth dynamics of the Solow-Swan model with migration. In contrast with the closed-economy case discussed in Sect. 10.2, the effective depreciation curve is now an upward sloping line, rather than a horizontal line as in Fig. 10.3. The steady state is given by \tilde{k}^* , where the two curves intersect and, as

before, the growth rate for any value of \tilde{k} is given by the vertical distance between two points. Of special interest is \tilde{k}^{closed} , which is the capital per unit of effective labor for the case where $m = 0$, and there is no migration. As drawn, the steady state level of capital per unit of effective labor \tilde{k}^* is higher than the no-migration level \tilde{k}^{closed} , so the economy will be a perpetual recipient of migrants. The diagram can be used to study the dynamics of the model. For instance, an increase in the domestic savings rate will lead to an upward shift in the $sf(\tilde{k})/\tilde{k}$ curve and therefore in higher values of \tilde{k}^* and m^* . This occurs because an increase in the savings rate raises domestic wages and makes the economy more attractive for migrants. Conversely, an exogenous increase in migration, such as that resulting from a more liberal immigration policy, leads to a lower \tilde{k}^* . This occurs because migrants arrive with relatively little capital, thus lowering the capital per effective worker in the economy.

We are also interested in the effects on the speed of convergence once migration is introduced to the model. It can be shown (see Barro and Sala-i-Martin 2004, p. 389) that the new speed of convergence is given by

$$\beta^* = (1 - \alpha - \eta)(\delta + g + n) + b + b(1 - \alpha) \log \frac{\tilde{k}^*}{\tilde{k}_{world}} \quad (10.44)$$

where the last two terms in Eq. (10.44) now incorporate the element e , defined as the derivative of $\xi(\tilde{k})$ with respect to $\log \tilde{k}$, and \tilde{k}_{world} is the capital per unit of effective labor in other regions or countries. The model therefore predicts that the speed of convergence in the model with migration is higher than the speed of convergence in the closed-economy model by the amount e , if we assume that $\tilde{k}^* = \tilde{k}_{world}$ holds for the typical economy. Empirical estimates presented by Barro and Sala-i-Martin (2004) suggest that this difference is of the order of $e = 0.003$ or 0.3 % per year for both countries and regions.

If migration is indeed an important determinant of convergence, including a measure of migration in a growth regression will lead to a lower estimate of the speed of convergence, all other things being equal. Barro and Sala-i-Martin (2004) show that the estimated speed of convergence is indeed lower once migration is accounted for, as long as the method used controls for endogeneity in the migration variable. However, the model assumes that labor is relatively homogenous, while in reality, migrants tend to be younger, better educated, and more entrepreneurial than nonmigrants (McCann 2001). An influx of migrants, especially in the regional context, can therefore lead to productivity gains in the form of technological progress, exacerbating the differences between regions and leading to divergence. In addition, since migratory workers have relatively little physical capital endowments, migration will tend to increase the rate of return to capital, leading to capital inflows. This is likely to further exacerbate the differences between receiving and sending economies. The overall effect of migration on growth may therefore be positive, negative, or insignificant, depending on the characteristics of the study (see Ozgen et al. 2010, for meta-analytical evidence).

10.4 The Ramsey-Cass-Koopmans Model

The models discussed above all have one thing in common: they are macroeconomic models that abstract from the utility maximization decisions of individual households. Thus, the choice between consumption and saving is determined exogenously. We now turn to a specification of the neoclassical model that explicitly incorporates consumer behavior with the Solow-Swan model as a special case. Our model in this section is based on Ramsey (1928), which was later refined by Cass (1965) and Koopmans (1965). For simplicity, we assume a simple production function without technological progress.

10.4.1 Households

The model assumes that households provide labor services to firms in exchange for wages, receive interest income from assets, spend a fraction of their income on the consumption of goods produced by firms, and save the remainder by accumulating assets. Households are assumed to care about their descendants, so that consumption by future members of the household enters the present utility function. Since households are assumed to be identical, we can simplify the analysis by assuming there is only one, infinitely lived, household, and that at time $t = 0$, there is only one worker in the economy. Population at time t is then given by

$$L_t = e^{nt} \quad (10.45)$$

where n is the population growth rate. Since all the income that is saved is used to accumulate assets, the household budget constraint at time t is given by

$$\dot{B} = wL + rB - C \quad (10.46)$$

where B are assets, w the wage rate, r the interest rate, and C consumption (and we have suppressed time subscripts). As before, it will be useful to express Eq. (10.46) in per-worker terms. Defining b as assets per worker, we use the relationship $b = B/L$, take logs, and differentiate to give

$$\frac{\dot{b}}{b} = \frac{\dot{B}}{B} - \frac{\dot{L}}{L} \quad (10.47)$$

Substituting Eq. (10.45) and Eq. (10.46) into Eq. (10.47) and rearranging, we arrive at an expression for the change in assets per worker:

$$\dot{b} = w + rb - nb - c \quad (10.48)$$

where c is consumption per worker. At this stage, we also make the assumption that households cannot borrow unlimited amounts to finance arbitrarily high current

levels of consumption. The present value of current and future assets must therefore be positive, households cannot borrow indefinitely until the end of their economic life cycle, and household debt cannot increase at a rate asymptotically higher than the interest rate.

The intertemporal utility function of the representative household is then given by

$$\begin{aligned} U &= \int_0^{\infty} u(c_t) L_t e^{-\rho t} dt \\ &= \int_0^{\infty} u(c_t) e^{nt} e^{-\rho t} dt \end{aligned} \quad (10.49)$$

that is, the utility of the household at $t = 0$ is a weighted sum of all future flows of utility to members of the household, where $\rho > 0$ is the rate of time preference. A higher ρ implies that consumption by future members of the household is less desirable compared to current consumption. The utility function $u(c)$ gives the utility per worker and is assumed to be increasing in c , to be concave, and to satisfy the Inada conditions.

Households maximize their intertemporal utility, given by Eq. (10.49), subject to their budget constraint Eq. (10.40). Using the Hamiltonian approach, the problem is given by

$$J = u(c)e^{-(\rho-n)t} + v[w + (r-n)b - c] \quad (10.50)$$

where v is the present value of the shadow price of income in terms of utility units. The first-order conditions are

$$\begin{aligned} \frac{\partial J}{\partial c} = 0 &\Rightarrow v = u'(c)e^{-(\rho-n)t} \\ \frac{\partial J}{\partial b} = -\dot{v} &\Rightarrow \dot{v} = -(r-n)v \end{aligned} \quad (10.51)$$

and transversality condition

$$\lim_{t \rightarrow \infty} (v_t b_t) = 0 \quad (10.52)$$

The latter expression indicates that the value of the assets of the representative household must approach zero as time approaches infinity or, in other words, that households do not hold valuable assets in perpetuity. From the first-order conditions, we obtain the first fundamental equation of the model, also known as the Euler equation:

$$r = \rho - \left[\frac{u''(c)c}{u'(c)} \right] \frac{\dot{c}}{c} \quad (10.53)$$

which shows that households choose consumption so as to equate the return to savings r to the *rate of return* to consumption, the latter of which is given by the right-hand side of Eq. (10.53). In other words, households are indifferent between consumption and saving if the rates of return to the two activities are equal.

In order to parameterize the model, a commonly used functional form for the utility function is the *constant intertemporal elasticity of substitution* (CIES) function:

$$u(c) = \frac{c^{1-\theta} - 1}{1-\theta} \quad (10.54)$$

where $\theta > 0$. The elasticity of substitution is the constant $\sigma = 1/\theta$, which reflects the willingness of individuals to accept deviations from a uniform pattern of consumption over time. Using the functional form Eq. (10.54) in the Euler equation Eq. (10.53) gives

$$\frac{\dot{c}}{c} = \frac{1}{\theta}(r - \rho) \quad (10.55)$$

Intuitively, the growth rate of consumption per worker fluctuates with the optimizing behavior of households. Households save more if the rate of return r is high relative to the rate of time preference ρ . This effect is magnified when the rate of intertemporal substitution is high, indicating that future consumption is considered a good substitute for current consumption.

10.4.2 Firms

The second side to the problem concerns the behavior of a large number of identical firms, producing a homogenous good Y . Each firm uses a neoclassical production function $Y = F(K, L)$ and pays wages w and rent R in exchange for a unit labor and capital, respectively. The net rate of return to capital is given by $R - \delta = r$, where δ is the capital depreciation rate and r is the interest rate on loans to other households. The representative firm maximizes profits given by

$$\pi = F(K, L) - (r + \delta)K - wL \quad (10.56)$$

or in terms of per-worker units

$$\pi = L[f(k) - (r + \delta)k - w] \quad (10.57)$$

The first-order conditions of the maximization problem of the firm are thus

$$\begin{aligned} \frac{\partial \pi}{\partial K} = 0 &\Rightarrow f'(k) = r + \delta \\ \frac{\partial \pi}{\partial L} = 0 &\Rightarrow f(k) - kf'(k) = w \end{aligned} \quad (10.58)$$

10.4.3 Equilibrium and Transitional Dynamics

To find the equilibrium, we combine the first-order conditions for the firm given in Eq. (10.58) with the expression for the growth rate of consumption in Eq. (10.55) to find expressions for the change of capital and consumption over time. Since in equilibrium the stock of assets per worker equals the stock of capital per worker, we have $b = k$. Starting from Eq. (10.48) and substituting $k = b$, and the expressions for w and r from Eq. (10.58), we obtain

$$\dot{k} = f(k) - (n + \delta)k - c \quad (10.59)$$

Similarly, substituting the expression for r from Eq. (10.58) into Eq. (10.55) gives

$$\frac{\dot{c}}{c} = \frac{1}{\theta}(f'(k) - \delta - \rho) \quad (10.60)$$

In the steady state, the growth rates of capital and consumption per worker are zero and so is the growth rate of output per worker. As with the Solow-Swan model, the simple Ramsey-Cass-Koopmans model therefore predicts that the growth of output per capita is zero in the long run. The two equations, Eqs. (10.59) and (10.60), together with the initial level of capital per worker k_0 and the transversality condition determine the time paths of capital and consumption per worker.

To see the equilibrium points of the model, we once again make use of a phase diagram. The steady state values of c and k are determined by setting expressions (10.59) and (10.60) to zero. The curve labeled $\dot{k} = 0$ on Fig. 10.5 shows the (k, c) pairs for which expression (10.59) is equal to zero, which is given by $c = f(k) - (n + \delta)k$. The peak of the curve occurs where $f'(k) - \delta = n$ or where the interest rate equals the steady state growth rate of output n , the capital per worker for which consumption is maximized. The vertical line labeled $\dot{c} = 0$ shows the (k, c) pairs for which Eq. (10.60) is set to zero. Note that the value of k for which this holds is independent of c . Since the $\dot{k} = 0$ and $\dot{c} = 0$ lines cross three times, there are three steady states. The first is at the origin, where $c = k = 0$. The second is at the point corresponding to c^* and k^* , and the third occurs at the point k^{**} where there is positive capital per worker but zero consumption.

We focus on the second steady state. The arrows on Fig. 10.5 show the direction the economy will move in for each combination of c and k . The economy can converge to the steady state given by (c^*, k^*) only if it starts in two of the four quadrants that divide the space. The dynamic equilibrium follows a saddle path shown by the diagonal line on the diagram. If the initial capital per-worker level is given by k_0 , the economy will converge to the steady state only if initial consumption per worker is equal to c_0 .

Unlike the Solow-Swan model, the Ramsey-Cass-Koopmans model predicts that the savings rate will vary with the level of development, although the exact path that it takes is complex and depends on the relative strength of income and substitution

Fig. 10.5 The Ramsey-Cass-Koopmans Model

effects. Intuitively, as k rises, a decline in $f'(k)$ lowers the rate of return on saving given by r . This reduces the incentive to save as the economy develops and constitutes an intertemporal substitution effect. However, households have a preference for consumption smoothing and therefore wish to consume a larger proportion of their income when their income is low. As k rises and they become richer, the gap between current and permanent income falls, and the savings rate tends to rise. This is the income effect. The overall behavior of the savings rate as an economy develops is therefore an empirical question. Barro and Sala-i-Martin (2004) review the empirical evidence and find that, in general, the savings rate tends to rise with per-capita income during the transition to the steady state. This in turn implies that the predicted speed of convergence is lower in the Ramsey-Cass-Koopmans model, although the growth rate in income per capita is still higher for countries or regions that are furthest away from their steady states.

10.4.4 Extensions of the Ramsey-Cass-Koopmans Model

The Ramsey-Cass-Koopmans model can be extended to allow for an open economy, a much more realistic assumption in the context of regions. This involves incorporating the mobility of goods across borders and international borrowing and lending (Barro and Sala-i-Martin 2004). However, extending the model in this way leads to extreme (and paradoxical) results. The speed of convergence becomes infinite for all but the most patient country (defined in terms of the rate of time preference), so that consumption tends to zero and assets become negative. The most patient country owns all the assets and consumes almost all output. Additional constraints, such as imperfect international credit markets, are needed to ensure less extreme predictions.

In addition, the model can be extended to allow for migration. The key relationship is now between the migration rate and the behavior of the savings rate. Migrants enter the economy with a quantity of capital, mainly in the form of

human capital. However, unlike in the standard Ramsey-Cass-Koopmans model, consumption of migrant workers does not enter into the utility function of existing residents, or in other words, existing residents do not *care* about the consumption level of migrants. If the domestic economy is attractive to migrants in its closed state, the opening up of the economy leads to a steady state with positive migration and reduced capital intensity. As with the Solow model, migration in the Ramsey-Cass-Koopmans model results in a higher speed of convergence to the steady state.

The models become increasingly complex if additional forms of spatial interaction, such as trade and technological spillovers, are also considered. In a comprehensive survey, Nijkamp and Poot (1998) discuss a range of open economy growth models that are particularly applicable to regions. For instance, introducing trade into the neoclassical models will speed up the rate of convergence and result in a pattern of specialization that reflects equilibrium factor intensities. However, if the model is extended to allow for technological spillovers, a steady state equilibrium is unlikely to exist (Nijkamp and Poot 1998). Models with technological spillovers, although no longer strictly neoclassical, can also be considered extensions of the models discussed in this chapter (Fischer 2011).

10.5 Conclusions

The chapter has provided an overview of the fundamental models of neoclassical growth and has discussed their key features, predictions, and limitations. The review starts with the simple Solow-Swan model, with an exogenous savings rate and in a closed-economy setting. This model, although simple, has considerable predictive power and provides the basis for several extensions. Several of these extensions are reviewed, among them a model that allows for exogenous technological progress, one that includes a broader definition of capital to also encompass human capital, and one that relaxes the assumption of a closed economy. Finally, the chapter considers a more complex model of neoclassical growth, the Ramsey-Cass-Koopmans model, which incorporates consumer behavior and allows for an endogenously determined savings rate. Additional extensions incorporating trade and technology diffusion are also briefly discussed.

Abstract

In this chapter, we outline the basic mechanisms in endogenous growth theory that identify knowledge creation and diffusion as the core driver of economic growth. Then we discuss how new economic geography, urban economics, organizational science, and entrepreneurship theory have *regionalized* the mechanisms involved. Knowledge creation, however, has been dubbed a *proximate cause* of growth, and the quest for *fundamental causes* has continued. We then discuss this recent development in macroeconomic growth theory and argue that the new *institutional approach to growth* opens up a lot of new avenues for further research. Once again, the importance of cities, organizations, and entrepreneurship is being ignored in macro growth theory. Yet economic geography, urban economics, organizational science, and entrepreneurship theory have a lot to contribute to growth theory by both empirically and theoretically developing our understanding of local institutions and linking these to regional economic development and growth.

11.1 Introduction

Growth at the regional level can be understood as the increase in economic activity in that region over a period of time. We can measure this empirically (with all well-known caveats) by the annual increase in GDP or employment at the regional level. The sources of economic growth have always been the subject of intense academic investigation. However, the resulting state-of-the-art modern economic growth theories – for example, presented in Barro and Sala-i-Martin (2004) and Acemoglu (2009) – largely abstract from geography. That is, the process of economic growth is investigated without considering the location and regional setting in which it is taking place. Of course, that will not do for the purposes of this handbook.

The literature shows that there is large variation in regional levels and growth of GDP. Barro and Sala-i-Martin (2004) present tests of convergence among regions, showing slow convergence exists, but migration and capital mobility fail to eliminate regional variation in development levels, even over long periods of time and among well-integrated regions. We have seen many possible explanations being offered and empirically investigated in other chapters of this part of the handbook. All in one way or another suggest that although cross-regional spillovers are significant, the growth and development process is also very much a localized process. In this chapter, we will discuss at some length the models and theories that explicitly link economic activity and development to regional circumstances.

But before we discuss such extensions to the basic framework, it is useful to review modern growth theory. Then we can discuss the various ways in which these models have been *regionalized* in the literature on new economic geography, urban economics, and the spillover theory of entrepreneurship. These literatures all build on the first generation of ideas in innovation-driven endogenous growth theory. We can then review the implications of the more recent institutional approach to

economic growth. Barro (1996) and Acemoglu, Johnson, and Robinson (2001) pioneered this approach, but here too, geography is largely ignored. One way to link institutions and growth at the regional level is to consider the link Baumol (1990) proposed between productive entrepreneurship and institutions. The institutional approach to growth may well open up new and exciting research avenues for building regional endogenous growth models. As this literature is very much in an embryonic stage, however, the final sections will raise questions for further research.

11.2 Modern Growth Theory

11.2.1 Empirical Findings on Growth

In his analysis of changes in the aggregate production function, Solow (1957) referred to earlier research that found that over 90 % of the variation across US states in GDP per capita growth was due to productivity increases. His work sparked a large literature on the rate of technological change, where the empirical literature sought to adequately measure productivity and look for statistically significant correlations with possible explanatory variables (e.g., Denison 1967). The (mainstream) theoretical literature, meanwhile, built on the evidence and formulated new hypotheses and models that try to endogenously explain technological change and productivity growth as the result of (rational) behavior of economic agents.

At around the same time as Solow, however, Kaldor (1963) posited his stylized facts of growth and presented economists with another puzzle. Kaldor (1963) showed that over time, while per capita capital stocks grow, the income shares in GDP are approximately stable. This implies that technological change is biased and purely labor augmenting. This finding sparked a literature on the bias in technical change that received a big push from the observation that in the 1980s the labor income share of the low skilled workers started dropping dramatically. The empirical literature again focused on measuring and separating the various biases in technological change and related them statistically to a host of explanatory variables while the theoretical literature struggled to develop a model that would explain how rational agents generate such biases in response to price and demand developments.

As innovation is an illusive concept that is hard to measure or observe directly, the empirical evidence in support of the claim that innovation is important is convincing yet circumstantial. Technological change and innovation have been identified as the source of long-run economic growth by elimination of all other possible sources. As more and better data became available, recent studies then found regularities in the data that strongly suggested that the rate of innovation indeed drives long-run economic growth. The empirical literature on economic growth has been surveyed in much more detail than we can hope to achieve in this chapter by, for example, Temple (1999) and Barro and Sala-i-Martin (2004). From their surveys, we learn that growth rates tend to remain positive in the long run and differ a lot for long time spans among countries. Temple (1999) surveys the

evidence that links these cross-country differences to the proximate causes of growth: investment in physical capital (machinery, equipment, and infrastructure), investment in human capital, and investment in research and development.

In particular, in explaining differences between developing and developed countries, the investment in physical capital seems a strong candidate. Differences among developed countries are attributed inter alia to knowledge creation (e.g., R&D), although there is also strong evidence for international spillover of knowledge. The evidence on human capital accumulation through education is mixed. The empirical literature on these issues, however, typically struggles with the statistical problem to separate cause and effect as investments in knowledge creation and education may both affect and be affected by economic development.

In addition to these proximate causes, Temple (1999) discusses evidence on the impact of population growth, trade openness, financial development, macroeconomic stability (low and stable inflation and unemployment rates), inequality, political and civil rights, the size of government, and public infrastructure investments. All these factors are, however, believed to work through, or as moderators of, the impact of knowledge creation.

In the empirical literature, one can find various exogenous and semi-endogenous representations of technological change. Through introducing time trends, accumulated production, new capital investment, imports and exports, etc., as arguments in growth regressions or regression equations for production frontiers or cost curves, this literature has explicitly or implicitly introduced and developed ways to represent learning by doing (cumulative production), learning by investing (capital accumulation), embodied technical change (new capital goods), imported technology (imports), and learning by exporting (exports). The latter representations, however, can still not be called *endogenous technological change* in the true sense of the word. The empirical models assume a relation between technology and other (endogenous) variables such as cumulative production, but do not explain the mechanism and behavior behind this relation. But this is as far as empirics can take us. Going from empirical measures and representations of technology to actually explaining the phenomenon requires a theoretical model that illustrates how behavior of agents in response to incentives and constraints leads to innovation and technological change.

A fundamental proposition in new growth theory is that rational agents create and accumulate knowledge for a purpose. In accordance with the findings in the empirical literature discussed above, theory has explored R&D and education (human capital) as the sources of growth. In addition, and more recently, organizational change and institutional development have been identified as key enablers or *fundamental causes* of economic growth.

11.2.2 Modeling R&D as the Source of Growth

With Romer (1990), Aghion and Howitt (1991), and Grossman and Helpman (1991a), a strand of models has developed in which R&D, the conscious and

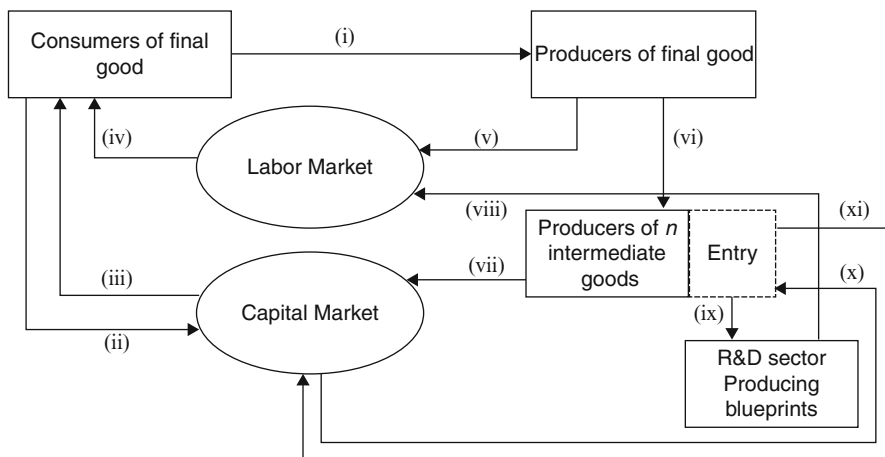

Fig. 11.1 The Romer (1990) model

deliberate investment of resources in knowledge creation, generates inventions that generate productivity growth. The structure of the Romer (1990) models is illustrated in Fig. 11.1.

The arrows (i)–(xiii) represent financial flows. Consumers spend on final goods (i) and save part of their income (ii) by purchasing assets. Their income consists of capital (iii) and labor income (iv). The final goods producers hire labor (v) and buy intermediate goods (vi) that are imperfect substitutes in production and supplied by monopolistic intermediate producers that only hire raw capital (vii) as their input. Given that there are monopoly profits in intermediate goods production and latent demand for new intermediates is positive, there is an incentive for the R&D sector to hire labor (viii) and produce new blueprints that are sold (ix) to new entrants, who have to borrow (x) and repay (xi) this loan. The diagrams for the Grossman and Helpman (1991a) (there are no intermediates, but final goods are imperfect substitutes in consumption) and Aghion and Howitt (1991) (there is no variety expansion but quality improvement of existing intermediates) models would look slightly different, but as Grossman and Helpman (1991a) show, the qualitative results and key driving mechanisms remain the same. Based on these four basic models, a large literature has emerged, presenting models that focus on the accumulation of tradable knowledge embodied and codified in patents, products, and processes.

The basic behavioral assumption in these models is perfect rationality. Representative agents maximize utility or profits and are constrained by market (demand functions) and technological (production functions) circumstances. These behavioral assumptions are very strong and lack a strong empirical basis. The models should therefore not be taken too literally. Rather, in explaining the mechanism through which an economy with pure rational agents would generate innovation, the models show why it pays to innovate. Such mechanisms then also produce a tendency toward productivity growth when more realistic behavioral heuristics are applied. Such extensions and adaptations, however, usually come at the cost of

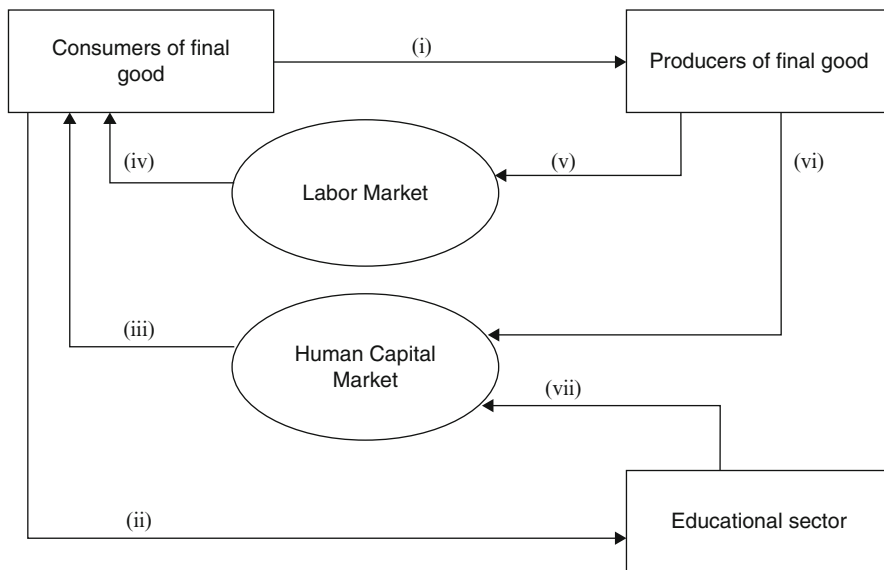

Fig. 11.2 The Lucas (1988) model

more complexity and loss of tractability. As consumption, (intermediate) production, and R&D are typically geographically concentrated and distributed in space, a clear link to regional models of growth can easily be built in.

The key insight to be taken away from these models is that investments in knowledge creation will generate innovation and economic growth when the private returns to knowledge creation, ultimately related to the consumers' preferences, justify private investments in knowledge creation. The public good nature of knowledge (non-rivalry) then implies increasing returns to knowledge accumulation in the aggregate and allows for growth to be positive in equilibrium. Typically, the knowledge generated in the past is assumed to be available and increase the productivity of knowledge generation in the present. This externality drives growth and is assumed to arise automatically, but it is not a big leap to link such spillovers to regional and local variables such as proximity and density. The private rewards to innovation, in addition, typically come from some sort of entry barrier that protects the innovator. This is another way in which (local, regional, or (inter)national) conditions enter the debate.

11.2.3 Modeling Education as the Source of Growth

Following the original ideas of Becker (1964), Lucas (1988) pursued the idea that human capital accumulation through education generates productivity growth. Lucas (1988) presented a model (see Fig. 11.2) in which rational agents consume (i) and invest in their education (ii) in response to expected private future benefits. Production uses raw labor (iii) and human capital (iv), so it benefits from higher human

capital levels, but because the educational sector also uses human capital (v), education makes both production and the future education process more productive in his model. Lucas thereby introduces aggregate increasing returns to knowledge accumulation as in the models above. In this model, however, the knowledge accumulates in the working population, not in some disembodied knowledge base or in the technology embodied in the physical capital stock. It would therefore make sense to interpret that type of technological change as quality improvement of labor inputs.

The key to generating endogenous growth with human capital is again introducing externalities and spillovers that create increasing returns at the aggregate level. As Lucas (1988) himself immediately recognized, however, the productivity of human capital depends a lot on the presence of other educated workers in close proximity. He therefore discussed at some length the role of cities in economic growth and of human capital spillovers in holding cities together.

Of course, the educational level of the population also plays a role in the R&D-driven growth models, as R&D typically requires high-skilled (technical) personnel. The two models combined would therefore allow for education to affect productivity directly but also indirectly through the increased (productivity of) R&D activities.

11.2.4 Concluding Remarks

Modern economic growth theory has focused on knowledge accumulation in the workforce and the aggregate production system as the long-run sources of economic growth. It models how rational decision makers are privately induced to produce knowledge and thereby economic growth as a positive externality. Education makes all workers more productive, new technologies make further innovation easier, and knowledge, once created, is non-rival in use. Economic growth comes from the increasing returns to human capital and knowledge creation that exist at the aggregate level.

The first generation of endogenous growth models thus predicted that economies with a larger workforce would experience higher growth (the so-called scale effect), which flew in the face of empirical evidence. This led many to propose alternative specifications that did not suffer from this apparent flaw. But once one realizes that the *aggregate level* of an economy is not the same as the size of a nation's workforce and the appropriate level of analysis is not the national but the regional or even local level, scale and density become similar concepts, and we can start to rethink the implications of endogenous growth in a slightly different direction.

11.3 The Geography of Knowledge Creation and Diffusion

11.3.1 Clusters and Agglomeration

It is a well-established empirical regularity in economic geography that population, and with it economic activity, is highly concentrated in urban centers. In addition, it follows

often at least approximately a remarkably stable distributional pattern, known as Zipf's law. Zipf's law states that population centers, ranked by size, will decline in size proportionately to their rank. This implies that if the second city in a region has half the population as the first, the third has one third, etc. Moreover, Zipf's law has been shown to hold for the distribution of population in space at the national, regional, and even agglomeration level in, for example, Germany by Giesen and Suedekum (2011).

This pattern of spatial distribution interacts with another important empirical regularity in economic geography, known as the gravity equation. The gravity equation was proposed to explain the intensity of interactions between countries but can also be applied to interaction between and within clusters of economic activity at lower aggregation levels. The gravity equation explains, for example, trade and migration flows as a function of GDP of the origin and destination regions and the distance between two locations. In empirical work on Zipf's law and the gravity equation, the explanatory power of these relatively simple models is often above 90 % of the variation to be explained across regions. This suggests that core-periphery clusters are remarkably common, and their general spatial structure and the linkages between constituent parts are similar.

Early work on the economics of agglomeration of industries identified the availability of inputs (specialized labor, other non-tradable specialized inputs) and access to output markets as key reasons for the spatial agglomeration of industries and argued that in agglomerations, the informational spillovers would improve productivity. In his seminal contribution, Paul Krugman (1991) presented a model that would generalize this intuition using among other things newly developed endogenous growth modeling tools. By now, there are many excellent textbook treatments of his basic model.

Intuitively, the model exploits a *circularity* or positive feedback loop. Consider an economy with agriculture and manufacturing. Agriculture is obviously located where the land is fertile. With high transportation costs and limited economies of scale in manufacturing, manufacturers will want to locate close to their demand. In a largely agricultural economy, this implies manufacturing is distributed in space pretty much in the same way as arable land. If on the other hand economies of scale are strong and transportation costs are low, manufacturing will begin to cluster. And if manufacturing workers also provide most of the demand for manufactured products, the process of agglomeration will feed on itself.

The model can be represented in a figure similar to the one provided for the Romer (1990) and Lucas (1988) models above. It is immediately clear from Fig. 11.3 that the ingredients of the Krugman (1991) model can easily be connected to the core elements in innovation-driven endogenous growth models. Krugman (1991) assumed two regions and imperfect substitutes and monopolistic competition in both manufacturing sectors. That is, consumers from both regions receive labor income (i) and consume local food (ii), but both purchase locally produced (iii) and imported (iv) manufactures. Both food production (v) and manufacturing (vi) use labor only in the basic model. Krugman (1991) then focused on labor migration and investigated how differences in wages (vii) might trigger movements of labor, explaining the emergence of core-periphery patterns.

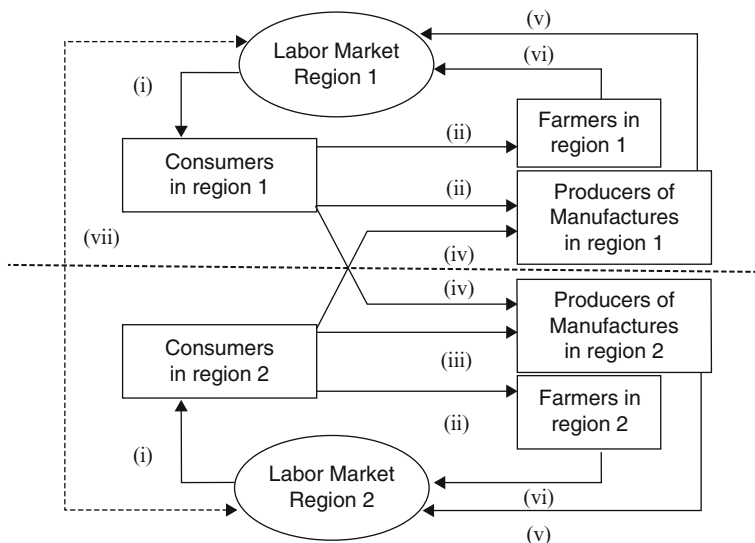

Fig. 11.3 Krugman (1991) model

The Krugman (1991) model predicts that in a perfectly symmetric situation, the wages for manufacturing workers are equal in both regions, and there will be no pressure for migration or clustering. If, however, the initial manufacturing workforce is not symmetrically distributed, there are three competing effects on the relative (real) wage of manufacturing workers. On the one hand, the region with the larger market pays higher manufacturing wages because scale economies reduce costs and the larger market is cheaper to service in the presence of transportation costs. In addition, the lower price of manufactures due to competition increases the real value of wages in the larger market. On the other hand, there is less competition for the demand for manufactures from agricultural workers in the smaller market. The strength of these competing forces depends on the share of agriculture and manufacturing in total income, the degree of competition among manufacturers, and the level of transportation costs.

For regional endogenous growth, this model has important implications. The sources of aggregate increasing returns in modern manufacturing and services sectors are easily related to the sources of increasing returns that drive endogenous growth in modern growth theory. Baldwin and Forslid (2000), for example, introduced a Romer (1990) R&D sector into the Krugman (1991) model by allowing for new manufactured goods and show that the integration of knowledge bases creates growth, even in the periphery, that compensates for losses of agglomeration there. What these models have in common is that they make regional development highly path dependent. Initial conditions determine to a large extent where what type of economic activity will establish itself and how it will (fail to) grow.

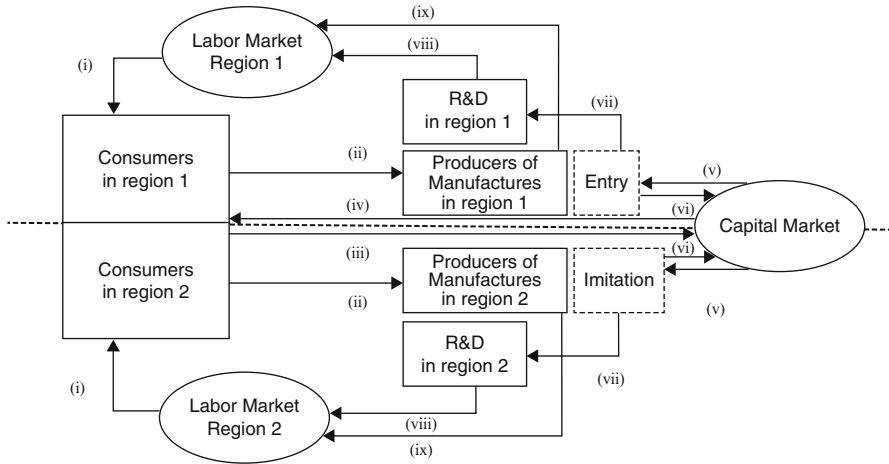

Fig. 11.4 The Grossman and Helpman (1991a) model

A model that explicitly uses endogenous growth theory is a model of the product life cycle by Grossman and Helpman (1991b). As can be seen in Fig. 11.4, in this model, Grossman and Helpman introduce an R&D sector in both regions but have the advanced region develop new products, whereas the lagging region is merely imitating them.

In the model, total wage income (i) is spent on consumption (ii) of diversified final goods from regions 1 and 2. Consumers also save in a global capital market (iii) and receive interest (iv) on their assets. These savings are invested in new ventures (v) and repaid out of profits (vi). The required knowledge for a new or imitation venture is produced by and auctioned off by a local R&D sector (vii), and both the R&D and production sector compete and pay for labor (viii) and (ix), closing the model. There is free trade, but all final goods production is monopolistic, and consumers value variety and new product designs. This implies monopoly rents are available to incentivize knowledge creation. The backward region in the model, however, does not invent but rather copies the products developed in the advanced region, and of course, this is easier when a lot of advanced products are available. Thus, the model explicitly endogenizes regional and intertemporal knowledge spillovers and shows that growth in the periphery will benefit from knowledge creation in the core. In fact, in equilibrium, the growth rates in both regions will equalize, and the core has to *run to stand still* in terms of relative wages and income levels. Audretsch and Sanders (2011) extended this model to a three-stage life cycle, showing inter alia that new labor-rich countries and regions joining the global economy will leave the advanced region a more limited range of products and cause the fringe to catch up. In these models, however, information and knowledge will flow between the *advanced* and the *backward* region as water will run down a hill. Moreover, this model assumes labor immobility, suggesting the regions are geographically not very near.

11.3.2 Knowledge Spillovers and the Role of Cities

As endogenous growth theory has emphasized knowledge accumulation, either in the labor force or in the form of new products and processes, it is useful to distinguish *knowledge* from *information* as in Feldman and Audretsch (1999). Information is codified and can be transmitted over large distances at low costs. In fact, with modern communications technology, the costs of reproducing and transferring information are effectively zero. Knowledge, in contrast, is partially tacit and requires proximity and high-quality two-way communication for effective knowledge transfer. If the positive externalities and increasing returns depend on others also benefiting from past knowledge creation, the intensity of personal interaction becomes a relevant factor in determining growth to the extent that knowledge is not information. And as this intensity is higher and more diverse in a densely populated region, this puts urban, high-density regions center stage in the discussion.

Glaeser et al. (1992) in their seminal study of growth in cities tested three alternative theories of endogenous knowledge-spillover-driven economic growth in a sample of US cities. They tested the Marshall-Arrow-Romer approach that relies on within industry knowledge spillovers and monopoly profits to motivate knowledge creation against the Porter approach that also emphasizes intraindustry knowledge spillovers but rather relies on competitive pressures to innovate and the Jacobs approach that instead relies on interindustry knowledge spillovers, where ideas cross-fertilize over industry boundaries. Perhaps surprisingly, Glaeser et al. (1992) found that the data favor the latter theory, suggesting that specialization at the regional level is detrimental for growth. Feldman and Audretsch (1999), however, found that specialization does promote regional growth and development. De Groot, Poot, and Smit (2009) concluded from a meta-analysis of this literature that although most research supports Porter and Jacobs, the heterogeneity across regions, periods, and sectors seems large.

Whether good or bad for growth, it is an established fact that cities and urban regions typically are quite specialized and have become increasingly so. Smaller cities are more specialized than the large metropolitan areas, however, so as cities grow in size, they also tend to become more diversified. This is because larger cities attract the much more diversified business services. So cities specialize, and so do industries. Ellison and Glaeser (1999) studied the reason for industries to concentrate in regional clusters and found that only 10–20 % of the spatial pattern could be explained by natural advantages (access to port facilities and navigable rivers, presence of natural resources, etc.). The remaining 80–90 % would have to be attributed to intraindustry spillovers. Cities attract these so-called *footloose* production activities, where location is not important, but agglomeration is.

Florida (2005) discussed the impact of the creative class on regional development and finds that more open cultures perform better. This suggests that it is indeed the exchange of knowledge, particularly tacit knowledge, that drives prosperity and growth. And the exchange of tacit knowledge requires open and intensive communications between people of very diverse backgrounds and perspectives.

Only considering the positive knowledge spillover externalities in the models, however, would lead us to the conclusion that agglomerations are typically too small. Given that there are positive externalities connected to the decision to locate in a given area by increasing its density, it would then make economic sense for cities to grow without bounds. But of course, there are also negative externalities to consider. Henderson (2006) presents models of urban growth that rely heavily on endogenous growth models as described above. But he explicitly introduces the negative externalities connected to congestion and commuting. This introduces an inverted u-shaped relationship between city size and total welfare and implies cities have an optimal size. This optimal size is shown to depend negatively on transportation and congestion costs and positively on benefits of agglomeration, total factor productivity, and human capital accumulation. Henderson shows that it depends on their institutional setting and quality whether actual cities will achieve this optimal size. One needs to either have local governments that can limit city size or free markets in which both negative and positive externalities are priced into land rents and local public goods provision, respectively. In the absence of such institutions, as arguably is the case in many developing countries, cities will grow beyond their optimal size. When the marginal migrant is indifferent between living in an overcrowded city or a sparsely populated rural village, the positive externalities of density in knowledge creation are fully offset.

11.3.3 Concluding Remarks

This section has reviewed the main models that turn endogenous growth models into models of regional endogenous growth. As endogenous growth models build on positive externalities connected to knowledge accumulation at the aggregate level, regional models of endogenous growth all have in common that they localize this process. New economic geography models will distinguish between knowledge accumulation in agriculture, manufacturing, and services to explain the core-periphery patterns of economic activity, whereas urban economics models explain the existence and growth of urban agglomerations by focusing on the centripetal forces of localized knowledge spillover externalities. These models thus explicitly localize the knowledge spillovers that cause increasing returns in the aggregate growth models discussed above. One can localize the knowledge base on which new knowledge is created or link the creation of positive spillovers to density and proximity to explain spatial patterns of economic development. What these models do not endogenize, however, is the selection of what agents will take what actions to create and/or diffuse the knowledge into the regional economy. New economic geography and urban economics share with endogenous growth theory a relative neglect for the organizations and people that create or build on the new knowledge.

11.4 The Organization of Knowledge Creation and Diffusion

11.4.1 Organizational Change as the Enabler of Economic Growth

Aghion et al. (1999) pointed out the possible relevance of organizational change for economic growth. The organizational change literature stresses the fact that introducing new technology always requires a rethinking of the organization of the production process. In this literature, however, organizational change is not considered a root cause of economic growth and innovation. By optimizing the organization, productivity can be increased for a given set of technologies. But it is likely that this type of productivity increases run into severe diminishing returns in the absence of true technological innovation or knowledge accumulation.

Organizational change can never improve efficiency above 100 % and push the technology frontier out by merely reorganizing the existing production techniques, knowledge, and outputs. The rate of knowledge accumulation thus ultimately limits productivity growth. But only when the appropriate organizational changes are made will newly acquired knowledge actually create growth.

For the current chapter, this model relies primarily on the short- and medium-run adjustment process to new technology. Adopting new technology requires adaptive skills at the regional, local, and organizational level. The absence of such skills will slow down the rate of technological change even if knowledge creation is not the bottleneck in the innovation process, whereas an abundance will facilitate spillovers from outside. The Aghion et al. (1999) approach looks at this adjustment to new knowledge and technology as taking place predominantly *within* existing organizations and concludes that generally high-skilled workers will be in higher demand when technical and therefore organizational change is intense. The implicit assumption in this framework is that existing firms and organizations adopt and commercialize new knowledge and ideas. The entrepreneurship literature has focused instead on new firms and organizations as the vehicle for new knowledge commercialization.

11.4.2 Entrepreneurship as the Conduit for Knowledge Spillovers

Endogenous growth theory has largely considered knowledge accumulation as the key determinant of growth and consequently focused on explaining the accumulation of new knowledge. New economic geography and urban economics had already recognized the importance of local knowledge spillovers and were quick to link the tools in endogenous growth theory to local and regional economic activity. And organizational change theory addressed the skill requirements that follow from knowledge implementation in existing organizations. All these approaches, however, ignored the Schumpeterian distinction between *invention*, the creation of an idea, and *innovation*, the commercialization of that idea. The working assumption in most of the models discussed above is that inventions will

automatically or trivially diffuse throughout the (local) economy causing innovation. There are telling examples, however, of firms that failed to commercialize the new knowledge developed in their own R&D departments. Similarly, regions and organizations have sometimes failed to develop competitive advantages based on knowledge that was available. There can be many reasons, but it is obvious that idle knowledge will not cause economic growth. More generally, knowledge creation is a fundamental and definitely necessary, but not a sufficient, condition for generating economic growth.

A large body of literature on entrepreneurship shows that innovation and knowledge spillovers are far from trivial and automatic. Moreover, the process of commercialization is driven and restricted by very different incentives and constraints than knowledge creation. Arguably, the entrepreneurial skill, attitudes, and infrastructure in a region will then co-determine how effectively that regional or urban economy implements and benefits from knowledge creation. There is quite some empirical evidence that supports the claim that at regional and local levels, it is the (lack of ambitious) entrepreneurship that explains the success and failure to turn knowledge creation into economic growth. The entrepreneurship literature long took the creation and existence of new business opportunities as exogenous and zoomed in on the entrepreneurial process of recognizing and exploiting opportunities instead. Its focus to date is largely empirical and shows strong regional differences in entrepreneurial activity that are closely correlated with economic growth and development. These differences can of course be related to the local presence or absence of new knowledge and ideas, but it has been shown that many other regional and individual variables play a role. Entrepreneurial attitudes and ambitions, local outside options for entrepreneurs and the presence of many small firms and entrepreneurs, a skilled labor force, and a high population density all seem to be of importance.

In Acs et al. (2009) and Acs and Sanders (2012), it was argued that entrepreneurship should be considered the *missing link*, the key conduit (and bottleneck) for knowledge spillovers. It is not through the mere presence of or random interaction among many agents in a densely populated urban setting that knowledge diffuses and creates the positive externalities that endogenous growth theory assumes. The *knowledge spillover theory of entrepreneurship* (KSTE) as Acs et al. (2009) dubbed their approach argues that it is entrepreneurs that deliberately transfer knowledge and transform invention into innovation in the pursuit of profit. In doing so, this theory endogenizes the spillovers that were assumed to exist or arise costless and semi-endogenously in endogenous growth models discussed above. In that sense an *entrepreneurship theory of knowledge spillovers* might have been equally appropriate.

As such, the KSTE opened up a range of new opportunities for thinking about endogenous models of regional growth. Consider the Acs and Sanders (2012) model represented in Fig. 11.5, where we took the Romer (1990) model and added the possibility for the final goods sector to hire labor to do R&D (vii). To fund these investments, they need to borrow (viii) and repay (ix) their loans from

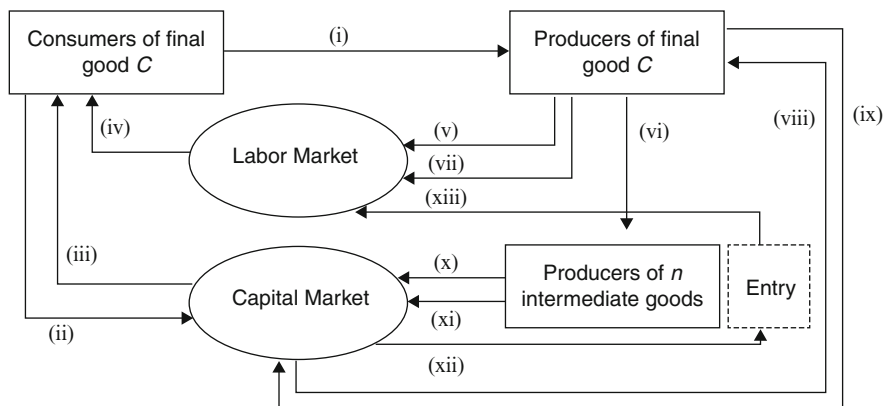

Fig. 11.5 The Acs and Sanders (2012) model

additional profits. The R&D in the final sector creates *upstream* knowledge spillovers that are free. The R&D in a car-manufacturing firm, for example, may create an occasional opportunity for an entrepreneur to become a new supplier of some part in the intermediates sector. The entrepreneurs can set up such a firm, but this requires labor (xiii) that has to be financed (xii), implying all existing intermediate firms also repay the start-up loan (xi).

The implications of the model are intuitive. In the absence of a pool of ambitious and skilled entrepreneurs, the knowledge spillovers are limited to within firm accumulation of knowledge. Entrepreneurs facilitate the knowledge spillovers that seem important in the Jacobs and Porter approaches, described above. One can also put more emphasis on the occupational choice trade-offs, implicit in the model. By making entrepreneurship and employment perfect substitutes, wages equalize and one implicitly assumes that workers are indifferent and homogenous. But of course, one can extend this simple model in the spirit of Krugman (1991) and include many other individual and regional variables that will affect the basic trade off. Such a model would explain clustering of entrepreneurs in urban regions and detach the dynamics in the global knowledge base from local knowledge implementation. In dynamic settings with multiple regions, one will then be in a steady state when the labor allocation is more or less stable across regions and occupations and the marginal products of labor in knowledge generation, knowledge commercialization, and routine production equalize.

The many different externalities that exist in all three stages of the innovation life cycle all provide a link to location and urban economics, as some are closely related to proximity and density and others less so. The key conclusion from this theory is, however, that more knowledge creation will increase growth and development only through the innovative activities of entrepreneurs who turn information and ideas into a widely used and readily available knowledge base that facilitates further knowledge creation.

11.4.3 Concluding Remarks

When we turn our focus on the organizations and people that create and commercialize the new knowledge, new linkages through which endogenous growth is localized can be explored. On the one hand, existing organizations require skilled employees to absorb appropriate new technologies from outside and from within. In the absence of such absorptive capacity, existing firms in a region will not be able to internalize and build upon the knowledge created. The spillover theory of entrepreneurship on the other hand stresses the role of entrepreneurs in transferring knowledge from the drawing board to the market place, providing an alternative missing link between invention and innovation. Both approaches shift the focus from local knowledge creation to local knowledge commercialization, where different mechanisms may be at work.

11.5 Fundamental Causes of Growth and Development

11.5.1 Institutions and Economic Growth

Institutions are broadly defined as *the man-made rules of the game*. For a long time, (growth) economists have treated institutional differences, much like, for example, differences in geography and preferences, simply as given. In searching to explain the cross-country differences in growth performance over longer periods of time, however, several authors have now argued that institutions play an important role in determining growth. The empirical evidence that causality runs from institutional quality to economic performance is mounting, since Acemoglu, Johnson, and Robinson (2001) showed a clear link between sixteenth-century settler mortality rates and modern institutional quality and used this as an instrument in their empirical analysis. Without going into technical detail too much, this chapter clearly establishes the importance of institutional quality for development and growth. This takes the endogenization of economic growth and innovation one step further. The institutional approach is more fundamental than the modeling approaches above and puts a strong emphasis on growth as a historical process.

Still, the institutional approach to date largely abstracts from geography and location. Acemoglu (2009) dismisses geography (and the alternative hypotheses that it is all about luck or culture) as a fundamental cause of economic growth by arguing that climatic and geographic circumstances fail to explain why some countries did and some did not industrialize. This exclusive focus on *first-nature* geography obscures the importance of second-nature geography that new economic geographers and urban economists tend to stress and that has been the core of their work. It is, however, hard to see where this neglect will take institutional growth theory. Recent contributions focus on explaining the endogenous emergence and persistence of growth-enhancing or inhibiting institutions, where the natural inclination is to think about political institutions at the national level supporting or inhibiting knowledge creation. Models in this field, for example, explain the

transition from autocracy to democracy as a result of power struggles and apply game theory and political economy techniques to explain institutional change. Many of the formal institutions (property rights, rule of law, democracy, etc.), however, do not vary across regions and locations in the same country, whereas informal institutions (culture, attitudes toward the new, experimentation, etc.) differ quite a bit between core and periphery in general and across different regions and cities as well.

As Florida (2005) has shown, more open cultural attitudes also correlate highly with standards of living and economic performance. And Baumol (1990) already argued that it is institutions that will also mobilize entrepreneurial talent into or out of the productive activity of taking knowledge from the drawing board to the market place. Both would probably agree that it is local, informal institutions in cities and regions that matter as much or more than the formal, legal, and political institutions at the national level for enabling and promoting the knowledge spillovers that endogenous growth theory assumes at the aggregate level.

An interesting but to date largely unexplored line of research would therefore focus more on the importance of local and regional institutional differences and zoom in on their beneficial or detrimental effects on knowledge creation and diffusion at the regional level. Attempts in this direction have been made by scholars taking a much more empirical and case-based *regional systems of innovation* approach that is very popular with policy makers that try to identify regional strengths and weaknesses, also in the institutional setting. Anselin et al. (1997) already showed that knowledge spillovers are highly localized, whereas Audretsch and Lehman (2005) establish a link between local knowledge creation and commercialization activity.

The institutional approach to economic growth is currently asking very different questions, however. Inspired by aggregate endogenous growth theory, it focuses almost exclusively on the process of knowledge creation, and the supporting empirical work will continue to draw predominantly on panel databases that have countries as their geographic unit.

11.5.2 Concluding Remarks

Recent contributions to the empirics of economic growth have established that institutions play a key role in driving growth and development at the aggregate level. The current challenge in this literature is to link these national institutions to the process of knowledge creation. We feel that such an effort is likely to suffer from the current neglect of endogenous knowledge spillovers at the aggregate level. Likewise, recent evidence in economic geography suggests that local growth and development patterns are driven largely by the interaction between knowledge creation and commercialization, but this literature still largely ignores local institutions as, for example, very different cultural attitudes toward entrepreneurship and innovation in cities and their periphery. The institutional approach to aggregate economic growth will remain free of geography as long as it ignores the importance

of proximity for the assumed knowledge spillovers, whereas economic geography and urban economics will remain free of institutions as long as their importance for attracting and mobilizing creative and entrepreneurial talents is not recognized. Of course, exploring the implications of institutional differences among regions and cities on the one hand and second-nature geography in knowledge creation and spillover opens up a broad research agenda for both theory and empirical research in the field of endogenous regional growth.

11.6 Conclusions

In this chapter, we have first reviewed basic endogenous growth theory to show that economic growth is ultimately dependent on new knowledge creation. This new knowledge creation, however, builds on the existing knowledge base, causing increasing returns to scale at the aggregate level. This same mechanism has been shown to operate at the local and regional level in models of new economic geography and urban economics that aim to explain spatial patterns of economic activity and growth. More specifically, we showed that the mechanism of endogenous economic growth can account for stable city growth and core-periphery patterns of economic activity. When we dig into the process of knowledge creation a bit more, we have to distinguish between knowledge creation and commercialization. The former is of course a necessary condition for growth, but the latter may well be the more important bottleneck for growth at the regional level. In addition, commercialization is a way to make new knowledge available to those who would otherwise not be able to build upon it. Arguably, the commercialization, rather than the inception of a new idea, has the biggest impact on economic performance and enables future knowledge spillovers to take place. Moreover, a focus on the people and organizations that are responsible for commercialization allows for another fruitful avenue for localizing endogenous growth. Finally, we have discussed how the most recent developments in economic growth theory, toward a more institutional approach to economic growth, once more seem to neglect the importance of geography. Institutions have been shown to affect local, organizational absorptive capacity and both the attitudes and actions of entrepreneurs. Linking such insights with the modeling tools as they are developed in the mainstream of macroeconomic growth theory will certainly constitute a fruitful and important agenda for future research.

Abstract

We describe how endogenous growth theory has now incorporated spatial factors. We also derive some of the policy implications of this new theory for growth and economic integration. We start by reviewing the product variety model of endogenous growth and discuss similarities with modeling techniques in the new economic geography. Both use Dixit-Stiglitz competition. Increasing returns provide an incentive for innovation in endogenous growth theory, and in combination with transport costs, increasing returns provide an incentive for firm location decisions in the new economic geography. Since innovation is the engine of growth in endogenous growth models and knowledge spillovers are a key input to innovation production, we also explore how innovation and knowledge have distinctly spatial characteristics. These modeling similarities and the spatial nature of knowledge spillovers have led to space being incorporated into the theory of endogenous growth. We guide the reader through how space is modeled in endogenous growth theory via the new economic geography. Growth by innovation is a force for agglomeration. When space is included, growth is enhanced by agglomeration because of the presence of localized technology spillovers. We consider the many other spatial factors included in models of space and growth. We explore the spatial effects on economic growth demonstrated by these theoretical models. Lastly, we consider policy implications for integration beyond lowering trade costs and discuss how lowering the cost of trading knowledge is a stabilizing force and is growth enhancing.

12.1 Introduction

Theoretical models of endogenous growth explain the engine of economic growth with intentional investments in innovation motivated by monopolistic competition. But these theories have typically ignored space. Endogenous growth and the new economic geography (NEG) have grown quite separately despite similarities in modeling using Dixit and Stiglitz (1977) preferences. Within the literature on innovation, contributions on systems of innovation and the geography of innovation (Audretsch and Feldman 1996) have the potential for a number of spatial aspects to also be incorporated into the theory of growth. More recently, endogenous growth theory has been combined with the NEG and provided insights on how geographic space can influence economic growth.

There are persistent differences in growth rates and incomes between even highly integrated regions such as the European Union or the United States. Endogenous growth theory offers some explanations for varying growth rates. Firms invest in research and development (R&D) to design new innovations, whereby knowledge of existing products is an integral input to R&D. Profits provide an incentive for investment and are protected by patents. The theory implies that varying rates of economic growth may be caused by regions specializing in different sectors with varying rates of productivity or rates of innovation and by

differing institutions that protect patents. The theory fails to provide an adequate explanation of varying growth rates because it does not explain differences in levels of innovation when regions have similar institutions or innovations that are not protected by institutions (e.g., process innovations, firm structure). Spatial factors offer some explanation for these differences, but economic growth theory typically ignores the role of space in determining economic growth outcomes.

Kaldor (1970) explains how trade can drive apart even identical regions as industry agglomerates in a single location. Some contributions to endogenous growth theory include this trade mechanism (Lucas 1988; Grossman and Helpman 1991b, 1995) but still ignore the role of space (distance-related factors) in economic growth. Despite the increasing use of space in economic theory through developments in new trade theory (Krugman 1979), new economic geography (Krugman 1991), and similarities in modeling, it has only been a recent development to incorporate geographic space into growth theory to create spatial models of endogenous growth (Martin and Ottaviano 1999). Developments from the NEG have now led to the incorporation of spatial factors related to both production and knowledge into theoretical growth models. These types of models may help explain varying growth rates between even highly integrated regions with similar institutions. For example, McCann (2009) suggests an economic geography perspective of New Zealand might help explain the difference in growth rates with Australia.

Hence, the new economic geography and growth (NEGG) literature incorporates space into the theory of growth by combining endogenous growth theory with the NEG. This chapter starts by describing the basic theory of endogenous growth (Romer 1990; Grossman and Helpman 1991a) followed by a typical NEGG approach where the theory accounts for the spatial factors of transport costs, migration, and imperfect knowledge spillovers. We review the contribution of these types of spatial models and variations in the use of spatial parameters and discuss the consequences for regional growth policy.

12.2 A Simple Model of Endogenous Growth

Endogenous growth theory uses increasing returns as an incentive for firms to make intentional investments to develop innovations. In all theoretical models of growth, the accumulation of capital (physical and human capital) is the engine of growth. Romer (1990), Lucas (1988), and Aghion and Howitt (1992) treat investment in innovation as investment in an additional type of capital, with increasing returns. While accumulation of physical and human capital suffers from diminishing returns, returns to investment in innovation are not diminishing and growth is sustained in the long run. These theoretical models are separated into two groups: Grossman-Helpman-Romer models (Romer 1990; Grossman and Helpman 1991a) use a love of variety with Dixit and Stiglitz (1977) competition and an increasing number of varieties as the source of growth. Alternatively, Schumpeterian growth models (Aghion and Howitt 1992) use creative destruction or quality ladders where higher-quality products replace existing varieties.

In this section, we present a simple product variety model of endogenous growth through research and development (Romer 1990; Grossman and Helpman 1991a). In subsequent sections, we explore contributions that add space to this model of endogenous growth. To focus on innovation, the models here overlook factor accumulation (such as investments in physical and human capital) so that all investment is in the form of creating new technologies (innovations). In the product variety model, growth comes from an expanding variety of goods. We treat these as final goods using Dixit-Stiglitz preferences as in Grossman and Helpman (1991a). In contrast, Romer (1990) has an expanding variety of intermediate goods which are used to make a final good with a Dixit-Stiglitz production function. Grossman and Helpman (1991a) acknowledge the alternative Dixit-Stiglitz specification of the production function rather than the utility function. The outcomes of the model are essentially the same. We use the final goods version for consistency with the global and local spillover models in Baldwin et al. (2003).

There are two sectors – final goods and the R&D sector. Labor is either employed in producing final goods or in R&D which produces new designs. Workers are free to choose the sector in which they are employed and supply their labor inelastically. Consumers have a taste for diversity and are made better off by an expanding number of varieties. For each new good, there is a sunk cost of innovation that occurs once, when the product is developed. Each firm must first obtain a design from the R&D sector, but once the design is obtained, the firm can produce that variety forever at a constant marginal cost. The presence of fixed costs leads to monopolistically competitive markets. The up-front cost is financed by monopoly profits that are later earned in sales.

12.2.1 Demand

The representative consumer is infinitely lived and has intertemporal preferences:

$$U = \int_{t=0}^{\infty} e^{-\rho t} \ln C_t dt \quad (12.1)$$

where C_t is the consumption index of goods, ρ is the rate of time preference, and time is indexed by t (for simplicity, the subscript t will be dropped hereafter where the time dimension is clear). Consumers have constant elasticity of substitution (CES) preferences over the continuum of final goods $[0, K]$:

$$C = \left[\int_0^K c_i^{\frac{\sigma-1}{\sigma}} di \right]^{\frac{\sigma}{\sigma-1}}, \quad \sigma > 1 \quad (12.2)$$

where c_i is the consumption of variety i and σ is the constant elasticity of substitution. Consumers have a taste for diversity over an infinite set of products $i \in [0, \infty]$ where at any point in time, a subset K is available in the marketplace.

Consumers allocate income between consumption and savings and distribute consumption across available varieties. Intertemporal utility optimization implies that expenditure changes over time according to the Euler equation:

$$\frac{\dot{E}}{E} = r - \rho \quad (12.3)$$

where E is consumer expenditure, \dot{E} is expenditure differentiated with respect to t , and r is the risk-free rate of return on savings. In equilibrium, we have $r = \rho$, $\forall t$. Subject to the budget constraint

$$\int_0^K c_i p_i di \leq E \quad (12.4)$$

consumers allocate expenditure across varieties to maximize utility. With aggregate consumption defined as $C = \left[\int_0^K c_i^{\frac{\sigma-1}{\sigma}} di \right]^{\frac{\sigma}{\sigma-1}}$ in the utility function, we define the price index as $P = \left[\int_0^K p_i^{1-\sigma} di \right]^{\frac{1}{1-\sigma}}$, where p_i is the price of variety i , so that $E = CP$. It can be shown (e.g., Appendix 2.A of Baldwin et al. 2003) that the demand function facing an individual firm is

$$c_i = E p_i^{-\sigma} P^{\sigma-1} \quad (12.5)$$

Hence, demand is inversely related to relative price.

12.2.2 Production

There are L workers/consumers. Each worker produces one unit of labor per period and supplies its labor inelastically. We assume that each firm takes other firms' prices as given, and with a large number of varieties, firms ignore the effect of their own price on the price index. Some portion of labor $L_M < L$ is employed in the manufacturing sector. Remaining labor is employed in the innovation sector L_I such that $L_I + L_M = L$. Firms choose optimal prices in order to maximize profit $\pi_i = (p_i - \beta w) c_i$, where β describes the marginal units of labor per unit of production and w describes the wage, such that βw is the marginal cost of production. This implies that optimal prices are a constant markup over marginal cost:

$$p_i = \frac{\sigma}{\sigma-1} \beta w, \quad \forall i \in [0, K] \quad (12.6)$$

It is possible to impose a normalization $\beta = \frac{\sigma-1}{\sigma}$, which implies that $p_i = w$. We avoid this normalization here so that the reader can identify in the formulas how the productivity of labor in both manufacturing and R&D is important for the allocation of labor between sectors. As there are symmetric demands for all varieties, every

firm in the manufacturing sector yields the same price, production, and operating profit per period. We normalize expenditure $E = 1 \forall t$. With $E = 1$ and all firms being otherwise identical, individual firm profit in each period is given by

$$\pi_i = \frac{E}{K\sigma} = \frac{1}{K\sigma} \quad (12.7)$$

12.2.3 Research and Development

A manufacturing firm has a one-off fixed cost to develop the patent to the good (or purchase it from an entrepreneur) in the R&D sector which generates designs for new varieties of final goods. Each variety requires one unit of knowledge capital produced by the R&D sector. Individual firms face an innovation cost of a_I units of labor per unit of capital produced. We follow Grossman and Helpman (1991a) and Romer (1990) using a learning curve such that the marginal cost of new knowledge capital a_I declines as cumulative knowledge output increases. Romer (1990) rationalizes this assumption by referring to the non-rival nature of knowledge, emphasizing the role of knowledge spillovers. Labor and the stock of knowledge (equal to the number of varieties) are used to develop new innovations. Each innovation adds to the stock of knowledge that can be used for developing future innovations. Innovation production is given by

$$\dot{K} = \frac{L_I}{a_I}, \quad F = wa_I, \quad a_I = \frac{1}{K_I} \quad (12.8)$$

where \dot{K} is knowledge capital differentiated over time, L_I is the labor employed in the innovation sector, F is the fixed cost of innovation to develop a new variety in the R&D sector, and $a_I = \frac{1}{K_I}$ describes the productivity of the R&D sector increasing with cumulative output (i.e., the fixed cost of each innovation decreases over time). The model is based on Grossman and Helpman (1991a), but for consistency, the functional form used here is adapted from Baldwin and Forslid (2000). From Eq. (12.8), it follows that the rate of growth in the number of varieties is equal to L_I , which may be scaled by a constant to calibrate the model as described in Grossman and Helpman (1991a).

An entrepreneur seeks funding for up-front costs (R&D wages) from credit markets (or provides that credit in foregone wages). We assume there are no frictions in credit markets and no aggregate uncertainty so the purchasing of a patent can also be thought of as the entrepreneur issuing debt or equity (or some combination). Once a patent has been obtained, the manufacturer has monopoly rights to produce variety i forever at constant marginal cost. Equity owners are paid the infinite stream of profits from the firm. Free entry into the research sector implies that labor is hired such that its wage equals its marginal product. At time t and with constant interest rates, the present value of the future stream of profits, v_t , is

$$v_t = \int_{s=t}^{\infty} \pi_s e^{-r(s-t)} ds \quad (12.9)$$

Differentiating and rearranging, we find the no arbitrage condition:

$$\dot{v}_t = -e^{-r(s-t)} \pi_s + r v_t \quad (12.10)$$

This can also be written as a rate of return, $\frac{\dot{v}_t}{v_t} + \frac{\pi_t}{v_t} = r$. The “no arbitrage” condition describes that in the interval between t and $t + dt$, the owners of the patent (equity holders) receive a return (made up of the profit rate $\frac{\pi_t}{v_t}$ and the rate of capital gain (loss) $\frac{\dot{v}_t}{v_t}$) equal to the yield on a riskless loan. In other words, for a manufacturing firm to purchase a patent (or investors to hold equity/debt), the payoff must exceed the opportunity cost.

The cost of research that yields $\dot{K} = \frac{l_t}{a_l}$ incremental varieties is $w a_l$ and has the value $v_t \dot{K} = v_t \frac{l_t}{a_l}$, where l_t is the labor input by a typical entrepreneur. Continuous growth, $\dot{K} > 0$, involves an active research sector, and free entry requires the research costs to be equal to the value of research for all t . If the costs of research are greater than the value of R&D, no research would occur in equilibrium. A situation where the cost of research is less than the value of R&D will never occur in equilibrium because it would cause an unbounded demand for research labor. Equilibrium therefore requires $v_t \leq w a_l$ with equality when $\dot{K} > 0$.

12.2.4 Equilibrium

Rather than deriving equilibrium, we just describe the equilibrium or steady state. For a full discussion of equilibrium conditions, see Grossman and Helpman (1991a), Baldwin and Forslid (2000), or Baldwin et al. (2003). In equilibrium, we have a flow of new innovations:

$$\dot{K} = \begin{cases} \frac{L}{a_l} - \frac{\beta}{\bar{v}} & \text{for } v > \bar{v} = \frac{\sigma - 1}{\sigma} \frac{a_l}{L} \\ 0 & \text{for } v \leq \bar{v} = \frac{\sigma - 1}{\sigma} \frac{a_l}{L} \end{cases} \quad (12.11)$$

with $L = L_I + L_M$, i.e., total employment is the sum of R&D employment and manufacturing employment. Substituting the interest rate $r = \rho$ and the profit rate $\pi = \frac{1}{K\sigma}$ into the no arbitrage condition, the change in firm value is a function of the value of a firm and the number of firms:

$$\dot{v} = \rho v - \frac{1}{K\sigma} \quad (12.12)$$

These two differential equations, Eqs. (12.11) and (12.12), describe the dynamic equilibria.

12.2.5 Balanced Growth

If conditions allow for employment in R&D, there are an increasing number of varieties. As firms compete for a fixed supply of labor, the output per firm and the value of a firm go down over time. Research into new varieties remains profitable since the cost of innovation decreases as the number of varieties increases. We denote the steady growth rate of the number of varieties, $\frac{\dot{K}}{K}$, by g_K . If we define a new variable $V = \frac{1}{K^v}$, representing the inverse of the economy's aggregate equity value, the growth rate is

$$g_K = \frac{\dot{K}}{K} = \begin{cases} L - \beta V & \text{for } V < \frac{\sigma}{\sigma - 1} \frac{L}{a_I} \\ 0 & \text{for } V \geq \frac{\sigma}{\sigma - 1} \frac{L}{a_I} \end{cases} \quad (12.13)$$

These definitions also imply $\frac{\dot{V}}{V} = -g_K - \frac{\dot{v}}{v}$. By substitution of $\dot{v} = \rho v - \frac{1}{K^\sigma}$, we find

$$\frac{\dot{V}}{V} = \frac{1}{\sigma} V - g_K - \rho \quad (12.14)$$

The model is reduced to one differential equation, and the condition for growth is given by Eq. (12.13). We can calculate the steady state rate of innovation by setting $\dot{V} = 0$:

$$g_K = \frac{L}{\sigma} - \beta \rho \quad (12.15)$$

This is positive, so long as $L > \rho(\sigma - 1)$; otherwise, growth is zero. Growth is positively related to the scale of the economy (L), which is a common property of these models. Innovation (and incentives for R&D investment) is sustained because there are offsetting forces of declining profits due to expanding varieties and falling product development costs due to research externalities.

This is not the overall growth rate of the economy. To understand macroeconomic growth, we are interested in the growth rate of the consumption index, $C = \left[\int_0^K c_i^{\frac{\sigma-1}{\sigma}} di \right]^{\frac{\sigma}{\sigma-1}}$. Since $E = CP = 1 \forall t$, growth is also the rate at which the price index $P = \left[\int_0^K p_i^{1-\sigma} di \right]^{\frac{1}{1-\sigma}}$ declines. The growth rate of consumption g_C can be shown to be $g_C = \frac{g_K}{\sigma-1}$. This is also not GDP growth. GDP is defined as the value added in both manufacturing and R&D. GDP grows at a rate equal to a weighted average of the growth rates of the index of manufacturing output/consumption and of research output. Since R&D is usually only a small percentage of a country's GDP, the difference is negligible. See Grossman and Helpman (1991a, p. 63) for a discussion.

12.3 A Two-Region Model of Growth

Virtually all endogenous growth models rely on technical externalities such as knowledge spillovers and production externalities. Endogenous growth models usually assume a frictionless spillover of knowledge. The reality is that knowledge is not transferred so effortlessly. While some knowledge can be codified and transferred easily, much knowledge is at least partially tacit. Spillovers of tacit knowledge occur over space and time through face-to-face contact (McCann 2007) and migration (Faggian and McCann 2009). Eaton and Kortum (1999) show that knowledge spillover and production externalities are related to the geographic distribution of manufacturing and R&D. A better understanding of the economics of innovation (Nelson 1993) and its geographic characteristics (Audretsch and Feldman 1996) significantly improves our understanding of economic growth.

Innovation is a predominantly local event and is now included in economic geography. Acs and Varga (2002) note the similarities between modeling techniques of endogenous growth theory and the new economic geography, suggesting a new model of technology-led regional economic development that combines the two fields with insights from the economics of innovation. Knowledge and innovation also have space, time, and cost characteristics in their spillover between locations. This role of space and time in knowledge spillovers means economic growth also has spatial characteristics.

Given this understanding of innovation, the concentration of economic activity also results in greater knowledge spillovers between firms in concentrated locations. In endogenous growth literature, there is recognition of partial international knowledge spillovers. Grossman and Helpman (1991b) model foreign knowledge as an innovation input in a small economy where the availability of foreign knowledge is dependent on the level of trade, yet these models ignore the role of space. Space can be added to the theory of growth by including spatial characteristics in knowledge spillover inputs to innovation production.

Transport costs are also a key spatial parameter typically ignored in endogenous growth models. The new trade theory (Krugman 1979) and the new economic geography (NEG) (Krugman 1991) include transport costs and have Dixit-Stiglitz competition in common with many theoretical endogenous growth models. Transport costs can therefore be included easily within endogenous growth. The result of transport costs is the concentration of production in specific locations, when transport costs reach some low threshold. This is known as the core-periphery model. With low enough transport costs, firms choose to locate close to their customers to reduce transport costs. When models also allow for migration, workers choose to locate near producers to reduce their cost of living. These transport cost-related phenomena are known as the home market effect because it causes the concentration of firms and people.

Higher transport costs may induce firms to seek locations where there are fewer firms to compete with. This is known as the market crowding effect. It is the balance of these two effects that determines equilibrium and the steady state. Concentration

occurs at low transport costs when the home market and cost of living effects dominate the market crowding effect, while dispersion occurs at higher transport costs, where market crowding dominates. The NEG suggests that imperfect integration may create regional winners and losers (Krugman 1991; Krugman and Venables 1995). A particularly interesting characteristic is that the economic conditions of two regions can be exactly the same yet yield dramatically different economic outcomes.

12.3.1 Incorporating Space in the Theory of Growth

New economic geography and growth (NEGG) models combine horizontal innovations *à la* Grossman-Helpman-Romer with the NEG (e.g., Baldwin et al. 2001; Baldwin and Forslid 2000; Martin and Ottaviano 1999; Fujita and Thisse 2003) predominantly due to the fundamental use of Dixit-Stiglitz competition. Different NEGG models vary assumptions on the mobility of capital, labor, and industry or consumer demand to influence the forward and backward linkages. Here, we describe a typical NEGG modeling approach (Baldwin and Forslid 2000) that includes the spatial factors:

- Location
- Migration
- Transport costs
- Local knowledge spillovers
- Imperfect global knowledge spillovers

The model has two regions that trade. There is a traditional goods sector with perfect competition that employs immobile unskilled workers L_T . Consumers have a taste for traditional goods such that $C = C_M^\mu C_T^{1-\mu}$, where C_M is the index of manufactured goods (similar to C in the previous section) and C_T is the traditional goods sector. Foreign region variables are denoted by an asterisk (*). The representative consumer is infinitely lived and has intertemporal preferences:

$$U = \int_{t=0}^{\infty} e^{-\rho t} \ln[C_{Mt}^\mu C_{Tt}^{1-\mu}] dt \quad (12.16)$$

In what follows, the time subscripts will again be suppressed for simplicity. Transport costs are zero in the traditional goods sector, and workers in this sector cannot migrate between regions. In the real world, workers in the traditional goods sector are not necessarily unskilled or immobile. The important feature here is that the factor of production for traditional goods is immobile, and “unskilled” is the commonly used term in these models. The purpose of the additional sector in this model is that some residual demand remains in the periphery, even when there is full agglomeration, so that regions continue to trade.

Skilled workers (L_K) are employed in either manufacturing or innovation (similar to workers in the previous section with subscript K since they work in the knowledge sectors of manufacturing or innovation). The world population of

skilled and unskilled workers is normalized to one such that $L = L_K + L_T = 1$. Skilled workers and manufacturing firms have a choice of location. Skilled workers respond to wage pressure when making a decision to migrate between regions. If there are differences in real wages, there will be migration. The perfect price index describes the price index of utility and therefore includes traditional goods such that $P \equiv P_T^{1-\mu} P_M^{\frac{\mu}{\sigma-1}}$. The change in skilled workers in the home region is given by the ad hoc migration equation in Fujita et al. (1999):

$$\dot{L}_K = (\omega_K - \omega_K^*)s_H(1 - s_H) \quad (12.17)$$

$$s_H = \frac{L_K}{L_K + L_{K^*}}, \quad \omega_K = \frac{w}{P}, \quad \omega_K^* = \frac{w^*}{P^*} \quad (12.18)$$

where \dot{L}_K is skilled labor in the home region differentiated over time, s_H is the share of skilled workers in the home region, and ω_K is the real wage of skilled workers in the home region. Since the real wage is defined by means of the perfect price index, workers migrate to the region that provides the highest level of utility.

Manufactured goods transported between regions incur transport costs that take Samuelson's "iceberg" form where transport costs are incurred in the good itself. The manufacturer produces more of the good than actually arrives because some portion of the good "melts" in transit. If τ represents the proportion of the final good that arrives at the destination, the remaining portion is used up during transportation. Hence, $\tau < 1$ is a measure of the freeness of trade or an index of the inverse of transport costs. Transport costs for the traditional goods sector are assumed zero ($\tau = 1$). Firms are incentivized to locate in the largest market to minimize transport costs. From the migration equation above, skilled workers try to locate in the region with more firms as this reduces their cost of living (since they have a taste for diversity) by increasing real wages.

So far, we have added space with migration and transport costs which affect manufacturing, but we now also add space to innovation production. Since knowledge does not transfer completely between regions, not all knowledge is available to entrepreneurs when manufacturing is shared between regions. Innovation is included in the manufacturing sector the same as in the endogenous growth model of Sect. 12.2 but now with partial spillovers of knowledge between regions. Individual firms face the innovation cost of a_I units of labor for each unit of knowledge capital produced. Innovation production in the home region is given by

$$\dot{K} = \frac{L_I}{a_I}, \quad F = wa_I, \quad a_I = \frac{1}{K + \lambda K^*}, \quad 0 \leq \lambda \leq 1 \quad (12.19)$$

where \dot{K} is knowledge capital differentiated over time, L_I is the skilled labor employed in the innovation sector, λ is the ability for foreign knowledge to be used in the home region, and $a_I = \frac{1}{K + \lambda K^*}$ describes how productivity of the R&D sector increases with cumulative output. Hence, the model assumes perfect local knowledge spillovers but imperfect spillovers between regions. The parameter λ

represents how space affects knowledge production such that firms choose a location that considers how existing knowledge can be used for innovation. In this way, firms are attracted to regions where other firms are located because the cost of innovation is lower.

12.3.2 Model Description

Consider the product variety model of the previous section together with these additional spatial factors. Again, we normalize world expenditure $E_w = 1, \forall t$. Subject to the budget constraint, consumers allocate expenditure across varieties to maximize utility. Hence, in the home region, $P_M C_M + P_T C_T \leq E$, where P_M is the local price index of manufactured goods (the world equivalent is a weighted average price index such that $\overline{P_M C_M} + P_T C_T \leq E_w$) and P_T is the price of traditional goods. Consumers spend a constant portion of their expenditure on manufactured goods and the rest on traditional goods:

$$P_M C_M = \mu E, \quad P_T C_T = (1 - \mu)E \quad (12.20)$$

Total expenditure on traditional goods is equal to $(1 - \mu)E_w$. The traditional goods sector is perfectly competitive, with 1:1 technology (one unit of unskilled labor input yields one unit of traditional goods output) and constant returns to scale. Total production of traditional goods is shared across both regions. Let L_T and L_T^* be the supply of unskilled workers in the home and foreign regions, respectively. We follow Krugman (1991) and set the worldwide stock of skilled workers to μ and the stock of unskilled workers to $(1 - \mu)$ shared equally between regions:

$$L_T = \frac{1 - \mu}{2}, \quad L_T^* = \frac{1 - \mu}{2} \quad (12.21)$$

The choice of units ($1 - \mu$ unskilled workers and μ skilled workers) follows Krugman (1991) and ensures that prices and wages in the traditional goods sector are the numéraire and that the nominal wage rate of skilled workers equals that of unskilled workers. If the number of skilled workers was specified differently, the wages of skilled workers are a constant multiple of the wage rate of unskilled workers. We maintain simplicity by avoiding this additional multiple. A scaling factor could also be used to calibrate the model to any arbitrary growth or wage rate.

Unskilled workers provide one unit of production per period, i.e., $\int_0^{L_T} C_T + \int_0^{L_T^*} C_T^* = (1 - \mu)$. Free trade ensures the same nominal price of traditional goods and equal nominal wages in the two regions. With full employment of $1 - \mu$ unskilled workers and 1:1 technology, the traditional goods sector is the numéraire:

$$w_T \left(\int_0^{L_T} C_T + \int_0^{L_T^*} C_T^* \right) = w_T(1 - \mu) = P_T \left(\int_0^{L_T} C_T + \int_0^{L_T^*} C_T^* \right) \quad (12.22)$$

$$= P_T(1 - \mu) = (1 - \mu)E_w$$

$$w_T = P_T = w_T^* = P_T^* = 1 \quad (12.23)$$

The remainder of the analysis focuses on the manufacturing sector. The home region produces K manufactured varieties and the foreign region produces K^* varieties. Consumers have a CES preferences over the continuum of manufactured goods $[0, K + K^*]$, such that

$$C_M = \left[\int_{i=0}^{K+K^*} c_i^{\frac{\sigma-1}{\sigma}} di \right]^{\frac{\sigma}{\sigma-1}}, \quad \sigma > 1 \quad (12.24)$$

where c_i is the consumption of variety i and σ is the constant elasticity of substitution. Defining the local price index of manufactured goods as in the model of Sect. 12.2, $P_M = \left[\int_0^{K+K^*} p_i^{1-\sigma} di \right]^{\frac{1}{1-\sigma}}$ where p_i is the price paid by local consumers, the demand function in the home region facing an individual manufacturer is $c_j = \mu E p_j^{-\sigma} P_M^{\sigma-1}$, and the equivalent demand function exists in the foreign region with the foreign region's price index.

Manufacturing firms in each region face the same optimization problem as in the endogenous growth model: $\max_{p_i} \pi_i = [p_i - \beta w] c_i$, where βw is the marginal cost of production. Firms ignore the effect of their own price on the index. Once again, optimal prices are a constant markup over marginal cost, and transport costs are passed on directly to consumers:

$$p_i = \frac{\sigma}{\sigma-1} \beta w, \quad p_i^* = \frac{\sigma}{\sigma-1} \frac{\beta w}{\tau} = \frac{p_i}{\tau}, \quad \forall i \in [0, K] \quad (12.25)$$

where p_i and p_i^* are the local and export prices of a home manufacturer. A foreign manufacturer has analogous prices, with transport costs on goods exported to the home region. Here, it is also possible to impose the same normalization $\beta = \frac{\sigma-1}{\sigma}$ such that $p_i = w$ and $p_i^* = \frac{w}{\tau} = \frac{p_i}{\tau}$. While its distribution is subject to worker migration, by following Krugman's (1991) choice of units where the worldwide stock of skilled workers is μ , nominal skilled wages in equilibrium are $w = 1$ or $w^* = 1$ for the core-periphery outcome and $w = w^* = 1$ in the equal distribution outcome.

12.3.3 Long-Run Location

We characterize the long run as a “steady state”: defined by an unchanging growth rate in the number of manufactured varieties, its regional division, as well as the prices and quantities defined by short-run equilibrium above. Migration of

knowledge workers due to spatial inequality of real wages leads to the long-run equilibrium. With the migration equation above and particularly the role of the perfect price index in this equation, we can intuitively see that real wages will only be unequal when one region has a larger share of manufacturing. When this occurs, the larger region is also the lowest cost location for innovation to occur because of greater knowledge spillovers. Furthermore, at low levels of transport costs, there are higher profits in the larger region. At high levels of transport costs and only a slightly unequal equilibrium, there may be higher margins in the smaller region due to the market crowding effect which would return the system to the equal distribution outcome. Through intuition, we can see that there are two long-run types of steady states:

- The equal distribution outcome
- The core-periphery outcome

See Baldwin and Forslid (2000) for a more formal discussion of the conditions of the steady state in the NEGG model here and Baldwin et al. (2003) for a discussion of other NEGG models.

The equal distribution outcome is where both regions have half the skilled workers, half the manufacturing, and half the traditional goods production. The other steady state is the core-periphery outcome where all manufacturing concentrates in a single region (either home or foreign) known as the core and only unskilled workers (the traditional goods sector) remain in the other region known as the periphery. Traditional goods production is split equally between regions.

If there are asymmetric transport costs, it is not inevitable that the region with the lowest transport costs will be the core. The core region will be the one which has the higher share of varieties and where the difference in the number of varieties is large enough to trigger a switch from the equal distribution outcome to the core-periphery outcome. This could be for several reasons. Since every variety has a patent forever, hysteresis plays a large role in determining which region is the core. For example, an initial higher endowment of resources might lead to a greater number of manufacturers and innovators, or greater infrastructure investment at some stage (and temporarily freer trade) might also trigger agglomeration. Similarly, temporarily different policy settings between regions where one region has favorable policies for R&D could lead to initially higher rates of innovation, a greater share of varieties, and agglomeration. While not included in typical NEGG models, stochastic effects could mean one region gets “lucky.” In the model here, innovations are simply costs where each firm has to employ a certain amount of skilled labor in R&D in order to achieve an innovation. In reality, successful innovations are not so guaranteed. The inclusion of probabilistic outcomes in the R&D sector could mean one region achieves a higher rate of innovation by luck, resulting in it becoming the core.

Figure 12.1, reproduced from Baldwin and Forslid (2000) but with a different measure of trade freeness, describes the possible equilibria with different combinations of trade freeness and knowledge diffusion. As the level of trade freeness increases (i.e., transport costs decline), the break point τ_B describes the level of trade freeness where the equal distribution outcome is no longer a steady state. The sustain point τ_S describes the level of trade freeness at which the distribution of

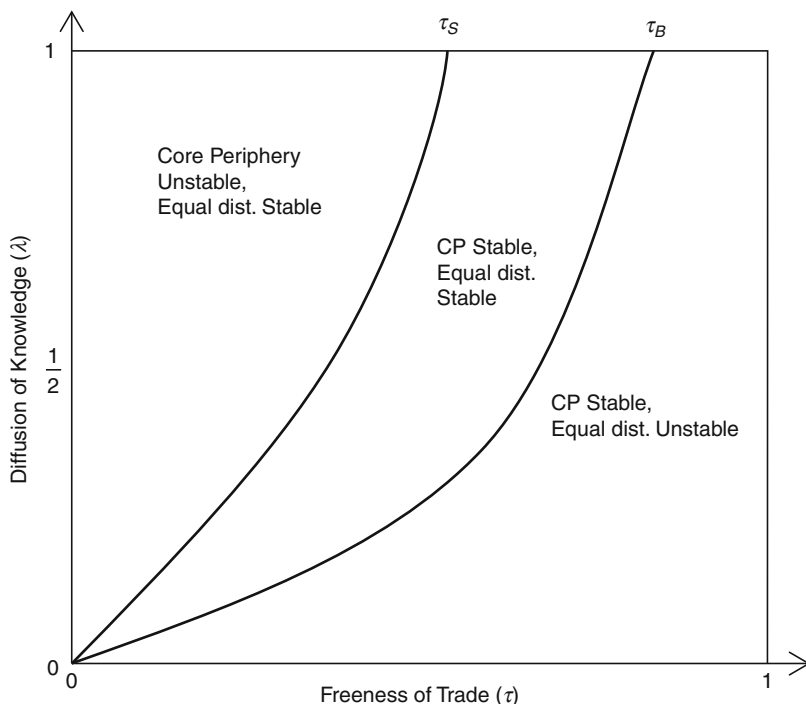

Fig. 12.1 Core-periphery and symmetric equilibrium stability map

firms and workers switches from the core-periphery outcome to the equal distribution outcome when trade freeness is declining (transport costs increase). The values of trade freeness between the sustain and break points represent situations which both the potential equilibria outcomes are stable. As the level of knowledge spillovers λ varies, so do both the break and sustain points. Figure 12.1 describes how the break and sustain points increase as knowledge spillovers increase. Alternatively, Fig. 12.1 describes the combinations of knowledge spillovers and trade freeness that result in stable (and unstable) equilibria for both the equal distribution outcome and the core-periphery outcome. There are three sections within the knowledge spillover (λ) and trade freeness (τ) space. In the top-left corner, the core-periphery equilibrium is unstable and the equal distribution is stable. In this situation, trade freeness is sufficiently low (high transport costs) that the market crowding effect means firms make a higher margin by locating away from other firms. There is very little trade (if any) between regions. Closer to the curve, regions will trade, but the market crowding effect always dominates the home market, cost of living, and innovation cost effects. In the middle section, both the equal distribution and core-periphery equilibrium are stable. If there is an equal distribution, regions will trade, but it is possible that with an external shock, the home market, cost of living, and innovation cost effects could dominate the market crowding effect and the system would switch to the core-periphery outcome. Similarly, if there is a core-periphery

equilibrium, an external shock to the distribution could lead to the market crowding effect dominating the home market, cost of living, and innovation cost effects causing a switch to the equal distribution outcome. Lastly, the bottom right section describes combinations of knowledge spillovers and trade freeness where only the core-periphery outcome is stable. In this situation, the home market, cost of living, and innovation cost effects always dominate the market crowding effect.

12.4 Spatial Consequences for Economic Growth

The incorporation of space in the theory of growth means the model recognizes the role of space through transport costs and through knowledge not transferring perfectly between locations. Let us consider world and regional growth in both the short and long run in the two possible types of equilibria: core-periphery and equal distribution. Because regions are able to trade, even a periphery region benefits from growth in the number of varieties produced in the core. Over time, the price index for manufactured varieties falls as more varieties are invented, and producers of traditional goods experience growth in real income because they trade for manufactured goods. We consider growth in terms of the number of manufactured varieties and growth in terms of the consumption bundles available to all consumers.

12.4.1 Integration

While traditional conceptions of integration refer to lowering of the cost of trading goods, Fig. 12.1 shows that incorporating space and growth gives a more detailed view of integration where we can also view integration as lowering the cost of trading ideas. Integration policies which focus solely on free trade may be destabilizing and result in a deindustrialization of the periphery region. That is, when we lower trade costs alone, the region that emerges as the periphery suffers relative to the region that emerges as the core. Integration policies that also focus on knowledge spillovers (or entirely on knowledge spillovers) will be growth enhancing for both regions. The model shows how this form of integration is stabilizing, while pure trade cost integration can be destabilizing.

12.4.2 Growth in Varieties

The number of manufactured varieties worldwide evolves according to

$$\dot{K} + \dot{K}^* = \frac{L_I}{a_I} + \frac{L_I^*}{a_I^*}, \quad a_I = \frac{1}{K + \lambda K^*}, \quad a_I^* = \frac{1}{\lambda K + K^*} \quad (12.26)$$

For simplicity, we drop the subscript i for p_i because home firms are symmetric and prices are equal for all home firms. Once a blueprint or variety is invented,

manufacturers require β marginal units of labor per unit of production, so aggregate demand for labor in the manufacturing sector in the home region is $\frac{\beta}{p}$. As in the endogenous growth model without space, equilibrium in the skilled labor market in the home region requires $L_K = L_I + L_M = a_I \dot{K} + \frac{\beta}{p}$. In the equal distribution outcome, prices are higher than the core-periphery outcome because of the additional cost to transport goods between regions. A larger share of skilled labor is used in manufacturing because each producer has to produce a larger amount to cover the cost of transport. In other words, the cost of transport increases the marginal cost of production such that some labor is no longer available for innovation. When freeness of trade is greater, i.e., the cost of transport is lower, more labor is available for growth. As such, incorporating space in the theory of growth shows how trade liberalization and agglomeration are growth enhancing for world growth.

Turning to regional growth, the number of manufactured varieties in the home region evolves according to

$$\dot{K} = \frac{L_I}{a_I}, \quad a_I = \frac{1}{K + \lambda K^*} \quad (12.27)$$

Trade liberalization and agglomeration (in the home region) are growth enhancing because they reduce the cost of transport. However, if transport costs induce the core-periphery outcome, there is no manufacturing in the periphery and therefore no growth in varieties produced by that region. That is, reducing transport costs means growth in varieties may be limited to a specific region(s). Therefore, trade liberalization is not growth enhancing for growth in varieties for the region that emerges as the periphery.

For both world and regional growth, the inclusion of space means firms face an innovation cost that is dependent upon location. The output of skilled workers in the innovation sector is greater when knowledge is more available. With s being the home region's share of manufacturing, the rate of growth is $\frac{L_I^w}{K+K^*} [s(K + \lambda K^*) + (1 - s)(\lambda K + K^*)]$. That is, when λ is greater, both world and regional growth increase. Including space in the theory of growth shows how closer economic integration is growth enhancing for world and regional growth in varieties. Similarly, when one region has a greater share of manufacturing than the other region, growth increases for the agglomerated region. Agglomeration in either region is growth enhancing for world growth and for regional growth in the region where agglomeration occurs. However, in the core-periphery outcome, there is zero growth in the number of varieties in the periphery region as no varieties are manufactured there, no skilled workers are employed, and no innovation occurs.

12.4.3 Consumption Growth

While so far we have described the effect of space on the growth rate of the number of varieties, this is not the overall growth rate because we have ignored traditional goods. In considering the growth rate of the overall economy, we are interested in

the growth rate of what people actually consume. In other words, we are interested in what the income to workers allows those consumers in each region to purchase which is measured by the growth rate of the consumption index, C , where $E = CP = 1$. This best describes how the well-being of consumers increases over time. While there is no growth in the number of varieties produced in the periphery, the ability to trade traditional goods for manufactured goods allows the unskilled workers to benefit from innovations in the core.

Since $E = CP$, the rate at which the consumption index grows is the rate at which the perfect price index declines. In the endogenous growth model of Sect. 12.2, the growth rate of consumption g_c was shown to be $g_c = \frac{g_K}{\sigma-1}$. With the addition of the traditional goods sector, the overall perfect price index is to a power of $\frac{(\sigma-1)}{\mu}$. The perfect price index is falling at a rate of $g_c = \frac{\mu g_K}{(\sigma-1)}$. Notably, the growth rate of consumption is the same in both regions whether we have a symmetric outcome or the manufacturing concentration outcome. This is because the price index for both regions falls at the same rate, since consumers in both regions still spend the same portion of their earnings on traditional goods – in the steady state, the growth rate of consumption is equal in both regions. The inclusion of space does not explain the differences in growth rates between locations in the long run. Instead, space affects the world rate of growth and the share of wealth/earnings in each location.

In the short run, however, there can be different growth rates between locations if the regions are in transition between steady states. Given $\tau < 1$, the price index will be permanently lower in a core location because core location consumers do not pay transport costs for manufactured goods. If the economies are shifting from an equal distribution to the core-periphery outcome, growth rates in the periphery will be temporarily lower (or even negative) as periphery consumers transition to paying transport costs on a greater share of the manufactured goods they consume (eventually all goods). Consumers in the core gradually pay transport costs on a smaller share of manufactured goods, and the core will have higher growth rates.

12.4.4 Agglomeration, Freeness of Trade, and Economic Growth

Agglomeration is growth enhancing in the long run through both transport costs and knowledge spillovers. Agglomeration minimizes the total cost of transport if all manufacturing and the majority of consumption is in one location. Agglomeration is also growth enhancing because it increases knowledge spillovers if all R&D occurs in one location.

Increased freeness of trade is growth enhancing in the long run, but in the short run, the outcome is ambiguous. Increased freeness of trade is always growth enhancing if there is no change in the distribution of economic activity. However, as described in Fig. 12.1, increased freeness of trade can lead to a switch from the equal distribution outcome to the core-periphery outcome. While this is significantly growth enhancing for the region that becomes the core, it is temporarily growth diminishing for the periphery, while the two regions transition to the new equilibrium.

12.4.5 Impact of Knowledge Spillovers upon Economic Growth

Knowledge spillovers are generally growth enhancing. Increased knowledge spillovers mean firms have a lower cost of innovating, and therefore, there is a greater growth rate in varieties and consumption. If we are in the core-periphery equilibrium, increasing knowledge spillovers has no effect on growth because knowledge is unaffected by space since all production is in a single location.

However, as with agglomeration, the effect is ambiguous if there is a change in the steady state. A large enough increase in knowledge spillovers could lead to a switch from the core-periphery outcome to the equal distribution outcome (see Fig. 12.1). With a change in the location of production from one region to multiple regions, the knowledge spillover parameter now has an effect on growth when there was previously no effect. That is, firms initially had access to all knowledge because all manufacturing was in the same region, but in the new steady state, foreign knowledge is only partially available. While knowledge spillovers are generally growth enhancing, there is the possibility of knowledge spillovers being growth reducing in the former core region if it brings about the sharing of manufacturing.

If we consider the steady state where production is shared between locations, knowledge spillovers are growth enhancing. Furthermore, knowledge spillovers also make production in the equal distribution outcome more stable. That is, increasing knowledge spillovers means changes in trade costs are less likely to lead to a switch to the core-periphery outcome (see Fig. 12.1). With greater knowledge spillovers, production in both regions is a stable equilibrium for a greater range of trade freeness.

12.5 Variations to Incorporating Space in the Theory of Growth

In the NEGG literature, there are many variations of the model presented here. These include differences in the mobility of labor or capital, the inclusion of intermediate goods, heterogeneous firms, multiple labor types, and heterogeneous skill levels. Other areas of economics also incorporate space by using continuous space (rather than discrete regions), by defining location on an interval, by incorporating land as a factor of production, and by introducing congestion costs. All of these variations have different effects on the role of space, location, and geography on growth, but in general, incorporating space in the theory of growth has similar effects to those presented here.

12.5.1 Mobility of Labor and Capital

The model here describes the typical approach by NEGG scholars to incorporate space in the theory of growth with the inclusion of migration of skilled labor. The effect of footloose skilled labor can lead to catastrophic agglomeration, which

means the model is unable to show other unequal internal steady states. We describe the model that includes skilled worker migration to demonstrate the role of firm and worker location choices and how migration influences innovation. Highly skilled workers and innovators are internationally mobile, so it is important to consider how this affects the location of innovation and subsequently economic growth.

Capital mobility is the ability for capital to shift between locations. In all endogenous growth models, growth comes from the accumulation of capital. Capital can come in a number of forms: human capital, physical capital, or knowledge capital. We think of labor and education as human capital, which is able to migrate between locations in the model above. Physical capital is the equipment used in production such as machinery and production plants. This has been excluded from the model above. Knowledge capital is the ideas generated in the innovation sector which are marketable and tradable through patents. This is the type of capital commonly modeled in endogenous growth and NEGG literature.

There are two options for the mobility of knowledge capital. With mobile capital, the owners of capital can decide where to locate production. If knowledge capital is mobile, the number of innovations produced (and owned) by one region may be different from the number of firms actually producing in that region. That is, the developer of a patent may choose to produce in a region other than their own. In this situation, the decision to accumulate capital is the same in all locations; the mobility of capital eliminates demand-linked causality such that the shifting of production does not shift the location of consumption or the earnings from owning a manufacturing firm. Alternatively with immobile capital, the owners of capital are only able to produce within the region where they are located. With immobile capital, any shift that favors production in one location leads to new capital in that region. Since owners are local, this also leads to expenditure shifting and further production shifting via the home market effect.

In many NEGG models, such as in Martin and Ottaviano (1999), Baldwin et al. (2001), and Baldwin and Martin (2004), migration is not allowed. In these models, workers are instead completely mobile between traditional manufacturing and innovation sectors but not between regions. These models require an extra assumption that a single country's labor endowment must not be enough to meet global demand for traditional goods, to avoid complete specialization in manufacturing goods only.

In models with labor immobility and capital mobility, when we reach the steady state, the owners of capital are indifferent between producing in either region. With localized knowledge spillovers, however, innovators prefer to be located in the region with the highest level of manufacturing. Despite the differences, these models reach similar steady states to the model presented above. In particular, space has the same effects on growth because space is included using the same mechanisms with localized knowledge spillovers and transport costs. Agglomeration is growth enhancing due to localized knowledge spillovers, and knowledge spillovers are growth enhancing because they reduce the cost of innovation.

In models without labor or capital mobility, agglomeration is enabled by either vertical linkages in production or the spatial influence on knowledge creation and

transfer. If NEGG models have immobile capital and mobile labor, these models have the same catastrophic agglomeration described by the model above (and most NEG models) because innovation occurs at a faster rate in a region with greater capital, and this is self-reinforcing as all new firms prefer to innovate in the location with the largest share of manufacturing. Whenever labor is mobile, agglomeration is catastrophic.

However, models with immobile capital and immobile labor offer an alternative advantage of unequal internal solutions. That is, a range of transport costs and knowledge spillovers that yields steady states where one region has a larger share of manufacturing (but not all) than the other. As there is no migration, this means the region with the larger share of manufacturing has a share of traditional goods production smaller than the other region's share of traditional goods production. Even though these models ignore the role of migration in economic activity and growth, it does allow us to consider the effect on knowledge spillovers and growth when there are unequal levels of agglomeration. The effect is very similar to the core-periphery outcome. Growth rates are equal in both regions because consumers in the low manufacturing region still benefit from innovations made in the high manufacturing region because of trade. Similarly, the growth rate in varieties is greater in the high manufacturing region because of localized knowledge spillovers. Real wages are also higher in a high manufacturing region. Without migration, there is no mechanism to equalize real wages between regions.

Another advantage of modeling with labor immobility between regions is there is no need for the modeling trick of the Krugman's (1991) core-periphery model which fixes the share of skilled and unskilled workers. Instead, labor mobility between sectors equalizes real wages between manufacturing and traditional sectors within region, and zero transport costs in the traditional goods sector equalize nominal wages. Even though these alternative models have some features that are mathematically elegant, we chose to explore the model including migration because we view it as a more realistic description of spatial endogenous growth.

12.5.2 Vertically Linked Industry

Other types of NEGG models have vertically linked industry following the practice of some NEG models (Krugman and Venables 1995; Venables 1996). This is where goods are a factor of production. For example, final goods may be produced from a variety of manufactured intermediate goods (Yamamoto 2003), manufactured goods may be produced using a variety of manufactured goods (which have not been consumed), and/or the innovation sector could use manufactured goods as a factor of production (Martin and Ottaviano 1999).

If the vertical linkage is in the innovation sector, this generates a feedback between growth and agglomeration with a similar result to localized knowledge spillovers. Martin and Ottaviano (1999) do not use the localized knowledge spillover mechanism demonstrated here, and instead, their innovation sector uses manufacturing goods as an innovation input such that the location of manufacturing affects the

cost of innovation through trade costs. Similarly, Yamamoto (2003) describes a model where final goods and innovation are produced using manufactured intermediate goods. This creates circular causation in growth and agglomeration because of the vertical linkages between intermediates and innovation.

12.5.3 Other Characteristics

There are many different factors which affect firm location decisions and subsequently space, innovation, and economic growth. Above, we have explored how these are dealt with in NEGG models by combining endogenous growth with the new economic geography and recognizing localized knowledge spillovers. But there are many more modeling choices for spatial factors which influence growth. For example, studying heterogeneous firms (Baldwin and Forslid 2010) helps describe the characteristics of which firms choose to locate in core or lagging regions. Other models include land requirements and continuous space (Desmet and Rossi-Hansberg 2009), whereby every firm is in a different location but willing to pay higher land rents to access more valuable locations. All of these have some influence on location choices for firms but ultimately demonstrate the same role of space in growth – that space is a barrier to knowledge transfer and technology diffusion which are inputs to innovation – and that policies or decisions by firms that reduce these spatial costs are growth enhancing.

12.6 Conclusions

We have described how NEGG models incorporate space into the Grossman and Helpman (1991a) product variety model of endogenous growth. Incorporating space into endogenous growth increases the complexity of these theoretical models. In all of these models with full local knowledge spillovers and partial global knowledge spillovers, space affects growth and growth affects location. The circular linked causality reinforces the core-periphery outcome of the NEG models. We show that integration between regions is more complex than is described by international trade models. In particular, we find that the cost of transferring knowledge between locations is important for firm location, stability, innovation, and growth.

From our discussion of the effect of space on growth through freeness of trade, agglomeration, and knowledge spillovers, there are a number of implications for economic policy in different locations. Agglomeration, freeness of trade, and knowledge spillovers are generally growth enhancing. The natural conclusion is that closer integration of economies will lead to increased growth rates. However, in these spatial models of growth, integration has two dimensions: trade costs and knowledge spillovers.

While traditional conceptions of integration refer to lowering of the cost of trading goods, Baldwin and Forslid (2000) show that combining theories of growth and space produces a more subtle view of integration where we can also view

integration as lowering the cost of trading information. Integration policies which focus solely on free trade may be destabilizing and result in a deindustrialization of the periphery region. Alternatively, integration policies that also focus on knowledge spillovers (or entirely on knowledge spillovers) will be growth enhancing for both regions. The model here shows how this form of integration is stabilizing, while pure trade cost integration can be destabilizing.

While lowering trade costs induces uneven development, it also results in higher rates of economic growth. Alternatively, policies that improve knowledge spillovers improve stability of the location of economic activity. Growth policies should consider the effect of trade, knowledge spillovers, labor, and capital market integration.

Acknowledgments We would like to thank Jacques Poot for excellent comments on earlier drafts of this chapter. Steven Bond-Smith would also like to thank the Royal Society of New Zealand Marsden Fund and the University of Waikato for financial support.

Abstract

Oligopolies are a fundamental economic market structure in which the number of competing firms is sufficiently small so that the profit of each firm is dependent upon the interaction of the strategies of all firms. There are alternative behavioral assumptions one may employ in forming a model of spatial oligopoly. In this chapter, we study the classical oligopoly problem based on Cournot's theory.

The Cournot-Nash solution of oligopoly models assumes that firms choose their strategy simultaneously and each firm maximizes their utility function while assuming their competitor's strategy is fixed. We begin this chapter with the basic definition of Nash equilibrium and the formulation of static spatial and network oligopoly models as variational inequality (VI) which can be solved by several numerical methods that exist in the literature. We then move on to dynamic oligopoly network models and show that the differential Nash game describing dynamic oligopolistic network competition may be articulated as a differential variational inequality (DVI) involving both control and state variables. Finite-dimensional time discretization is employed to approximate the model as a mathematical program which may be solved by the multi-start global optimization scheme found in the off-the-shelf software package GAMS when used in conjunction with the commercial solver MINOS. We also present a small-scale numerical example for a dynamic oligopolistic network.

13.1 Introduction

The theory of oligopolistic markets and competition is introduced in Greenhut et al. (1987) and Greenhut and Lane (1989). Some basic models of spatial oligopoly are presented by Raa (1984), Dafermos and Nagurney (1987), Henderson and Quandt (1980), Novshek (1980), and Matsushima and Matsumura (2003). Moreover, Harker (1984), Dafermos and Nagurney (1987), and Nagurney (1999) studied the variational inequality (VI) approach to determine market equilibrium for a general static oligopoly model.

The motivation for this chapter is to construct computable general equilibrium models for static and dynamic spatial oligopoly with emphasis on computation rather than theory. We begin this chapter with the definition of Nash equilibrium and formulation of static spatial and network oligopoly as a variational inequality. In the network case, a few firms compete as Nash agents in the output market for a single homogeneous commodity. The firms are located at nodes of a transportation network in which common freight tariffs expressed as a fee per unit of flow on each arc are known and faced by each oligopolist. We then move on to computable modeling of dynamic network oligopoly described by differential Nash equilibria formulated as a differential variational inequality (DVI).

Models like those presented in this chapter arise when constructing spatial computable general equilibrium models, examples of which are Tobin and Friesz (1983), Friesz and Harker (1984), Dafermos and Nagurney (1987), Beckmann and Puu (1990), and Friesz (1993), as well as partial equilibrium models, when detailed freight flows are needed for a specific application. Throughout, our emphasis is on computation rather than theory, and our style is that of a simple primer in order to make the material accessible by the widest possible audience. Although some of the network models considered herein are notationally complex, our presentation relies only on very basic notions from microeconomic theory and elementary optimization.

13.2 The Notion of a Nash Equilibrium

Nash (1950, 1951) generalized the concept of equilibrium for the behavioral model consisting of N players who cannot improve their own self-interest by deviating from their equilibrium strategy, given that the other players use their equilibrium strategies (Friedman 1979). Suppose there are N players in a game and each player $i \in [1, N] \subseteq I_{++}$ (I_{++} being the set of positive integers) chooses a feasible strategy tuple x^i from the strategy set Ω_i to maximize the utility function $\Theta_i : \Omega_i \rightarrow \mathbb{R}^1$ (where \mathbb{R}^n refers to the real n -dimensional space), which will generally depend on other players' strategies. Every player $i \in [1, N]$ is trying to solve their best response problem:

$$\begin{aligned} \max \quad & \Theta(x^i; x^{-i}) \\ \text{subject to} \quad & x^i \in \Omega_i \end{aligned} \tag{13.1}$$

Note that, in Eq. (13.1), we use the notation

$$x^{-i} = (x^j, j \neq i) \quad i \in [1, N]$$

to refer to the tuple of strategies of players other than i . It is assumed that the non-own tuple x^{-i} is known to player i . A Nash equilibrium is the vector of strategies

$$x = (x^i : i \in [1, N])$$

formed from player-specific tuples such that each x^i solves the mathematical program (13.1). We denote a Nash equilibrium by $NE(\Theta, \Omega)$ (Friesz 2010).

13.3 Aspatial Oligopoly

Market structures are characterized by the existence of either a single or multiple firms. The former case, where the firm has no competitor, is referred to as a monopoly. Thus, he/she need not be concerned about the influence his/her strategy may have on competitors. The second case is known as an oligopoly, where the number of competing firms is sufficiently small so that the actions of any individual have a perceptible influence on the other firms. This interdependence of the firms' actions is the essential feature of oligopoly markets (Henderson and Quandt 1980).

Suppose there are N firms $i = 1, 2, \dots, N$ who supply a homogeneous commodity in a noncooperative fashion. Let $\pi(Q) : \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$ (where \mathbb{R}_+^n is the set of

n tuples whose elements are real and nonnegative) denote the inverse demand function, where $Q \geq 0$ is the total supply in the market and $q^i \geq 0$ is the supply for firm i :

$$Q = \sum_{i=1}^N q^i \quad (13.2)$$

Further, let $V^i(q^i) : \mathbb{R}_+^1 \rightarrow \mathbb{R}_+^1$ denote the total production cost of firm i to supply q^i units. Given the other firms' strategy, q^{-i} , firm i tries to maximize its total profit $\Theta_i(q^i; q^{-i}) : \mathbb{R}_+^N \rightarrow \mathbb{R}^1$ by choosing the production quantity, q^i . To do so, firm i must solve the following mathematical program known as firm i 's best response problem:

$$\max_{q^i} \Theta_i(q^i; q^{-i}) = q^i \pi(Q) - V^i(q^i) \quad (13.3)$$

subject to

$$\begin{aligned} Q &= \sum_{i=1}^N q^i \\ q^i &\geq 0 \end{aligned}$$

There is a Nash game between the players (firms) choosing a feasible strategy $q^i \geq 0$ where every player's objective function depends on all other players' strategies. The strategy $q^* = (q^{*1}, q^{*2}, \dots, q^{*N}) \in \mathbb{R}_+^N$ is the solution of this game, and, in general, we refer to the solution of a Nash game as a Nash equilibrium, $NE(\Theta, \Omega)$ (Harker 1984).

If $V^i(\cdot)$ is convex and continuously differentiable for $i = 1, 2, \dots, N$, the inverse demand function $\pi(\cdot)$ is strictly decreasing and continuously differentiable, and the industry revenue function $Q^T \pi(Q)$ is concave, then $q^* = (q^{*1}, q^{*2}, \dots, q^{*N})$ is a Nash equilibrium solution if and only if

$$\begin{aligned} (i) \quad & [\pi(Q^*) + q^{i*} \nabla_{q^i} \pi(Q^*) - \nabla_{q^i} V^i(q^{i*})] q^{i*} = 0 \quad \forall i = 1, 2, \dots, N \\ (ii) \quad & \pi(Q^*) + q^{i*} \nabla_{q^i} \pi(Q^*) - \nabla_{q^i} V^i(q^{i*}) \leq 0 \quad \forall i = 1, 2, \dots, N \end{aligned}$$

where

$$\begin{aligned} Q^* &= \sum_{i=1}^N q^{i*} \\ q^{i*} &\geq 0 \end{aligned}$$

Conditions (i) and (ii) are the first-order necessary (and sufficient) conditions for the set of problems defined by Eq. (13.3) for each $i = 1, 2, \dots, N$ (Murphy et al. 1982).

13.3.1 Spatial Oligopoly

Spatial models try to determine the factors governing the distribution and/or location of economic activity over space. In spatial models, space is often represented as a set of discrete locations at a certain level of resolution.

We may now generalize the classical model of oligopoly to the spatial case in which a few firms are competing in spatially separated markets. Assume there are N firms and M demand markets that are generally spatially separated. Further, assume a homogenous commodity is produced by N firms and consumed in M markets. Let q^i denote the output of firm $i \in [1, N] \subseteq I_{++}$ and c^j denote the demand for the commodity at market $j \in [1, M] \subseteq I_{++}$. Let s_j^i denote the commodity shipment from firm i to market j . The following conservation of flow equations for the total supply and demand must hold

$$q^i - \sum_{j=1}^M s_j^i = 0 \quad \forall i = 1, 2, \dots, N \quad (13.4)$$

$$c^j - \sum_{i=1}^N s_j^i = 0 \quad \forall j = 1, 2, \dots, M \quad (13.5)$$

where

$$0 \leq c \leq c^{\max}, 0 \leq q \leq q^{\max}, 0 \leq s \leq s^{\max} \quad (13.6)$$

Note that in Eq. (13.6), these column vectors are employed:

$$\begin{aligned} q &\in \mathfrak{R}_{++}^N \\ c &\in \mathfrak{R}_{++}^M \\ s &\in \mathfrak{R}_{++}^{N \times M} \end{aligned}$$

denote the production outputs, demands, and the commodity shipments. As previously, $V^i(q^i)$ is the total production cost for firm i to supply q^i units, r_j^i is the freight rate (tariff) charged per unit of flow s_j^i , and $\pi_j(c^j)$ is the inverse demand function of market j . To consider the general situation, we assume the production cost may depend on the entire production pattern $V^i = V^i(q) : \mathfrak{R}_{++}^N \rightarrow \mathfrak{R}_{++}^1$, the inverse demand

function at market j may depend on the entire consumption pattern, $\pi_j = \pi_j(c) : \mathbb{R}_{++}^M \rightarrow \mathbb{R}_{++}^1$, and the freight rate (tariff) may depend on the entire shipment pattern, $r_j^i = r_j^i(s) : \mathbb{R}_{++}^{N \times M} \rightarrow \mathbb{R}_{++}^1$ (where \mathbb{R}_{++}^n is the set of n tuples whose elements are real and positive). The aforementioned dependency means the transportation cost functions allow for interactions among the firms' shipments (as would be the case when the transportation system has limited capacity and the firms all use the same system). In this model, each of the firms wants to maximize their profit. The profit function of each firm i may be expressed as follows (Dafermos and Nagurney 1987):

$$\Theta_i(c, q, s) = \sum_{j=0}^M \pi_j(c) s_j^i - V^i(q) - \sum_{j=0}^M r_j^i(s) s_j^i \tag{13.7}$$

In light of Eqs. (13.4) and (13.5), one may write

$$\Theta = \Theta(s)$$

Now we consider the usual market mechanism associated with an oligopoly, for which the N firms behave as noncooperative agents and supply the commodity while maximizing their own profit. We will seek a commodity shipment pattern s for which the N firms will be in a state of equilibrium per the following definition (Nagurney 1999):

Definition i

(spatial Cournot-Nash equilibrium) A commodity shipment pattern s^* is said to constitute a Cournot-Nash equilibrium if for each $i = 1, 2, \dots, N$,

$$\Theta_i(s_j^{i*}, s_j^{-i*}) \geq \Theta_i(s_j^i, s_j^{-i*}) \quad \forall s_j^i \in \Omega$$

where

$$\Omega = \{s_j^i : (4), (5), (6)\}$$

So, firm i can maximize its profit, Θ_i , by choosing s_j^{i*} among all other possible shipment patterns when the shipment patterns of the other competitors, s_j^{-i*} , are known and fixed.

13.3.2 Variational Inequality (VI) Formulations of Spatial Oligopolist Competition

Variational inequalities have been used to study equilibrium problems, but now are increasingly used to formulate a much wider array of mathematical problems.

In this section, we present the variational inequality equivalent to a Cournot-Nash equilibrium in the following theorem:

Theorem i

(Nash equilibrium equivalent to a variational inequality). The general Nash equilibrium $NE(\Theta, \Omega)$ is equivalent to the following variational inequality $VI(\nabla\Theta, \Omega)$:

$$\text{find } x^* \in \Omega$$

such that

$$[\nabla\Theta(x^*)]^T(x - x^*) \geq 0 \quad \forall x \in \Omega$$

the following regularity conditions hold: (i) each $\Theta^i(x) : \Omega_i \rightarrow \mathbb{R}^1$ is convex and continuously differentiable in x^i , and (ii) each Ω_i is a closed convex subset of \mathbb{R}^n . See Friesz (2010) for a proof of the above result.

In geometric terms, the variational inequality states that $[\nabla\Theta(x^*)]^T$ is orthogonal to the feasible set Ω at the point x^* . Applying Theorem i, the oligopoly model can be formulated as the following VI (Nagurney 1999):

find $q^* \geq 0$ such that :

$$\sum_{i=1}^N [\nabla_{q^i} V^i(q^{i*}) - \pi(Q^*) - \nabla_{q^i} \pi(Q^*) q^{i*}] (q^i - q^{i*}) \geq 0 \quad \forall q \geq 0 \tag{13.8}$$

where

$$Q^* = \sum_{i=1}^N q^{i*}$$

The VI formulation (13.8) states that if each firm i chooses strategy q^{i*} , no firm can increase their profit by changing their strategy, while the other players' strategies remain unchanged.

13.3.3 Diagonalization Algorithm for Variational Inequality

In this section, the diagonalization algorithm (or diagonalization for short) discussed is one of several algorithms that can be used to solve a variational inequality. Its algorithmic philosophy is very similar to the Gauss-Seidel method from the numerical analysis literature (Friesz 2010). Diagonalization is suitable for solving finite-dimensional variational inequalities because the resulting subproblems are nonlinear

programs that can be efficiently solved with well-understood nonlinear programming algorithms, which are often available in the form of commercial software. This fact notwithstanding, diagonalization may fail to converge, and its use on large-scale problems can be frustrating. We are now ready to state the so-called *diagonalization algorithm* to solve $VI(F, \Omega)$. The algorithm is composed of three main steps:

Step 0. Initialization. Determine a feasible solution $x^0 \in \Omega$ and set $k = 0$.

Step 1. Solve diagonalized variational inequality. Form the separable functions $F_i^k(x_i)$ for all $i \in [1, N] \subseteq I_{++}$ and solve the associated diagonalized variational inequality problem. That is, find $x^{k+1} \in \Omega$ such that

$$\sum_{i=1}^N F_i(x_i^{k+1})(x_i - x_i^{k+1}) \leq 0 \quad \forall x \in \Omega$$

which may be solved using the following nonlinear program:

$$\max J(x) = \sum_{i=1}^N \int_0^{x_i} F_i^k(z_i) dz_i \quad \text{s.t. } \forall x \in \Omega$$

where z_i are dummy variables of integration.

Step 2. Stopping criteria. For a small positive number $\zeta \in \mathfrak{R}_{++}^1$, a preset tolerance, if

$$\max_{i \in [1, N]} |x_i^k - x_i^{k+1}| < \zeta$$

stop; otherwise, set $k = k + 1$ and go to Step 1.

Other numerical methods for VI such as gap function method, fixed-point method, and successive linearization and Lemke's algorithm are presented in Friesz (2010) with some numerical examples.

13.4 Static Network Oligopoly

A transportation network allows firms to ship their commodity to multiple markets through multiple paths. In this section, we consider the impact of spatial transportation networks on the firms' economic decisions. For the time being, we restrict our consideration to the static case, while in a later section, we will extend this model to the dynamic case. Several papers exist in the literature about modeling spatial network oligopoly. For example, Hakimi (1983) chooses locations for new facilities in an oligopolistic environment. Tobin and Friesz (1983) show that an equivalent optimization problem for spatial price network equilibrium may be formulated without path variables. Moreover, Rovinsky et al. (1980) developed a model for Cournot-Nash equilibrium of firms who are spatially separated but supply a commodity to a single market. Hashimoto (1985) and Harker (1986) formulated more general Cournot-Nash models in which consumers are also spatially dispersed.

In this section, we are going to present the static network oligopoly model. Suppose we have a transportation network with several spatially separated markets for a particular commodity located at nodes within a network. Each market may be supplied by several firms with production facilities located at nodes within the network (these nodes may or may not be the same nodes as a market). Further, a firm may have production facilities at more than one node. Each firm is seeking to maximize its total profit by making decisions about their output rate, allocation of this output to each market, and shipment pattern between OD (origin–destination) pairs. So, there is a Nash game among firms whose facilities and final demand markets are fixed at distinct nodes of a distribution network and connected by paths involving chains of arcs of that network. The network is represented by $G(N, W)$, in which N is a set of nodes and W is a set of OD pairs (i, j) for which there exists at least one path from i to j . Further, F is a set of firms that compete in the network. N_f is the set of nodes at which firm f has economic presence, and W_f is the set of OD pairs used by firm f to transport the commodity. Moreover, s_{ij}^f is the shipment of firm f for OD pairs (i, j) , r_{ij} is the freight rate (tariff) charged per unit of flow for OD pair (i, j) , c_i^f is the allocation of output of firm $f \in F$ at node $i \in N_f$ to consumers, q_i^f is the output of firm $f \in F$ at node $i \in N_f$, and $V_i^f(q_i^f)$ is the variable cost of production for q_i^f units. The best response problem for firm f is

$$\max \Theta_f(c^f, q^f, h^f; c^{-f}, q^{-f}, h^{-f}) = \sum_{i \in N_f} \pi_i \left(\sum_{g \in F} c_i^g \right) c_i^f - \sum_{i \in N_f} V_i^f(q_i^f) - \sum_{(i,j) \in W_f} r_{ij} s_{ij}^f$$

subject to

$$c_i^f = q_i^f + \sum_{(i,j) \in W} s_{ji}^f - \sum_{(j,i) \in W} s_{ij}^f \quad \forall i \in N_f \quad (13.9)$$

$$0 \leq c_i^f \leq c_i^{\max}, 0 \leq q_i^f \leq q_i^{\max}, 0 \leq s_{ij}^f \leq s_{ij}^{\max} \quad (13.10)$$

In keeping with the above, each firm maximizes its total profit $\Theta_f(c^f, q^f, h^f; c^{-f}, q^{-f}, h^{-f})$. Constraint (13.9) guarantees that flow is conserved at each node. Moreover, by Eq. (13.10), all consumption, production, and shipping variables are nonnegative and bounded from above. Applying Theorem i, the static network oligopoly can be formulated as the following VI:

$$\begin{aligned} & \text{find } (c_i^{f*}, q_i^{f*}, s_{ij}^{f*}) \in \Omega \text{ such that} \\ & \sum_{f \in F} \left[\sum_{i \in N_f} \nabla_{q_i^f} \Theta_f(q_i^f - q_i^{f*}) + \sum_{i \in N_f} \nabla_{c_i^f} \Theta_f(c_i^f - c_i^{f*}) + \sum_{(i,j) \in W_f} \nabla_{s_{ij}^f} \Theta_f(s_{ij}^f - s_{ij}^{f*}) \right] \geq 0, \forall (c, q, s) \in \Omega \end{aligned} \quad (13.11)$$

where

$$\Omega = \{(c_i^f, q_i^f, s_{ij}^f) : \text{Eqs. (13.9), (13.10)}\}$$

13.5 Dynamic Network Oligopoly

We now turn to the problem of modeling and computing differential Nash equilibria among the oligopolistic firms. The oligopolistic firms of interest, embedded in a network economy, are in oligopolistic competition according to dynamics that describe the trajectories of inventories/backorders and correspond to flow conservation for each firm at each node of the network. The oligopolistic firms, acting as shippers, perfectly compete as price takers in the market for physical distribution services. Perfect competition in shipping arises because numerous shipping companies serve numerous customers due to the involvement of shippers in the numerous output markets of the network economy. The time scale we consider is neither short nor long, but rather of sufficient length to allow output and shipping pattern adjustments, while not long enough for firms to relocate, enter, or leave the network economy. This model, which takes the form of a differential variational inequality, is presented in this section. Dynamic network oligopoly models were studied by Brander and Zhang (1993), Nagurney et al. (1994), Wie and Tobin (1997), Nagurney et al. (2002), Friesz et al. (2006), and Markovich (2008). To develop the mathematical formulation of network oligopoly, we follow the exposition in Friesz (2010).

13.5.1 Notation

Fortunately, much of the notation introduced in previous sections of this chapter is still relevant. Yet, because there are some subtle differences between the dynamic oligopoly model that we now study and problems explored previously in this chapter, we choose to give an exhaustive list of the notation to be employed below, even though that will involve some duplication. We let continuous time be denoted by the scalar $t \in \mathbb{R}_+^1$, initial time by $t_0 \in \mathbb{R}_+^1$, and final time by $t_f \in \mathbb{R}_{++}^1$, with $t_0 < t_f$ so that $t \in [t_0, t_f] \subset \mathbb{R}_+^1$. There are several sets important to articulating a network oligopoly model; these are as follows: \mathcal{F} for firms, \mathcal{A} for directed arcs, \mathcal{N} for nodes, and \mathcal{W} for origin–destination (OD) pairs. Subsets of these sets are formed as is meaningful by using the subscripts f for a specific firm, i for a specific node, and ij for a specific OD pair (i, j) .

Each firm $f \in \mathcal{F}$ controls production (output) rates q^f , allocation of output to meet demand c^f , and shipping pattern s^f . Inventories I^f are state variables determined by the controls. In particular, concatenations of the firm-specific vectors c^f , q^f , and s^f for the vectors c , q , and s , respectively.

13.5.2 The Firm's Objective Functional, Dynamics, and Constraints

Each firm has the objective of maximizing net profit expressed as revenue less cost and takes the form of an operator acting on allocations of output to meet demands, production rates, and shipment patterns. For each firm $f \in \mathcal{F}$, net profit is given by the following functional:

$$\begin{aligned}
\Phi_f(c^f, q^f, s^f; c^{-f}, q^{-f}) &= e^{-\rho t_f} Z_f [I(t_f), t_f] \\
&+ \int_{t_0}^{t_f} e^{-\rho t} \left\{ \sum_{i \in \mathcal{N}} \pi_i \left(\sum_{g \in \mathcal{F}} c_i^g, t \right) c_i^f - \sum_{i \in \mathcal{N}_f} V_i^f(q^f, t) \right. \\
&- \sum_{(i,j) \in \mathcal{W}_f} r_{ij}(t) s_{ij}^f - \sum_{i \in \mathcal{N}_f} V_i^f(q^f, t) - \sum_{(i,j) \in \mathcal{W}_f} r_{ij}(t) s_{ij}^f \\
&\left. - \sum_{i \in \mathcal{N}} \psi_i^f(I_i^f, t) \right\} dt
\end{aligned} \tag{13.12}$$

where $\rho \in \mathfrak{R}_{++}^1$ is a constant nominal rate of discount, $r_{ij} \in \mathfrak{R}_{++}^1$ is the freight rate (tariff) charged per unit of flow s_{ij} for OD pair $(i, j) \in \mathcal{W}_f$, ψ_i^f is firm f 's inventory cost at node i , and I_i^f is the inventory/backorder of firm f at node i . In Eq. (13.12), c_i^f is the allocation of the output of firm $f \in \mathcal{F}$ at node $i \in \mathcal{N}$ to consumption at that node. Also $Z_f [I^f(t_f), t_f]$ is the liquidation value of inventory remaining at the terminal time, where $I^f = (I_i^f : i \in \mathcal{N}_f)$. Because our formulation is in terms of flows, it is convenient to employ the inverse demand functions $\pi_i(c_i, t)$ where $c_i = \sum_{g \in \mathcal{F}} c_i^g$ is the total allocation of output to consumption for node i . Furthermore, q_i^f is the output of firm $f \in \mathcal{F}$ at node $i \in \mathcal{N}$. Again $V_i^f(q, t)$ is the variable production cost for firm $f \in \mathcal{F}$ at node $i \in \mathcal{N}$. The reader should note that $\Phi_f(c^f, q^f, s^f; c^{-f}, q^{-f})$ is a functional that is determined by the controls c^f , q^f , and s^f when non-own allocations to consumption and non-own production rates

$$c^{-f} \equiv (c^{f'} : f' \neq f), q^{-f} \equiv (q^{f'} : f' \neq f)$$

are taken to be exogenous data by firm f . The first term of the objective functional $\Phi_f(c^f, q^f, s^f; c^{-f}, q^{-f})$ in expression (13.12) is the firm's revenue, the second term is the firm's cost of production, the third term is the firm's shipping costs, and the last term is the firm's inventory or holding cost.

We next impose the terminal time inventory constraints

$$I_i^f(t_f) \geq \tilde{K}_i^f \forall f \in \mathcal{F}, i \in \mathcal{N}_f \tag{13.13}$$

where $\tilde{K}_i^f \in \mathfrak{R}_{++}^1$ are exogenous. Again all consumption, production, and shipping variables are nonnegative and bounded from above; that is,

$$C^f \geq c^f \geq 0 \tag{13.14}$$

$$Q^f \geq q^f \geq 0 \tag{13.15}$$

$$S^f \geq s^f \geq 0 \tag{13.16}$$

where

$$C^f \in \mathfrak{R}_{++}^{|\mathcal{F}|}, Q^f \in \mathfrak{R}_{++}^{|\mathcal{F}|}, S^f \in \mathfrak{R}_{++}^{|\mathcal{W}_f|}$$

As for the monopoly, constraints (13.14), (13.15), and (13.16) are recognized as pure control constraints, while (13.1) are terminal conditions for the state space variables. Naturally

$$\Omega_f = \{(c^f, q^f, s^f) : \text{Eqs. (13.14), (13.15), (13.16)}\}$$

is the set of feasible controls.

Firm f solves an optimal control problem to determine its production q^f , allocation of production to meet demand c^f , and shipping pattern s^f by maximizing its profit functional $\Phi_f(c^f, q^f, s^f; c^{-f}, q^{-f})$ subject to inventory dynamics expressed as flow balance equations and pertinent production and inventory constraints. The inventory dynamics for firm $f \in \mathcal{F}$, expressing simple flow conservation, obey

$$\frac{dI_i^f}{dt} = q_i^f + \sum_{(i,j) \in \mathcal{W}} s_{ji}^f - \sum_{(i,j) \in \mathcal{W}} s_{ij}^f - c_i^f \quad \forall i \in \mathcal{N}_f \tag{13.17}$$

$$I_i^f(t_0) = K_i^f \quad \forall i \in \mathcal{N}_f \tag{13.18}$$

$$I_i^f(t_f) = \tilde{K}_i^f \quad \forall i \in \mathcal{N}_f \tag{13.19}$$

where $K_i^f \in \mathfrak{R}_{++}^1$ and $\tilde{K}_i^f \in \mathfrak{R}_+^1$ are exogenous. In addition to the terminal time inventory (state) constraints (13.19), the model is general enough to handle inventory constraints over the entire planning horizon $[t_0, t_f]$. For instance, nonnegativity of the inventory (state) variables could be imposed to restrict firms from taking backorders.

We next note that firm f 's problem is with the c^{-f} and q^{-f} as exogenous inputs; compute c^f , q^f , and s^f (thereby finding I^f) in order to solve the following extremal problem:

$$\left. \begin{array}{l} \max \quad \Phi_f(c^f, q^f, s^f; c^{-f}, q^{-f}) \\ \text{s.t.} \quad (c^f, q^f, s^f) \in \Omega_f \end{array} \right\} \forall f \in \mathcal{F} \tag{13.20}$$

where

$$\Omega_f = \{(c^f, q^f, s^f) : \text{Eqs. (13.13), (13.14), (13.15), (13.16), (13.17), (13.18), (13.19) hold}\}$$

also for all $f \in \mathcal{F}$. That is, each firm is a Nash agent that knows and employs the current instantaneous values of the decision variables of other firms to make its own noncooperative decisions. As such, Eq. (13.20) is a differential Nash game. Moreover, each firm’s best response problem (13.20) is a continuous time optimal control problem.

13.5.3 The DVI Formulation of Dynamic Network Oligopoly

To continue our discussion of oligopoly, we assume the Nash game expressed above is regular in the sense of the following definition:

Definition ii

The dynamic oligopolistic network competition problem introduced above will be considered regular if (i) the state operator $I(c, q, s)$ exists and is unique, while each of its components is continuous and G differentiable; (ii) the inverse demand, production cost, and inventory cost functions are continuously differentiable with respect to controls and states; and (iii) for each $f \in \mathcal{F}$, the composite terminal cost function

$$Z_f [I^f(t_f), t_f] + \sum_{i \in \mathcal{N}_f} \gamma_i^f \left[\tilde{K}_i^f - I_i^f(t_f) \right]$$

is continuously differentiable with respect to $I_i^f(t_f)$ for all $i \in \mathcal{N}_f$.

In the above definition, each γ_i^f is a constant dual variable that prices out the terminal constraint on inventory. We also note that Eq. (13.20) is an optimal control problem with fixed terminal time. Also

$$\Psi_f(c^f, q^f, s^f, I^f, \alpha^f, \beta^f, \lambda^f) = \sum_{i \in \mathcal{N}_f} \lambda_i^f \left(q_i^f + \sum_{(j,i) \in \mathcal{W}} s_{ji}^f - \sum_{(i,j) \in \mathcal{W}} s_{ij}^f - c_i^f \right) \quad (13.21)$$

where $\alpha_i^f \in \mathbb{R}_+^1$ and $\beta_i^f \in \mathbb{R}_+^1$ are dual variables for the inventory-bounding constraints (13.13), while $\alpha^f \in \mathbb{R}^{|\mathcal{N}_f|}$ and $\beta^f \in \mathbb{R}^{|\mathcal{N}_f|}$; also $\lambda_i^f \in \mathbb{R}_+^1$ is the adjoint variable for the dynamics of firm f at node i , while $\lambda^f \in (\mathcal{H}^1[t_0, t_f])^{|\mathcal{N}_f|}$. Clearly Φ_f is the instantaneous profit. To interpret Ψ_f , we need to understand the relevant dynamic shadow benefits and shadow costs of this model. To that end, recall that, along an optimal trajectory, the adjoint variables obey

$$\lambda_i^f = \frac{\partial J_f}{\partial I_i^f}$$

Consequently,

$$\Psi_f = \sum_{i \in \mathcal{N}_f} \frac{\partial J_f}{\partial I_i^f} \frac{dI_i^f}{dt}$$

which is recognized as the shadow value of dynamic benefits arising from current inventory held; it can be either a cost or a benefit, depending on its sign.

Familiarity with variational inequalities suggests that the following variational inequality has solutions that are differential Nash equilibria for a noncooperative game in which individual firms maximize net profits in light of current information about their competitors:

$$\begin{aligned} & \text{find } (c^{f*}, q^{f*}, s^{f*}) \in \Omega \text{ such that} \\ 0 \geq & \sum_{f \in \mathcal{F}} \int_{t_0}^{t_f} \left[\sum_{i \in \mathcal{N}_f} \frac{\partial \Phi_f^*}{\partial c_i^f} (c_i^f - c_i^{f*}) + \sum_{i \in \mathcal{N}_f} \frac{\partial \Phi_f^*}{\partial q_i^f} (q_i^f - q_i^{f*}) \right. \\ & \left. + \sum_{(i,j) \in \mathcal{W}_f} \frac{\partial \Phi_f^*}{\partial s_{ij}^f} (s_{ij}^f - s_{ij}^{f*}) \right] dt \quad \text{for all } (c, q, s) \in \Omega \end{aligned} \tag{13.22}$$

where

$$\Phi_f^* = \Phi_f(c^{f*}, q^{f*}, s^{f*}, I^{f*}; c^{-f}, q^{-f}; t) \tag{13.23}$$

$$\Omega = \prod_{f \in \mathcal{F}} \Omega_f \tag{13.24}$$

We note that Eq. (13.22) is a differential variational inequality expressing the differential Nash game that is our present interest. This formulation also provides guidance in devising a computational strategy, as we show in Sect. 13.5.4.

The issue of immediate concern is to formally demonstrate that solutions of Eq. (13.22) are differential Nash equilibria. In fact, we state and prove the following result:

Theorem ii

(Differential variational inequality formulation of dynamic oligopolistic network competition.) Any solution of Eq. (13.22) is a solution of the dynamic oligopolistic network competition problem when regularity in the sense of Definition i holds. See Friesz (2010) for a proof of the above result.

We next note that the following existence result holds:

Theorem iii

(Existence of dynamic oligopolistic network equilibrium.) When the variational inequality of Theorem ii is regular in the sense of Definition i, there exists a solution of the dynamic oligopolistic network competition problem. The preceding result is proven in Friesz (2010).

13.5.4 Discrete-Time Approximation

If we define the discrete instant of time $t_k = t_0 + k\Delta$, where Δ is the time step employed, while

$$N = \frac{t_f - t_0}{\Delta}$$

is the number of discretizations, and $t_N = t_f$. Then, a finite-dimensional mathematical program is created, which forms a computable approximate solution if its objective is convex.

13.5.5 A Comment About Path Variables

It should be noted that one may introduce path flows in the above formulation by reexpressing the state dynamics as

$$\frac{dt_i^f}{dt} = q_i^f + \sum_{j \in \mathcal{N}_f} \sum_{p \in P_{ji}} h_p^f - \sum_{j \in \mathcal{N}_f} \sum_{p \in P_{ij}} h_p^f - c_i^f$$

for every firm $f \in \mathcal{F}$ and node $i \in \mathcal{N}_f$, where P_{ji} is the set of paths from node $j \in \mathcal{N}_f$ to node $i \in \mathcal{N}_f$; furthermore, h_p is the flow on path $p \in P_{ji}$. There are corresponding, but quite obvious, changes in the firm's objective function and the upper and lower bound constraints on its controls. We omit a complete statement of such details for the sake of brevity.

13.5.6 Numerical Example

Let us consider a network of five arcs, four nodes, and four firms, where a single firm f is located at each node $i = 1, 2, 3, 4$. Consumption of each firm's output potentially occurs at every node; this consumption may be of local or of imported output as the network topology permits. Figure 13.1 illustrates the network.

Fig. 13.1 Network of five arcs, four nodes, and four firms

The time interval of interest is $[0, 20]$; that is, $t_0 = 0, t_f = 20$. In this example, firm 1 has an economic presence at all nodes; firm 2 at nodes 2, 3, and 4; firm 3 at nodes 3 and 4; and finally firm 4 at node 4 only. Therefore, $\mathcal{F} = \{1, 2, 3, 4\}$, $\mathcal{N}_1 = \{1, 2, 3, 4\}$, $\mathcal{N}_2 = \{2, 3, 4\}$, $\mathcal{N}_3 = \{3, 4\}$, and $\mathcal{N}_4 = \{4\}$. Before time discretization, there are 29 controls and ten state variables associated with this example; these are enumerated in Table 13.1:

At time $t_0 = 0$, every firm has an initial inventory of 100 units at their respective locations. That is, $I_i^f(0) = 100$ for $f \in \mathcal{F}$ and $i \in \mathcal{N}_f$. In addition, we impose the condition that no backordering is allowed by any firm at any node at the terminal time $t_f = 20$. That is,

$$I_i^f(20) \geq 0 \text{ for } f \in \mathcal{F} \text{ and } i \in \mathcal{N}_f \tag{13.25}$$

The inventory dynamics are the flow balance equations

$$\begin{aligned} \frac{dI_1^1}{dt} &= q_1^1 - h_1^1 - h_2^1 - h_3^1 - h_4^1 - h_5^1 - h_6^1 - c_1^1 \\ \frac{dI_2^1}{dt} &= h_1^1 - h_7^1 - h_8^1 - h_9^1 - c_2^1 \\ \frac{dI_3^1}{dt} &= h_2^1 + h_3^1 + h_7^1 - h_{10}^1 - c_3^1 \\ &\vdots \\ \frac{dI_4^4}{dt} &= q_4^4 - c_4^4 \end{aligned} \tag{13.26}$$

which we only partially enumerate in the interest of saving space. We assume the inverse demands at each node i take the following form:

$$\pi_i(c_i, t) = \alpha_i - \beta_i (c_i)^m \tag{13.27}$$

Table 13.1 State and control variables

Firm	Controls by node or path				States					
1	c_1^1	c_2^1	c_3^1	c_4^1	I_1^1	I_2^1	I_3^1	I_4^1		
2		c_2^2	c_3^2	c_4^2		I_2^2	I_3^2	I_4^2		
3			c_3^3	c_4^3			I_3^3	I_4^3		
4				c_4^4				I_4^4		
all	q_1^1	q_2^2	q_3^3	q_4^4						
1	h_1^1	h_2^1	h_3^1	h_4^1	h_5^1	h_6^1	h_7^1	h_8^1	h_9^1	h_{10}^1
2							h_7^2	h_8^2	h_9^2	h_{10}^2
3									h_{10}^3	

Table 13.2 Path–arc

Path	Arc sequence

p_2	a_2
p_3	a_1, a_3
p_4	a_1, a_4
p_5	a_1, a_3, a_5
p_6	a_2, a_5
p_7	a_3
p_8	a_4
p_9	a_3, a_5
p_{10}	a_5

where $m \in \mathfrak{R}_{++}^1$ is a constant. Also $\alpha_i \in \mathfrak{R}_{++}^1$ and $\beta_i \in \mathfrak{R}_{++}^1$ for all i are constants. The production cost functions of each firm f have the form

$$V_i^i = \frac{1}{2} \rho_i^i (q_i^i)^2 + \frac{1}{3} \sigma_i^i (q_i^i)^3 \text{ for all } i = 1, \dots, 4 \tag{13.28}$$

where ρ_i^f and $\sigma_i^f \in \mathfrak{R}_{++}^1$ are also constants for all allowed i and f . In Eq. (13.28), we consider a nonconvex production cost functions in order to capture both increasing and decreasing economies of scale for different production rate regimes. We assume the holding costs are quadratic and of the form

$$\psi_i^f = \frac{1}{2} \eta_i^f (I_i^f)^2 \text{ for } f \in \mathcal{F} \text{ and } i \in \mathcal{N}_f \tag{13.29}$$

where $\eta_j^i \in \mathfrak{R}_{++}^1$ are constants, again for all allowed i and f . The relationships between arc and path variables are summarized in Table 13.2.

Furthermore, the relevant arc-path incidence matrix is

$$\Delta_p = (\delta_{ap}) = \begin{bmatrix} 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \end{bmatrix}$$

The associated path costs are

$$R = \Delta^T r \tag{13.30}$$

where

$$r = (r_{a_i} : i = 1, 2, 3, 4, 5)$$

and

$$r_{a_i} = A_i + B_{a_i}(f_i)^n \quad i = 1, 2, 3, 4, 5$$

are unit freight rates for individual arcs and the $A_i \in \mathfrak{R}_{++}^1$ and $B_i \in \mathfrak{R}_{++}^1$ are known constants. We impose the following vectors of bounds on control variables:

$$C^f = Q^f = H^f = 75$$

Each firm’s instantaneous profit function is found by substituting Eqs. (13.27), (13.28), (13.29), and (13.30) into Eq. (13.12), where $\rho \in \mathfrak{R}_{++}^1$ is again the fixed nominal interest rate. A discrete-time approximation of the corresponding differential variational inequality is created using $N = 21$ equal time steps. The resulting finite-dimensional variational inequality is restated as a nonlinear complementarity problem and solved using GAMS with the PATH solver. The numerical values of the model’s parameters are presented in the Table 13.3:

13.5.7 Interpretation of Numerical Results

In Fig. 13.2, we compare the net present of cumulative production, inventory holding, and transportation costs incurred by the four firms. The net present value of profit for firm 1 is $-\$185,592$, $-\$926,070$ for firm 2, $+\$248,179$ for firm 3, and $-\$314,978$ for firm 4. Thus, the only firm to realize a positive profit is firm 3, whereas all other firms experience losses. Further, Fig. 13.3 shows that firm 1, which has an economic presence at all 4 nodes, has the highest transportation costs. By comparison, firms 2 and 3 have relatively small transportation costs, while firm 4 incurs no transportation cost. This is expected, since the economic presence of firms

Table 13.3 Model's parameters

Parameter	Value	Parameter	Value	Parameter	Value
ρ	0.05	A_1	2	A_2	2
A_3	2	A_4	2	A_5	2

Δ	1	n	1	m	1

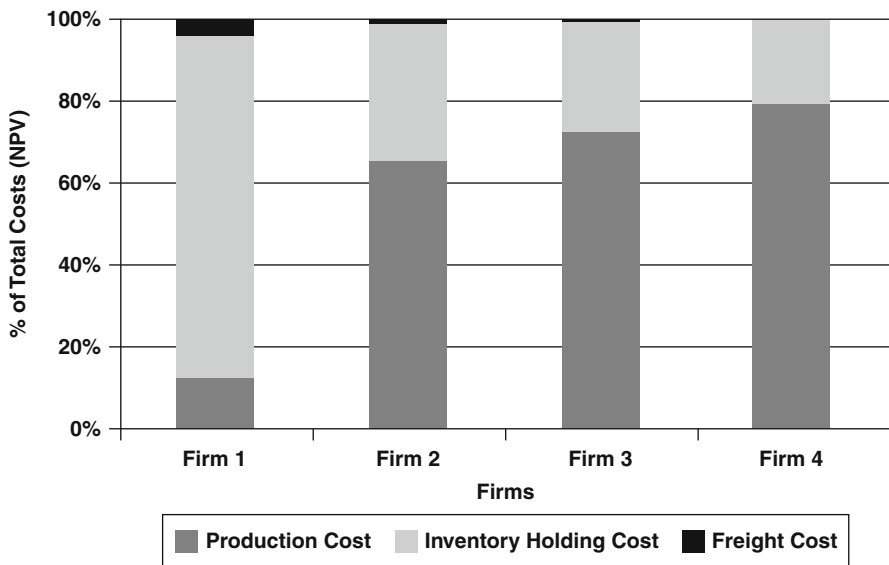

Fig. 13.2 Cost by firms

2 and 3 throughout the network is comparatively small, and firm 4 only has economic presence in its home market.

The production rates of the four firms and the prices of finished goods in the four markets are plotted in Fig. 13.3. Figure 13.3a shows that in market 4, where all the firms can compete, the price increases significantly over time. In contrast, market 1, in which only firm 1 has economic presence, shows a relatively small change in price.

Fig. 13.3 Production rates and market price

Figure 13.3b shows that each firm follows a different production plan. Firm 1 slowly increases production until it nears the end of the planning horizon, where production begins to decline. Alternatively, firm 2 operates at its full capacity for the first ten periods, then abruptly halts production only returning to full production for the last period to meet the final inventory constraint. Figure 13.2a suggests that firms must be capable of dramatically altering production schedules if they are to compete in the final goods market successfully. The numerical results for dynamic network oligopoly show complicated temporal behavior that cannot be deduced prior to numerical analyses.

13.6 Conclusions

This chapter has discussed static and dynamic spatial oligopoly. In this market structure, there is a sufficiently small number of firms competing in such a way that the strategy of any individual firm has a significant effect on the strategies of the other firms. We began with the spatial oligopoly model and moved on to the static and dynamic models by considering both static and dynamic transportation networks with several spatially separated markets for a single commodity.

Since this chapter emphasized computation rather than theory, we have formulated the static model as a variational inequality (VI) which can be solved numerically by the diagonalization algorithm. Further, it has been shown that dynamic oligopolistic network competition is easily and naturally formulated as a differential variational inequality (DVI). A discrete-time approximation method has been proposed to solve the DVI problem. One advantage of time discretization is that we can completely eliminate state variables and obtain finite-dimensional control variables involving only upper and lower bound constraints. Another advantage of our formulation is that its solution methodology takes advantage of well-documented and available optimization techniques. In particular, one may employ a standard nonlinear mathematical programming package to obtain a solution to the dynamic network oligopoly model.

To extend the network models discussed in this chapter, one might consider introducing traffic congestion in the distribution network. Another natural extension for spatial oligopoly models would be considering stochasticity which might emerge from the uncertainty of parameters. The games associated with such a model are known as stochastic games, and one may obtain a probability distribution for the Nash equilibrium.

Abstract

In this chapter, we focus on theories and models of growth that have their origin in Keynesian economics. Their common features are that firstly, growth is largely export-driven; secondly, increasing returns yield path dependencies and possible divergence; thirdly, full resource utilization is not guaranteed; fourthly, economic expansion may face a balance of payments constraint, even at the regional level; and fifthly, institutions matter. We first briefly contrast demand-driven growth theories with neoclassical and other perspectives in taxonomy of growth theories. We then show how growth in exports yields regional income growth via a multiplier that is positively associated with the propensity to consume locally produced output and the propensity to invest but

negatively related to regional tax rates and the extent to which government transfers are countercyclical. We show that Verdoorn's law – economic expansion generates productivity growth – leads to both sustained export growth and steady-state income growth, with the latter in balance of payments equilibrium equaling the rate of growth of exports divided by the income elasticity of the demand for imports. Next, theories are reviewed that suggest that policies that encourage regional growth in wages and public expenditure can be growth enhancing. Finally, we argue that the effectiveness of such demand-driven growth policies depends on institutional settings.

14.1 Introduction

The models of economic growth that were discussed extensively in the previous chapters of this section of the major reference work can be broadly labeled as supply-side-oriented general equilibrium explanations of regional economic development. Given resources of labor and capital, preferences, and technology, the allocation and accumulation of regional resources is in supply-side growth models determined by market forces that generate a general equilibrium in which prices, wages, and profits are simultaneously determined with employment, the allocation of capital, and production in all sectors, including new capital goods. The demand side of the economy is in these models fully determined by this general equilibrium with, for example, consumption determined by factor incomes, prices, and the propensity to consume. Productivity improvements are in such general equilibrium models generated by implicit or explicit innovation sectors and by human capital investments that enhance the stock of knowledge. Such models may be either stylized or calibrated by regional data in the form of spatial computable general equilibrium (SCGE) models (Donaghy 2008). Dynamic versions of such models can describe how the production of capital goods and population growth in each period contribute to an expansion of the regional production factors that, jointly with technologically driven changes in factor productivity, determine growth. These models can provide a complete and detailed bottom-up quantitative description of the growth path of the regional economy.

However, regional economies often exhibit features that are inconsistent with the smooth adjustments and economic expansion that such general equilibrium models imply. Firstly, many goods in the regional economy have prices determined outside the region, modified by transportation costs. Secondly, local incomes may depend greatly on external demand for local production and on government transfers. Thirdly, barriers to the mobility of labor may lead to considerable differences in regional unemployment rates and wages. Fourthly, the available capital may be underutilized, or alternatively, finance for new investment may be constrained by unfavorable local expectations. Finally, the diffusion of technological change may also vary between regions and depend on local investment and entrepreneurial activity. It is these features of regional economies that have led to the development of regional models in which demand for goods and services produced by the region

becomes the main driver of regional economic activity. Textbook examples are the economic base model and the regional Keynesian multiplier model. When investment in the local economy is determined by the income generated by local production, or expectations of future income, and technological change is embodied in such new investment and also depends on the scale of local production, regional growth becomes then primarily dependent on the evolution of regional demand or dependent on an exogenous demand shock that triggers an endogenous growth process. Demand-led growth models are a key focus of this chapter. Following a discussion of demand-led growth models and the implications of a regional balance of payments constraint, we also briefly discuss related Keynesian theories of growth and theories that emphasize the role of institutions.

This chapter is organized as follows. The next section briefly outlines the taxonomy of theoretical perspectives on long-run growth, while [Sect. 14.3](#) highlights the central role that regional exports and other forms of regional exogenous demand, such as local government expenditure and infrastructural investment, play in determining regional economic activity. [Section 14.4](#) discusses a model of export-driven growth via productivity improvements that are assumed to result from regional expansion. We also show how limited export opportunities may generate a balance of payments constraint on economic expansion. [Section 14.5](#) presents theories that suggest how high wages and government consumption may trigger productivity improvements that can generate regional growth. [Section 14.6](#) considers the role of institutions. [Section 14.7](#) concludes.

14.2 Taxonomy of Theoretical Perspectives on Long-Run Growth

It is important to note that the various theoretical perspectives available on long-run growth are not necessarily contradicting but may offer different but often complementing perspectives on a complex reality. This is illustrated in [Fig. 14.1](#) which charts different economic schools of thought in terms of some of the key paradigms that may be emphasized in the study of economic growth. The first paradigm is that of a permanent tendency of the economy to move toward a stable equilibrium, driven by market forces. An alternative paradigm is that of path dependency, evolutionary change, and complex dynamics. A third paradigm emphasizes the need for coordination and intervention in dynamic processes in order to reach desirable goals. These three paradigms may be juxtapositioned with two additional guiding principles that are both dichotomies: a distinction between static and dynamic perspectives and a distinction between the policy goals of economic efficiency on the one hand and an equitable distribution of wealth and income on the other.

By combining the three paradigms with the two dichotomies, we obtain a classification that may be helpful to highlight the features and perspectives of different theories of economic growth. [Figure 14.1](#) provides a single example for each school of thought regarding economic growth. At the top, neoclassical theory

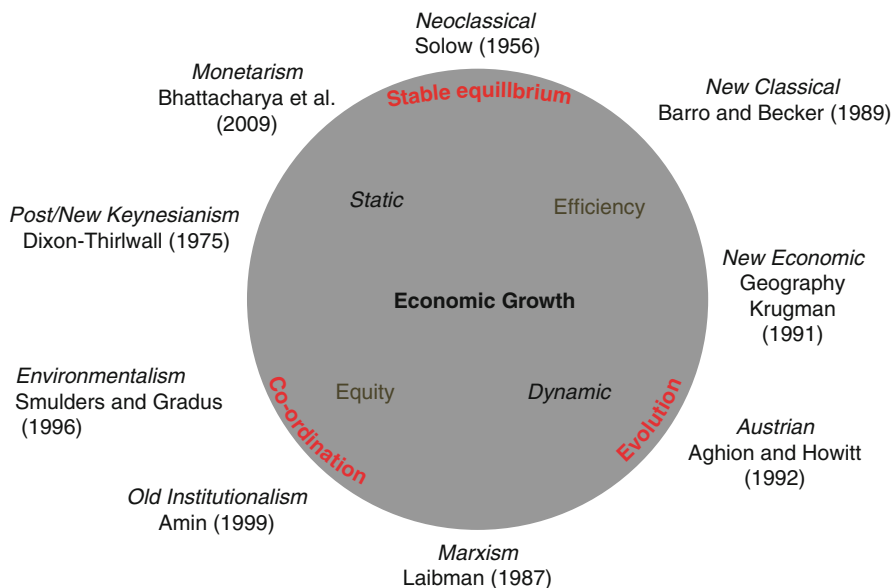

Fig. 14.1 Schools of thought on economic growth with selected examples

can be characterized by the emphasis on economies moving toward a long-run exogenously determined steady-state growth path, of which the Solow (1956) growth model is clearly the leading proponent. Toward the right, and emphasizing efficiency and micro-foundation-based rationality, even in terms of, for example, dynastic utility across generations, are new classical growth models such as Barro and Becker (1989). Moving away from stable equilibrium and toward dynamical systems modeling, one reaches core-periphery models of new economic geography, as first formulated by Krugman (1991). Next, toward even greater dynamical complexity and evolution, we reach Schumpeterian endogenous growth models of creative destruction (Aghion and Howitt 1992).

While having become largely a historical school of thought, completeness warrants inclusion of Marxist perspectives on growth, which are diagrammatically opposite those of neoclassical thinking (e.g., Laibman 1987). In the lower left quadrant of the figure in which equity and coordination are emphasized, we find institutionalism, also referred to as old institutional economics (e.g., Amin 1999) as discussed in Section 14.5, and models that are concerned with sustainability, externalities, and resource depletion (e.g., Smulders and Gradus 1996). Given the emphasis on rigidities, persisting unemployment but with nonetheless the possibility of long-run demand-driven steady-state growth, the post-Keynesian growth models are in the top left quadrant. The exemplar is the Dixon-Thirlwall model discussed in detail in this chapter. Finally, monetarist perspectives, originating from the ideas of Milton Friedman, also have been linked to long-run growth; see, for example, Bhattacharya et al. (2009).

14.3 Exogenous Demand Determined Regional Expansion

Demand-driven models of regional growth have their origin in the Keynesian theory of macroeconomic equilibrium. In this theory, equilibrium is determined by the equality of income generated by regional production and expenditure funded by this income, rather than by the available supplies of production factors. The latter are assumed abundantly available and short-run equilibrium may coincide with underutilization of the available capital, unemployment of labor, relatively rigid wages, and limited interregional migration. We develop the model largely along the lines of McCann (2001). Given the equality of regional income and expenditure,

$$Y_r = C_r + I_r + G_r + X_r - M_r \quad (14.1)$$

in which Y_r is value added or income, C_r private consumption, I_r gross fixed capital formation, G_r government consumption, X_r exports, and M_r imports, all referring to region r . Consumption expenditure is partially autonomous and partially a function of regional income:

$$C_r = AC_r + c_r Y_r (1 - \tau_r) \quad (14.2)$$

with c_r the marginal propensity to consume out of disposable income and AC_r representing autonomous consumption that is unrelated to regional income which, for example, could be consumption funded by national pensions. The parameter τ_r represents the regional average tax rate. Investment has similarly an autonomous component AI_r (e.g., reflecting expectations and replacement investment) and a component that is linked to regional disposable income:

$$I_r = AI_r + i_r Y_r (1 - \tau_r) \quad (14.3)$$

in which i_r is the marginal propensity to invest in new capital goods for given disposable income. Government consumption at the regional level will be the combination of expenditure initiated by local government and by national government. It is not implausible to assume that it negatively related to regional disposable income, as governments often have a nationally determined equity objective in which declines in regional disposable income due to depressed regional economic activity are partially offset by additional public consumption or by publicly funded private consumption through benefit payments. Hence,

$$G_r = AG_r - g Y_r (1 - \tau_r) \quad (14.4)$$

in which AG_r stands for autonomous public consumption and g measures the propensity of government consumption to be larger in regions with lower disposable income. Exports are partially autonomous (AX_r) and partially a function of income in the rest of the country and the world Z , the local price level p_r , the foreign

price level p_f , and the exchange rate e . Following Dixon and Thirlwall (1975) and others, this relationship is defined as one with constant elasticities rather than linearly. Hence,

$$X_r = AX_r Z^{\varepsilon_r} [p_f / (ep_r)]^{\eta_r} \quad (14.5)$$

The term $[p_f / (ep_r)]$ represents the price competitiveness of the regional economy in trade, with η_r the competitiveness elasticity of exports. Similarly, ε_r represents the world income elasticity of local exports (both elasticities may vary across regions).

Finally, imports are partially autonomous (AM_r) and partially a function of regional disposable income and price competitiveness of the regional economy in trade, again with potentially spatially varying elasticities, here π_r and μ_r , respectively:

$$M_r = AM_r [Y_r (1 - \tau_r)]^{\pi_r} [(ep_r) / p_f]^{\mu_r} \quad (14.6)$$

In order to make the model easily solvable, we assume that the elasticity of imports with respect to regional disposable income is one, that is, $\pi_r = 1$. This implies that for a given competitiveness of the regional economy, imports are proportional to disposable income. Defining $m_r \equiv AM_r [(ep_r) / p_f]^{\mu_r}$, Eq. (14.6) then simply becomes

$$M_r = m_r [Y_r (1 - \tau_r)] \quad (14.7)$$

Similarly, defining $x_r \equiv AX_r [p_f / (ep_r)]^{\eta_r}$, gives

$$X_r = x_r Z^{\varepsilon_r} \quad (14.8)$$

Substituting Eqs. (14.2)–(14.4), (14.7), and (14.8) into Eq. (14.1), and solving for Y_r , yields the equilibrium level of regional income:

$$Y_r = \{1 - [(c_r - m_r) + (i_r - g)](1 - \tau_r)\}^{-1} \{AC_r + AI_r + AG_r + x_r Z^{\varepsilon_r}\} \quad (14.9)$$

The first term on the right-hand side is the Keynesian multiplier. This multiplier, which we will denote by k_r , is expected to be greater than one because firstly, the marginal propensity to consume locally produced goods ($c_r - m_r$) is expected to be less than one; secondly, the regional marginal propensity to invest, corrected for countercyclical government transfers, is also expected to be between zero and one; and thirdly, the average tax rate is less than one. The Keynesian multiplier will increase when the marginal propensity to consume locally produced goods increases, when the demand for imports from other regions and countries declines, when the regional marginal propensity to invest increases, when government transfers are less countercyclical, and when the average tax rate declines.

The greatest source of regional fluctuation in autonomous demand is likely to be regional exports, which are – for given competitiveness – fully driven by incomes in

other regions and countries. If we assume that the other components of autonomous demand are constant, a change in regional exports (ΔZ^{e_r}) leads to the following change in regional income:

$$\Delta Y_r = k_r x_r \Delta Z^{e_r} \quad (14.10)$$

If q_r refers to average labor productivity in the regional economy, q_{x_r} refers to average productivity in the export sector, and these productivities are assumed to be constant in the short run, Eq. (14.10) can be transformed to one describing changes in employment:

$$\Delta T_r = k_r (q_{x_r} / q_r) \Delta B_r \quad (14.11)$$

in which T_r refers to total regional employment and B_r refers to employment in the export sector. The latter is often referred to as basic sector employment. All other sectors are then referred to as nonbasic sectors. Equation (14.11) shows that there is a multiplier relationship between basic sector employment and total regional employment. This multiplier is referred to as the economic base multiplier. The multiplier will be higher when the basic (export) sector has a relatively large demand for local inputs from nonbasic sectors. Given that labor productivity in the export/basic sector is likely to be higher than in the regional economy generally, that is, $q_{x_r}/q_r > 1$, the economic base multiplier would be larger than the Keynesian multiplier.

However, both models describe the short-run response of the regional economy to regional demand shocks but not long-run growth. In the model summarized in Eq. (14.9), sustained export-led growth requires either a sustained increase in external (“world”) demand for regional exports or continual productivity improvements in the regional economy that lead to sustained increases in regional competitiveness (i.e., increases in x_r and decreases in m_r). The next section describes such a model of trade and productivity growth.

14.4 The Kaldor-Dixon-Thirlwall Model

This model was first formulated in Dixon and Thirlwall (1975) but was based on ideas discussed by Kaldor (1970). In turn, the fundamental mechanism that drives regional growth along Kaldorian lines is the so-called Verdoorn’s law (following Verdoorn 1949) which states that labor productivity growth is positively correlated with output growth. Following Armstrong and Taylor (2000), we will assume that this correlation can be interpreted as a causal relationship in which output growth in any period causes productivity growth in the following period. Adoption of the notation that * refers to the growth rate of a variable, for example, $*Y_{rt} = (Y_{rt} - Y_{rt-1})/Y_{rt-1}$, Verdoorn’s law can then be expressed as follows:

$$*q_{rt} = *\alpha_r + \lambda_r *Y_{rt-1} \quad (14.12)$$

with q_{rt} again being regional labor productivity and Y_{rt-1} regional output (which equals income), as in the previous section. Equation (14.12) states that the growth in regional labor productivity ($*q_{rt}$) in any given period is partially exogenous ($*\alpha_r$) and partially a function of output growth in the previous period ($*Y_{rt-1}$), with coefficient λ_r . Clearly, an empirically detected correlation between output growth and productivity growth is in itself not informative of the channels through which an increase in the scale of production leads to greater labor productivity. A range of models with increasing returns or agglomeration economies discussed elsewhere in this section of the major reference work and also included in the bottom right quadrant of Fig. 14.1 may yield such a relationship. What distinguishes the present model from those supply-side-driven models is that in the present context, the accumulation of resources is not made explicit. Nonetheless, it is clear that steady-state growth triggered by an expansion of demand can only exist if resource capacity utilization is stable in the long run (e.g., Setterfield 2010).

As is typical in a model of Keynesian origin, prices are a markup on costs. Consequently, regional price inflation $*p_{rt}$ is directly related to labor cost inflation $*w_r$, which is assumed exogenous, and to productivity growth:

$$*p_{rt} = *w_r - *q_{rt} \quad (14.13)$$

To close the model, current output growth $*Y_{rt}$ is assumed to be driven by export growth. In the simplest form,

$$*Y_{rt} = \gamma_r *X_{rt} \quad (14.14)$$

in which γ_r measures the export elasticity of regional output. To solve the model, we first linearize Eq. (14.5) by expressing the export demand function in terms of growth rates:

$$*X_{rt} = *AX_{rt} + \varepsilon_r *Z_t + \eta_r (*p_{ft} - *e_t - *w_{rt} + *q_{rt}) \quad (14.15)$$

The Kaldor-Dixon-Thirlwall model now consists of the four Eqs. (14.12)–(14.15) that can be solved to yield the following first-order linear difference equation for the growth rate of regional income:

$$*Y_{rt} = \gamma_r [*AX_{rt} + \varepsilon_r *Z_t + \eta_r (*p_{ft} - *e_t - *w_{rt} + *q_{rt})] + \gamma_r \eta_r \lambda_r *Y_{rt-1} \quad (14.16)$$

It is clear from Eq. (14.16) that when the exogenous variables are assumed time invariant, the time path of the regional growth rate is fully determined by the product of three parameters, namely, the elasticity of regional output with respect to “world income” (γ_r), the elasticity of regional exports with respect to regional competitiveness (η_r), and the extent of increasing returns in the regional economy (λ_r). A steady-state growth rate requires $\gamma_r \eta_r \lambda_r < 1$. Given

that regional exports are roughly a constant proportion of regional output, $\gamma_r = 1$. Similarly, in a small regional economy that is a price taker in global markets, the export price elasticity may be at most around one as well. These empirically based assumptions can be combined with estimates of the Verdoorn coefficient that are around 0.5 (e.g., Fingleton and McCombie 1998). Together, this suggests that Eq. (14.16) indeed may converge to a steady-state growth rate:

$${}^*Y_r = \{\gamma_r [{}^*AX_r + \varepsilon_r {}^*Z + \eta_r ({}^*p_f - {}^*e - {}^*w_r + {}^*\alpha_r)]\} / [1 - \gamma_r \eta_r \lambda_r] \quad (14.17)$$

which shows that the steady-state growth rate will be (i) positively related to local returns to scale or agglomeration benefits (a larger λ_r and/or a larger ${}^*\alpha_r$), (ii) positively related to sustained growth in external demand (a larger *Z), (iii) positively related to export-facilitating policies such as growth in port or airport infrastructure or structural change that benefits export industries (a larger *AX_r and/or ε_r), and (iv) negatively related to regional cost inflation (a larger *w_r or smaller η_r). Note also that according to Eq. (14.17), a change in world prices and/or the nominal exchange rate will have regionally specific impacts that depend on the regionally specific parameters γ_r , η_r , and λ_r .

If we combine the growth path of regional income as defined by Eq. (14.16) with regional expenditure given in Eq. (14.1), which is largely endogenous, it becomes clear that any net surplus (deficit) in a region's trade in goods and services with other regions and countries, given by $(X_r - M_r)$ in Eq. (14.1), is balanced by the region's net acquisition (disposal) of assets from elsewhere, or

$$Y_r - A_r = X_r - M_r \quad (14.18)$$

in which $A_r = C_r + I_r + G_r$ refers to regional absorption of income. It has been argued by Thirlwall (1980, 1997) that such a spatial redistribution of equity and debt cannot last forever. If a region has a balance of payments deficit, this deficit must be financed by borrowing from other regions or countries, which effectively increases the claims of outsiders on regional assets. Conversely, a region with a balance of payments surplus will acquire assets outside the region. Although this may be considered a less severe situation than a balance of payments deficit, sustained surpluses constrain the disposable income of other regions and countries, net of borrowing costs. Consequently, in the long run, the regional balance of payments will tend to equilibrium, which implies that export receipts (in foreign currency) equal import payments, that is,

$$ep_r X_r = p_f M_r \quad (14.19)$$

Rewriting Eq. (14.19) in growth terms gives

$${}^*e + {}^*p_r + {}^*X_r = {}^*p_f + {}^*M_r \quad (14.20)$$

If we assume that in the long run the exchange rate will adjust to a difference in the growth of local prices and foreign prices, that is, purchasing power parity holds in the long run or $e + p_r = p_f$, then

$$X_r = M_r \quad (14.21)$$

From Eq. (14.6) we can derive that $M_r = \pi_r Y_r$ and from Eq. (14.5) that $X_r = \varepsilon_r Z$. Substituting this in Eq. (14.21), we see that long-run balance of payments equilibrium is only compatible with the following long-run growth rate of regional income:

$$Y_r = \varepsilon_r Z / \pi_r \quad (14.22)$$

In long-run balance of payments equilibrium, the growth rate of regional income is proportional to the growth in external income. The proportionality constant is regionally specific and equal to the ratio of elasticity of regional exports with respect to global income over the regional income elasticity of the demand for imports.

Given that Z does not vary across regions, Eq. (14.22) is an empirically testable proposition that long-run balance-of-payments-constrained regional growth rates are proportional to ε_r / π_r . Unfortunately due to data deficiencies, it is not easy to test this relationship, referred to as Thirlwall's law in the literature, at the regional level. The relationship has instead been tested empirically with cross-country and panel data. These econometric tests have yielded mixed results. Nonetheless, McCombie (2011) concludes in a recent review of this literature that "After over thirty years since its development, Thirlwall's Law is still proving a powerful explanation of why growth rates differ" (pp. 388–389). Both the evidence of contagion in the international economy (financial crises that start in one country quickly spread to countries that have a strong trading relationship with the former country) and the evidence of spatial spillovers in regional modeling indeed provide convincing support for the idea that economic growth in small open economies is strongly dependent on demand elsewhere. The challenge is, however, to derive policy recommendations from this empirical regularity. In this respect, Krugman (1989) argues that causation in Eq. (14.22) runs in the opposite direction: output growth leads to productivity growth. Sustained output growth coincides with an increase in varieties of output, quality improvement, other forms of innovation, and/or agglomeration. These processes lower unit production costs and enable regions to compete more effectively. Such scale effects may also lessen the reliance on imports. Together, these phenomena lead to a greater ε_r / π_r ratio.

In conclusion, demand-driven growth models and endogenous growth models have more in common than proponents of either tend to admit. The distinction is a matter of emphasis, both in terms of the underlying engine of growth and in terms of the time frame (e.g., Setterfield 2010). Verdoorn's (1949) law and Myrdal's (1957) theory of cumulative causation are consequences of behavioral and

technological phenomena that lead to increasing returns and that have been analytically formulated and empirically tested in endogenous growth models. Moreover, demand-driven growth theories emphasize short- to medium-term constraints in demand that lead to less than full resource capacity utilization, combined with slowly changing regional structures and some price and wage stickiness. In contrast, neoclassical growth theories emphasize the mobility of production factors and relative price adjustments in the long run that lead to trade following the emerging patterns of comparative advantage. As already illustrated in [Fig. 14.1](#), these different perspectives provide complementing rather than contradicting insights into regional economic development.

14.5 The Benefits of High Wages and Public Expenditure for Growth

From the end of the Second World War until the early 1980s, regional development in the Western world was heavily influenced by the principles of Keynesian economic management. Development policy, then, was highly interventionist and aimed to promote growth in less-favored regions through income redistribution and welfare programs (bolstering local aggregate demand), the provision of state-funded incentives to induce firms to locate in these regions, and through the funding of large-scale infrastructural investment with the dual aims of improving the productivity of existing firms and inducing new firms to locate in the region (Amin 1999, p. 365). As a consequence of such capital-oriented bolstering of demand, regional output and employment may be expected to grow, as shown in [Sect. 14.3](#). In the presence of increasing returns to scale, as modeled by Verdoorn's law in the previous section, the region's long-run growth rate may then be expected to increase. Martin (2005, pp. 2–7) provides a useful summary of the Keynesian approach (see [Table 14.1](#)).

In keeping with the reorientation of mainstream economics to micro-foundations and supply-side-oriented general equilibrium theory, Keynesian approaches to regional development, and demand-driven policies in general, fell from favor. However, this was more pronounced in the theorizing of regional development than in the practice, with practitioners and regional policymakers often resisting attempts by central government at introducing regional policy inspired by neoclassical economics. The move away from Keynesian approaches was not solely a function of hegemony of neoclassicism but also reflected the rather modest results achieved by Keynesian policy in lifting the long-run growth rate of particularly peripheral or “rust belt” regions. While there were conspicuous successes in implementing these policies, such as the Tennessee Valley Authority, there were (at least) an equal number of spectacular failures. Furthermore, there was a lack of theorizing of how growth could be maintained, a tendency for regional development agencies to fund activities that would have taken place at any rate (Pike et al. 2006, p. 77) or, worse, investment in activities for primarily short-run political

Table 14.1 Key elements of Keynesian theory

Key assumptions	Key driving factors
<ul style="list-style-type: none"> • Price adjustments might be slow, leading to adjustments in quantity • Markets are not necessarily in equilibrium • Shortages on demand or supply side • Possibility of “false” trading (i.e., with non-equilibrium prices) • Capital and labour are complementary 	<ul style="list-style-type: none"> • Capital intensity • Investment • Government spending, such as investment in the public domain and subsidies/tax cuts for enterprises
Implications for (regional) competitiveness	
<ul style="list-style-type: none"> • Governments can intervene successfully in the cycles of the economy: timing is crucial • Assumption of imperfect markets allows for regional differences • Convergence of regions can only be achieved through economic policy 	

Source: Martin (2005)

purposes. In addition, much investment in Keynesian policies was directed at maintaining declining industries in less-favored regions (LFR) that stood little chance of success once support was removed rather than in facilitating the growth of new industry or the mobility of workers both between regions and between industries or occupations. More generally it was difficult to see how the indiscriminate application of Keynesian policy would, in isolation, lead to higher levels of employment for the most disadvantaged or how these policies would contain inflationary dynamics (Mitchell and Juniper 2006, p. 14).

The regional development policy arising from neoclassical theorizing, however, fared arguably no better than the Keynesian in changing the fate of LFR with some, such as Amin (1999, p. 365) arguing that the results of the implementation of these policies were a “far worse outcome, by removing financial and income transfers which have proven to be vital for social survival, by exposing the weak economic base of the LFRs to the chill wind of ever enlarging free market zones, and by failing singularly to reverse the flow of all factor inputs away from the LFRs (i.e., no proof of price-seeking inflow of opportunities leading to regional specialisation in the appropriate industries).”

This failure, and subsequent events, such as the global financial crisis beginning in 2007, revived interest, particularly among those with social democratic or corporatist orientations, to look for alternate approaches. One such approach argues for demand- or wage-led strategies to underpin long-run sustainable growth as opposed to profit-led strategies that purportedly dominate “New Right” policy agendas.

The history of this wage-led growth approach is long with a lineage stretching back to debates in eighteenth- and nineteenth-century political economy on the possibility of what was then called “underconsumption.” Contemporary debates tend to take as their starting point the seminal works of Rowthorn (1981) and Dutt (1987), all influenced by Kalecki and to a lesser extent Keynes, and have been taken up by more recent authors such as Stockhammer, Palley, Lavoie, Naastepad, and others (see the *International Journal of Labour Research*, 2011, 3(2) for a recent compilation of work on this topic).

Taking Palley (2011) as an example of the wage-led approach to economic growth, it can be argued that prior to the 1980s, the economies of the Western world could largely be described by a Keynesian growth model “built on full employment and wage growth tied to productivity growth” (Palley 2011, p. 222). The logic of this model was that productivity growth drove wage growth which led to increased demand and hence full employment. This in turn incentivized investment which underpinned further increases in productivity thus the elements of this mode of development were linked together in a “virtuous circle,” which is consistent with Myrdal’s (1957) theory of cumulative causation and with the Verdoorn (1949) effect. Post 1980, this pattern of development was displaced by supply-oriented models of growth which renounced two key elements of the Keynesian growth model – namely, the commitment to full employment and the linkage of wage growth to productivity growth – replacing them with a focus on maintaining low levels of inflation, removing impediments to capital mobility, and reducing “rigidities” in the labor market. The shortfall in aggregate demand generated by stagnant or falling wages was met by increasing levels of debt and speculation-driven asset price inflation which ultimately compromised the systemic stability and reproduction of the global economy.

Hence, in Palley’s (2011) narrative, the current economic crisis is primarily a crisis of demand. Supply-side measures are therefore unlikely to improve matters and – in so far as they seek to reduce real wages in an attempt to restore profitability – may very well worsen matters considerably. Thus, the only alternative in his view is to rebuild the virtuous circle of the Keynesian growth model. To achieve this, he has a number of clear policy suggestions:

- Rebuild the wage-productivity link.
- Large-scale use of public expenditure to compensate for inadequate levels of private demand – particularly in private infrastructure.
- Refocus monetary policy on full employment.
- Reregulate the finance sector and focus it on the needs of the real sector rather than on speculation.
- Reform corporate governance to emphasize long-term objectives and to direct investment to the real sector.
- Direct any tax cuts at those with high propensities to consume, thus bolstering aggregate demand.
- Coordinate economic policy at an international level to eliminate long-run balance of payments deficits and surpluses and to protect the ability of nation states to engage in demand-led policies.

What then does this mean for regional development? A return to Keynes in terms of regional development requires a high level of national, probably international, coordination as without this it is hard to see that regions “going it alone” and pursuing Keynesian policies would not suffer from the equivalent of a balance of payments constraint or significant problems with debt financing, akin to nations pursuing such strategies in a currency union. Thus, demand-led growth is not a regional development policy as such but rather a national or international project within which regional strategies can be articulated.

Perhaps of more direct relevance to regional development is the work of Mitchell and Juniper (2006) and others advocating a new “spatial Keynesianism.” Speaking from a modern monetary theory (MMT) perspective, they eschew both the supply-side policies of neoclassicism and the generalized expansionist policies favored by Keynesians. Instead, they advocate policies that aim to achieve full employment, price stability, and environmental sustainability while preserving social settlements. The preservation of social settlements is justified both on equity grounds and to preserve networks and spatial spillovers (Mitchell and Juniper 2006, p. 20). Central to this approach is a job guarantee scheme designed to ensure full employment through the use of regionally targeted public sector employment at the minimum wage.

Under the job guarantee scheme, the state functions as an employer of last resort, providing a buffer stock of jobs that are available upon demand and as of right. This approach minimizes the impact of fluctuation in private sector demand – expanding in downturns and contracting as the private sector recovers. As the employment is at the minimum wage rate, the effects of the scheme are neither likely to distort the structure of the wage distribution nor prove inflationary. This last point is particularly important as the Keynesian approach lacks an explicit means of containing wage and price inflation, relying usually on income policy which has proved relatively ineffective and often counterproductive as it weakens the resolve of employers to rationalize and tends to hurt efficiency and investment projects.

14.6 Institutional Theories of Regional Growth

Institutional views on regional economic growth can be seen as belonging to one of two distinctly different viewpoints – “old institutional economics (OIE)” and “new institutional economics (NIE),” both of which emphasize the centrality of institutions in determining the economic trajectory of regions. While both OIE and NIE share a focus on institutions, they differ markedly in their conceptualizations of what constitutes an institution and are positioned very differently with respect to neoclassical economics. NIE is essentially a branch of neoclassical theory that emphasizes micro-foundations, although it rejects two central ideas of conventional neoclassical theory, namely, costless transactions and neutral institutions (Lakshmanan and Button 2009). OIE is however much closer to a wholesale rejection of the neoclassical paradigms.

Given that the focus of this chapter is on demand-driven theories of regional growth, this section will largely be concerned with the OIE though it should be noted that while the OIE and NIE share little in the way of common ground, at an abstract level their policy recommendations are often surprisingly similar, stemming from a shared view that regional-level industrial configurations, supply-side characteristics, and institutional arrangements, can play a critical role in securing the economic success of a region (Amin 1999, p. 368). As such the policy recommendations of institutionalists tend to go considerably beyond the traditional preserves of economic development, concentrating their attention on building the

wealth of a region, rather than the individual firm and often arguing for comprehensive renovation of the economic and social infrastructure of a region as a necessary precursor to the revitalization of economic activity in an area (Amin 1999, p. 370). Lakshmanan and Button (2009) provide an NIE perspective on regional development in which they emphasize the importance of institutions to benefit from positive externalities from education, healthcare, and infrastructure, as well as the importance of institutions for fostering entrepreneurship and innovation.

Following a line of theory development dating back to the works of Veblen, Ayres, Commons, and Mitchell, the OIE tradition argues that institutions not only act as constraints on economic actors but also are constitutive, in large part, of an individual's habits, preferences, and values as well as the range of actions available to them. Though the individual is born into a preexisting web of social relations, the relationship between the individual and the ensemble of institutions they are born into is not one of pure subordination but is reflexive in that the individual and institution(s) are mutually constitutive of each other, though institutions tend to have temporal priority over the individual. This line of reasoning is rooted in a conception of institutions that is considerably broader than those that conceive of them as largely being made up of the various organs of the state apparatus plus various legally constituted entities such as firms and trade unions. The OIE view of institutions is founded in Veblen's (1961) formulation, and its subsequent extensions, that institutions are "the settled habits of thought of the generality of men" or "systems of established and prevalent social rules that structure social interactions."

In terms of its methodological commitments, the OIE views with considerable antipathy the assumptions of neoclassical economics or of the new economic geography as developed by Krugman (1991, 1994) and others. OIE criticizes these approaches on the grounds of their (alleged) lack of realism and failure to adequately appreciate that economic processes are "embedded," operating within a social framework shaped by the history and culture of a region. Against the methodological individualism of neoclassicism, the OIE adopt holistic qualitative approaches such as in-depth case study research and largely reject formal econometric modeling on the grounds that it is incapable of capturing place-specific qualitative factors (such as culture and institutions) which they view as central to understanding differences in the economic trajectory of regions.

How then do these largely theoretical concerns translate into an understanding of the growth trajectory of a particular region? Martin (2005, p. 79) suggests that the starting point for enquiry within the OIE tradition is to pose the question "to what extent and in what ways are the processes of geographically uneven capitalist economic development shaped and mediated by the institutional structures?" The answer in the OIE literature emphasizes that regional economies are not collections of atomistic optimizing firms and markets, propelled by rational preferences operating under a common set of rules (Amin 1999, p. 367). Instead, OIE stresses the importance of geographical proximity, networking, embeddedness, and the development trajectories of regions, institutions, and technology in determining regional economic outcomes. Specifically Amin (1999, p. 368) derives a number of general axioms of economic governance associated with an institutionalist approach:

- “First, a preference for policy actions designed to strengthen networks of association, instead of actions which focus on individual actors.
- Second, that policy action should involve a plurality of decentralised and autonomous organisations since effective economic governance extends beyond the reach of both the state and market institutions (Hirst 1994).
- Third, within a frame of plural and autonomous governance, the role of the state, as the prime collective organisation with societal reach and legal power, should be that of providing resources, arbitrating between decentralised authorities, securing collective results, and, above all, establishing the strategic goal, rather than that of central planner or market facilitator (Hausner 1995).
- Fourth, the aim of policy action should be to encourage voice and negotiation, together with procedural and recursive rationalities of behaviour, rather than self-serving or rule-following behaviour, in order to secure strategic vision, learning and adaptation (Amin and Hausner 1997).
- Fifth, solutions have to be context-specific and sensitive to local path-dependencies.
- Sixth, there is a need to encourage intermediate forms of governance, building up to a local ‘institutional thickness’ (Amin and Thrift 1994) which includes enterprise support systems, political institutions, and social citizenship.
- Finally, and as a consequence, building economic success is as much a matter of devising appropriate economic policies as wider social and political reforms to encourage the formation of social capabilities for autonomous action (Putnam 1993).”

Hence, institutionalist strategies to promote regional economic development are highly place specific as they are largely reliant on the ability to mobilize, foster, and coordinate local institutions which are the product of a unique developmental trajectory. The local cannot however be abstracted from its macro context. Regions, while perhaps possessing considerable latitude at times, are subsumed within nation states who set national-level macroeconomic and social policy which may not be congruent with the development of optimal institutional arrangements at a regional level.

14.7 Conclusions

In this chapter, we contrasted the neoclassical perspectives on economic growth with a range of alternative perspectives that we broadly referred to as demand-driven models of regional economic growth. Such demand-driven models have a number of important elements in common that were emphasized in the chapter (see also Setterfield 2010). Firstly, we showed how aggregate demand and in particular exports can affect the long-run growth path. Moreover, changing demand conditions can create path dependencies in regional development trajectories. Secondly, technological change is driven by a complex and broad range of processes that from this perspective are best modeled by the increasing returns to a greater scale of production, as formulated by Verdoorn’s law. Thirdly, full

resource utilization is not guaranteed given limited substitution possibilities, particularly in the short run. Fourthly, long-run stability is not ensured but dependent on a range of behavioral parameters. Additionally, economic expansion may face a balance of payments constraint and economies may diverge, even at the regional level. Fifthly, institutions matter and they embody a concern for equity and the potential feedback mechanisms of income inequality on growth.

We showed in Sect. 14.2 how growth in exports yields regional income growth via a multiplier that is positively associated with the propensity to consume locally produced output and the propensity to invest but negatively related to regional tax rates and the extent to which government transfers are countercyclical. We then formulated the Dixon-Thirlwall model in which Verdoorn's law – economic expansion generates productivity growth – leads to both sustained export growth and steady-state income growth, with the latter in balance of payments equilibrium equaling the rate of growth of exports divided by the income elasticity of the demand for imports. We also reviewed theories that suggest that policies that encourage regional growth in wages and public expenditure can be growth enhancing. Finally, we argued that the effectiveness of such demand-driven growth policies depends on institutional settings.

All theories of regional development have positive and normative elements. They may lead to testable hypotheses that highlight incompatibilities to the extent that acceptance of empirical evidence of a key feature of one theory is incompatible with the predictions of another. However, the greater the level of abstraction and the more aggregate the nature of the data, the greater the likelihood that various competing theories may lead to predictions that are observationally equivalent. In general, as Fig. 14.1 attempted to point out, the broad range of available theories may all contribute to a better understanding of the complex reality that we refer to as regional economic growth.

Abstract

Our understanding of people's well-being was, until very recently, inferred from observable objective indicators such as their income and education. These measures were then aggregated to generate an average that characterized the city or region. With the growing availability of sample survey data, we now have at our disposal an increasing range of subjective measures of well-being that capture quality of life assessments made by individuals themselves. It is these internal measures of subjective well-being from microdata that are now being widely used throughout the social sciences to study what we call well-being or "happiness."

Contemporary interest in subjective measures of well-being stems from a wish to supplement market-based criteria such as GDP per capita with other more direct measures of societal well-being. Subjective measures are particularly useful in areas where the distribution of outcomes is not easily identified using other, especially market, criteria. The effect of investment in public infrastructure or the provision of green space or in fostering community networks or in

redeveloping neighborhoods can be captured in responses to questions on well-being, preferably over time. These subjective measures, which have been shown to be highly correlated with clinical and other assessments of well-being, are likely to be of particular interest in regional science because of the way changes to places result from, or generate, a range of positive or negative externalities.

The decisions we as individual citizens make depend on what we measure, how good our measurements are and how well our measures are understood. . . .For example, traffic jams may increase GDP as a result of the increased use of gasoline, but obviously not the quality of life. (Stiglitz et al. 2009, pp. 8–9)

15.1 Introduction

The attention being given to well-being as a possible complement to the conventional measures of economic performance constitutes one of the notable turning points in our measurement of progress. However, the extent to which the ideas promulgated in the Stiglitz Report get translated into national policy remains to be seen (Stiglitz et al. 2009). Much will depend on our agreement over the measurement of both growth and well-being. At this stage, we are still seeking a consensus on the measurement of well-being and have only just begun assessing its value in a number of policy arenas. This is in spite of the listing of over 10,000 published papers on the World Database of Happiness since it was set up a decade ago.

Despite the impressive growth in what is routinely referred to as the “happiness” literature, relatively little attention has been paid to well-being in a regional context. A review of papers published in 17 regional science and related journals over the last 30 years uncovered less than two dozen papers. A broader search under regions in the World Database of Happiness revealed only 74 references. There has therefore only been a minor overlap between the concerns of regional scientists and those addressing happiness and well-being.

The limited material on well-being within regional science journals falls into four categories. The first involves the mapping and interpretation of distributions of well-being within and between regions. A second distinct subset of this literature identifies the way in which well-being varies by population density (urban versus rural). Another extends the regional convergence literature to embrace well-being (often comparing results to convergence in income). A fourth attempts to identify the way contexts, that is, the features that make places different, are associated with higher or lower well-being. However, except for environmental concerns, few studies have attempted to measure well-being returns to public investment in places.

The opportunities subjective well-being measures offer to regional scientists are unusual. The discipline’s twin concerns with the spatial dimension and public policy means that much of our concern for well-being derives from our interest in context, in the role that place plays in people’s livelihood. Over much of the history of regional science, we have sought to measure the impacts of increasing accessibility of locations, for example, via their effect on price by means of land rent.

By contrast, subjective well-being measures offer an opportunity to consider the effect of location (accessibility) and other changes to place more directly on people's well-being especially where impacts through the market are either not present or difficult to disentangle.

When it comes to individual well-being, the central question faced by the regional scientist is that posed by equilibrium theory – the idea that in the long run, people and places will mutually adjust so that well-being no longer varies geographically: see, for example, the standard Roback model (1982). Over time, people will move or adapt to the point where there is no further advantage to be gained from moving elsewhere. For a variety of reasons, including lack of information or the cost of mobility, the distribution of population may remain in a state of disequilibrium, with some people not making the adjustment from an existing suboptimal location to a better alternative. The relief map of well-being will therefore typically exhibit peaks and troughs.

People adjust their location as they do other aspects of their lives – in order to minimize tensions between aspirations and their realization (Clark et al. 1984). They do so by adapting as stayers or adjusting as movers. Any relief map of well-being will therefore reflect both frictional and structural pockets of low well-being. The challenge to regional scientists lies in separating out individual from context effects on well-being in ways that also take into account the dynamics of the adjustment process itself – at the level of both the individual and the society.

This chapter consists of six sections beginning with an introduction to the concept of well-being as a subjective measure. The literature's central question is raised in Sect. 15.3 – the relationship between regional economic growth and well-being. Section 15.4 reviews several examples of the way well-being has been analyzed from a regional perspective. Section 15.5 considers one of the main ways the subjective measures differs from objective measures of well-being, namely, the sensitivity of well-being to relative social position or rank and the implications this has for the way in which people cluster in space. The chapter ends with a summary of the conceptual and empirical challenges which subjective measures of well-being pose for regional science.

15.2 Well-Being

The literature on the “economics of happiness” has succeeded in establishing the broad demographic and other personal attributes that influence subjective well-being to the point where we can measure with some reliability not only the effects of material standards of living but also the marginal impact of “external shocks” on people's perception of their own well-being (Frey and Stutzer 2002; Kahneman and Krueger 2006). Changes in external conditions of general (Oswald 2003) or of particular events such as unemployment (Winkelmann 2009) are associated with changes in our level of well-being.

Drawing heavily on relevant literature in psychology, economists have now gained sufficient confidence in the properties of responses to questions on subjective well-being to use them as dependent variables in multivariate modeling contexts.

If modeled appropriately, responses to these questions can identify consistent correlations with respondent attributes like gender, age, and income. In doing so, the vast majority of studies within the economics of happiness literature employ a single metric of happiness – responses to the life satisfaction question: “All things considered, how do you feel about your life (right now)?” Possible answers are selected from an ordinal scale ranging from Very Satisfied to Very Dissatisfied.

One of the reasons for the rapid spread of research on well-being within economics in particular has been the fact that the outcome or dependent variable is relatively easy to collect and key parameters are straightforward to estimate plus the fact that there are now a wide range of sample surveys of individuals available in most countries. Although ordinal probit or logit models are technically the most appropriate approach to analyzing ordinal scales of this type, very similar results with more straightforward interpretations are frequently obtained using more familiar OLS regression estimation (Ferrer-i-Carbonell and Frijters 2004).

Readily available microdata from large surveys offer new opportunities for regional scientists to examine the way economic growth affects people’s well-being not just at the national level but also in specific regional settings. Surveys which leverage off natural experiments, for example, have allowed the influence of external circumstances on internal expressions of happiness to be estimated (Easterlin and Zimmermann 2008). The lessons from research at the level of the country as a whole suggest considerable potential for analysis at the regional level.

15.3 Economic Growth and Well-Being

One of the most influential stimulants to the growth of “happiness economics” has been the much referred to evidence that continued economic growth among affluent countries has failed to raise average levels of happiness. In referring to his seminal paper (1974), Richard Easterlin drew our attention to the fact that “At a point in time persons with higher income are, on average, happier than those with less; over time, however, as incomes increase generally in the course of modern economic growth, there is no improvement in the average level of happiness” (Easterlin 2011, p. 6). There is therefore a “distinction between the shorter term association between happiness and income, which is positive, and the longer term relation, which is nil” (Easterlin 2011, p. 7) – other things equal.

The key to the puzzle lies in the interplay between a subjective variable, material aspirations, and an objective one, household income. At a point in time the dispersion among individuals in material aspirations is less than in household income, and those with higher income are consequently better able to realise their aspirations, and are happier. Over time, however, material aspirations rise, on average, in about the same proportion as average income and undercut the increase in happiness that higher income would otherwise bring. (Easterlin 2011, p. 8)

In other words, while people adapt hedonically to an increase in income, their material aspirations tend to rise commensurately, but material aspirations are much

less flexible downward because once people have attained a given level of income, they cling to this reference point.

Developed originally for countries, there is no reason, except for data availability, why the same argument could not be applied to regions, that is, to particular subnational territories such as cities. Indeed, local expressions of the Easterlin paradox have already been suggested (Morrison 2011). The relationship between well-being and development, which has been debated at a global level, has a counterpart in the internal interaction between growth and well-being within countries. The transfer is not seamless, however, and there are some particular complications in transferring questions about well-being from countries to regions.

15.4 Subjective Well-Being and the Region

In his now classic 1981 book, *The Sense of Wellbeing in America*, Angus Campbell explored the impact of various domains of people's lives on their well-being (Campbell 1981). The domain of relevance was "where you live," and Campbell observed how subjective indicators of quality of life in the different regions departed dramatically from what he had learned from comparison of their objective characteristics (Campbell 1981, p. 147). The central point of difference was their variability. Regional differences in perceived well-being were modest at best and could not be explained by the much greater variability in economic and related characteristics of regions (Campbell 1981 148). This is of course what one would expect on the basis of spatial equilibrium theory.

The greater similarity regions exhibit in average subjective well-being compared to objective measures of well-being has been complemented by evidence showing that subjective well-being measures converge more quickly over time. Since Campbell wrote, there have been several studies which have showed the way in which broad quality of life indicators converge more quickly across regions than does income (Merchante and Ortega 2006), although convergence does not have to occur across all the indicators (Royuela and Artis 2006).

That regional differences in subjective measures of well-being show less variation than the objective conditions which partly give rise to them and converge more rapidly over time is consistent with the notion of adjustment undertaken through migration and adaption that underlies the concept of spatial equilibrium in well-being. However, the presence of persistent geographic pockets of low well-being raises important questions about the way in which differential economic growth distributes people spatially according to their ability to realize expectations either globally, as in overall well-being, or locally, as in domain-specific well-being.

Astra Bonini, for example, wanted to understand which of the national level indicators that are frequently used as proxy measures of development best reflect average life satisfaction and whether it was possible for universal indicators to capture such variations (Bonini 2008, pp. 224–225). "Understanding whether and how individual life satisfaction varies across countries is important because if the

goal of development is to increase wellbeing, we must identify the causes of wellbeing in different national and regional contexts.” (Bonini 2008, p. 223). She goes on to use hierarchical linear modeling of World Values Survey data to test not only whether individual well-being varies by country but also whether the same characteristics of individuals explain satisfaction across different countries. Different factors predict subjective well-being in different nations (Inglehart and Rabier 1986), as was discovered early on in the history of well-being research (Cantril 1965; Andrews and Withey 1976). The key research question is the source of this heterogeneity and the way country context influences the way individuals judge their own well-being.

Not only do different factors contribute to well-being in different countries but the same factors can also exert different levels of influence in different regional contexts. Bonini finds, for example, significant variations in the slopes of individual predictors of life satisfaction across both countries and regions (Bonini 2008). Context, she observes, acts as a filter: “aging one year in Latin America decreases life satisfaction more than aging one year in Europe” (Bonini 2008, p. 226); “individual income do(es) not increase life satisfaction as much in nations with relative high GDP per capita,” “increases in GDP per capita significantly decreases the positive effect that individual income has on life satisfaction,” and “unemployment in high income [countries] causes a greater reduction in life satisfaction than in [lower income] countries” (Bonini 2008, p. 231).

Just as Bonini, a sociologist, showed how country context filters the effect that individuals’ attributes have on well-being, so have economists Andrew Clark and colleagues. After comparing samples from European countries, they strongly reject the hypothesis that individuals transform income into well-being in the same way in different countries (Clark et al. 2005).

To the economist focused on individuals, place is often treated simply as a source of unobserved individual heterogeneity (in contrast to human geographers who have constructed a whole discipline around the presence of such heterogeneity). Two sources of heterogeneity are of specific interest in the well-being-income relationship. The first is intercept heterogeneity, which is the difference in the level of well-being at given incomes across regions. The second is slope heterogeneity, which is the difference in the degree to which utilities rise with income from one region to another.

From their European survey, Clark et al. find that different (endogenously identified) “classes” of individuals show very sharp differences in the effect of income on their declared satisfaction (Clark et al. 2005, p. 125). “The marginal effect of income on subjective wellbeing depends,” they explain, “on unobserved heterogeneities relating either to the underlying utility function or to the way people label their utility” (Clark et al. 2005, p. 127). One group, they find, is both highly satisfied and has large marginal effects of income on well-being (the older, more affluent but less active in the labor market), while another is the least satisfied and has the lowest marginal effects of income on wellbeing (the less well educated, the unemployed and single) (Clark et al. 2005, p. 127). Northern European countries are overrepresented in the former and southern European countries in the latter.

Using a similar methodology, John Helliwell notes how “life satisfaction rises less with relative income in the OECD than the non-OECD countries,” and how female advantage is larger in OECD countries due to higher status of women (Helliwell 2008, p. 6). Applying multilevel modeling to subjective well-being measures across the European Union, Pittau et al. also point to the role of context in interpreting income effects, noting in particular how personal income matters more in poor regions than in rich regions (Pittau et al. 2010, p. 341). They find that, even after controlling for individual characteristics (and different effects of income and employment status across regions), the unexplained regional-level variability of the estimated life satisfaction is still high, “indicating that geography still matters considerably” (Pittau et al. 2010, p. 358).

In another study, devoted to the British experience, Ballas and Tranmer asked whether levels of happiness among individuals in Britain reflect different characteristics of residents in different districts, regions, and areas (compositional effects) or whether there are environmental or other factors such as social capital, cohesion, and socioeconomic inequality (contextual effects) that cause their inhabitants to be happy or unhappy (Ballas and Tranmer 2012, p. 80). Such issues also attract the attention of health geographers and epidemiologists with respect to mental health and morbidity.

Ballas and Tranmer find only weak contextual effects, a result which can surprise geographers conditioned to focus on differences across space. However, this is precisely the result economic theory would suggest. People move to the places that suit them best and move again if either their own circumstances or the characteristics of the place they live in changes away from an acceptable degree of harmony. Therefore, while at any point in time there will be a set of individuals dissatisfied with their place, this disconnect is likely to be primarily frictional. After controlling for the characteristics of individuals themselves, one would not expect persistent differences in the contribution place makes to subjective well-being across regions, especially in countries like Britain or the United States that are used to high levels of interregional migration.

However, such a spatial equilibrium argument only applies to those who are free and able to move and have reasonable knowledge of alternative locations. Excluded from this assumption are at least three population groups whose ability to escape less than optimal locations is dependent on others: children, the unemployed, the poor and the elderly. One of the challenges in estimating regional context effects therefore lies in measuring the greater sensitivity of the less mobile to context effects.

While recent research has drawn attention to the way in which geographical context affects the way attributes of individuals are reflected in assessments of their own well-being, only recently has it been explicitly recognized that contexts themselves not only have scale but neighboring properties. Using NUTS level 1 regions for Europe, Okulicz-Kozaryn (2011), for example, has shown that happy regions tend to be surrounded by other happy regions, and unhappy regions tend to be surrounded by unhappy regions, in what he has identified in Europe as happiness clusters.

Another example of systematic effects of context on well-being has emerged in the study of population density, or urbanization, on well-being. Here, there are three distinct perspectives. The first argues that economic growth closes (or in some cases reverses) the gap between well-being in urban and rural areas. The second explores the cross-sectional negative relationship between well-being and settlement density, and the third, more disparate, literature attempts to identify those attributes of cities that actually generate variations in well-being.

In the first case, Easterlin et al. (2011) view spatial differences in well-being as the geographical expression of the increasing marginal utility of income: as some places become richer, their average level of well-being rises.

At low levels of economic development there are substantial gaps favouring urban over rural areas in income, education and occupational structure, and consequently a large excess of urban over rural life satisfaction, despite important urban problems of pollution, congestion, and the like. At more advanced development levels, these economic differentials tend to disappear, and rural areas approach or exceed urban in life satisfaction (Easterlin et al. 2011, p. 2189)

There are now many examples in which the largest cities in an urban hierarchy now report relatively low levels of life satisfaction: Dublin, “inner London,” the largest US cities, Sydney, and Auckland City – even after controlling for both individual and, in some cases, neighborhood fixed effects. However, the relationship between population density and well-being may be more general than the focus on primate cities suggests. Berry and Okulicz-Kozaryn (2011), for example, identify a gradient of subjective well-being (happiness) that rises from its lowest levels in large central cities to its highest levels on the small town/rural periphery (at least in the USA). In response to those documenting the manifold economic returns to increasing city size, they show that while there are many benefits of big-city living, high levels of happiness are not among them (Berry and Okulicz-Kozaryn (2011), p. 872).

The geography of well-being may not mirror the geography of growth. As Campbell (1981) observed much earlier on, “Despite . . . widely proclaimed failings of urban life, Americans have stubbornly persisted in migrating from the rural areas into the nation’s towns and cities.” People went to the cities because that is where the jobs were. Had they had their choice, they might have preferred to remain in their rural setting, but the exigencies of making a living compelled them to move to the city” (Campbell (1981), p. 149). Metropolitan people are therefore, “most inclined to believe that they have not had their full share of happiness in life” (Campbell (1981), p. 150).

A third approach to well-being in the regional literature has tried to identify those attributes of settlements that actually contribute to well-being. Here Marans and Stimson (2011) have built on the seminal work of Campbell in arguing that the quality of a place is a subjective phenomenon and therefore can vary across individuals, their demographic and socioeconomic characteristics, as well as their past experiences and aspirations.

In summary, the focus of well-being research in economics has been either on the way in which average levels of individual well-being rise with economic

growth or the way well-being declines without it. The finding that the local engines of growth, the large agglomerations, are those least likely to return high levels of well-being within their localities is a salient reminder that objective and subjective measures of well-being can diverge. The reasons for this divergence and the contexts in which they take place are both research frontiers.

One such reason has to do with the way the subjective is sensitive to relativities. Lying behind the Easterlin paradox, for example, is the argument that people compare themselves to others, and the closer they are both personally and geographically, the more influential the comparison is on subjective reports of well-being. Interdependency in preferences has an important distance decay property, and this is why comparisons between countries show an association between income and happiness which is so much weaker than those comparisons that take place within countries (Easterlin 2011, p. 35). The spatial properties of interdependencies in preferences may be particularly significant in understanding subjective well-being. As the positional goods literature suggests, consumption behaviors reflect this feature in ways that have yet to be fully exploited by the regional scientist (Cheshire et al. 2003; Durlauf 1996; Frank 2005).

15.5 Well-Being and Relativities

One of the challenges that regional science faces is how to handle the spatial properties of the comparisons that appear so influential in the measurement of subjective well-being. As is well established in the workplace and in residential location decisions, relative incomes and associated social status have a direct bearing on people's assessment of their own well-being (Marmot 2005).

One of the advantages of taking a subjective approach to well-being is that it allows us to view the residential location decisions as a way of resolving tensions arising out of relative status. This feature of residential location remains largely untouched in the conventional bid rent curve interpretation of location by income group in part because the interdependencies of preferences remained unrecognized in such models (Duesenberry 1949). Those that have been developed, using agent-based modeling, for example, show how even mild preferences for association can lead, as Schelling argued, to spatial patterns of segregation (Clark and Fossett 2008; cf Schelling 1978). Cellular automata simulations have also shown how the attraction of cheaper goods used by neighbors can lead to a spatial clustering of consumption patterns (Bell 2002).

Interdependencies in consumption highlight the fact that one person's utility is not independent of others. Since people are sensitive to the social status of others, their own status may well increase by adopting consumption patterns of neighbors or by moving to areas where they occupy higher relative rank and they can demonstrate their higher *relative* income (expenditure). However, individuals look up but not down when making comparisons (Duesenberry 1949, pp. 234–235), and empirically, there is little evidence that individuals prefer low-income reference groups as a way of “self-enhancement”; instead they are more likely to move to areas where the gap between them and the next up is minimized.

According to this second argument, people perform better and are more successful if they set themselves high goals or compare with high reference standards (Clark et al. 2008, p. 113). The fact that social externalities impinge asymmetrically on individuals' well-being and behavior has influenced the way we think about the spatial adjustments people make including where they migrate (Stark and Wang 2005). Reference group choice can therefore be used to explain migration decisions of heterogeneous individuals: "What happens . . . when people who care about their relative position in a group have the option to react by staying in the group or exiting from it?" (Stark and Wang 2005, p. 223).

Stark and Wang go on to describe an endogenous process of voluntary segmentation, although based explicitly on relative social rank rather than preference per se (cf Schelling 1978). When individuals who initially belong to one group act (costlessly) upon their distastes for relative deprivation and self-select into any one of two groups, they end up splitting into two groups in a manner that is sensitive to the way in which relative deprivation is sensed and measured (Stark and Wang 2005, p. 233). By this process, aggregate relative deprivation is lowered, and social welfare is enhanced (largely due to a reduction of social tensions).

While looking up may dominate, people do also look down, and this provides a useful link back to the relationship between relativities of consumption and the spatial clustering of consumption levels. As Stark and Wang note, "while the utility of an individual rises in his own consumption, it declines in the consumption of any of his neighbours if that consumption falls below some minimal level" (Stark and Wang 2005, p. 235). In other words, individuals are adversely affected by the material well-being of others in their reference group when this well-being is sufficiently lower than theirs.

Placing subjective measures of well-being in geographical context requires regional scientists to consider relativities and to do so in a much more spatially sensitive way than Easterlin was required to do at the country level. What remains conceptually problematic is the adjustment path people take when they face discomforting levels of social relativity. People may be prepared to undergo short-term loss of well-being as they move closer to those some social distance above them in the hope that this proximity will eventually raise them up. A willingness to experience such temporary initial discomfort may help explain why well-being tends to be lower in very large centers where income inequalities are wider but where chances of upward mobility are also greater, or believed to be so. Another possibility is that if countries as a whole do not become happier as they become richer, individuals may still continue to adjust where they live within the country (or city) in order to extract greater status out of the increases in income that occur to them personally. We might ask therefore whether the search for greater well-being as subjectively measured within affluent economies is being increasingly sought *within* countries through spatial segregation?

This same issue of relativities suggests that we ask whether, as they become richer, people are more likely to spatially cluster in order to exploit the externalities from positional goods and whether, as a result, the poor need to cluster more in order to compensate (Durlauf 1996). This involves the deeper welfare question

involving the longer run polarizing effects of residential segregation – the possibility that residence in well-endowed areas on one hand and deprived areas on the other actually inhibits social mobility of the latter, thus widening the gap between rich and poor (Clark and Morrison 2012).

In summary, considering well-being as a subjectively generated measure opens up avenues for assessing the influence of economic growth on localities that have scarcely been addressed by regional scientists. The way in which sensitivities to social rank can lead to residential location decisions, for example, runs the possibility of increasing levels of spatial inequality in ways that might not be captured through the usual market signals.

15.6 Conclusions

If the development of policy instruments lags behind the flurry of attention paid to well-being in general, then the gap is considerably wider when it comes to understanding the link between *regional* growth and changes in local well-being. This is not because the spatial distribution of well-being has not received attention, for there are multiple papers on this topic, but most are motivated by the literature on social indicators rather than the economics of happiness. The latter is not focused on the spatial distribution of well-being per se but in how sensitive changes in well-being are to changes in income – on whether economic growth increases happiness at both the macro and individual levels.

What the regional literature has yet to grapple with is how the relationship between income and well-being works out locally both within and across regions. We do not know enough about how people adapt to suboptimal locations nor how sensitive people's mobility is to their perceptions of their own well-being. However, approaching the location issue from the perspective of subjective well-being throws into sharp relief the role of social relativities or rank. Therefore, one of the major differences between the study of well-being subjectively and at the regional level is the greater importance of the local reference group. At the national level, reference groups are treated as national norms, but once people are anchored locally by their spatial subscripts, the local frames of reference become important. One of the spatial issues the attention to subjective well-being raises is how responses to local reference groups are related to socio-spatial segregation. So far little attention has been paid to the way in which socio-spatial segregation is used as a way of regulating happiness levels locally.

Central to any such advance is how we measure well-being itself. After several decades of well-being research, there is a growing realization, particularly now that policy applications are being actively considered, that if we are to judge the impact of external events on place, then our measurement of well-being needs to become more sophisticated. It is now well established that there is a difference between happiness as a measure of everyday emotions, and happiness as satisfaction with life; the former addresses everyday moods, while the latter is more reflective of a longer time span. A third dimension has to do with meaning, the purposive aspect

of life, often referred to as eudaemonic happiness (from the Greek word *eudaimonia*). It may even be necessary to capture the entire range of dimensions by relying on five separate questions (Graham 2011, p. 37): “the ladder-of-life question (Cantril 1965), the life satisfaction question, two questions to measure experienced utility (for example, both positive affect, as indicated by smiling, and negative affect, as indicated by worry), and a question that captures life purpose (Dolan et al. 2008).”

How we measure people’s expression of their own well-being has received considerable attention in positive psychology, and this chapter has asked how the study of well-being from this subjective perspective might contribute to regional science. A second and somewhat more challenging question is how regional science can now contribute to the study of well-being.

predictions from formal neoclassical and other growth theories have been tested using cross-sectional and panel data and the distribution approach, which typically examines the entire distribution of output per capita across regions. In each case, we show how the analysis of regions rather than countries emphasizes the need to take proper account of spatial interaction effects.

16.1 Introduction

Given the persistent disparities in aggregate growth rates between countries and even within countries, the question whether incomes are converging across regions has received a lot of attention in the last two decades. From a theoretical point of view, regional growth modeling has been largely motivated by work done at the cross-country level, notably by Barro (1991), Barro and Sala-i-Martin (1995), and Mankiw et al. (1992), who developed empirical models based on the Solow-Swan economic growth model. These neoclassical models have as a major prediction the convergence of countries or regions to an equilibrium at which growth settles down to a constant rate, referred to as the steady state. Set against this are numerous variants on the basic theory and more radical departures from neoclassical principles, which allow non-convergent outcomes.

This chapter provides an overview of the main developments related to the study of regional convergence. We discuss the methodological issues at stake and show how a number of techniques applied in cross-country studies have been adapted to the study of regional convergence. In doing this, we focus on the two main strands of growth econometrics: the regression approach where predictions from formal neoclassical and other growth theories have been tested using cross-sectional and panel data and the distribution approach, which examines the entire distribution of regions. In each case, we show how the analysis of regions rather than countries emphasizes the need to take proper account of spatial interaction effects.

The chapter is organized as follows. In Sect. 16.2, we present a simple theoretical framework for two regions describing the neoclassical growth model. Section 16.3 provides a survey on the regression approach based on the concept of β -convergence and its spatial extensions. Section 16.4 examines the distribution dynamics approach together with exploratory spatial data analysis techniques. Section 16.5 concludes.

16.2 Growth Regressions: From Theory to Empirics

Consider two regions, each of which is governed by the same production technology, although there are differences between the regions, which lead them to separate parallel growth paths. The production technology can be described as

$$Y_{jt} = K_{jt}^{\alpha} (A_t H_{jt})^{\beta} \quad (16.1)$$

in which Y_{jt} is the level of output (GDP) in region j at time t , K_{jt} denotes the level of capital in region j at time t , A_t is labor augmenting technology (total factor productivity), and H_{jt} is the level of skilled labor. Dividing variables on both sides by $A_t H_{jt}$, we have output and capital per unit of effective labor:

$$\tilde{y}_{jt} = \tilde{k}_{jt}^\alpha \quad (16.2)$$

where $\tilde{y}_{jt} = Y_{jt}/A_t H_{jt}$ and $\tilde{k}_{jt} = K_{jt}/A_t H_{jt}$. In writing this, we assume that $\alpha + \beta = 1$, that is, constant returns to scale, with capital's share of income equal to α and augmented labor's equal to $1 - \alpha$, with diminishing returns to capital and augmented labor.

Consider now the dynamics entailed by this model. First, we assume that technology A grows at the constant rate g and raw labor L grows at the rate n_1 in region 1 and n_2 in region 2. For the moment, this is the only difference assumed between the regions. Second, assume that skilled labor H is determined by the years of schooling (c) and the rate of return per year of schooling (ϕ) that raw labor experiences. The product $c\phi$ determines the rate at which raw labor turns into skilled labor. Finally, the level of capital K is determined by the investment rate I and the depreciation rate d of existing capital, with investment equal to a share s of output Y . We capture the dynamics with the following system:

$$\begin{aligned} A_t &= A_{t-1} (1 + g) \\ L_{jt} &= L_{jt-1} (1 + n_j) \\ H_{jt} &= L_{jt} (1 + \phi c) \\ K_{jt} &= I_{jt-1} (1 - d) K_{jt-1} \\ I_{jt} &= s Y_{jt} \end{aligned} \quad (16.3)$$

Figure 16.1 shows the evolution of the system based on some assumptions (for visual effect rather than realism) about initial values and parameters α , g , n_1 , n_2 , $c\phi$, d , and s . We assume that $g = 0.025$, $s = 0.5$, $A = 110$, $K = 88.875$, $L = 20$, $Y = 90$, $c = 9$, $\phi = 0.1$, $\alpha = 0.333$, $d = 0.025$, $n_1 = 0.01$, and $n_2 = 0.1$. While both regions start from the same position, they move onto different steady-state paths of growth in output per worker as a result of their differing labor force growth rates.

Convergence to equilibrium is determined by the fundamental assumption of the neoclassical growth model that there are diminishing returns. To show this, consider the derivative of output per unit of effective labor with respect to capital per unit of effective labor:

$$\begin{aligned} \frac{\partial \tilde{y}_{jt}}{\partial \tilde{k}_{jt}} &= \alpha \tilde{k}_{jt}^{\alpha-1} > 0, & \lim_{\tilde{k} \rightarrow 0} \left[\frac{\partial \tilde{y}_{jt}}{\partial \tilde{k}_{jt}} \right] &= \infty, & \lim_{\tilde{k} \rightarrow \infty} \left[\frac{\partial \tilde{y}_{jt}}{\partial \tilde{k}_{jt}} \right] &= 0 \\ \frac{\partial^2 \tilde{y}_{jt}}{\partial \tilde{k}_{jt}^2} &= (\alpha - 1) \alpha \tilde{k}_{jt}^{\alpha-2} < 0 \end{aligned} \quad (16.4)$$

Fig. 16.1 Conditional convergence for two regions

The first derivative is positive but goes to 0 as $\tilde{k}_{jt} \rightarrow \infty$, indicating that although the marginal product of capital is positive, capital deepening in the form of additional amounts of capital produces a diminishing rate of return (these are the Inada conditions).

The steady state to which the economy evolves is determined by the fact that although increasing income produces increasing investment, as shown by $I_{jt} = sY_{jt}$, there is a simultaneously occurring increase over time in aggregate depreciation, the most obvious component of which is due to capital depreciation, but which also depends on the growth in the effective number of workers. Moreover, while depreciation per effective worker is linear in capital per effective worker, investment is nonlinear, reflecting the diminishing marginal product of capital. This is shown in Fig. 16.2, which is the outcomes if we run our model and plot investment $sY_{jt}/(A_t H_{jt})$ (solid line) and depreciation per effective worker $(n_j + g + d)K_{jt}/(A_t H_{jt})$ (dotted line) against capital per effective worker $K_{jt}/(A_t H_{jt})$ using the data for region $j = 1$. Figure 16.2 shows that at low levels of capital per effective worker, investment is at a higher level than “depreciation.” However, with diminishing returns, the gap between the investment and depreciation schedule narrows progressively to the point where all savings are absorbed offsetting the effects of depreciation and effective labor force growth. Beyond this point, although additional income would generate additional savings and investment, the curvilinear savings schedule is now below the linear depreciation schedule, and the change in capital per effective worker becomes negative, and so the system moves back in the direction of falling income toward the equilibrium point. Thus, we have a stable equilibrium at which investment is just sufficient to balance the effects of depreciation and effective labor force growth and maintain the level of capital per effective worker.

Fig. 16.2 Investment vs capital per effective worker; First region

Fig. 16.3 Investment vs income per effective worker; First region

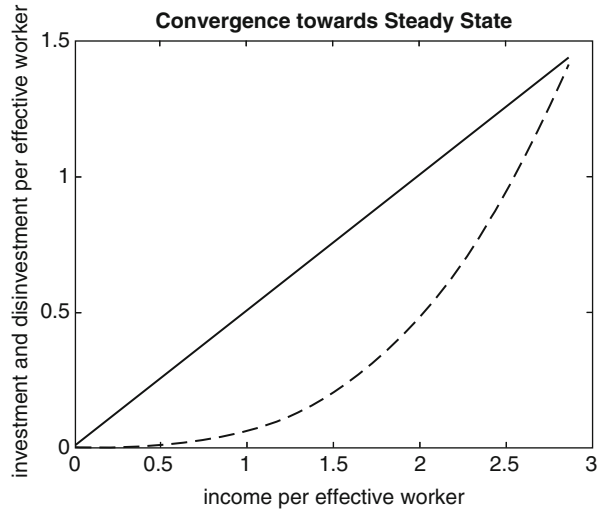

Figure 16.3 plots the same data but with income per effective worker $Y_{jt}/(A_t H_{jt})$ as the horizontal axis. Thus, using the data for region 1, this identifies the stable equilibrium point for income per effective worker as 2.86. Figure 16.4 is the equivalent data for the second region. Here, we see the effect of faster labor force growth, which produces a lower equilibrium point at about 1.81.

Figure 16.5 plots the two components of the right-hand side of the equation showing how capital per effective worker evolves, which is equal to

$$\dot{\tilde{k}}_t = s\tilde{y}_t - (n + d + g)\tilde{k}_t \tag{16.5}$$

Fig. 16.4 Investment vs income per effective worker; First region

Fig. 16.5 Change in capital per effective worker

where $\dot{\tilde{k}}_t$ is the derivative of \tilde{k}_t with respect to time. From this, it is possible to obtain the equilibrium point equal to $\dot{\tilde{k}}_t = 0$, so that as we have shown graphically $s\tilde{y}_t = (n + d + g)\tilde{k}_t$. Figure 16.5 shows the evolution of $\dot{\tilde{k}}_t$ identifying our two equilibrium income per effective worker points at which $\dot{\tilde{k}}_t = 0$ for our two regions. It follows that at equilibrium

$$s\tilde{y}_j^* = (n_j + d + g)\tilde{k}_j^* \tag{16.6}$$

Hence,

$$\begin{aligned} s\tilde{k}_j^{*\alpha} &= (n_j + d + g)\tilde{k}_j^* \\ \tilde{k}_j^* &= \left[\frac{s}{n_j + d + g} \right]^{\frac{1}{1-\alpha}} \end{aligned} \quad (16.7)$$

and the equilibrium output per effective worker is

$$\tilde{y}_j^* = \tilde{k}_j^{*\alpha} = \left(\frac{s}{n_j + d + g} \right)^{\frac{\alpha}{1-\alpha}} \quad (16.8)$$

This means that equilibrium output is

$$Y_{jt}^* = \left(\frac{s}{n_j + d + g} \right)^{\frac{\alpha}{1-\alpha}} A_t H_{jt} \quad (16.9)$$

and equilibrium output per worker is

$$\frac{Y_{jt}^*}{L_{jt}} = \left(\frac{s}{n_j + d + g} \right)^{\frac{\alpha}{1-\alpha}} \frac{A_t H_{jt}}{L_{jt}} \quad (16.10)$$

Hence we have

$$\ln y_{jt}^* = \ln A_t + \frac{\alpha}{1-\alpha} \ln s - \frac{\alpha}{1-\alpha} \ln(n_j + d + g) + \ln \left(\frac{H_{jt}}{L_{jt}} \right) \quad (16.11)$$

Equation (16.11) provides the equilibrium level of output per worker as traced by the broken lines of Fig. 16.1 for our two regions. It shows a steady growth, at rate g , but with different levels at any one point in time on account of the different labor force growth rates. In terms of output per unit of effective labor, we have seen from Fig. 16.5 and earlier that this converges to a constant 2.86 for region 1 and 1.81 for region 2. Following Eq. (16.10), the evolution toward this steady state is given by the constant

$$\ln \left(\frac{Y_{jt}^*}{A_t H_{jt}} \right) = \frac{\alpha}{1-\alpha} \ln s - \frac{\alpha}{1-\alpha} \ln(n_j + d + g) \quad (16.12)$$

This is illustrated by Fig. 16.6.

We have given a highly stylized account of the determinants of regional growth, with regional differences existing purely as a consequence of differences in the rate of growth of labor. Thus, we have assumed that depreciation, returns to scale, the rate of technical progress, initial levels of technology, skilled labor, capital, and the savings rate are equal across our regions. Nevertheless, we see that this simple

Fig. 16.6 Evolution of output per effective worker

difference has consequences for the equilibria to which each region converges and the rate of convergence.

There is much interest in estimating convergence rates. As a result of linearizing the steady-state dynamics using a Taylor series expansion, we find that, approximately, the growth of output per effective worker is given by the gap between log level of output per effective worker and the log equilibrium level, thus

$$\frac{\partial \ln(\tilde{y}_{jt})}{\partial t} = -(1 - \alpha)(n_j + d + g)(\ln(\tilde{y}_{jt}) - \ln(\tilde{y}_{jt}^*)) \tag{16.13}$$

where the rate of convergence is $\beta_j = (1 - \alpha)(n_j + d + g)$. Note that for the parameters values in our example, $\beta_1 = 0.04$ and $\beta_2 = 0.1$, which compares with $\beta = 0.02$ (the so-called 2 percent rule) suggested by Barro and Sala-i-Martin (1995) which has in fact been observed in many growth studies. Integrating and writing in per worker terms, we obtain

$$\frac{1}{T} \ln\left(\frac{Y_{jt}}{L_{jt}}\right) = k - \frac{1}{T} e^{-\beta_j T} \ln\left(\frac{Y_{jt-T}}{L_{jt-T}}\right) \tag{16.14}$$

With large $\beta_j T$ the left-hand side is equal to k , which is proportional to the equilibrium level of output per worker.

One interesting prediction from the neoclassical growth model is the phenomenon of “catching up.” Consider two regions starting from different levels of output per worker. If we keep the equilibrium growth path for each the same for simplicity, then we find that there is faster growth in the initially poorer region. However, the prediction is more complex when both starting level and equilibrium path are different, as is more likely in the real world, as a result, for example, of a lower level of capital endowment and faster labor force growth rate. In our simulation,

Fig. 16.7 Convergence for two regions

the initially poorer country experiences a short-lived spurt of possibly faster growth at the outset, but over the longer term, we see growth moving sooner onto the equilibrium growth path entailing a lower equilibrium level of output per worker (obtained by setting $K = 1$ and $n_2 = 0.4$). Figure 16.7 illustrates this outcome.

It should be noted that in the neoclassical growth model described above, there is no explicitly modeled spatial interaction between the regions, although the common growth rate of technology g may be interpreted as implying perfect diffusion of technological change across the regions. The model also assumes that the investment share of output is fixed over time. Once regional differences in investment behavior, innovation diffusion, and interregional migration are taken into account, the extent of catching up will strongly depend on the strength of these types of spatial interaction (see Nijkamp and Poot 1998).

16.3 Estimating the Rate of Convergence

In this section, we review the main econometric issues associated with the estimation of the rate of convergence.

The debate on convergence has given rise to numerous empirical studies with often contradictory results due, partially, because various conceptions of convergence were tested and because various methodological approaches and procedures of tests have been used (cross section, panel data, temporal series, etc.). The first developments concern the idea of convergence-catching up, which is associated with the concept of β -convergence. This is based on the relationship between initial output and subsequent growth.

There are however two main approaches allowing the test of this hypothesis: absolute β -convergence and conditional β -convergence. Take again Eq. (16.11), which gives the equilibrium output per worker. This level depends upon several

parameters $\theta = (g, n, c, \phi, d, s, \alpha)$. If all elements of θ are similar for all regions, which then only differ by their initial effective per worker capital, then there is absolute β -convergence. If some elements of θ differ between regions, as was the case in our simulations, then there is conditional β -convergence.

16.3.1 Unconditional and Conditional β -Convergence

Consider first the simplifying case where all regions are structurally identical and have access to the same technology. They differ only by their initial conditions. In this case, they converge toward the same steady state and have the same growth rate at steady state. It is only in this case that poor regions grow faster than rich ones and eventually catch them up in the long run.

When cross-sectional data are available for two periods, initial period 0 and final period T , then Barro and Sala-i-Martin (1995) show that the hypothesis of this assumption of unconditional β -convergence is usually tested using the following model:

$$\frac{1}{T} \ln \left(\frac{y_{iT}}{y_{i0}} \right) = \alpha + \beta \ln(y_{i0}) + u_i \quad u_i \rightarrow iid(0, \sigma_u^2) \quad (16.15)$$

where $i = 1, \dots, N$, N is the number of regions in the sample; Y_{iT} is the per capita output (measured, for instance, by income or per capita GDP) for region i at time t , $t = 0$ or T ; $(1/T) \cdot \log(y_{iT}/y_{i0})$ is the average growth rate of per capita output between the two dates; and α and β are the unknown parameters to be estimated. There is unconditional β -convergence if β is negative and significant. The rate of convergence between regions can then be estimated as $\gamma = -\ln(1 + T\beta)/T$.

Consider now the case of regions with different steady states. Then, as we showed before, the growth rate of a region is positively related to the distance that separates it from its own steady state. This is the concept of conditional β -convergence. In order to test for this assumption, it is necessary to hold constant the steady states specific to each region. This may be done by adding in Eq. (16.15) explanatory variables that control the heterogeneity of the long-term path:

$$\frac{1}{T} \ln \left(\frac{y_{iT}}{y_{i0}} \right) = \alpha + \beta \ln(y_{i0}) + \gamma X_i + u_i \quad u_i \rightarrow iid(0, \sigma_u^2) \quad (16.16)$$

Where X_i is the vector of variables adjusting for the steady state of region i . As before, there is conditional β -convergence if β is negative and significant. The additional variables can be divided in two groups. On the one hand, state variables in accordance with the Solow-Swan model or some version of it must be introduced. As in Eq. (16.11), these are physical capital, human capital, and population growth rate. On the other hand, empirical studies often include numerous control variables, the expected effects of which correspond to their influence on the position of the steady state. For instance, Durlauf et al. (2005) identify 145 potential

growth determinants. This concept of convergence is compatible with a high degree of inequality if the regional steady states are very different. The question then is why the steady states of some regions remain so low.

16.3.2 Space and Growth

While lots of papers analyzing convergence at subnational scales initially employed techniques used in cross-country analysis, there is recognition that countries and regions are not interchangeable. Indeed, regions usually display a greater deal of openness, and various forms of regional interdependencies exist. Consequently, a vast strand of the regional science literature has made use of spatial econometric techniques and specifications to analyze regional convergence. We briefly review here some of the main issues at stake.

One major issue associated with the spatial dimension of the data is spatial autocorrelation in the error terms. Indeed, in the cross-sectional context, units are spatially organized and the *iid* assumption usually imposed in convergence specifications is overly restrictive. Various specifications are appropriate to control for spatial dependence; we present here the most commonly used. Consider Eq. (16.16) in matrix form such as $y = X\gamma + u$ where y is a vector containing the observations of average regional growth rates and X is the matrix containing the observations on all explanatory variables: constant term, initial income, and all the other control variables – and u is the vector of error terms.

In the spatial lag model, a spatially lagged variable Wy is added as an additional explanatory variable:

$$y = \rho Wy + X\gamma + u \quad (16.17)$$

where W is the spatial weight matrix and ρ is the spatial autoregressive parameter. The error term u is *iid*. The spatial lag Wy is always endogenous so that this specification should be estimated using maximum likelihood or instrumental variables. Particular attention should be given to the interpretation of the coefficients in this model as they only include the direct marginal effects of an increase in the associated explanatory variables, excluding all indirect induced effects (LeSage and Pace 2009 and ► [Chap. 77, “Interpreting Spatial Econometric Models”](#) in this handbook).

The spatial error model is a special case of a nonspherical error covariance matrix in which the spatial error process is based on a parametric relation between a location and its neighbors. In the spatial autoregressive specification, the error vector u takes the form

$$u = \lambda Wu + \varepsilon \quad (16.18)$$

where ε is *iid* and λ is the spatial autoregressive parameter. Conversely, the moving average specification can be expressed as

$$u = \gamma W\varepsilon + \varepsilon \quad (16.19)$$

Both models can be estimated using maximum likelihood or generalized method of moments. The two specifications differ in the terms of the range of spatial dependence in the variance-covariance matrix and of the diffusion process they imply. In particular, in the first case, the spillovers are global: a random shock in one observation impacts upon the income of all the regions in the sample. In the second case, the spillovers remain local: a shock in location i only affects the regions directly interacting with i , that is, the regions j for which $w_{ij} \neq 0$.

In the convergence context, both models have been extensively used to capture regional interdependence (Rey and Le Gallo 2009). Interestingly, some cross-country studies also acknowledge the need of taking spatial dependence into account and hence use spatial econometric techniques. Models incorporating spatial lags of the dependent and independent variables (spatial Durbin model) or higher-order spatial models have also been suggested (for a recent review, see Fischer and Wang 2011). As the spatial Durbin model encompasses the spatial lag and the spatial error model, it can be used as a basis for specification search (see ► Chap. 27, “Classical Contributions: Von Thünen, Weber, Christaller, Lösch” in this handbook for more details on specification search in cross-sectional spatial models).

Finally, note that a recent trend of the literature consists in providing sound theoretical foundations for the inclusion of spatial dependence in β -convergence models. For instance, Ertur and Koch (2007) show how a spatial Durbin model version of the β -convergence model can be obtained from a theoretical growth model with Arrow-Romer externalities and spatial externalities that imply inter-economy technology interdependence. Likewise Fingleton and Lopez-Bazo (2006) introduce substantive spatial externalities in the neoclassical convergence equation and show how this leads to a different steady-state level of output per unit of effective labor than would otherwise occur.

16.3.3 Econometric Issues

Although the conditional β -convergence approach has given rise to hundreds of studies, it has also been widely criticized.

16.3.3.1 Endogeneity of Explanatory Variables

In a regression setup, error terms are often correlated with the explanatory variables, leading to endogeneity and inconsistent estimates. In β -convergence models, there are numerous sources of endogeneity.

The first source of correlation between errors and some explanatory variables is simultaneity: some explanatory variables are not exogenous, they are determined simultaneously with growth rates, and thus they may affect growth but also depend on growth. For instance, given the Solow-Swan framework, state variables such as investment, initial per capita GDP, or human capital are equilibrium outcomes, as are regional growth rates. More generally, the causality versus the correlation issue is a prevalent one in growth econometrics. On the one hand, this implies biased estimation. On the other hand, this calls into question the interpretation of regression results and the extent to which these variables affect the steady-state levels.

Finding appropriate instruments, that is, variables that are correlated with the endogenous explanatory variables but uncorrelated with, or orthogonal to, the error terms, is a difficult task. Indeed, appropriate instrumental variables are rarely available. Since growth can be explained by numerous determinants, it is difficult to identify instruments that are correlated with the endogenous variables and yet can legitimately be eliminated from the regression. Moreover, as the effect of some variables on growth may be delayed, using lagged explanatory variables as their exogenous instruments is not optimal either.

The second source of correlation between errors and explanatory variables is measurement errors or errors in variables. This is of particular concern in growth regressions. Indeed, many countries build databases in which the accuracy of the variables is undoubtedly measured with error, and also in many cases, pragmatic decisions have to be made to use a variable that is only a proxy of a true variable. When the initial per capita GDP is mismeasured, the attenuation bias tends to bias the estimates of β in favor of the β -convergence hypothesis. For instance, Temple (1998) argues that the famous result of conditional convergence of economies at a rate of 2 % per year could be entirely due to measurement error.

Correcting for this is not an easy task and is further complicated in the presence of spatial error autocorrelation. Indeed, Le Gallo and Fingleton (2012), using Monte Carlo simulations, show that OLS and instrumental variable estimation, which do not take into account spatial error autocorrelation, outperforms GMM-based and ML estimation. These results would indicate that measurement error plus a disturbance process involving spatial dependence is best accommodated by an estimation method that ignores spatial dependence. Clearly, the interaction between spatial autocorrelation and measurement errors, which are both easy to find in β -convergence models, should be further investigated.

The third source of correlation between errors and explanatory variables is omitted variables. In practice, it is unlikely that researchers are able to find all the variables controlling for the differences in steady states between regions. Hence, the error term in conditional β -convergence models will probably contain a number of omitted variables correlated with the included regressors, though if in the unlikely event they are orthogonal to the included regressors, then there is no problem. Trying to solve this by increasing the number of explanatory variables typically runs into the problem of simultaneity and possibly multicollinearity. Note that LeSage and Fischer (2008) have shown that the existence of omitted explanatory variables exhibiting nonzero covariance with variables included in the model yields a data-generating process for a growth regression that includes both an endogenous spatial lag and exogenous spatial lags (spatial Durbin growth model).

16.3.3.2 Robustness of Explanatory Variables

This critique relates to the choice of control variables and is linked to the lack of robustness of conditional β -convergence regression models. Indeed, the finding of conditional β -convergence and the subsequent estimation of the convergence rate is dependent upon a specific choice for the set of control variables. The lack of consensus about the most important growth determinants amplifies this problem:

if most regressors included in the empirical analysis are found to be statistically significant in some specification, it means that there are as many growth theories as the number of significant regressors and that it is impossible to distinguish between them. This is referred to as the problem of observational equivalence of competing theories, which is common in macroeconomic analysis generally.

Confronted by the variety of explanatory variables available for use in these regressions, Levine and Revelt (1992) employ extreme bound analysis, which consists of estimating the upper and the lower extreme bounds of a coefficient of a variable of interest across a range of different model specifications. The variable is considered to be robust if the coefficients at these extreme bounds are significant and if they maintain their signs and statistical significance across a diverse range of other included variables. Using this approach, they show that most variables tested turn out to be insignificant given additional control variables.

This approach has been criticized as being excessively conservative. More recently, the use of model averaging and Bayesian model averaging has been advocated in order to guide in the choice of control variables (Fernandez et al. 2001; Sala-i-Martin et al. 2004). In a spatial context, an additional source of uncertainty pertains to the choice of the spatial weights matrix. A Bayesian model averaging approach for selecting appropriate explanatory variables together with an appropriate spatial weights matrix has been suggested by LeSage and Fischer (2008). An alternative is to explain the variation in results by means of meta-analysis (Abreu et al. 2005).

16.3.4 Panel Estimation

If unmodeled region-specific unobserved effects on output levels are present, this implies a link between the error terms and initial output per capita. In order to correct for this, a number of researchers advocate convergence analysis via the use of panel data (Islam 1995). We have a choice as to how we model the individual effects: fixed effects, essentially dummy variables, one per region, or random effects, in which the individual-specific (region) effect is captured as a random variable. The setup of fixed effects models follows on naturally from the pure cross-sectional growth models considered thus far, typically having the form

$$\begin{aligned} \ln y_{it} &= \gamma_t + \alpha \ln(y_{it-\tau}) + X'_{it}\beta + a_i + u_{it} \quad t = 2, \dots, T \\ u_{it} &\rightarrow iid(0, \sigma_u^2) \end{aligned} \quad (16.20)$$

which can be written as a growth equation as follows:

$$\begin{aligned} \Delta \ln y_{it} &= \gamma_t + (\alpha - 1) \ln(y_{it-\tau}) + X'_{it}\beta + a_i + u_{it} \quad t = 2, \dots, T \\ \Delta \ln y_{it} &= \ln y_{it} - \ln y_{it-\tau} \\ u_{it} &\rightarrow iid(0, \sigma_u^2) \end{aligned} \quad (16.21)$$

where growth $\Delta \ln y_{it}$ is measured between period t and some previous period $t - \tau$ (usually $\tau \geq 5$ years to avoid business cycle effects). In this approach, all the unobserved time-invariant regional heterogeneity is captured by individual-specific effects, denoted by a_i . Following Eq. (16.11), the matrix X includes other possibly time-varying factors affecting growth. In addition, growth depends on the start-of-period level $\ln(y_{it-\tau})$, so the estimate of the coefficient α gives the rate of convergence. The term γ_t represents time (dummy variable) effects that are constant across locations.

The presence of the lagged dependent variable together with the time-invariant effect a_i in Eq. (16.20) renders OLS inconsistent even when the transient disturbances u_{it} are not serially correlated. The most obvious way to fix this is to first difference the data, so that the individual-specific (fixed or random) effects are eliminated. Thus, our differenced specification is

$$\Delta \ln y_{it} = \Delta \gamma_t + \alpha \Delta \ln(y_{it-\tau}) + \Delta X'_{it} \beta + \Delta u_{it} \quad t = 3, \dots, T \quad (16.22)$$

While the convergence parameter α is identified in Eq. (16.20), eliminating the time-invariant individual-specific effects does not solve the problem of inconsistent and biased parameter estimation via OLS because the lagged dependent variable is correlated with u_{it} , and there is also potential endogeneity of other regressors (including measurement error), omitted variables and spatial dependence. Rather, the reason to first difference is to create instruments that are not correlated with the individual effects.

With regard to spatial dependence, this can exist as a result of direct autoregressive interaction across space of the dependent variable, as a consequence of a spatial error process, or both. A good, comprehensive summary for static spatial panel models is provided in Chap. 12 of Pirotte (2011). If we add a spatially lagged dependent variable to the difference equation we obtain:

$$\Delta \ln y_{it} = \Delta \gamma_t + \alpha \Delta \ln(y_{it-\tau}) + \rho \Delta W_N \ln y_{it} + \Delta X'_{it} \beta + \Delta u_{it} \quad (16.23)$$

The variable $\Delta W_N \ln y_{it}$ is also endogenous, as in the pure cross-section case. While difference-GMM estimation may appear to be appropriate, by using lagged levels of variables as instruments, it does typically create a weak instrument problem. One estimator that can potentially deal with these problems is the system GMM estimator (Arellano and Bond 1991; Bond et al. 2001); this estimates Eq. (16.23) combining both the difference equation and the corresponding levels equation, with lagged first differences as instruments for the levels equation, and lagged levels for the equation in first differences. One should however use this cautiously because, using all available lags of variables as instruments, this estimator in particular presents significant practical problems relating to overfitting and thus failure to purge endogeneity. The solution seems to restrict the number of lags employed as internally generated instruments so as to clearly satisfy the relevant diagnostics, but one may still have use external instruments in order to obtain the

necessary instrument orthogonality for consistent estimation. For the additional moments conditions associated with the levels equation to be orthogonal, it is sufficient for the variables to be mean stationary, having controlled for common time effects γ_t .

The other form of spatial dependence in panel models involves the disturbances. Pirotte (2011) classifies static spatial panel models according to whether the spatial disturbance process is autoregressive (SAR), or a moving average process (SMA), and whether the individual effects are considered to be fixed (deterministic or FE), or random effects (RE). If the random individual effects are not spatially autocorrelated, but the transient component of the compound error is, then he refers to the model as RE-SAR or RE-SMA. If the spatial error process applies in the same way to both transient and individual error components, so that the spatial process is at the level of the compound errors and not its individual components, then this is referred to as SAR-RE or SMA-RE, according to whether we are considering an autoregressive or moving average specification. If however the individual effects are fixed, and spatial effects are restricted to the transient errors, then the model is referred to as FE-SAR or FE-SMA according to whether we have an autoregressive or moving average process.

Accordingly, introducing the RE-SAR (or the FE-SAR) specification to our levels model gives

$$\begin{aligned} \ln y_{it} &= \gamma_t + \alpha \ln(y_{it-\tau}) + X'_{it}\beta + a_i + u_{it} \\ u_{it} &= \lambda M_N u_{it} + \xi_{it} \end{aligned} \quad (16.24)$$

where M_N is an $(N \times N)$ matrix specific to time t , where N is the number of regions (and therefore M_N has similar properties to W_N) and a_i are random (or fixed) effects. The two forms of interactions can also be combined and one might even extend the spatial dependence in the error to include both the transient errors and the individual effects to give the spatial autoregressive equivalent of SAR-RE:

$$\begin{aligned} \ln y_{it} &= \gamma_t + \alpha \ln(y_{it-\tau}) + \rho W_N \ln y_{it} + X'_{it}\beta + \psi_{it} \\ \psi_{it} &= a_i + u_{it} \\ \psi_{it} &= \lambda M_N \psi_{it} + \xi_{it} \\ \xi_{it} &\sim iid(0, \sigma_\xi^2) \end{aligned} \quad (16.25)$$

Alternatively, the equivalent of SMA-RE entails the moving average error process involving both individual and transient errors (Fingleton 2008) with $\psi_{it} = \lambda M_N \xi_{it} + \xi_{it}$.

With spatially dependent (moving average or autoregressive) errors combined with an endogenous spatially autoregressive spatial lag, the GMM approach typically has several stages, first one uses instrumental variables, assuming no spatial error process, to obtain consistent estimates of the residuals. These then become the basis for GMM estimates of the error process parameters. Finally, the data are

purged of the error dependence and consistent estimates obtained via instrumental variables in the final stage. Overall, with these more complex models, it is evident that methods based on GMM are the most versatile because they can handle multiple endogeneity and are robust to alternative error distributions, issues that are problematic under maximum likelihood.

16.3.5 Multiple Regimes and Convergence Clubs

As we have shown above, $\beta < 0$ is consistent with the assumptions of the neoclassical growth model. However, this condition is also potentially consistent with economic alternatives, such as endogenous growth models or models with poverty traps. For instance, Azariadis and Drazen (1990) develop an endogenous growth model characterized by the possibility of multiple, locally stable steady-state equilibria. Which of these different equilibria a region will be converging to depends on the range to which its initial conditions belong? In other words there are convergence clubs, that is, groups of economies whose initial conditions are near enough to make group members converge toward the same long-term equilibrium. From an empirical point of view, the existence of convergence clubs can be inferred from the fact that while absolute β -convergence is frequently rejected for large samples of countries and regions, it is usually accepted for more restricted samples of economies belonging to the same geographical area.

While the Arariadis-Drazen model does not exhibit convergence since different initial conditions lead to different steady states, Bernard and Durlauf (1996) show that the data generated by this model will not necessarily lead to the finding that $\beta \geq 0$. Therefore, tests for β -convergence have low power against the alternative hypothesis of multiple steady states. The problem is then to distinguish evidence of club convergence from that of conditional convergence.

From an econometric point of view, the existence of multiple equilibria is characterized by parameter heterogeneity in convergence regressions. A vast range of techniques has been used in order to detect convergence clubs. Some use a priori criteria to define club members, such as belonging to the same geographical zone or having similar initial incomes. Durlauf and Johnson (1995) use regression trees (CART algorithm) where initial income and literacy rates are used to detect the convergence clubs. In the context of regional data, a number of authors have made use of exploratory spatial data analysis (ESDA) to detect spatial regimes in the data. In particular, Moran scatter plots and Getis-Ord statistics facilitate the detection of spatial clusters of high values of regional incomes and spatial clusters of low values of regional incomes. The hypothesis of β -convergence is then tested on each group (see, for instance, Ertur et al. 2006).

At the extreme, rather than partitioning the sample into regimes based on some structural characteristics, parameter heterogeneity might also be region specific. For instance, in Eq. (16.15), region-specific parameters α_i and β_i must be estimated. While varying coefficient models might be used for that purpose (see ► Chap. 73, “Geographically Weighted Regression” in this handbook for

a presentation of these models), we note that for regional samples, similarities in legal and social institutions, as well as culture and language, might create spatially local uniformity in economic structures. This leads to situations where convergence rates are similar for regions located nearby in space. In order to capture this combination of parameter heterogeneity and local similarity, spatial autoregressive local estimation (SALE) model has been suggested by Pace and LeSage (2004).

16.4 Sigma-Convergence and Distribution Approach to Convergence

We now turn to alternative concepts of convergence that have been used in the literature on regional growth.

16.4.1 σ -Convergence

In this approach, convergence is linked to the study of the dynamic evolution of some indicator of dispersion of output per capita between regions. The focus is then on whether this indicator increases or decreases over time. Two indicators of cross-sectional dispersion are commonly used: the standard deviation of log income or the coefficient of variation coefficient of this distribution.

Specifically, the test of σ -convergence consists of comparing an indicator of dispersion, computed at the end of the period, to the value of this indicator computed at the beginning of the period. There is σ -convergence if this indicator decreases over time. Formal tests using regression specifications have also been suggested by Carre and Klomp (1997) and Egger and Pfaffermayr (2009).

It is possible to show that β -convergence is a necessary but not a sufficient condition to σ -convergence. The point of departure is the absolute β -convergence equation where the dependent variable is the cumulated growth rate:

$$\ln(y_{iT}/y_{i0}) = a + \beta \ln(y_{i0}) + u_i \quad (16.26)$$

This equation is rewritten as

$$\ln(y_{iT}) = a + (1 + \beta) \ln(y_{i0}) + u_i \quad (16.27)$$

By taking the variance of each term in this equation, we have $V[\ln(y_{iT})] = (1 + \beta)^2 V[\ln(y_{i0})] + V(u_i)$, from which it is easy to show that

$$VR = \frac{V[\ln(y_{iT})]}{V[\ln(y_{i0})]} = \frac{(1 + \beta)^2}{R^2} \quad (16.28)$$

where R^2 is the multiple correlation coefficient associated with Eq. (16.27).

From this, it is evident that β -convergence ($\beta < 0$) is a necessary but not a sufficient condition for σ -convergence ($VR < 1$). In fact, the final result depends upon two opposite effects. The first is the existence of β -convergence implying mean reversion. The second is linked to the existence of specific shocks to which the regions are submitted and that permanently generate per capita output dispersion. σ -convergence is the result of these two mechanisms and exists if the beneficial effects of mean reversion dominate the negative effects of perturbations affecting the regions.

This concept has been subject to a number of criticisms, the first of which obviously concerns the dependence of σ -convergence on the initial date. Second, it only focuses on the second moment of the distribution and is not informative about other moments that may be of interest, such as skewness or kurtosis. Third, interpreting measures of dispersion is not straightforward when distributions are not unimodal, and it is often the case that we encounter multimodality and twin-peakedness in practice. Fourth, it is subject to a spatial identification problem. Indeed, given a map of N incomes with a sample variance σ^2 then there are $N!$ spatial permutations on the map that would have the same sample variance.

Finally, Quah (1993) forcefully argues that it does not provide meaningful information about income dynamics nor about the mobility of regions within a distribution. For instance, if two regions exchange their relative position between the initial and final date while the gap between the two remains unchanged, then the standard error of this distribution is constant over the period even if the situation of the two regions has changed radically.

16.4.2 Studying the Evolution of the Cross-Sectional Distributions

In the light of these criticisms, Quah (1993, 1996) argues that the cross-sectional distributions of income should be considered in their entirety rather than just computing one synthetic indicator such as dispersion. Indeed, with regard to σ -convergence, it tells us nothing about distribution dynamics. Rather, the evaluation of distribution dynamics can be accomplished on the basis of two criteria: the study of the evolution of income level distributions and analysis of the position of the regions or groups of regions within distributions.

Concerning the first point, the method consists of comparing the cross-sectional distributions of regional income at different points in time and evaluating the degree to which the location and shape of these distributions changes.

One possibility is to estimate, using nonparametric smoothing methods, such as kernel estimates, the density function of income for the sample, and examining the changes in the form of this density. For instance, Fig. 16.8 represents two possible ways in which the distribution might evolve over time, each representing two types of convergence. If, given the initial distribution, the regions in the sample evolve toward a tighter distribution, then there is global convergence of all regions toward the same level of income. On the contrary, if the distribution becomes bimodal or multimodal, then the regions converge toward different levels, which is symptomatic of different

Fig. 16.8 Density functions for three different convergence issues

convergence clubs. In order to go beyond simple visual impression, tests for multimodality can also be undertaken (Henderson et al. 2008).

It is also possible to estimate cross-sectional distribution densities using mixture models, which are weighted sums of component distributions. In this case, one can say that convergence occurs when the distributions are better approximated over time by a small number of components, while multiple components are an indication of multiple regional steady states. The number of components can be evaluated using a bootstrap LR test.

Concerning the second point on the position of the regions or groups of regions within the distributions, we observe that shape dynamics does not directly address this issue. Nonetheless, it may be of interest to study whether, for a given time period, the regions have changed their relative position in the income distribution, that is, which regions move up and down in this distribution.

One method that allows detection of the movements of the regions from one period to another consists of estimating transition matrices or Markov chains. These are constructed using a discretization of the distribution of income into several classes (using for instance quartiles or quintiles of the distribution). Transition matrices allow one to estimate the probabilities of passage from one income class to another, or of remaining in the same income class, over time. If the probabilities of passage from one class to another are high, then mobility is high. If the probability of staying in the same class is high, then mobility is low. By extension, it is possible to detect whether the level of income is tending toward homogeneity or, on the contrary, if distinct groupings of regions with different incomes are emerging and being maintained over time. Formal mobility indices may also be computed, while the ergodic distribution,

that is the long-term distribution, allows one to see the type of convergence mechanism that is at work. Concentration of the frequencies in the median class would imply convergence to the mean, while concentration of the frequencies in several of the classes, that is, a multimodal limit distribution, may be interpreted as a tendency toward stratification into different convergence clubs.

In order to operationalize this, some strong assumptions are usually made, such as stationarity of transition probabilities and a first-order process. Formally, denote F_t as the cross-sectional distribution of income at time t relative to the sample average. A set of K different GDP classes is defined. If the frequency of the distribution follows a first-order stationary Markov process, then the $(K \times 1)$ vector F_t , indicating the frequency of the regions in each class at time t , is described by the following equation:

$$F_{t+1} = MF_t \quad (16.29)$$

where M is the $(K \times K)$ transition probability matrix representing the transition between the two distributions. If the transition probabilities are stationary, that is, if the probabilities between two classes are time invariant, then

$$F_{t+s} = M^s F_t \quad (16.30)$$

The ergodic distribution of F_t is approached as s tends toward infinity in Eq. (16.30). Such a distribution exists if the Markov chain is regular, *that is*, if and only if for some N , M^N has no zero entries. In this case, the transition probability matrix converges to a limiting matrix M^* of rank 1. The existence of an ergodic distribution, F^* is then characterized by

$$F^*M = F^* \quad (16.31)$$

Each row of M^t tends to the limit distribution as $t \rightarrow \infty$. According to Eq. (16.31), this limit distribution is therefore given by the eigenvector associated with the unit eigenvalue of M . The estimation of the transition matrix is based on maximum likelihood estimation.

As indicated, strong assumptions must usually be made to estimate such transition matrices. Moreover, the results are sensitive to the number and size of the groups of observations used to discretize the data. In fact, discretization of the state space may significantly alter the probabilistic properties of the data.

To overcome this problem of sensitivity of the results to the discretization, stochastic kernels have been suggested. They are the continuous counterpart of transition probability matrices. Formally, if $f_{X(t)}$ is the regional income density for n regions in period t , then the evolution of the cross-sectional distribution is modeled as

$$f_{X(t+s)} = \int_{-\infty}^{\infty} M_{t,s} f_{X(t)} dx \quad (16.32)$$

where $M_{t,s}$ is the stochastic kernel representing where points in $f_{X(t)}$ move to in $f_{X(t+s)}$. The estimation of this kernel may be based on an estimate of the conditional distribution. In order to explore the transitional dynamics provided by this approach, three-dimensional representations and two-dimensional contour plots are used. For example, polarization or convergence clubs in the per capita GDP distribution are reflected in peaks in the 3D kernel or by concentrated values in the contour plot. Fischer and Stumpner (2008) introduce three-dimensional stacked conditional density plots and highest density regions plot for the visualization of the transition function.

16.4.3 Distribution Dynamics and Space

As in the confirmatory econometric analysis of growth and convergence, the spatial dimension of the data invalidates some of the restrictive assumptions regarding random sampling on which σ -convergence and distribution dynamics rest. We briefly consider in this section how this impacts on the measures of convergence and distribution dynamics. First, we note that the concepts of convergence that have been developed in the preceding sections must be adjusted to take into account spatial autocorrelation in the data. Secondly, we observe that much work has been done in exploratory spatial data analysis (ESDA) and Exploratory Space-Time Data Analysis (ESTDA), and their application to convergence and growth analysis has led to interesting new insights.

Regarding the first point, consider the σ -convergence measure presented earlier. We have already pointed out that it is uninformative with regard to the morphology of the distribution and the degree of intradistributional mobility. Moreover, in a spatial context, the presence of spatial dependence complicates the interpretation of, and inference based on, this concept. For instance, Rey and Dev (2006) show that the sample variance also reflects the level and structure of spatial dependence in the data. This should be purged in order to correctly interpret this concept of convergence.

Similarly, spatial autocorrelation has been incorporated into measures of intradistributional dynamics. In the case of discrete Markov chains, Rey (2001) extends the approach by estimating transition matrices subject to the spatial lag of the income values for each region. This allows one to analyze how the spatial environment affects the transition probabilities of a region through the income distribution. It is usually found that the probabilities of a given region staying in the same class or of moving up one class are ameliorated when the region is surrounded by other wealthy regions.

Spatial autocorrelation must also be considered when analyzing the shapes of per capita GDP distributions and when estimating stochastic kernels. This is done using regional conditioning, that is, basing density function and kernel estimation on a region's income expressed relative to its geographical neighbors. A formal inferential framework to test hypotheses about distribution dynamics in the presence of spatial effects still needs to be developed however.

Regarding the second point, traditional convergence measures can be usefully augmented by the different ESDA and ESTDA measures. First, the classical Moran's I statistics is naturally used to assess the level of spatial dependence in the income series and its evolution over time.

Second, local measures of spatial autocorrelation can also be used. In particular, local spatial instability is studied by means of the Moran scatterplot, which plots the spatial lag of standardized income against the original values. The four different quadrants of the scatterplot correspond to the four types of local spatial association between a region and its neighbors: HH denotes a region with a high value surrounded by other regions with high values and LH indicates a low value region that is surrounded by regions with high values, etc. Quadrants HH and LL (resp. LH and HL) refer to positive (resp. negative) spatial autocorrelation indicating local spatial clustering of similar (resp. dissimilar) values. This approach has been used extensively to analyze the evolution of the spatial distribution of income in several regional samples. Whenever these Moran scatterplots are constructed for several years, Rey (2001) has suggested using the discrete Markov methodology: in any period, there are four possible states: HH, LL, LH, and HL so that between any two periods, 16 different spatial transitions are possible, which can be summarized by a transition probability matrix.

16.5 Conclusions

We have reviewed alternative approaches to regional growth and convergence empirics, focusing on the various methodological problems and solutions that have been offered in the literature. Clearly, there is no obvious consensus regarding the most appropriate approach, or modeling strategy, or even whether convergence is actually a real phenomenon, or simply a feature of the theoretical model that has been the dominant one in the literature, the neoclassical growth model.

There is a point at which some of these approaches do give comparable conclusions, however. Indeed, we can obtain estimates of the time it will take for economies to converge both from the neoclassical growth model and from the Markov chain approach. According to Fingleton (1999), for the regions of the EU, the time needed to achieve neoclassical (conditional) convergence will be of the order of 200–300 years. This is simply due to diminishing returns to capital setting in very slowly, that is, effectively α is close to 1 in the model of Sect. 16.2. Under the Markov model, convergence to the ergodic distribution should, it is estimated, take a similar amount of time, at least 300 years. Of course, the latter is stochastic convergence, implying constant probabilities of different income states but allowing movement of regions across income states. It is evident that, for the EU at least, convergence of some sort, if it occurs at all, will not be a rapid phenomenon and be characterized by distributed income levels rather than the homogeneity associated with unconditional neoclassical convergence.

Abstract

The past couple of decades have seen what amounts to an intellectual revolution in urban and regional economic research concerning the role of skills in economic growth. From industrial location theory and Alfred Marshall's concern for agglomeration to more recent research on high-tech districts and industrial clusters, firms and industries have been traditionally the dominant unit of analysis. But since the 1990s, there has been a growing focus on skills. This broad research thrust includes studies of human capital; the creative class and occupational class more broadly; and physical, cognitive, and social skills, among others. This research highlights the growing geographic divergence of skills across cities and metros and their effects on regional innovation, wages, incomes, and development broadly. An expanding literature notes the growing

importance of place in organizing and mobilizing these skills. Studies have focused on the role of amenities, universities, diversity, and other place-related factors in accounting for the growing divergence of skills across locations. This chapter summarizes the key lines of research that constitute the skills revolution in urban and regional research.

17.1 Introduction

A large and influential body of research on the role of skills in regional economic growth and development has emerged over the past decade or so. This work on skills has greatly expanded our understanding of the nature, role, and mechanics of regional growth and development. This relatively recent line of research can be divided into two main thrusts – studies that focus on and measure human capital in terms of educational attainment and those that measure skills via occupations.

This work represents something of a break with an earlier focus on the role played by firms and industries. Classical location theories, such as developed by Weber, von Thünen, and Christaller before World War II (McCann 2001), emphasize the transportation costs and tradeoffs made by large industrial firms. Marshall long ago noted forces and factors that cause firms to agglomerate. Building on his work, economists have catalogued the factors including proximity to natural resources and transportation routes, shared inputs, knowledge spillovers, and access to labor that lie behind such agglomerations or clusters. During the 1980s, economic geographers identified the rise of industrial districts and flexibly specialized industrial networks as alternatives to vertically integrated production by large firms (Piore and Sabel 1984). Porter (1990) identified four key reasons behind geographic clusters including factor conditions, demand conditions, related and supporting industries, and strategy, structure, and rivalry. Others have noted the role of social factors such as social capital and trust as additional factors orienting geographic clusters (e.g., Saxenian 1994).

Interest in skills and human capital dates back a long way. In his classic work on *The Wealth of Nations* (1776), Adam Smith identified the “acquired and useful abilities of all the inhabitants or members of the society” as something akin to a “fourth factor of production” operating alongside land, labor, and production, noting that “The greatest improvement in the productive powers of labour, and the greater part of the skill, dexterity, and judgment with which it is anywhere directed, or applied,” he wrote, “seem to have been the effects of the division of labour” (Smith 1776; Book 1, p. 7). Still, until recently, the great preponderance of economic and regional research has focused on the firm and firm location in order to understand geographical differences in economic performance.

Nearly a half century ago, however, Jane Jacobs (1969) noted that what distinguished cities and propelled their economic growth and development was not firms, but the geographic clustering of diverse and talented people in cities. In the mid-1980s, attention was called to the role of occupations in regional development and that we need to look beyond the products a city makes and instead

examine the roles workers play and the skills they perform. This in turn will shift the emphasis from the industry perspective to more long-run power and potential of local (human) resources (Florida 2002). Building on Jacobs, Lucas (1988) suggested that knowledge is embodied in human beings rather than in industries and that human capital externalities that stem from a concentration of highly educated individuals are the key motivating force in economic growth and development. Over the past decade or so, a growing body of research has identified the growing concentration and geographic clustering of skill as the key factor in regional growth and development. This research has noted a growing divergence in the geographic location and concentration of skills and their increasing importance to regional innovation, productivity, and growth. A debate has emerged over how best to measure skill. There is a long literature on the role of educational-based human capital, at the regional as well as national levels, in economic performances. More recent research has shifted attention to occupation-based measures of skill and also to more discrete measures of occupational skill itself.

Some have also invoked the classic chicken and egg question: what comes first they ask – firms or skills? In our view, this is a misleading question. It can be better framed in terms of demand and supply, where firms comprise the demand for skill, with skills thus functioning as supply. This is not so much a chicken and egg or either/or question, but a question of how firms and skills interact to inform regional economic growth. The analog is of course producers and consumers: one cannot entangle which of these came first. They require each other.

This chapter focuses on the growing attention paid to, and the importance of, skills for regional economic development and growth. It summarizes the major thrusts and contributions of the field. In doing so, it distinguishes between education-based and occupational definitions of skills. It discusses the opportunity to link firms and skills – or industries and occupations – in order to gain more robust theories and empirical research on the key factors that shape regional economic growth and development.

17.2 The Firm/Industry Focus in Regional Research

Historically, regional economists, such as von Thünen, Weber, Christaller, Ohlin, Hoover, Lösch, and others, have focused on the firm as the unit of analysis (McCann 2001). This also stems from a strong tradition built on the work by Marshall in the 1890s, who argued that firms cluster to achieve the advantages of collocation, such as shared labor markets, shared inputs, risk minimization, and knowledge spillovers. Hotelling a few decades later showed how firms producing similar types of products and that do not compete based on price have incentives to collocate next to one another. This focus on the firm developed just as the economy was moving away from agriculture toward large industrial firms and heavy industry. This was a time when transportation costs were high and location decisions were heavily influenced by proximity to natural resources (McCann 2001).

This was the backdrop for the focus on the firm and, in particular, on the large firm as the dominant unit of analysis in urban economics, economic geography,

and regional science. Many studies focused on the location and site selection decisions by these firms and later on the location choices of their branch plants. Vernon (1966) advanced a simple model of industrial location based on the product cycle – firms would decentralize production through branch plants once production processes became standardized. Others later focused on the growing international spatial division of labor informed by the location decisions and global reach of these multinational firms (e.g., Massey 1984). There was little inclination to examine the role of human capital or occupations as most jobs were standardized. When labor was considered, it was mainly seen as a cost to minimize.

17.3 Postindustrialism and the Knowledge Economy

This changed however with the shift from an industrial to postindustrial economy. Machlup (1962) and Drucker (1993) described the rise of the “knowledge economy” and of “knowledge workers.” Bell (1973) identified the shift to a “postindustrial society” with a new class structure based on scientists, managers, administrators, and engineers. Andersson (1985) emphasized the broader societal change from the manufacturing-based economy to the “C-society” based on creativity, communication, culture, and knowledge. Kenney and Florida identified the rise of new systems of industrial production, especially among Japanese firms, which gained competitive advantage by tapping the knowledge and intelligence of factory workers (Florida 2002).

The 1980s saw increasing interest in the shift from vertically integrated to flexibly specialized production systems (Piore and Sabel 1984). This body of research identified the rise of networked production systems based on “flexible specialization.” As production standardization decreased, workers were enabled to have a wider range of expertise, which led to a continuous firm learning process.

This distinction between knowledge-based production and more standardized goods production has several implications for regional development. First, standardized production can take place almost anywhere, (where labor and land rent are cheap), and the final product can thereafter be sent to the market place for consumption. In other words, production and consumption do not need to take place in the same location. Knowledge production, on the other hand, is most often related to service goods, where there is a need for producers and consumers to meet contemporaneously in the market place. Knowledge products are therefore in general more distance sensitive and more attached to the region where the economic activity is located. Second, knowledge and creative workers not only function as producers of high value goods, they also consume them. Glaeser et al. (2001) describe how increased average incomes based on the reallocation of labor into more productive sectors have changed the role of the regions. As incomes rise, people demand more normal and luxury goods rather than necessity goods, and those will mainly be provided in bigger cities. Higher incomes also increase the opportunity cost of not working as well as the cost for commuting. Altogether, the increasing incomes and increased cost for commuting create stronger incentives to locate in cities.

The distinction between knowledge-based and standardized manufacturing industries can be problematic when industry data is being used. The same industry codes may imply very different functions and tasks, and those often come with a spatial fragmentation. Multinational companies often locate the labor-intense low-skilled functions in less developed, low-wage countries, but keep the more high-skilled functions in the western world. To best illustrate this, one needs to understand the occupational and educational structure within the growing creative and knowledge-based industry sectors compared to the one within more traditional sectors.

17.4 Human Capital

Most research on skills is organized around the construct of education-based human capital. Human capital theory postulates that wages rise with the level of knowledge or skill (Becker 1964) and a traditional Mincer (1974) equation suggests that the hourly wage is a function of skills and education. Optimally, wage levels offered by employers are determined by the value of workers' marginal product and therefore declining when employment increases. On the other hand, human capital available in the market will be positively related to wages offered. At the aggregated level, wages are thus set by the regional supply and demand for labor. Regional wage levels would thereby be directly related to regional labor productivity. At the micro level, this may be distributed unevenly. Two regions can reach the same wage levels based on (i) a homogenous labor force or (ii) a labor force consistent of high- and low-knowledge labor that together reach the same result. But at the aggregate level, the regional wage level will reflect regional labor productivity. Wages can also be a function of a number of other factors, such as gender, immigration background, and race. Becker suggests that discrimination, for example, based on factors such as race and gender, may disturb the relation to wages, and also decrease productivity, since some people may be hired based on individual traits than how suitable they are for the job. Furthermore, wages can also be related to the available amenities, with, for example, a nice climate compensating for a lower wage, all else being equal.

A wide range of empirical studies have documented the role of human capital in national growth. A number of studies (e.g., Barro 1991; Mankiw et al. 1992) provide empirical support for this basic model. However, these studies do not account for regional spillovers and interdependencies. Fischer (2011) extends this basic approach utilizing spatial econometrics which takes technological interdependencies into account to examine the connection between knowledge diffusion and growth across regions in 22 European countries.

There is also a wide range of research on the contribution of human capital to city or metropolitan level growth (e.g., Glaeser and Saiz 2003). This research stream notes that the metro may be a more appropriate context to evaluate the effects of human capital. They note that it is harder to estimate the human capital (educational effect) on economic growth for nations than for cities, since national

growth to a larger extent will be affected by institutional differences as well. Cities also make up economically delimited units, while regional and national divisions otherwise tend to be more arbitrary and based on political decisions.

While human capital externalities affect regional productivity in cities, there are also more straightforward explanations to why we would expect a relation between higher levels of human capital and productivity. Human capital has become more unevenly distributed and concentrated over time. Berry and Glaeser (2005) have shown how human capital levels have become more and more concentrated over the last century, and how this is an endogenous self-reinforcing process where places with initially high values have increased their human capital levels more over time than other places that started off a lower position.

Ullman (1958) was one of the first to note the role of human capital for regional development. Ever since, considerable research has found significant relations between education levels and wages in cities and metropolitan areas. Rauch (1993) found that human capital intense cities are more productive and that an increase by 1 year in average education increases productivity by 3 %. Glaeser and Saiz (2003) provide empirical evidence on the correlation between human capital and regional economic growth. Firms locate in areas of high human capital concentration to gain competitive advantages, rather than letting suppliers' and customers' geography alone dictate their location. They find that skilled cities grow, relative to less skilled cities, through increases in productivity.

17.5 Occupations and the Creative Class

While the great preponderance of research on regional development uses human capital as a proxy for skill, a second approach has also emerged over the past decade which suggests that occupations may be a better proxy for skill. Thompson long ago suggested the need to utilize occupational analysis in regional development research (Florida 2002). Feser (2003) later suggested that it is more important to focus on what regions do rather than what they make in order to understand regional development and that occupations then should be the natural unit of analysis.

Florida (2002) used occupational analysis to divide the workforce into three main occupational classes – the creative class, working class, and service class. Florida based his research on Bureau of Labor Statistics data on occupations. The creative class works with knowledge, the working class is engaged in physical work, and the service class performs routine service. The creative class is divided into two subgroups: the super-creative core (computer and math occupations; architecture and engineering; life, physical, and social science; education, training, and library positions; arts and design work; and entertainment, sports, and media occupations) and the creative professionals (management occupations, business and financial operations, legal positions, healthcare practitioners, technical occupations, and high-end sales and sales management).

This approach focuses on creativity itself and not education as a proxy for skill. Research in psychology has shown that creativity is a fundamental and intrinsic

human capability. Where Marx and other classical economists looked at physical labor – in other words, the ability of humans to transform nature, create farms, and build manufactured products – in reality, it is our underlying creativity which makes us different from other species. According to Sternberg and Lubart (1999), this is what entrepreneurs, CEOs, artists, and technologists, as well as all children, have in common – our creative capacity. Creativity can be defined as the development of new ideas – as embodied in products, practices, services, or procedures – that are potentially useful. Creativity can be separated from intelligence and education, and these three factors are regarded as both substitutes and complements in the productive process carried out by individuals. Creativity can also be seen as a necessary condition to adopt and react to the constant changes around us. On an individual level, there is a close relation between creativity and productivity, and creative people are even proven to be happier in general as well as more committed and self-actualized. Personality and cognitive characteristics make some individuals more creative than others, and the level of creativity is often affected by the social and organizational context (Sternberg and Lubart 1999). Poincaré made comparisons between the creativity of a mathematician and an artist in his famous work *Mathematical Creation*. The mathematician is described as an artist, rather than a scientist. Halmos makes a comparison between the creativity in mathematics with the creativity within painting: “mathematics is never deductive in its creation” – “perhaps the closest analogy is between mathematics and painting. . . Almost every aspect of the life and of the art of a mathematician has its counterpart in painting.” Sternberg and Lubart (1999) also notes that creativity is a common denominator across disparate fields: “If one wanted to select the best novelist, artist, entrepreneur, or even chief executive officer, one would most likely want someone who is creative.”

Florida (2002) identifies three types of creativity: (i) technological creativity or innovation, (ii) economic creativity or entrepreneurship, and (iii) artistic or cultural creativity. He argues that these three types are mutually dependent and that they simulate and reinforce one another. Creativity also comes with costs. It is often an uncertain process that includes the risk for failure, stress, and other negative effects. Creative ideas challenge established norms and bring disorder, which imply a risk since creative people tend to be met with resistance and skepticism. It can be very difficult to change systematic beliefs. One can even argue that the only reason that science will change is because old scientists die. Similar conditions hold for, for example, arts, music, and poetry, where orthodoxy can become a constraint on novelty and individual expression. Close interaction is needed when novel ideas are introduced in order to overcome the skepticism of the audience. Not only must new ideas be presented, they need to be accepted as well (Florida 2002). Jacobs’s (1969) saw cities as arenas for the generation of new ideas, and as ideal places for creative industries, whose production processes are related to higher risks, shorter life cycles, and often unique products.

The occupational approach differs from the more conventional human capital perspective in how skill is conceived and measures. The educational-based human capital is purely supply based, in other words, the amount of knowledge offered at the labor market. On the other hand, it says very little about how this knowledge is

being used. The creative class is a combination of supply and demand driven qualified labor. In order to be included in the creative class, you do not only have to have a certain amount of skill, knowledge, or creativity to offer at the labor market – the labor market must also be willing to pay for that kind of skill.

While human capital and creative occupations overlap, they are not the same thing. Research based on micro-data for the USA, Canada, Sweden, and Denmark illuminates this difference. For the USA, 35 % of the labor force belong to the creative class, and 29 % have a university degree. Out of everybody with a university degree, only 72 % have a creative job, and out of all creative class workers, only 59 % have a university degree (Florida 2012). Other research examined the differences between the occupational-based creative class and educational-based human capital for US metropolitan regions (Florida 2012) and finds that human capital is more related to regional income levels, while creative class is more linked to average wage levels, and also suggests that wages are more place based than income. Incomes can be earned and transferred more easily from other places (and even globally), while wage structures relate to the industrial and occupational setup in the region where the wage is being earned. Florida (2012) finds that the creative class significantly outperforms human capital in order to explain regional wage levels in Sweden.

McGranahan and Wojan (2007) find that the creative class is a strong explanatory factor not only in bigger cities but also in rural areas. However, they suggest that the measure becomes even more powerful if education, training, and library positions, as well as healthcare practitioners, are excluded in the measure. There is evidence for European regions that the creative class is significantly related to regional economic performance. Boschma and Fritsch find that creative class is a stronger explanatory variable than education-based human capital in relation to innovation and new firm formation, but that human capital is more strongly related to patenting (Florida 2012).

An important wave of recent studies has focused more on *skills* themselves. Rather than examining the occupation, there is instead a focus on the skills and knowledge required by that occupation. This research uses new data from the US Bureau of Labor Statistics O*NET database which collects detailed information on the actual skill content of work for more than 800 individual occupations. Bacolod et al. (2009) examined the association between four key skills – physical, motor, cognitive, and social skills – and found higher returns to cognitive and social skills, which in turn can help explain the decreased gender wage gap. They also observed a connection between skill type, finding social and cognitive skills to be associated with larger cities and metros. Feser (2003) identified the general knowledge requirements across occupations and the economic returns they generate. Feser also shows the need for an occupation-based analysis, where similarities and dissimilarities across occupations are taken into account and grouped in a more meaningful way, in order to understand regional development. Gabe (2009) differentiates between skill requirements and the returns they offer in private and public sectors. He also shows how spillover effects enhance earnings in metropolitan regions with higher shares of high-knowledge occupations.

Scott (2009) examined the connection between skills and regional employment, finding the largest increases in regional employment to be associated with cognitive-intensive occupations, with substantial employment declines for occupations that depend on physical skills. Florida (2012) defines three skill sets – analytical, social, and physical – and notes the increasing returns generated by analytical and social skills over time and decreasing returns by physical skill. They reinforce the key findings of Bacalod et al. (2009) regarding the concentration of analytical and social skills in larger metros. They conduct regression analysis including factors for both high-tech industry concentrations and education levels and find that analytical and social skills still are significantly associated with higher wage levels.

17.6 The Organizing Role of Place

While industrial production was organized in and around firms, knowledge-based or creative production is organized in cities. For decades, many assumed that advance in technology would underpin far-flung globalization enabling production to be broken apart and people to live virtually anywhere. Many proclaimed the end of geography, the death of distance, the decline of place, and the flattening of the world. But that is only half the story. As Porter (1990) has noted, many predicted the rise of globalization and end of place, and that confused many otherwise smart people. But the empirical fact is that more than half the world's population live in cities and urban areas, the highest at any point in history (Florida 2008). And the economic activity produced by the biggest metro areas account for a substantially greater economic value than their population size. The top ten metros, which house approximately 2.6 % of the world's population, account for more than 20 % of global economic activity (Florida 2008). Glaeser (2011) identifies cities as the world's key economic actors, indicating a triumph of the city. Cities not only make people and industries more productive, they even improve the conditions to the least well-off. Glaeser et al. (2001) suggest that this is the result of the relatively lower cost of transportation of the *latest* ideas and information, which tend to be more time-sensitive and in a higher demand of face-to-face interaction and urban density. This is in line with Keynes who, in *Essays in Persuasion*, emphasized the need for didactics and persuasion in relation to creative processes. Not only should new and innovative ideas be presented, they need to overcome the skepticism of the audience, which in practice only can be made through close interaction (Florida 2002).

As early as 1969, Jacobs leveled a fundamental critique of Adam Smith's notion of the division of labor captured in his famous pin factory example. Smith's story, she argued, emphasized efficiency. But the key to economic growth is innovation. Innovation, she continued, comes principally not from firms, but from cities which enable the constant combining and recombining of key inputs, including skilled people. While firms deepen and specialize the division of labor, cities, with their clustering force and combination and recombination of skilled individuals, give rise to new innovations and economic development.

Building on Jacobs' insight on cities (1969), Lucas (1988) modeled the importance of investment in education for productivity. His insights with respect to the engines of economic growth contributed to him being awarded the Nobel Prize. Lucas later said that Jane Jacobs was the one who should have received it for her contributions. Lucas also showed how collocation of skilled, talented, ambitious, and entrepreneurial people led to so-called human capital externalities. Having many driven people in the same locale will lead to spontaneous interaction and activities where they learn from one another, without any specific cost related to it. Lucas formalized the role of dense urban areas which localize human capital and information, create knowledge spillovers, and become engines of economic growth. Cities reduce the cost of knowledge transfer, so ideas move more quickly, in turn giving rise to new knowledge more quickly.

Caves (2000) showed how creative industries are more likely to be organized as geographic clusters of creative individuals as opposed to vertically integrated firms. Creative industries have higher levels of uncertainty and production challenges due to multiplicative production functions, where every input is non-substitutable and therefore must be present in order to produce. Further, shorter life cycles and a constant need for reinvention demand a closer interaction between consumers and producers, as well as more new skill combinations for a faster generation of new ideas. For these reasons, creative industries tend to be organized flexibly in places rather than in vertically integrated firms.

Florida (2002) focuses on the characteristics of places that attract highly skilled individuals. Building on research by, for example, Roback (1982) on migration across regions, Florida (2002) suggests that in addition to the human capital externalities and productivity and innovation enhancing functions of places, they also act on the consumption preferences of skilled individuals. This reasoning is a considerable advance over earlier theories that state that comparative advantage stems merely from business friendly environments, lower taxes, and lower overall firm costs. Clark et al. (2002) argue the regional winners will be those that maximize individuals' utilities and not just their incomes.

Glaeser et al. (2001) also examined the factors that attract skilled labor to cities and come to the conclusion that the most attractive cities are those that offer consumption rather than production. Cities with a diverse consumption of goods and services are more appealing than cities that do not. Glaeser et al. (2001) found that higher amenity cities attract more skilled labor and grow faster. This result is also in line with Florida (2012) who finds that individuals who find their communities aesthetically appealing are more satisfied with their places and that beauty is a stronger explanatory variable than, for example, job opportunities, housing markets, and high-quality public services. Florida (2012) also illustrates how place-specific characteristics, such as the ability to meet and make friends, quality of public schools, and being able to get from one place to another without too much traffic, are significantly more related to community satisfaction and the likelihood of staying in a place, even more so than economic variables, such as the ability to get a job or perceived future economic conditions, or individual characteristics.

Florida argues that skill needs to be considered not as a stock but as a flow of ideas that are highly mobile. A key factor here is low barriers to entry also referred to as tolerance (Florida 2002). Smart, talented people, whether in the form of human capital or creative class, are attracted to open and tolerant places where ideas will be accepted and can float freely between individuals. It will also improve the chances of a meritocracy based labor market, which is necessary for it to function efficiently, which Becker noted in the 1950s. Further, not only is openness and tolerance a condition for attracting talent, it is also a way of increasing the probability of turning new ideas into economic value.

Research by Inglehart finds that openness and tolerance are related to economic growth in studies covering more than 60 countries over four decades (Inglehart 1989). According to Inglehart, the best indicator of national tolerance is openness to gay and lesbian people. Florida (2002) used a similar variable, concentration of the same population group, to proxy for regional openness in the USA. Florida et al. (2008) later used it in a multivariate context and found it a significant contributor in order to explain the distribution of both highly educated and the creative class across metropolitan areas.

17.7 Conclusions

This handbook chapter has traced the skills revolution in urban and regional research. The long sweep of urban economics, regional science, and economic geography research has focused on the firm and industry as the key unit of analysis. But the past couple of decades have seen increasing concern for skills. The skills revolution is rooted in the changing nature of the economy – from an older industrial economy to a newer one based upon knowledge, innovation, and skill. Research has focused on the role of human capital, the creative class and occupational classes, and on skills themselves. The skills revolution has also informed increased concern for and understanding of how places operate. Research has focused on the role of amenities, universities, diversities, and other characteristics of places in accounting for the dispersion, uneven location, and geographic mobilization of skills.

We suggest it is time to get beyond the either/or focus on firms and skills, and industries and places. Both are veritable flip sides of the same analytic coin. The proverbial chick and egg problem is in our view a false dichotomy. Both firms and skills, and industries and places play a key role in and are required for regional development, a complex iterative development process. An important task for future research is to bring these foci together. With recent conceptual advances combined with the availability of micro-data on skills and firms, it is now time to bring the two together. An important line of future research needs to identify the ways firms and skills work together to structure regional growth and development. The skill revolution has been a powerful one, advancing our understanding of the importance of skills, their growing divergence over space, and the way they power

regional growth and development as well as identifying the key aspects and functions of place. Future research promise even greater advances of how firms and skills come together to power innovation and growth. It is an exciting time to be working in this incredibly rich field.

Abstract

This chapter outlines two models for analyzing the relationship between infrastructure and regional growth and discusses relevant empirical examples. The first model adopts a standard spatial equilibrium approach and shows that the effect of new infrastructure on regional activity depends on its direct impacts on local productivity, local amenities, and the price of non-traded goods, especially housing. These impacts are determined, in part, by how existing characteristics of the region complement the specific investment. If infrastructure contributes positively to real amenity-adjusted net wages, the local region increases its attractiveness, and the result is an influx of firms and individuals to the region. In turn, this has dynamic effects that may amplify or attenuate the initial growth impetus. It is also possible that an infrastructure project contributes negatively to real amenity-adjusted net wages, imparting a negative influence on equilibrium regional activity. The second model treats

a major infrastructure investment as a real option that gives private sector developers the option, but not the obligation, for further development. The value of this option must be included by authorities when assessing benefits of a new infrastructure project. They need to judge the direct private sector responses to an investment plus the indirect equilibrium responses under alternative states of nature. The model shows that for a major infrastructure project, as in the case of other real options, a certainty equivalent approach is generally inadequate for investment analysis since that approach may underestimate the benefit of a new project when future states are uncertain, learning occurs, and decision-making is sequential.

18.1 Introduction

Investment in major infrastructure items is costly. Costs are predominantly borne up front, while benefits may not be apparent for some years after the project's commencement. Benefits may, however, last for many decades. They can accrue to the region's initial inhabitants and may induce migration flows so accruing also to people shifting from outside the region. Moreover, there may be spatial spillovers in the form of positive or negative impacts on other regions, particularly nearby ones.

The scale, and even the nature, of benefits is frequently difficult to assess *ex ante*, so there are risks both of underinvestment (especially if investment authorities are risk averse) and of overinvestment ("white elephant" projects). Given the difficulties in planning major infrastructure investments, international comparisons (such as the World Economic Forum's *Global Competitiveness Report*) show that regions and countries have widely disparate standards of infrastructure.

This chapter sets out two analytical frameworks that can be used to assess impacts of infrastructure investments on regional growth outcomes. Examples of empirical literature that illustrate aspects of the frameworks are included. The two frameworks correspond to differing treatments of uncertainty. The first is a framework based on spatial equilibrium. It details key responses that must be assessed when analyzing the impact on regional growth of a new infrastructure investment. These include direct and indirect impacts of the new infrastructure on the level and growth of regional activity and population.

The spatial equilibrium approach is essentially a certainty equivalent approach with clearly defined responses of variables to the investment. The second framework, based on real options theory, is relevant in a world with uncertainty, learning, and sequential decision-making. In these circumstances, an infrastructure investment can provide an option, but not an obligation, for future development to contribute to regional growth. An illustrative model is outlined showing the implications of these conditions for infrastructure investment decisions and how these decisions may differ from those derived from a certainty equivalent cost benefit analysis.

We define key terms in the next section prior to describing the two frameworks. A short set of observations linking the two frameworks concludes.

18.2 Terminology: Infrastructure, Regions, and Growth

Infrastructure is a widely used, but imprecise, term. Gramlich (1994) defines infrastructure as “large capital intensive natural monopolies such as highways, other transportation facilities, water and sewer lines, and communications systems.” Most examples are publicly owned, but some are owned privately. Broader definitions of infrastructure exist that include human capital investment and research and development (R&D) capital. The term is used in this chapter to include capital-intensive investments that service multiple users. The definition is extended beyond Gramlich’s narrow definition to include large-scale capital-intensive amenity investments (e.g., a major waterfront redevelopment or a hospital) and large-scale knowledge centers such as a major university.

Region describes a spatial unit that may or may not correspond to an administrative unit. A region may refer to a country within a larger international grouping (e.g., Denmark within Europe). A state or administratively defined city may constitute a region within a country. An urban area or labor market area (“labor shed”) may constitute a region that crosses administrative boundaries (and the region may even stretch across a country border). The focus here is on economic rather than administrative relationships. Impacts of infrastructure investment are more likely to spill over across administrative rather than economic boundaries (e.g., a large county-funded parking building may affect commuters from surrounding counties).

In analyzing *growth*, we must define the measure that is growing and define the time horizon over which growth proceeds. Regional growth analysis typically deals either with production or employment (with the latter alternatively measured by labor force or population) as the measure that is subject to growth. Generally, all of these measures will be growing jointly. The time horizon is important for distinguishing between a level shift in activity (achieved over some finite-time period) and a step shift in the long-term rate of economic growth associated with endogenous growth mechanisms (Aghion and Howitt 1998). It is frequently difficult to distinguish empirically between the two cases. This is particularly so where amplification mechanisms exist in the case of a level shift that, over a long period, cause a multiplicative shift in activity relative to the initial shock, but nevertheless leave the long-term growth rate unchanged once a new higher equilibrium is attained.

18.3 Infrastructure and Growth: A Spatial Equilibrium Model

The concept of spatial equilibrium is at the heart of regional science analysis. Roback (1982), building on Rosen (1979), provided a model in which agents (firms and individuals) choose between locations to maximize their profit or utility. Firms trade off productivity against labor and rental costs to maximize profits; individuals trade off amenities and income (wages) against living costs, especially

costs of non-tradables such as housing. The resulting migration of firms and individuals across regions leads to changes in wage and land costs that, in equilibrium, equate the net benefits of locating in one region to those in each other region. A change in any variable that affects productivity and/or amenities, such as a new infrastructure investment, results in a change in population and prices so as to restore spatial equilibrium.

The spatial equilibrium concept can be summarized, as in Glaeser and Gottlieb (2009), by assuming that the utility level of individuals in any region i , $U(G_T^i, G_N^i, \theta^i)$, is determined by their consumption of traded goods (G_T^i), non-traded goods (G_N^i), and local amenities in region i (θ^i). Given the individual's budget constraint and the assumptions that traded goods prices follow the law of one price and that non-earned income is unaffected by location, utility can be expressed by the indirect utility function, $V(Y^i, P^i, \theta^i)$, where Y^i is locally earned wage income and P^i is the price of non-traded goods (including housing services). Both Y^i and P^i are endogenous and so reflect the population and productive characteristics of a region. In turn, these features will be influenced by the level and type of infrastructure within a region. In a spatial equilibrium, $V(Y^i, P^i, \theta^i) = \bar{U}$, where \bar{U} is the (equal) level of utility that would be obtained by locating in any other region.

We adopt a generic spatial equilibrium model to link regional growth outcomes to infrastructure. The generic model builds on the reduced form model of Overman et al. (2010), with the role of infrastructure made explicit. We concentrate on outcomes for a specific region, holding constant outcomes for other regions. The model can be extended to multiple regions to take account of the possibility that other regions' outcomes may be affected by decisions in the region under study. If the region under consideration is small relative to the others, these spillover effects may be small. Hence, for expositional purposes, the spillover complication to the simple model is unnecessary; we return to this issue in interpreting the model's properties and predictions.

The model comprises three reduced form relationships – determining wages, house prices, and amenity benefits, respectively. Let w be the after-tax wage received by an individual in the region, L be the region's labor force (which is assumed proportional to the region's population), and I be the level of infrastructure available in the region. In interpreting the model, we will at times treat each of L and I as a vector of alternative types of labor and infrastructure inputs, respectively, but the basic model treats each as a scalar.

The first relationship, reflecting the regional production function, is given by

$$w = W(L, I) \tag{18.1}$$

The signs of the partial derivatives (W_L and W_I) in Eq. (18.1) are both indeterminate. (Unless otherwise stated, partial derivatives are evaluated within the neighborhood of the initial equilibrium position.) A diminishing returns production environment has $W_L < 0$ since full employment can, ceteris paribus, only be achieved with lower wages given a larger labor force. Conversely, $W_L > 0$ for

a region with increasing returns to scale. This may be the case, for example, within a city that has unexploited agglomeration externalities. The sign of W_I is determined by the productive benefits of a new infrastructure project relative to the cost of the project. A new project that has costs higher than its benefits (i.e., a benefit cost ratio of less than one) and that is financed from within the region (either through added taxes or by raising debt) will cause w to fall (Coleman and Grimes 2010), that is, $W_I < 0$. An investment with a benefit cost ratio in excess of one has $W_I > 0$.

The second relationship relates house prices (or, more generally, prices of non-traded goods and services, which also includes commuting costs), denoted h to the labor force and to the level of infrastructure:

$$h = H(L, I) \quad (18.2)$$

We assume that $H_L > 0$ so that greater population places pressure on land and house prices for a given quality, where location of a property in relation to the CBD and amenities is included as a quality attribute. Greater population causes a city to expand if there is a new supply of lower priced housing on the periphery, but the true housing cost (embodying both direct housing costs plus transport costs to work and amenities) is assumed to rise even where the direct (quality-unadjusted) housing price falls. By contrast, we assume that $H_I < 0$, so that a new infrastructure project reduces the true housing cost at a given location once changes in accessibility costs are included. An example is a new transport route that reduces the cost of commuting from an existing location to work or that improves access to amenities. Another example is a new broadband connection that reduces the cost of accessing some services.

The third relationship relates amenity benefits, a , to labor force and infrastructure provision:

$$a = A(L, I) \quad (18.3)$$

The sign of A_L is indeterminate. A larger population facilitates improved amenities through increasing returns to scale. For example, a larger city may be able to afford an opera house or professional sports team, whereas a smaller city is unable to do so. However, a larger population may result in congestion externalities that reduce the amenity value of a city. There is also a possibility that a larger and more diverse population increases innovation and technological change and thereby the long-run growth rate of the region. Many new infrastructure investments will enhance amenity benefits for individuals (e.g., a better road to the beach, a new opera house, or improved broadband connectivity); for these investments, $A_I > 0$. However, some forms of new infrastructure investment (such as a new airport runway) will reduce amenity benefits for local residents and, for these investments, $A_I < 0$. For simplicity, the discussion below assumes that $A_I > 0$, but the model can equally be used to analyze the impacts of an investment that reduces amenity values.

Following Overman et al. (2010), an individual's utility, u , is defined as "amenity-adjusted net wages" deflated by living costs:

$$u = \frac{aw}{h} = \frac{A(L,I)W(L,I)}{H(L,I)} \quad (18.4)$$

In spatial equilibrium, $u = \bar{u}$, where \bar{u} is the utility that can be gained in a reference region. We hold \bar{u} constant in the analysis that follows, although this assumption can be relaxed in both theoretical and empirical work. Given the requirement that $u = \bar{u}$ in equilibrium, any infrastructure investment that alters any of a , w , or h must have an offsetting equilibrium effect on one or more of the other two variables. For instance, an infrastructure project that directly raises productivity, and hence w , must result in either a reduction in amenity values, a , or an increase in local living costs, h , at the new equilibrium.

To demonstrate this formally, differentiate u with respect to I and set the result equal to zero (since \bar{u} remains unchanged following a change in the region's level of infrastructure). In doing so, we treat L as endogenous. Given that we are interested in the growth effects of a change in I , our focus is on dL/dI , the change in labor force for a small change in infrastructure. The result is shown in Eq. (18.5):

$$dL/dI = \frac{\frac{w}{h}A_I + \frac{a}{h}W_I - \frac{aw}{h^2}H_I}{\frac{aw}{h^2}H_L - \frac{w}{h}A_L - \frac{a}{h}W_L} \quad (18.5)$$

Expression (18.5) enables us to analyze a variety of channels through which infrastructure affects regional activity. Assume initially that diminishing returns to scale exist in production and that extra population causes net congestion costs; thus, each of W_L and A_L is negative. In that case, the denominator of Eq. (18.5) is positive. Furthermore, if the productive benefits of the new infrastructure outweigh its costs, so that W_I is positive, then the numerator is also unambiguously positive. Under these conditions, an increase in infrastructure results in an increase to the local labor force (and hence population and activity) in the region.

We can relax the assumption that W_I is positive and still obtain the same (signed) result provided that A_I and/or H_I are sufficiently large in absolute value to leave the numerator positive. Thus, even if the infrastructure is not net positive for local production, provided it increases amenity values or decreases living costs sufficiently, it will still raise utility and so induce a population inflow to the area. Examples of such infrastructure projects may be a waterfront redevelopment (improved amenity) or a new transport link between housing and work locations (i.e., a reduction in the full cost of housing). The ensuing improvement in amenities, or reduction in housing costs, leads to a larger labor force through net inward migration; the required increased production to employ the larger workforce is achieved through a lower wage rate. In the case of improved amenities, people accept the lower wages so that they can remain living in a more desirable region. In the case of reduced housing costs following an infrastructure improvement, the

reduction in housing costs enables wages to fall while leaving people with the same real incomes as before the investment.

The corollary of this analysis is that a poorly chosen infrastructure project (i.e., one that has costs exceeding its productive, amenity plus housing benefits) will result in a *decline* in local population despite its potential to service a larger population. This result occurs since the cost of servicing the project exceeds the benefits it brings. This inefficiency case is particularly germane where all costs are borne by the local region and so are reflected in disposable incomes, w . As an example, Siegfried and Zimbalist (2000) provide evidence that the construction of large sports stadia in the United States may have caused declines in local activity and local real incomes after controlling for other factors affecting regional outcomes. This example also illustrates the potential for an infrastructure investment to affect the composition of population in a region through a Tiebout-sorting mechanism (e.g., sports fans may relocate to be near a stadium, whereas other citizens may depart the local area). While potentially important, we abstract from sorting issues in our analysis.

If, for an inefficient project, the infrastructure costs are borne elsewhere (e.g., by central government), the benefits are internalized within the region, but the costs are not internalized to that region and so are not reflected through a reduction in w . The result in this case is an expansion in L , but this expansion is inefficient due to the lack of internalization of costs to the region. Belich (2009) documents substantive cases of inefficient infrastructure investments (canals and railroads) in the new settler colonies, such as Canada, in the nineteenth century, with adverse economic and financial effects.

We now turn attention to the denominator of Eq. (18.5), assuming that the numerator is positive. Differing parameters in the denominator have the potential to cause significant multiplicative dynamic effects following an infrastructure investment. Consider an economy that exhibits increasing returns to scale relative to one with constant returns. In the increasing returns case, W_L is positive; this may be due to a larger labor force lifting overall wages through agglomeration effects (Fujita et al. 1999). Provided W_L is not “too large,” the denominator remains positive but declines in size relative to the constant returns to scale case, so that dL/dI increases. Thus, regional growth in response to an infrastructure investment is greater where agglomeration forces (positive W_L) are at work compared to an economy with no such forces. The importance of this aspect has been emphasized, especially in the United Kingdom, in recent official approaches to transport project assessment techniques (e.g., Eddington 2006).

A similar result occurs if net amenity benefits are positively linked to region size (i.e., positive A_L). In this case, the improvement in the range or quality of amenities as a region grows outweighs congestion costs of that growth. An increase in infrastructure provision supports a larger population, and this, in turn, enhances the attractiveness of the region which spurs further population growth.

A highly elastic housing supply (low absolute H_L) facilitates a larger population response to an infrastructure investment compared with the case where housing supply is limited and prices rise sharply as population expands (Glaeser et al. 2005).

Thus, there is a complementarity between new infrastructure provision and flexible zoning and construction regulations that enable a region to grow strongly in response to new infrastructure.

From Eq. (18.5), higher values of A_L and W_L , and/or a lower value of H_L , induce a heightened increase in u , leading to a greater inward migration response. Provided the denominator of Eq. (18.5) is positive, the offsetting contributions of the three factors that influence amenity-adjusted real wages ensure that the change in population following an infrastructure project is bounded. For instance, an increase in utility arising from improved amenities following a new infrastructure investment will be offset by an increase in housing costs and/or a decrease in wages as population and activity increases.

Population adjustment following an infrastructure project will, in practice, not be completed immediately. Instead, we may postulate a migration function such as

$$m = M(u - \bar{u}) \quad (18.6)$$

where m is defined as dL/dt , t represents time, and $M_u > 0$. Thus, people and firms migrate to a region for as long as location in that region yields higher utility than locating elsewhere. The partial adjustment mechanism in Eq. (18.6) may reflect nonlinear costs of adjustment. Expression (18.6) translates the equilibrium adjustment response analyzed above into a regional growth response. For a given investment project and a given migration sensitivity, the larger is dL/dI , the larger and the longer will be the growth phase following the project, until a new equilibrium is reached. Once this new equilibrium is reached, the growth rate will return to the initial path that existed prior to the infrastructure investment, albeit with activity and population at higher levels.

The analysis has so far considered only the stable case, where the denominator of Eq. (18.5) is positive, so that there are offsetting gains and losses from an expansion that cause the regional response to an infrastructure project to be bounded in the neighborhood of the initial equilibrium. If, instead, the denominator is negative, there are insufficient offsetting forces to limit region size within the neighborhood of the initial equilibrium. Thus, utility keeps rising as population expands in response to an initial upward shift in infrastructure provision.

This situation corresponds to one of explosive growth which continues until the population has grown sufficiently to bring about offsetting forces to curb the growth. Thus, the initial response to a new project may be a population influx that induces amenity and productive benefits that are not outweighed by steeply rising housing costs. This may be because the infrastructure has been planned so as to service a large area of developable land. However, once this developable land is fully utilized and/or once congestion costs rise as the infrastructure is used intensively, then H_L rises and/or A_L falls, so that dL/dI is once again stable and u is eventually equated to \bar{u} .

During the intervening period, the migration response in Eq. (18.6) operates, and a prolonged regional growth period may arise following an initial investment. The long-term equilibrium result is a “spikey” landscape in terms of concentrations of

infrastructure and economic activity (Florida et al. 2008). Some tightly defined regions grow to have dense concentrations of population and economic activity serviced by a comprehensive set of infrastructures, while others have low population density, sparse economic activity, and little infrastructure.

Shenzhen, in the Pearl River delta of Southeastern China, is a recent example of explosive development coupled with substantive provision of publicly provided infrastructure, followed by more gradual growth. The city expanded from a population of 350,000 in 1982 and 1,200,000 in 1990 to 7,000,000 in 2000. Its growth then slowed to reach approximately 10,000,000 in 2010. While still growing in the decade to 2010, the absolute and percentage growth rates both fell relative to the preceding decade reflecting the ending, or at least the slowing, of the explosive growth period.

The type of infrastructure, as well as its overall level, can have an important bearing on regional growth patterns. It is helpful to consider I in our model as a vector of infrastructure inputs, each element of which has differing direct (and indirect) impacts on wages, amenities, and house prices. An infrastructure investment designed to service a new industrial mill may be consistent with a diminishing returns to scale environment ($W_L < 0$). By contrast, the presence of a research university is positively associated with high value R&D and patenting activity locally (O'hUallachain 1999). This is particularly the case in a city with strong availability of skilled labor (Ceh 2001). High R&D activity and a high proportion of skilled labor, in turn, may be associated with strong regional growth through a variety of endogenous growth mechanisms (Aghion and Howitt 1998) so that $W_L > 0$.

The importance for regional growth outcomes of complementarities between the new infrastructure and the factors already in the region is highlighted also by Forman et al. (2012). Advanced Internet provision in the USA raised incomes in counties that already had high incomes, an educated workforce, dense populations, and IT-intensive industries. It had no effect on incomes in counties without those characteristics. Thus, one cannot simply extrapolate the findings of an infrastructure's impact on one set of regional outcomes to other regions. The characteristics of the region influence the sign (and size) of the key parameters in Eq. (18.5), and the impacts even of the same type of infrastructure can differ markedly across regions according to regional characteristics.

One of the key insights of the spatial equilibrium model is that any increase in amenity-adjusted wages following an infrastructure project must be matched by a proportionate increase in local prices, including land. Haughwout (2002) demonstrates that, under certain conditions, the aggregate increase in regional land values attributable to an infrastructure project is the appropriate measure of the benefits of that project. The fixed factor (land) reflects all net benefits of the project since the net return to each mobile factor (labor and capital), and the price of traded goods are all set externally and so do not change in response to the local infrastructure investment.

This approach to measuring benefits of an infrastructure project captures amenity as well as productive benefits. It therefore provides a more complete approach

to measuring benefits than captured by earlier methods that relied on regional aggregate production functions (Aschauer 1989) or regional aggregate cost functions (Morrison and Schwartz 1996). These earlier approaches are unable to capture the benefits of new infrastructure that accrue through all amenity, production (wage), and housing channels. Similar difficulties are faced in conventional cost benefit analyses that sum postulated benefits to arrive at an estimated benefit total. An example of the land value approach to measuring benefits of a new infrastructure investment is Grimes and Liang (2010) who analyzed the net value attributable to a new motorway link. In their application, the land value approach gives a considerably higher estimate of value creation than does a conventional transport cost benefit analysis.

18.4 Causality and Spatial Spillovers

The generic model developed above is based on spatial equilibrium relationships. A key issue in the analysis of the linkage between infrastructure and regional growth is whether the relationship between these two variables is purely associative or whether it is causal and, if it is causal, which is the direction of causality.

To understand the importance of this issue, consider a set of regions that are in spatial equilibrium, each with infrastructure at optimal levels given the features of each region (i.e., given the production relationships, level of natural amenities, and land availability). Now consider the impact of an increase in infrastructure in one region, j . If infrastructure was previously at its optimal level, an addition to region j 's infrastructure will raise costs (taxes) by more than it contributes to productivity plus amenity value. The numerator of Eq. (18.5) is negative for any level of infrastructure beyond the initial optimal level, so an infrastructure increase causes utility to fall from $u_j = \bar{u}$, leaving $u_j < \bar{u}$. The result, from Eq. (18.6), is an outflow of migrants from region j , that is, negative regional growth driven by the infrastructure investment.

Now consider a region, k , in which, initially, $u_k = \bar{u}$, but where infrastructure is at a suboptimal, constrained level. The suboptimal infrastructure level may have arisen because of a lagged response to some other factor that has raised the productive or amenity potential of the region. In this case, a new infrastructure investment is an endogenous response to the external factor that has caused the productive or amenity potential of the region to increase. The numerator of Eq. (18.5) is positive at the initial infrastructure level and so an expansion of infrastructure initially causes $u_k > \bar{u}$. In turn, this causes inward migration so that population and activity both rise in the region.

The two cases will initially be observationally equivalent in terms of migration patterns and growth (since both are in equilibrium with $u_j = u_k = \bar{u}$). However, in the former case, a new infrastructure investment causes population and activity to fall; in the latter case, a new infrastructure investment facilitates an increase in population and activity. These examples make it clear that there is no consistent causal relationship between new infrastructure and regional growth. The new

infrastructure must raise amenity-adjusted (net) wages and/or reduce housing (or other non-traded) costs to induce regional growth. Even in the second case (region k), it is questionable whether the new infrastructure can be said to *cause* regional growth. Regional growth would certainly be constrained without the new infrastructure, but it is best to consider the increase in infrastructure as codetermined with regional activity, rather than causing activity to rise.

The endogeneity of infrastructure makes it difficult to extract empirical estimates of the impact of an infrastructure investment on regional growth outcomes. Wu and Gopinath (2008) attempt to do so by instrumenting the endogenous variables (including infrastructure) in their three-stage least squares spatial model. In accordance with the previous analysis, they show that treating road density (their infrastructure measure) either as exogenous or endogenous has material effects on estimates of the impacts of other factors on regional wage, price, and activity outcomes.

The key practical difficulty in using an instrumental variables approach is to find strong instruments that affect not only the level of regional infrastructure but also its change over time. In this respect, models relying solely on fixed regional characteristics (such as climate or lagged road density) that may predict the *level* of infrastructure across regions do not generally contain sufficient information to predict *changes* in infrastructure. From a policy perspective, however, it is the impact of a change in infrastructure provision that is of interest. Use of exogenous instruments that contain time variation (e.g., Wu and Gopinath's use of an "agricultural net return" variable) provide greater promise as instruments in this respect than fixed regional characteristics.

The Wu and Gopinath analysis is useful also in that they test for spatial lags in the relationship between regional outcomes and infrastructure investments. They find positive spatial autocorrelation in human capital supply, developed area supply and demand, and road density. Thus, a major infrastructure development in one region spills over positively into neighboring regions for these variables. It may nevertheless be the case elsewhere that spatial lags are negative for certain types of investment (i.e., a displacement effect of infrastructure on activity). Hence, we cannot generalize about the spatial impact of infrastructure investment on neighboring regions' growth from analysis of particular examples.

An alternative approach to analyzing the causal impact of infrastructure investment is to examine the impacts of a natural experiment involving an infrastructure project. One such situation is where new infrastructure has been constructed for a purpose that is exogenous to the region concerned. Coleman (2012) examines the impacts of the Erie Canal on rural New York population and activity. The canal was constructed primarily to link New York City with Chicago and the Great Lakes, not specifically to service rural New York communities, so is a natural experiment with respect to these latter communities. The analysis shows that the decreased cost of transport due to the canal caused (a) existing households to switch gradually from home production, (b) an influx of migrants who were more oriented toward market production than incumbent households, and (c) a delayed copying by incumbents of migrants' production patterns. In this case, the relevant characteristics of the vector

L are the sources of the population, with knowledge and/or skills varying according to prior location. The influx of migrants and changes in market production following the canal's completion are consistent with the spatial equilibrium approach coupled with a partial adjustment mechanism. Given the exogeneity of the canal to these rural communities, the canal can be regarded as having a causal role in determining the patterns of growth in these regions.

Another natural experiment is documented by Duflo and Pande (2007) who examine productivity impacts of large irrigation dams in India. The analysis uses river gradient as an instrument for the choice of dam site, and contrasts outcomes above and below a dam following its construction. Downstream agricultural production increases, and its volatility falls, as a result of a dam. In contrast, upstream production shows no significant increase, whereas its volatility rises, causing increased hardship for upstream farmers. Given the exogenous choice of dam location, both impacts can be considered causal responses of production to the dam's construction. The negative impact of a dam on upstream farmers is an example of a negative spatial spillover that needs to be accounted for in assessing the overall benefits of the infrastructure project.

18.5 Infrastructure as a Real Option

The analysis in previous sections is formulated in terms of a deterministic or certainty equivalent concept of equilibrium. As an *ex post* concept, this approach is useful for understanding how variables have adjusted to infrastructure investments. The approach may also be appropriate for *ex ante* consideration of the regional growth impacts of small infrastructure projects with well-defined outcomes. However, most major infrastructure projects are built to last a long time and the future environment as well as future outcomes may be highly uncertain. *Ex ante*, therefore, it is not just the size but also the nature of benefits that may be difficult to determine.

For instance, public authorities may have reasonable *ex ante* estimates of the productivity impacts of a small infrastructure investment that is closely coordinated with a specific private sector development. In this case, the authority's estimates of responses, such as W_I in Eq. (18.5), may be sufficient to underpin its investment decision. However, the quality of information about potential private sector responses may be much less complete for infrastructure investments that are capable of inducing broader impacts. An example is the difficulty in predicting firm and household responses to widespread public provision of fiber-optic cable for ultrafast broadband services (Grimes et al. 2012). The Erie Canal project, cited in Sect. 18.4, is an example in which the canal-building authorities were unlikely to have known in advance that production would change in rural New York communities as a result of building the canal.

In such circumstances, a major infrastructure investment may create a real option for alternative development paths (Miller and Lessard 2008). As is the case for a financial option, there is no obligation for (private or public) developers

to make any specific use of the development option, but the value of the option may nevertheless materially influence the decision of whether or not to invest.

In analyzing infrastructure projects that create new development opportunities, we apply techniques derived from real options analysis (Dixit and Pindyck 1994; Guthrie 2009). Dixit and Pindyck show that a present discounted value analysis of cash flows (or of utilities within a broader cost benefit framework, as adopted in Sect. 18.3) may seriously distort investment decisions relative to the optimum under certain circumstances. The key combination of circumstances that makes real options analysis indispensable is where (a) uncertainty exists about future states of the world, (b) learning occurs about these states over time, and (c) future decisions can be made based on updated information about these states. The example that follows illustrates insights that can be gained through real options analysis. While simple, it demonstrates how incorporation of real options analysis can substantively change infrastructure investment decisions under conditions of uncertainty relative to decisions made under the certainty equivalent framework adopted in Sect. 18.3. As in Sect. 18.3, we assume that the public infrastructure investor adopts the perspective of social planner and wishes to invest where aggregate benefits exceed aggregate costs so that utilities are raised.

Consider a public sector infrastructure provider that has the opportunity to build a bridge that would open up a large new area for development. We adopt a three-period model ($t = 0, 1, 2$) in which the bridge can be built in $t = 0$, or not at all (“period” may refer to multiple years). This timing restriction is made so that we do not have to consider the potential option value of delaying the infrastructure investment (Dixit and Pindyck 1994); nevertheless, the generality of the example transfers to a model where timing of the infrastructure project is also a choice variable.

In each period, there is uncertainty about future states of the world, but learning occurs as time proceeds. If the bridge is not built, the (utility) payoff in each of $t = 0, 1, 2$ is normalized to 0. The cost of the bridge is X and, assuming no immediate benefits during construction of the bridge, the net payoff in $t = 0$ is $-X$ if the bridge is built. Henceforth, we consider payoffs on the assumption that the bridge is built. We assume that the private sector can develop the new area at $t = 1$ if and only if the bridge is built.

If the private sector proceeds with development in the new area following construction of the bridge, this development will induce growth in the population, labor force, and employment of the city as analyzed in Sect. 18.3. We assume that this growth is sourced from outside of the region of analysis. Private development only occurs in $t = 1$ if it is expected to be profitable over the life of the development (i.e., over $t = 1, 2$).

We can model the resulting choices and outcomes equivalently through a (visual) decision tree approach or by adopting a payoff matrix approach. While slightly more complicated, the latter approach enables extensions to more complex analytical problems and so is the approach adopted here. Following Guthrie (2009), news about the state of the world in $t = 1$ is assumed to be either “good” or “bad.” Similarly, a second set of news emerges about the state of the world at $t = 2$ that can be either good or bad. News about $t = 1$ ($t = 2$) is only revealed during $t = 0$ ($t = 1$),

Table 18.1 Payoff matrices for multistage investment

A: Payoffs $Y(i,t)$ for $[B,N]$			
i	t (period)		
	0	1	2
0	$Y(0,0)$	$Y(0,1)_N$	$Y(0,2)_N$
1		$Y(1,1)_N$	$Y(1,2)_N$
2			$Y(2,2)_N$

i is the number of “bad” events occurring prior to period t
 $[B,N]$ indicates that the bridge is built but no private development takes place

B: Payoffs $Y(i,t)$ for $[B,G]$			
i	t (period)		
	0	1	2
0	$Y(0,0)$	$Y(0,1)_G$	$Y(0,2)_G$
1		$Y(1,1)_G$	$Y(1,2)_G$
2			$Y(2,2)_G$

i is the number of “bad” events occurring prior to period t
 $[B,G]$ indicates that the bridge is built and private development takes place

and so is not known at the time the bridge investment decision has to be made. The private sector development choice occurs at the start of $t = 1$ following the first set of news but prior to the second. Table 18.1 shows two payoff matrices. Table 18.1A shows payoffs by period and state of the world if the private sector does not develop. Table 18.1B shows payoffs if the private sector chooses to develop. $[B,N]$ indicates that a public sector decision to build the bridge was taken $[B]$ but that the private sector decided not to further develop the area $[N]$. $[B,G]$ indicates that the public decision to build the bridge and the private decision to develop (grow) the area $[G]$ are both taken.

Payoffs are state-dependent. The state of the world in t is summarized by i , the number of bad news events that have occurred prior to t . At $t = 0$, $i = 0$ since there have been no prior bad news events. At $t = 1$, i can take the value of zero (no bad news event during $t = 0$) or one (one bad news event). At $t = 2$, i can be zero, one, or two. The payoffs to the bridge investment in each period decline as the state of the world worsens (i.e., as the number of prior bad news events increases).

The payoff matrices have elements $Y(i,t)$, each representing the payoff corresponding to the number of prior bad news events (i) at period t . For each of the $[B,N]$ and $[B,G]$ cases, the initial period payoff is $Y(0,0) = -X$, being the cost of the bridge project. For the $[B,N]$ case (the bridge is built but no subsequent private sector development takes place), $Y(0,1)_N > Y(1,1)_N$. If private sector development occurs in $t = 1$, that is, $[B,G]$, the net payoffs (after deducting the costs of private development) in $t = 1$ have the property that $Y(0,1)_G > Y(1,1)_G$.

After $t = 1$ (i.e., after the private sector development decision has occurred), further news is revealed. Thus, in $t = 2$, there are three potential states of the world ($i = 0,1,2$). If no private sector development has occurred, the payoffs in $t = 2$ corresponding to $i = 0,1,2$ are $Y(0,2)_N$, $Y(1,2)_N$, and $Y(2,2)_N$, respectively,

where $Y(0,2)_N > Y(1,2)_N > Y(2,2)_N$. If private sector development occurs, the respective payoffs in $t = 2$ are $Y(0,2)_G$, $Y(1,2)_G$, and $Y(2,2)_G$, where $Y(0,2)_G > Y(1,2)_G > Y(2,2)_G$.

We assume that $Y(0,2)_G > Y(0,2)_N$ so that private sector development is worthwhile where two good states of nature have emerged. Furthermore, we assume that $Y(1,2)_N > Y(1,2)_G$ and $Y(2,2)_N > Y(2,2)_G$ so that private sector development is not worthwhile where at least one bad state of nature occurs. The more pronounced negative outcomes given poor states of the world when private sector development proceeds (relative to a situation where development does not proceed) reflect the extra costs involved in expanding the city boundaries through the infrastructure investment when it would have been preferable, *ex post*, to have remained within the original boundaries. The larger benefit attributable to development when two good states have occurred ($i = 0$) reflects positive returns to expansion when that expansion is supported by a sequence of good news events.

A brief note is useful here about the specification of the payoffs. Each payoff is deterministic once the (i,t) combination is revealed. For instance, the payoff for $[B,N]$ with two bad outcomes is known to be $Y(2,2)_N$. This payoff is the utility payoff (corresponding to u in the previous analysis, so accounting for amenity, productivity, and local cost impacts) at $t = 2$ in state of the world $i = 2$. The consumption capital asset pricing model (Breedon 1979) can be used to assess the utility payoff for any dollar return. A corollary of measuring the payoffs in utility terms, where each payoff is deterministic once the (i,t) combination is known, is that the real risk free rate, r , is the appropriate discount rate to use to discount future payoffs to the present (Guthrie 2009).

The payoff matrices from Table 18.1 can be used to perform a present discounted value of utility (ΣDVU) analysis, akin to a discounted cash flow analysis, as would typically be done for a cost benefit analysis. In order to do so, we need to specify the per period discount rate (r), and we must specify the probability (p) of each news event (i.e., each state transition) being bad. Table 18.2 provides an example of payoffs corresponding to the elements of Table 18.1. The net discounted utility to $t = 0$ corresponding to this example is shown beneath the table. The calculation uses a per period discount rate of $r = 0.04$ and a probability of a bad news event each period of $p = 0.5$.

In a certainty equivalent world, the analysis proceeds by calculating whether either of the $\Sigma DVUs$ is positive and, if so, choosing the path which yields the larger discounted utility. If no path yields a positive ΣDVU , then the infrastructure should not be built. In the first case (the bridge is built but no further development proceeds), the *ex ante* discounted utility is negative (-1.43 to two decimal places).

In the second case (both the bridge and private developments proceed), the *ex ante* discounted utility is again negative (-0.31). Thus, *ex ante*, neither a single-stage nor a two-stage development is warranted given a certainty equivalent analysis. A standard methodology will reject the bridge project because it yields a negative ΣDVU (i.e., the benefit cost ratio is less than unity), and the negative ΣDVU pertains to the infrastructure investment whether or not the subsequent private development is undertaken.

Table 18.2 Payoff matrices: example

A: Payoffs $Y(i,t)$ for $[B,N]$

i	t (period)		
	0	1	2
0	-1	2	1
1		0	-1
2			-5

i is the number of “bad” events occurring prior to period t
 $[B,N]$ indicates that the bridge is built but no private development takes place

The sum of discounted utilities (ΣDVU) is given by
 $\Sigma DVU = -1.43 \cong (1)(-1) + [(0.5)(2) + (0.5)(0)]/1.04 + [(0.25)(1) + (0.5)(-1) + (0.25)(-5)]/1.04^2$

B: Payoffs $Y(i,t)$ for $[B,G]$

i	t (period)		
	0	1	2
0	-1	1	25
1		-1	-5
2			-12

i is the number of “bad” events occurring prior to period t
 $[B,G]$ indicates that the bridge is built and private development takes place

The sum of discounted utilities (ΣDVU) is given by
 $\Sigma DVU = -0.31 \cong (1)(-1) + [(0.5)(1) + (0.5)(-1)]/1.04 + [(0.25)(25) + (0.5)(-5) + (0.25)(-12)]/1.04^2$

However, certainty equivalent analysis misses the value of the option that the bridge investment creates. An option provides the opportunity, but not the obligation, to exercise an investment choice in future. In this example, the private developers, having observed the value of i at $t = 1$, have the option at $t = 1$ of choosing whether or not to invest in developing the area opened up by the bridge, but not the obligation to do so.

To examine the worth of the option, a value function approach is adopted, as displayed in Table 18.3, based on the values in Table 18.2. Each cell shows the forward-looking value of being in that position, given the existing value for i , at time t . In $t = 2$, the value in each cell, $V(i,t)$, is therefore identical to the equivalent payoff, $Y(i,t)$, in Table 18.2.

The value for $V(0,1)$ equals the payoff at that time, $Y(0,1)$, plus the discounted worth of the probability-weighted potential values in $t = 2$ [$V(0,2)$ and $V(1,2)$]. Thus, in the $[B,G]$ case,

$$V(0,1)_G = Y(0,1)_G + [pY(1,2)_G + (1 - p)Y(0,2)_G]/(1 + r) \tag{18.7}$$

The same approach is adopted for each other cell at $t = 1$ in the two matrices. Similarly, $V(0,0)_G$ is calculated as the payoff at that time, $Y(0,0)$, plus the

Table 18.3 Value function matrices: example

A: Value functions $V(i,t)$ for $[B,N]$			
	t (period)		
i	0	1	2
0	-1.43	2.00	1
1		-2.88	-1
2			-5

i is the number of “bad” events occurring prior to period t
 $[B,N]$ indicates that the bridge is built but no private development takes place

B: Value functions $V(i,t)$ for $[B,G]$			
	t (period)		
i	0	1	2
0	-0.31	10.62	25
1		-9.17	-5
2			-12

i is the number of “bad” events occurring prior to period t
 $[B,G]$ indicates that the bridge is built and private development takes place

discounted worth of the two probability-weighted potential value functions in $t = 1$ [$V(0,1)_G$ and $V(1,1)_G$]. Thus, in the $[B,G]$ case,

$$V(0,0)_G = Y(0,0)_G + [pY(1,1)_G + (1 - p)Y(0,1)_G]/(1 + r) \tag{18.8}$$

In the $[B,N]$ and $[B,G]$ cases, respectively, this approach produces a value for $V(0,0)_N = -1.43$ and $V(0,0)_G = -0.31$, each of which is identical to the sum of the discounted utilities presented below Table 18.2. Thus, the value function approach produces identical values to the ΣDVU method given the same decision-making restrictions.

However, these values are still calculated prior to taking the option into account and would only be an appropriate valuation of net benefit if the choice between private development (G) or none (N) were irrevocably committed to at the same time as the public infrastructure decision occurs ($t = 0$). In fact, the private sector choice is made only after new information has emerged at $t = 1$.

To see how this timing affects the analysis, consider the nature of the private development decision at $t = 1$ if the bridge had been built at $t = 0$. If $i = 0$, the developer has $V(0,1)_G = 10.62$ if the development proceeds, while $V(0,1)_N = 2.00$ if there is no development. Thus, if $i = 0$ at $t = 1$, the developer will maximize value by developing since $10.62 > 2.00$. Denote the resulting value (in italics) as $V(0,1)_G$.

If $i = 1$ at $t = 1$, $V(1,1)_G = -9.17$ if development proceeds, while $V(1,1)_N = -2.88$ if there is no further development. Thus, if $i = 1$ at $t = 1$, the

Table 18.4 Value function matrices incorporating option

A: Value functions $V(i,t)$: general		
		t (period)
i	0	1
0	$V(0,0)$	$V(0,1)_G$
1		$V(1,1)_N$

i is the number of “bad” events occurring prior to period t

B: Value functions $V(i,t)$: example		
		t (period)
i	0	1
0	2.72	10.62
1		-2.88

i is the number of “bad” events occurring prior to period t

developer will maximize value by choosing not to develop since $-2.88 > -9.17$. Denote the resulting value as $V(1,1)_N$.

Viewed from $t = 0$, the infrastructure investor will optimally recognize that the decision tree will diverge depending on the value of i at $t = 1$. If good news occurs after the bridge is built, the private development will take place, but no development will be undertaken if bad news occurs at $t = 1$. The two relevant values in $t = 1$ are therefore shown in italics in Table 18.3, one in each of the $[B,N]$ and $[B,G]$ cases. Table 18.4 combines these two values into a single table as viewed from $t = 0$ (dropping $t = 2$ since that period’s values are incorporated into the values at $t = 1$). Table 18.4A provides the general case, and Table 18.4B adopts the values based on Tables 18.2 and 18.3. The actual value of the project at $t = 0$ if the bridge is built, $V(0,0)$, will then be equal to the payoff in $t = 0$, $Y(0,0)$, plus the discounted worth of the two probability-weighted value functions in $t = 1$ being $V(0,1)_G$, and $V(1,1)_N$. In the example, this yields $V(0,0) = 2.72$.

The resulting project value, $V(0,0)$, is positive, and thus the infrastructure project should proceed. The choice to build the bridge is therefore optimal (given the values in the example), but this decision is contrary to that derived from a certainty equivalent analysis both for the case where it is assumed that subsequent private development occurs and for the case where it is assumed that no subsequent private development occurs. The optimal approach incorporates the value of the real option created by the infrastructure investment, whereas the certainty equivalent approach ignores this option value. Where multistage decision-making occurs under conditions of uncertainty, coupled with the ability to update both information and development decisions after the infrastructure is built, the analytical approach must therefore extend beyond a traditional certainty equivalent analysis to one that incorporates the option benefit created by the infrastructure investment. In practice, the larger the potential breadth of impact of the new infrastructure, the greater will be the uncertainty surrounding the nature and size of benefits, and the greater will be the ability to adjust (private and public) decisions in future periods. Hence, the

options framework may, in practice, be most applicable to potentially “game-changing” investments.

The results derived from this analysis are instructive for interpreting the impacts of actual historical infrastructure investment decisions on regional growth outcomes. In some circumstances, an investment may be optimal to proceed with *ex ante* when viewed from $t = 0$ where the real option value is included in the assessment. However, *ex post*, subsequent information may lead to little or no further development. Thus, one is left with a “white elephant” project such as an unprofitable canal or railroad (Belich 2009).

A simple historical *ex post* analysis, undertaken with the benefit of hindsight, might conclude that the regional growth response was mediocre and that the investment choice was therefore poor. (And, of course, this may be the case for some projects!) However, the investment decision to build may nevertheless have been optimal *ex ante* even though the subsequent information made the investment unprofitable.

The infrastructure investment approach analyzed here is analogous to the assessment of whether or not to drill an oil exploration well. New (bad) information revealed after the well is drilled may show that it should not or cannot be developed to become a production well. In a good state of nature (oil is discovered) there is an opportunity, but not an obligation, to develop the well further; the choice of whether to exercise that option will depend on conditions at that time. As in the case of an underutilized infrastructure asset, an unsuccessful oil well does not necessarily signify that the decision to undertake the first stage investment was poor.

One implication of the inevitable *ex post* failure of some infrastructure projects – that were optimally chosen to proceed – is that a portfolio approach to infrastructure investments, as in a standard finance application, may be warranted. Each investment can be considered as part of a portfolio of infrastructure investments designed to raise utility and hence contribute to regional growth. It is the return (and risk) on the total portfolio which is of importance, not the outcome for any single investment. Thus, rather than considering whether each infrastructure project turned out to be warranted *ex post*, a more appropriate assessment might examine whether the portfolio of infrastructure investments has contributed positively to regional outcomes given that each project was assessed legitimately *ex ante* inclusive of option value.

18.6 Conclusions

Infrastructure is an integral factor supporting regional growth. The types of infrastructure considered here are capital-intensive items that service multiple users. Their impact on regional activity will differ by infrastructure type, and so one cannot postulate a generalized relationship between infrastructure investment and regional growth. The spatial equilibrium model establishes that a few key mechanisms determine the relationship between infrastructure investment and growth

outcomes. The effect of a new infrastructure project on activity depends on its direct impacts on local productivity, local amenities, and the price of non-traded goods, especially housing. These impacts will be determined, in part, by existing regional characteristics and how they complement the specific investment.

If infrastructure contributes positively to real amenity-adjusted net wages, the local region becomes more attractive and there is an influx of firms and individuals to the region. This, in turn, has dynamic effects that may amplify or attenuate the initial growth impetus. The result is, at least, a finite period of raised regional growth until a new spatial equilibrium is attained. Certain investments (particularly knowledge-based investments) that are associated with endogenous growth mechanisms may lift the regional growth rate permanently, or for a long horizon. It is possible also that an infrastructure project contributes negatively to real amenity-adjusted net wages, particularly in cases where its benefit cost ratio is less than unity and the costs are met from the local region. In this case, the investment imparts a negative impetus to regional activity.

In light of these equilibrium outcomes, it is important to analyze decision-making processes for major investments. Given that decisions on public infrastructure investments are generally made prior to the full nature of private sector development being revealed, the public authorities must assess how private investors will respond to the investment given a range of circumstances (states of nature). New infrastructure creates an option, but not an obligation, for subsequent private sector development to occur. Indeed, the identity of future investors will often be unknowable (and hence uncontractable) since some agents may not even be in existence at the time the infrastructure decision is made.

The real options approach to infrastructure investment is conceptually appropriate in these circumstances. The authorities must include an assessment of the option value that they create when making decisions on a new infrastructure project. In doing so, they must judge the private sector responses to an investment (i.e., the W_I , A_I , and H_I from the spatial equilibrium model) plus the indirect equilibrium responses (W_L , A_L , and H_L) under alternative states of nature.

A certainty equivalent approach, as in standard cost benefit analysis, is conceptually inappropriate for this analysis since that approach may underestimate the benefit of a new project when future states are uncertain, learning occurs, and decision-making is sequential. However, the real options approach has greater information demands than the certainty equivalent approach, requiring information on the range and probabilities of potential equilibrium outcomes as opposed to requiring just expected values. Given these information demands under the real options approach, scenario analysis in which alternative distributions of potential outcomes are postulated can be a useful tool to test the robustness of the infrastructure investment decision.

No matter whether the certainty equivalent or real options approach is used, ex ante, to evaluate a major infrastructure investment choice, decision-making for such a project is inevitably a complex task. Even the certainty equivalent approach requires policy-makers to estimate indirect as well as direct impacts of an initial infrastructure investment on a region. Both approaches

nevertheless emphasize the importance of considering regional impacts of infrastructure in a systemic manner, and emphasize also the potential importance of infrastructure investments in supporting, and providing options for, regional growth outcomes.

strands of the theoretical literature, analyzes the results of empirical estimations in Europe and in the USA where regional development policies are already well established, and provides recommendations for future research in this field.

19.1 Introduction

Why would a country finance public programs aiming at minimizing regional inequalities within its territory? The first reason is because it is not obvious that regional disparities will disappear by themselves. Globalization and decreasing transportation costs have led to a fragmentation of the production process and increasing agglomeration in a few places. This process is often reinforced by internal migration and foreign investments. The second argument which results naturally from the previous one is that persistent regional inequalities have raised concerns of national solidarity. It is based on the idea that citizens should be given the same opportunities in terms of access to public services, such as health and education, and to jobs no matter where they live in the country. Furthermore, because problems in accessing jobs are sometimes exacerbated by problems of social exclusions and discontent that may take a violent form, regional cohesion may act as a form of social cohesion. Policy intervention also has an efficiency goal by enhancing competition, boosting productivity, and international competitiveness. Programs aiming at removing barriers to internal trade, fostering the movement of the factors of production, and enhancing fair competition belong to this category.

In addition, while changes in the exchange rate have often been used to support the economy of a country, their impact on regional cohesion at the subnational level is not necessarily straightforward. Because of differences in their specialization, economic structure, and trade linkages with foreign partners, regions are not all equally sensitive to changes in the exchange rate, so that devaluation can actually increase regional inequalities. Finally, in absence of systematic adjustments through devaluation, local decision-makers may want to concentrate their efforts on a tax policy that attracts the mobile factors of production. Empirical evidence indicates that it can lead to a tax competition across regions, thus taking the form of a “race to the bottom” where mobile factors are offered lesser tax levels and the decrease in tax revenues is compensated by higher taxes on the immobile factors. As a result, regional development policies can be seen as an efficient tool to avoid a regional tax competition as well.

Yet, and despite the phenomena highlighted above, implementation and support for regional policies are not straightforward because of the important controversy about their efficiency. From a theoretical viewpoint, regional policies lead to different conclusions in terms of convergence according to the economic growth school of thought one focuses on (Dall'erba and Le Gallo 2008). From a practical perspective, several countries experience a lot of difficulties in assessing which regional development strategies work as empirical evidence shows conflicting results.

Therefore, Sect. 19.2 of this chapter is devoted to the theoretical impact of regional development policies under the lens of the neoclassical growth,

endogenous growth, and new economic geography theories. The lack of consensus in their predictions is corroborated by empirical evidence, as indicated in [Sect. 19.3](#) which highlights the results of the key econometric studies that have measured the impact of public spending on regional growth. While many countries have ongoing regional development policies, we focus on the cases of the European Union and the USA. No other country or group of countries has a regional policy as developed and studied as the European Union. Starting with the first enlargement from 6 to 9 countries in 1973, it has since then been an intrinsic part of the EU integration process, and up to one-third of the European budget is devoted to it. Regarding the USA, the presence of a highly mobile labor force and of a federal tax adjustment mechanism have guaranteed that regional inequalities are much less pronounced than in Europe. However, the country is not immune of regional imbalances either. In addition, the implementation of the American Recovery and Reinvestment Act (ARRA) by the Obama administration in 2009 represents an example of why it is important to assess what regional development programs have been successful in the past in order to draw the right strategies for the future. As a consequence, the fourth section will provide a list, although not exhaustive, of elements that recent academic contributions have highlighted as necessary to consider for future developments in this field. Finally, the last section will provide a summary and concluding remarks.

19.2 Growth Theory and Regional Development Policy

From a theoretical viewpoint, the expected impact of regional policies is not straightforward. It varies from one strand of growth theory to the next. In a neoclassical framework based on Solow (1956), investments in physical capital per worker lead to a higher steady-state income. However, due to the decreasing marginal product of capital, the rate of investment must decline toward the steady-state income where the stock of capital per person is constant and of which growth is completely determined by technology. Therefore, regional policies in poor regions may stimulate their growth above their usual steady-state level, but it is only transitional and does not raise the steady-state income in the long run. On the other hand, public policies are granted a more central role in influencing long-run growth in the endogenous growth theory. Rejecting the neoclassical assumption of decreasing returns to scale, the endogenous approach sees public infrastructure as an input in the production function; hence, its presence increases the marginal product of private capital which fosters capital accumulation and growth. However, the addition of public capital in the production function does not allow one to look explicitly at the impact of regional policies on industry location. Indeed, firms choose to locate/relocate not only according to the transfers of purchasing power to the poor areas that accompany a regional policy, but also based on the effect of the latter on capital returns and trade costs between and within regions. Hence, the theoretical approach that is the most appropriate when analyzing the impact of regional policies on growth is the

new economic geography literature such as Fujita et al. (1999), as a large share of regional programs is often devoted to transportation infrastructure. Its appeal lies in returns which appear in the short run, a convenient feature for political purposes, and in its capacity to promote accessibility to/from any area which is commonly seen as beneficial to its economic development. The reality is more complicated. Supporting investments in interregional transportation infrastructure yields a decrease in transportation costs, which affects the process of industry location and often reinforces the agglomeration process which is already taking place in the rich regions. Agglomeration is due to the local labor/consumer market, knowledge externalities, local input–output linkages, and local infrastructures which are more developed in rich areas than poor ones.

Empirical evidence indicates that at the subnational level, transportation networks are firstly developed within and between rich regions because this is where the demand for transportation is the highest. In addition, in some cases, the transportation network is based on hub-and-spoke connections, like in Spain, where transportation costs from the hub (Madrid) to any spoke are lower than between spokes. As a result, connecting a poor area to the existing network may increase its accessibility, but the literature indicates that gains in accessibility will always be relatively higher in the central location than in the peripheral and poor one (Vickerman et al. 1999).

Even supporting transportation infrastructure projects within poor areas does not necessarily guarantees their sudden attractiveness as the spillovers they generate may be too small to counterbalance the agglomeration process already at work in the rich areas. In other words, accessibility is not the only challenge that poor areas have to deal with. It is often accompanied by a lack of infrastructure of any type, a less educated and smaller labor force and less efficient or inexistent local input–output linkages. While it may not be a problem to sectors interested in access to natural resources or cheaper labor, assuming that interregional wage differences exist, the poorest areas often offer very few factors to promote location/relocation within their territory. As a result, several authors in the field of regional development have come to qualify regional policy as a trade-off between efficiency, which can be achieved by fostering agglomeration in the rich areas, and equity, meaning that public spending is used to maintain some level of economic activity and well-being in the poor places.

19.3 Empirical Evidence and Lessons Learned in the EU and the USA

19.3.1 European Regional Policy

Three main groups of results appear in the literature that estimates econometrically the effectiveness of the European cohesion policy on regional growth. Most of them focus on the so-called structural funds, the main tool of the EU regional policy. The first group, which concludes that structural funds have a significant and positive

impact, is composed of the studies of Fayolle and Lecuyer (2000), Cappelen et al. (2003), Beugelsdijk and Eijffinger (2005), and more recently Becker et al. (2010). The contribution by Fayolle and Lecuyer (2000) concludes that the regions that benefited the most from structural assistance are the wealthiest regions in the poorest countries. They explain that the reason for this is twofold: first, the new demand generated by structural funds support in the poor regions is supplied by the rich regions of the same country and, second, new transportation infrastructure helps the rich regions sell their products to the poor ones. Fayolle and Lecuyer (2000) are also the first ones to tackle the issue of co-funding which obliges the recipient regions to provide a share (between 15 % and 85 %, depending on the project) of the investment cost, a practice that softens the redistributive effects of the funds (Dall'erba and Le Gallo 2008). This level of detail allows Fayolle and Lecuyer to account for the actual amount of public spending in each regional economy, as structural funds per se are just a fraction of it.

The conclusions of Cappelen et al. (2003) are somewhat similar to the ones of Fayolle and Lecuyer (2000) as it also indicates that support is the most efficient when it is allocated to regions with a good economic environment, such as low unemployment and high R&D capabilities, which often are experienced in the most developed recipient regions. Hence, support is least efficient where it is most needed, which supports the idea that there is indeed an efficiency-equity trade-off. Finally, to our knowledge, the most recent contribution of the estimation of the impact of the funds is Becker et al. (2010). They focus explicitly on the group of regions recipient of objective 1 structural funds (allocated to regions of which per capita GDP is below 75 % of the EU average) and regions which qualify for these funds but did not receive them. They do not consider the amount of funding allocated to each region, but instead whether a region is recipient or not. Their approach differs from previous works since they focus on European regions of similar economic development level.

The second group of studies concludes that the impact of the funds is either nonsignificant or significant but negative impact. This group consists of the two studies by Dall'erba and Le Gallo (2008) and by Fagerberg and Verspagen (1996), respectively. Dall'erba and Le Gallo (2008) include a spatial econometric approach to convergence which allows them to account for the nonrandom distribution of structural funds and regional income; to proxy various variables at the origin of spillover effects, such as interregional trade, migration, technology externalities; and to measure coefficient estimates which are efficient. While their 2008 contribution pools all forms of structural funding together, the Dall'erba and Le Gallo (2007) work proposes an approach disaggregated by cohesion objective.

The third and final group of studies advocates for more mitigated conclusions on the impact of the funds. This group is composed of Rodriguez-Pose and Fratesi (2004), Ederveen et al. (2002), Ederveen et al. (2006), Dall'erba and Le Gallo (2007), Esposti and Bussoletti (2008), Bähr (2008), and Mohl and Hagen (2010). Focusing on objective 1 regions only, Rodriguez-Pose and Fratesi (2004) are the first ones to measure if the type of project financed, such as support for human capital or for agriculture, and the time it takes for funding to support growth (up to 7 years) matter.

They conclude that support to infrastructure and to businesses does not have a significant effect, even in the long run. On the other hand, investment in education and human capital has medium-term positive effects, while support to agriculture has short-term positive effects on growth. Dall'erba and Le Gallo (2007) are also driven by the desire to differentiate the impact of funding by the type of project this funding finances. In the absence of data for every project, they focus on all the categories of structural funds instead and pay attention to the amounts of additional funds, as in Fayolle and Lecuyer (2000). They find that peripheral regions are significantly but very lightly affected by some structural funds (objectives 1 and 3 & 4 funds, Community Initiatives), whether additional funds are accounted for or not. Based on a spatial econometric approach, they also highlight that peripheral regions seem more affected by the funds allocated to their neighbors than to themselves, more especially when they are objectives 2, 3 and 4 funds, or Community Initiatives. In the frame of a spatial panel setting, Mohl and Hagen (2010) concur that the conclusions are sensitive to the cohesion objective that is being analyzed.

Ederveen et al. (2002) claim that the results depend on whether convergence is measured without fixed effects (convergence across all the European regions) or with a national or regional fixed effect. They conclude that the more optimistic one is about convergence (no fixed effect), the less efficient structural funds spending appears to be, and vice versa. They are the first ones to highlight three detrimental mechanisms in the allocation of the funding across regions: rent seeking which takes place when regional governments design projects that meet the criteria of the EU but are not necessarily effective in stimulating growth; moral hazard which happens when local/regional authorities use EU funds for low-productive projects, so as to keep their region within the eligibility criterion for cohesion support; and crowding out which represents the fact that EU support creates a disincentive for local/regional/national governments to support their poor regional economies themselves. This substitution effect also takes place when EU funding reduces the incentive of the private sector to invest locally and/or workers to migrate to more productive areas, which would promote greater cohesion. Both Esposti and Bussoletti (2008) and Bähr (2008) find that structural funds per se have a negative impact on regional growth, but their impact becomes positive and significant when they interact with another variable such as R&D investments or human capital (in the case of Esposti and Bussoletti 2008) or decentralization, measured by the level of regional autonomy, in the case of Bähr (2008).

19.3.2 Regional Policy in the USA

In the USA, the earliest contribution focusing on the role of public capital on output is Aschauer (1989). His findings rely on national-level data and put the elasticity of public capital at 0.39. This result is somewhat similar to the one of Munnell (1990a) who obtains an elasticity of public capital (net of military spending) of which magnitude is between 0.31 and 0.37. However, both studies adopt a national-level approach. Since then, an increasing number, though still not very large, of studies

have focused its attention on the subnational level. For instance, Munnell (1990b) measures the participation of public capital among 48 states, assuming a Cobb-Douglas production function in levels. At the regional level, it is necessary to have an estimate of private and public capital stocks for each state, since the elasticity of the factors is measured by a Cobb-Douglas production function. As such, Munnell (1990b) develops a methodology that distributes the national stock of capital to each state. It allows her to find an elasticity of public capital on output of around 0.15 in the unconstrained equation and of magnitude in between 0.06 and 0.08 when the Cobb-Douglas coefficients are constrained by constant returns to scale (the sum of their elasticity equals one). Based on a panel data set for the 48 contiguous states over 1969–1986 and capital stock data from Munnell (1990b), Holtz-Eakin (1994) finds an elasticity of 0.203, which is in line with previous works. However, once he uses more complex estimation techniques, such as a fixed effect approach, IV and GLS, he does not find any significant effects.

More recently, Shioji (2001) measures the impact of public capital on economic growth based on a beta-convergence model and a set of panel data for the US states over 1973–1993. While he uses different econometric techniques to refine his results (GMM, LSDV), his approach does not include the role of private capital. His findings are ambiguous since he finds a range of impacts that goes from 0.572 (pooled regression) to 0.407 or even nonsignificant impact (based on LSDV and GMM). Once he disaggregates public capital into education spending and infrastructure spending, his results indicate a negative impact of the former and a positive one of the latter. The negative impact of public spending for education on growth is a result that several other US-focused studies have highlighted also. It indicates the countercyclical nature of this type of policy, and it reflects the high degree of mobility of US workers (Garcia-Milà et al. 1996). Paying attention to local effects, Nizalov and Loveridge (2005) measure the impact of economic development policies and highway infrastructure on growth and jobs across Michigan counties. They define three types of public expenditures: the Michigan Economic Growth Authority (MEGA), a program that grants businesses with tax credits for 8–20 years and targets investments and job creation; the Renaissance Zone (RZ) which provides local tax waivers to firms and individual residents of economically distressed areas; and the Brownfield Development Authority (BDA) which targets the redevelopment of blighted, functionally obsolete, and contaminated sites on Brownfield sites and highway infrastructure. Their approach is a linear estimation of the impact on growth of the above programs in addition to education, manufacturing, government, farming, and business concentration. They find ambiguous results, from a positive and significant effect of highways on job growth to a negative and significant effect of MEGA on income.

Two key studies on the 48 contiguous US states are Garcia-Milà and McGuire (1992) and Garcia-Milà et al. (1996) who focus on the impact of publicly provided inputs on income. In the former article, the authors use a Cobb-Douglas production function and a panel data set over 1969–1983. Public capital is split between highway capital (expenditures on highways by state and local governments) and support to education (state and local expenditures for K–12 and postsecondary education).

They find a positive and significant impact of highways on output (0.045) and a positive and significant impact of publicly provided education with a magnitude in between 0.165 (without a variable of median years of schooling) and 0.072 (with a variable of median years of schooling). When it comes to private capital, the estimated elasticity is in between 0.373 and 0.449 when it is measured as capital in equipment, and it is in between 0.027 and 0.104 when it is measured as capital structures. In the latter study (1996), they extend previous results by considering highways as well as water and sewers as publicly provided inputs over almost the same time period (1970–1983). They also use various fixed and random state effects to address the issue of heterogeneity in the data. Without controlling for state effects, they find similar results as Munnell (1990b) where highways as well as water and sewers have a positive and significant impact on output (0.37 and 0.069, respectively). However, once they controlled for state effects, the coefficients diminish to 0.120 for highways and 0.043 for water and sewers. Because they assume a potential serial correlation in their results, they run their model once more but on the variables measured into first differences. In this specification, all the publicly provided services appear to have a negative and significant impact, which is in tune with the conclusions of Holtz-Eakin (1994). Private capital has an impact in between 0.289 and 0.348, as usually found in the literature.

Using an extended version of Munnell (1990b) data, Lall and Yilmaz (2001) construct private and public capital stocks in order to estimate a beta-convergence model across the 48 contiguous states over 1969–1994 while controlling for business cycles by time-period dummies. Their results indicate a nonsignificant impact of lagged public capital in two specifications (without state or time dummies and with state dummies) and a significant but negative impact with state and time dummies, when the human capital variable is excluded from the equation.

Finally, the two most recent contributions on this topic have taken note of the theoretical advances advocated by the new economic geography literature as well as of the developments of the spatial econometric techniques to detect, model, and measure the presence of interregional externalities. As such, the work of Garrett et al. (2007) provides a spatial econometric estimation of beta-convergence across states over 1977–2002. Among the explanatory variables, government expenditures are measured as a proportion of state gross product, while local government revenues are captured by the share of state and local revenues. They find a negative and significant impact of government share of which magnitude (between -0.3097 and -0.3270) varies with the absence or presence of spillover effects. When it comes to the role of local revenues, their impact on growth is significant and negative with a range in between -0.0207 and -0.0218 . Overall, they conclude that state-level fiscal policies can significantly influence income growth in neighboring states. The presence of interregional spillover effects is also at the core of the contribution of Dall'erba and Llamosas-Rosas (2012) who, in addition, measure *the actual* federal, state, and local public investments in education and other public capital from two databases: the Consolidated Federal Fund Reports (for federal spending) and the State and Local Government Finances (for local and state spending). It allows them to avoid using proxies for public

investments. Their results are in line with Holtz-Eakin (1994) since they find that public capital investments do not have a statistically significant impact, while public support for human capital has a negative and significant impact on per capita income. This corroborates the work of Kilkenny (2010) who shows that governments often neglect the negative feedback effects such as the rural “brain drain” of rural education to urban areas when rural development policies are implemented.

Looking at the previous results, we may wonder what reasons would explain such a diversity of outcomes both among European or US studies. We stipulate that there is a great deal of heterogeneity in the way they approach the same problem. The choice of the sample (only objective 1 regions vs. all the EU regions), time period (because of business cycles), estimation process (cross section vs. panel, presence or absence of fixed effects), the variables chosen (actual spending vs. some proxy), and the treatment of spatial dependence necessarily affect the estimation results. In addition, Ederveen et al. (2002) note that the conclusions are dependent upon the type of convergence estimated. In an absolute convergence framework, it is assumed that all the regions are converging to the same steady state, while adding spatial regimes (convergence clubs) or country dummies in the case of Europe allows for differences in regional steady states. The difference is not trivial since in the latter case the underlying assumption is that inequalities persist, even in the long run.

Differences in regional steady states are also controlled by the explanatory variables included in the model. The range and quality of explanatory variables that have been used in the studies above varies greatly. For instance, private investments statistics are available across EU regions but do not exist for the US states. As a result, they have to be constructed based on national data and following various methodologies such as the one of Munnell (1990b) or Garofalo and Yamarik (2002). There is no doubt that this affects the quality of the estimations.

19.4 Looking Ahead

19.4.1 Including Spatial Dependence and Reporting the Right Measurements

The last two decades have seen an increasing recognition of the role of spatial externalities in economic growth theory and empirical evidence. Because this movement has taken place in conjunction with a formalization of the spatial econometrics framework necessary for the estimation of various phenomena, the literature now displays a rather large number of studies estimating growth at the subnational level while accounting for spatial autocorrelation. As mentioned in Dall’erba and Le Gallo (2008), spatial autocorrelation refers to the fact that the spatial distribution of the variables used in the econometric model is not random. Rich areas tend to be close to other rich areas, and poor areas tend to be close to other poor areas. This phenomenon may come from factors such as trade, labor and capital mobility, technology, and knowledge diffusion that affect simultaneously nearby regions. It may also arise from model misspecifications

(omitted variables, measurement errors) or from a variety of measurement problems such as a mismatch between the administrative boundaries used to organize the data and the actual boundaries of the economic processes believed to generate growth.

If spatial autocorrelation proves to be present in an econometric model, the traditional assumption of independence of the error terms needs to be rejected; otherwise, it leads to unreliable estimates and inferences. Second, spatial autocorrelation allows the user to capture the presence of geographic spillover effects between observations, indicating that public funding in one location is not going to impact growth in the recipient location only. Third, spatial lags of the dependent variable can act as a proxy for omitted variables that are spatially dependent.

Among the studies listed in [Sect. 19.3](#), only three have used these techniques in the European case and 3 in the US case. Details about the form of the spatial model they use, the definition of the variable of interest, and the estimated mean, minimum, and maximum impact appear in [Table 19.1](#) above.

As can be seen in [Table 19.1](#), different spatial models have been used in the literature to account for spatial dependence in a regression framework. More precisely, all these contributions have rejected the traditional (OLS) way of formulating an econometric growth model given by

$$y = \alpha I_n + X\beta + \varepsilon \text{ with } \varepsilon \sim N(0, \sigma^2 I_n)$$

where y is the growth rate of a period, X is a set of explanatory variables including public spending, and β is a set of coefficients to be estimated. As such, the spatial econometric models they have measured in the contributions above are described below:

The spatial lag model (SAR):

$$y = \alpha I_n + \rho W y + X\beta + \varepsilon \text{ with } \varepsilon \sim N(0, \sigma^2 I_n)$$

$$y = (I_n - \rho W)^{-1}(\alpha I_n + X\beta + \varepsilon)$$

The spatial error model (SEM):

$$y = \alpha I_n + X\beta + u \text{ with } u = \rho W u + \varepsilon \text{ and } \varepsilon \sim N(0, \sigma^2 I_n)$$

$$u = (I_n - \rho W)^{-1} \varepsilon$$

$$y = \alpha I_n + X\beta + (I_n - \rho W)^{-1} \varepsilon$$

The spatial error and spatial lag model (SAC model):

$$y = \alpha I_n + \rho W_1 y + X\beta + u \text{ with } u = \theta W_2 u + \varepsilon \text{ and } \varepsilon \sim N(0, \sigma^2 I_n)$$

$$y = (I_n - \rho W_1)^{-1}(X\beta + \alpha I_n) + (I_n - \rho W_1)^{-1}(I_n - \theta W_2)^{-1} \varepsilon$$

Table 19.1 Summary of the impact of public spending on growth across spatial econometric studies

Primary study	Spatial model	Variable definition	Mean impact	Minimum impact	Maximum impact
European regions					
Mohl and Hagen (2010)	Spatial panel lag model	Structural funds per capita (objectives 1, 2, 3 – in log)	0.0003	–0.0092	0.0114
Dall’erba and Le Gallo (2008)	Spatial 2SLS lag model	Sum of structural funds per capita (in log)	–0.01 (not significant)	–0.01 (not significant)	0.002 (not significant)
Dall’erba and Le Gallo (2007)	Spatial error model	Sum of structural funds per capita (in log)	0.0005	–0.002	0.007
US states or counties					
Garrett et al. (2007)	Spatial lag and/or spatial error	Government share (first diff of log)	–0.3154	–0.3207 (spatial lag model)	–0.3097 (spatial lag and error model)
		Local revenue tax share (first diff of log)	–0.0211	–0.0218 (spatial error model)	–0.0207 (spatial lag and error model)
	Spatial lag model only	Government share (first diff of log)	–0.3169	–0.3214 (census divisions)	–0.3149 (census divisions)
		Local revenue tax share (first diff of log)	–0.0206	–0.0214 (census regions)	–0.0207 (census divisions)
Lall and Yilmaz (2001)	Lag on human capital only SLX	Public capital (constructed following Munnell 1990b)	0.002	–0.017 (public capital only)	0.036 (public and human capital) not significant
Dall’erba and Llamosas-Rosas (2012)	Spatial Durbin model	Public investment in infrastructure	–0.077	–0.154 (not significant) <i>Unrestricted model</i>	–0.067 (not significant) <i>Restricted model</i>

The spatial cross regressive model (SLX):

$$y = \alpha I_n + X\beta_1 + WX\beta_2 + \varepsilon \text{ with } \varepsilon \sim N(0, \sigma^2 I_n)$$

The spatial Durbin model (SDM):

$$y = \rho W_1 y + \alpha I_n + X\beta_1 + W_2 X\beta_2 + \varepsilon \text{ with } \varepsilon \sim N(0, \sigma^2 I_n)$$

$$y = (I_n - \rho W_1)^{-1} (\alpha I_n + X\beta + W_2 X\beta_2 + \varepsilon)$$

where W is the spatial weight matrix and α is the constant term. Note that in the case of the SAC and SDM models, W_1 and W_2 can be equal or different. The reader can refer to LeSage and Pace (2009) for other forms of spatial models. It is important to understand that the interpretation of the parameters is not as simple as in a traditional linear regression model and may vary across spatial models. In the linear case, it is easy to interpret the impact on the dependent variable of a change in any explanatory variable. Indeed, the value of this impact is the magnitude of the coefficient. In addition, since the model assumes independence across observations, the effect of a change in any exogenous variable affects the dependent variable of that specific region only. Formally, $\partial y/\partial x^r = \beta_r$ (for any exogenous variable “ r ”). In a spatial econometric model, the presence of spillover effects often, but not always, makes the interpretation of the beta coefficients more complicated but richer. For instance, in a spatial error model as used in Dall'erba and Le Gallo (2007) or Garrett et al. (2007), the coefficient beta has the same meaning as in an OLS model. On the other hand, in an SLX model as used in Lall and Yilmaz (2001), a change in an explanatory variable is measured by

$$\partial y/\partial x^r = (I_n \beta_r + W \theta_r)$$

In this formulation, since the weight matrix is standardized and contains zeros on the main diagonal, the coefficient β_r reflects direct effects, while θ_r captures local spatial spillovers. Finally, global spatial spillovers are measured in the frame of a spatial lag, as used in Dall'erba and Le Gallo (2008), Mohl and Hagen (2010), Garrett et al. (2007), or when estimating a spatial Durbin model as in Dall'erba and Llamosas-Rosas (2012). Indeed, in these studies the marginal effect is written as follows:

$$\text{SAR} : \partial y/\partial x^r = (I_n - \rho W)^{-1} I_n \beta_r$$

$$\text{SDM} : \partial y/\partial x^r = (I_n - \rho W)^{-1} (I_n \beta_r + W \theta_r)$$

Because the term $(I_n - \rho W)^{-1}$ can be expressed as the following infinite sequence: $(I_n + \rho W + \rho^2 W^2 + \rho^3 W^3 + \dots)$, it involves that a change in any region will affect not only the region itself, but its neighbors, the neighbors of its neighbors (which includes feedbacks to the original region), and so on.

It is important to stress that this nonlinear relationship implies that we cannot interpret the coefficients of a SAR or SDM model as in any of the other types of models, as the former measure both direct effects and spillover effects at the same time. This point has been overlooked in previous spatial econometric estimations of the role of public spending on growth where β is interpreted as in a nonspatial model, while the spatial lag coefficient is left capturing all kinds of spillover effects. Following the suggestion of LeSage and Pace (2009), the correct interpretation of a spatially lagged endogenous variable requires us to disaggregate the total effect of a change in an exogenous variable into direct effects which

capture the sum of the impacts in the region that experiences a change and indirect effects which capture the impact due to changes in other regions. In order to do so, direct effects are calculated as the mean of the main diagonal elements of the $n \times n$ matrices, while indirect effects correspond to the mean of the sum of the off-diagonal elements from each row of the $n \times n$ matrices. Details about the method to draw statistical inference on each effect can be found in LeSage and Pace (2009).

To our knowledge, there is no study so far that has used this approach to estimate the impact of regional development policies on growth in Europe or in the USA. The only study that comes close to it is Fischer (2011) who reports the magnitude of direct and indirect effects of (public and private) investments in physical and human capital across EU regions over 1995–2004.

19.4.2 Measuring the Actual Investments, Not Proxies

Earlier analyses, whether they focused on the European Union or on the USA, often used a (poor) proxy of the true amounts of public spending allocated across areas. Some popular proxies could be as simplistic as a dummy variable of which the value, 1 or 0, would reflect if a region is a recipient or not. The problem with this approach lies in its complete disregard for the actual amount of investment. Other contributions use the *stock* of human capital, such as the education level, in a Cobb-Douglas production function which is supposed to measure the role of human capital *investments*. Some authors recognize that the consistency and the reliability of their estimates, hence the quality of their conclusions, suffer from these proxies but not all.

While some scholars are to be blamed for their lack of rigor in collecting/constructing the appropriate data when they are available, the list of challenges they meet includes, but is not limited to the following: availability of the data at all, availability in electronic format vs. hard copy, updated vs. outdated data, data covering all types of projects vs. some only, detailed description of the project financed (for instance, “transportation” is too vague), description of the region where the projects have been allocated (the finer spatial scale the better), and data that correspond to the actual payments vs. investment commitments.

However, the prospects are much better. For instance, after years of relying on hard copy reports displaying data that would present many of the challenges listed above, the European Commission has moved on to creating a “computerized monitoring systems and electronic data exchange” site that serves as a unique reference for documenting the ways in which the funds are being used. The site is accessible here: http://ec.europa.eu/regional_policy/sources/exchange/exch_en.htm. It represents a significant step in the right direction, even though it is still very far from the level of transparency and detail that one experiences when working with the data of the US Census Bureau’s Consolidated Federal Fund Reports. They report electronically all types of federal spending, whether for regional policy purposes or not, for every county or smaller spatial units on

a yearly basis since 1993. These data are available here: <http://www.census.gov/govs/cffr/>. Recently, Dall'erba and Llamosas-Rosas (2012) have relied on this database to estimate the role of public spending on the regional economies of the USA in the frame of a Cobb-Douglas production function.

19.4.3 Combining Different Strands of Theory and Techniques

Many of the studies described in Sect. 19.3 rely on the famous neoclassical growth model initiated by Solow (1956) even though its underlying assumption of diminishing returns to capital and the eventual presence of Galton's fallacy have raised some doubts on its theoretical and empirical relevance. As a result, future works should consider theoretical models that mix different strands of the literature. In that sense, the contributions of Garrett et al. (2007) and Dall'erba and Le Gallo (2007, 2008) are innovative because they add the presence of interregional spillovers to a traditional neoclassical framework. Based on spatial econometric techniques, their results allow them to measure the extent to which structural funds impact not only the region where they are allocated but on neighboring regions as well. Another contribution that blends the various schools of economic growth theory even further is Ertur and Koch (2007). Based on a Cobb-Douglas framework, they propose to distinguish and model three factors that explain growth in technological progress: the first part is the stock of knowledge that is shared by all the firms and grows at an exogenous and constant rate as is usually assumed in the neoclassical approach. The second part of it is generated by the presence of knowledge externalities between nearby firms as described in the endogenous growth theory. Neither the first nor the second elements account for the role of dependence over space which has been brought to the forth by the new economic geography literature, which is why they attribute the third and final part of technological progress to localized interregional knowledge externalities.

Beyond a better integration of theoretical approaches, future contributions will also emphasize the need to integrate modeling techniques further. Spatial econometrics has become a popular and straightforward way to model and measure spatial dependence, but it does not rely on the "true" factors at the origin of interregional spillovers. It relies on a matrix of geographical proximity across regions which has the advantage of being determined exogenously. However, when it comes to economic growth and regional policy, it is mostly trade and migration that explains spatial dependence; hence, techniques capturing these interregional flows need to be adopted. It is the essence of interregional input-output (IO) analysis that has experienced increasing popularity since the early contributions of Wassily Leontieff. However, interregional IO data are long and costly to gather; hence, some authors such as Rey (2000) have suggested complementing the traditional input-output techniques with spatial econometrics to generate multiregional linkages that are both industrially and spatially disaggregated.

From a regional policy point of view, the advantage of combining techniques is twofold. First, it would allow scholars to avoid the "one-size-fits-all" approach that

has prevailed in the field of regional development. Indeed, in a global (econometric) approach which is the setting most empirical studies rely on, the coefficient associated to each variable corresponds to the average impact of the latter on the dependent variable across the entire sample. As a result, global econometric estimates could, for instance, reveal a significant impact of regional spending (from a statistical point of view) on the average regional growth rate, while in reality it is a nonsignificant impact that should be found in some localities and a positive or negative one elsewhere. The advantage of an approach that would be more disaggregated lies in its capacity to expose significant local and sectoral variations, which are masked by a global and aggregated approach. Secondly, most empirical estimations of the impact of regional policies have overlooked the potential endogeneity of regional spending. This problem comes from the fact that regional spending is mostly devoted to regions with a low per capita GDP, a measurement that is intrinsically part of the dependent variable, growth. Dall'èrba and Le Gallo (2008) address this problem and use a set of instrumental variables since their Hausman test results reveal that structural funds are indeed endogenous. As a result, an integrated IO-spatial econometric approach as suggested by Rey (2000) could alleviate this problem since, by definition, the IO approach models and measures shocks that are either endogenous or exogenous to the system at hand.

19.4.4 Need to Develop Tools That Foster Communication Between Stakeholders and Academia

Preparation of material for dissemination in the public policy arena is not necessarily the main objective of many scholars in the field of regional development. However, the latter component is extremely important and undervalued as stakeholders are much more project driven and interested in the policy arena than academic scholars. In addition, the former often take decisions based on reports that are not produced by the latter. As a result, the first author of this chapter has recently concentrated his efforts on developing an Internet-based, free-of-charge, tool called the Regional Economic Impact Simulator. It transmits complicated theory and estimation techniques commonly used among regional scientists to an audience of specialists and nonspecialists. In addition, it can be used as a decision-support tool for localities willing to compare the returns of various kinds of investments.

Based on a webGIS platform, the Regional Economic Impact Simulator allows anyone to build a regional policy scenario of his/her choice and to visualize on a map, in a matter of seconds, how regional economic growth is modified as a result of it. Because of interregional interactions captured by spatial econometric means, it is not only the locality where the scenario is implemented that will experience a change in growth, but also the entire system.

An example of regional policy scenario is depicted in Fig. 19.1 below. It reflects how economic growth over 2000–2008 in each of the counties of the sample has been

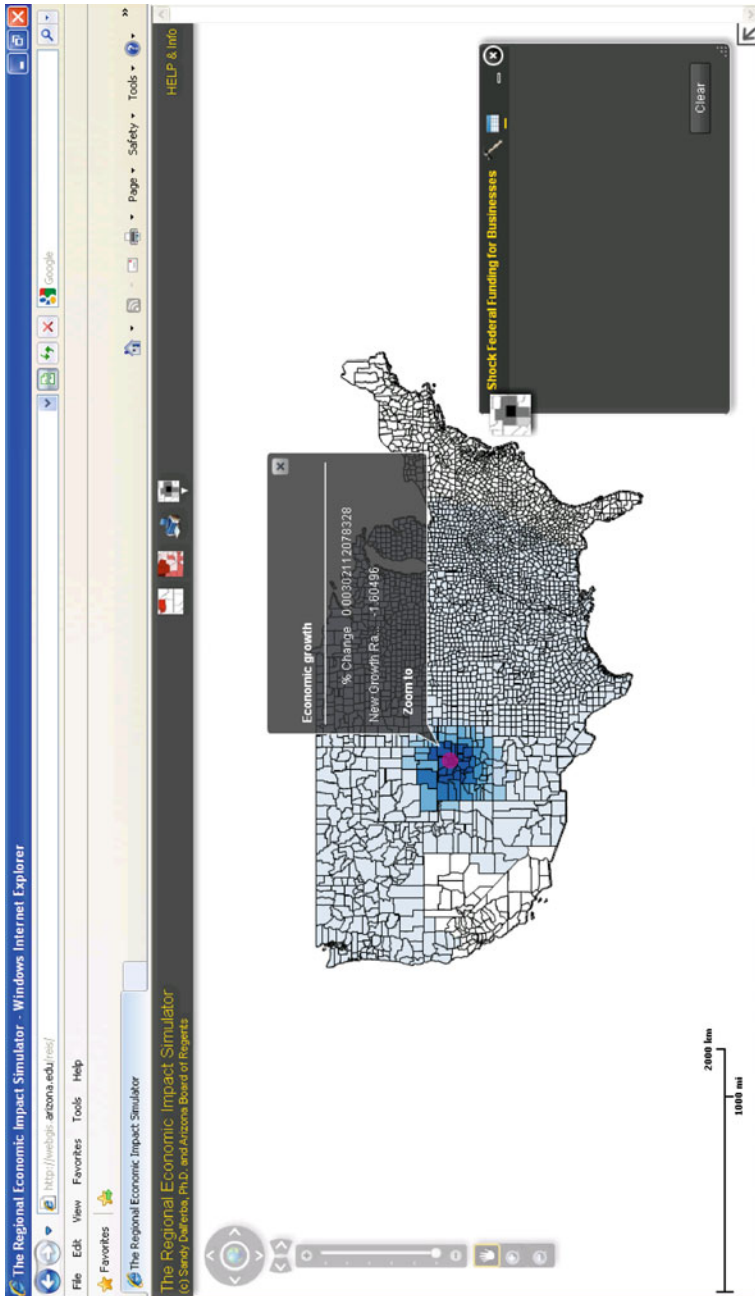

Fig. 19.1 Changes in county-level economic growth resulting from a simulated 50 % increase in federal support for private businesses in Boulder, Colorado

modified as a result of a 50 % increase in federal support for private businesses in Boulder, Colorado, over the same period. While this county is the one which has experienced the greatest change in growth, growth has also spread to its neighbors and the neighbors of its neighbors, etc., but with a decreasing magnitude as distance from Boulder increases. Note also how a pop-up window allows users to get details about the magnitude of the change experienced in each county. Many more simulations can be performed on the Regional Economic Impact Simulator as users are given the freedom of implementing shocks of any magnitude, on any of the 16 explanatory variables used in the model and any of the 3,076 counties of the database. The Regional Economic Impact Simulator is accessible here: <http://webgis.arizona.edu/reis/>. While it is, to our knowledge, the only tool of this nature available at the moment, we anticipate that the increasing desire for transparency and accountability in the use of public funding will lead to many more free, Internet-based, decision-support tools.

19.5 Conclusion

Increasing interest for regional development policies has led to new theoretical advances and a growing number of empirical works, but it has not succeeded in providing a standard model for economic development intervention. Past empirical evidence indicates that the conclusions are very sensitive to a set of parameters, such as sample size, estimation method, time period, and quality of the variables used, which confuses academic scholars, stakeholders, and policy-makers. An example would be the 2009 American Recovery and Reinvestment Act which led 200 economists to predict that it would benefit the US economy and 200 others to forecast the exact opposite. As a result, uncertainty calls for “place-tailored” policies where intervention is designed to meet the specific economic and geographic characteristics of the recipient locality targeted for development. For instance, it is now well accepted that transportation infrastructures are not necessarily an efficient tool to promote equality as their impact does not always benefit the recipient area. Indeed, they may lead to depopulation of the latter and increase agglomeration in rich regions.

The most recent contributions in the field of regional development are focusing their efforts on avoiding some of the shortfalls of the past such as the correct interpretation of spatial models and the overwhelming reliance on proxies as opposed to the actual amounts of public spending. In addition, there is an increasing desire to combine the different strands of economic growth theory with each other while integrating further the set of regional science techniques already available. Ultimately, it should provide a more complete picture of the regional dynamics at stake and of the actual role of policy intervention. Last but not least, regional development practitioners need to rely more often on current technology, such as webGIS, to bridge the gap between the interests of stakeholder and the expertise of academic scholars as well as demonstrate to the general public the level of transparency and accountability they operate in. Only an increasing awareness of today’s regional development challenges will oblige us all to make future interventions more effective and efficient than past ones.

Section III

Innovation and Regional Economic Development

A word cloud centered around the words "knowledge" and "innovation". The word "knowledge" is the largest and most prominent, written in a dark brown, bold, sans-serif font. To its right, the word "innovation" is written in a smaller, orange-brown, bold, sans-serif font. Surrounding these two main words are numerous other terms in various sizes and orientations, all in shades of brown and orange. The words are arranged in a roughly rectangular shape, with "knowledge" on the left and "innovation" on the right. The background is plain white.

Abstract

This chapter surveys the topic of the geography of innovation – not the economics of innovation – and asks several questions: What is innovation? Who innovates? Where do they learn to innovate? The research focus has shifted from innovation and technology to the broader issues of knowledge and innovative capability. The empirical literature has been much narrower in scope, previously focusing on research and development (R&D) and now rarely looking beyond patents.

E.J. Malecki

Department of Geography, Ohio State University 1036 Derby Hall, Columbus, OH, USA

e-mail: malecki.4@osu.edu

The chapter surveys a broader set of innovation indicators – inputs, outputs, and hidden innovation, much of which is uncovered in large-scale surveys. Empirically, there is a global shift in innovative capability toward Asia, primarily in R&D (but less so in basic research) and in process innovation related to manufacturing. The overall pattern is one of persistent spatial concentration. As a result, a thriving business has emerged to craft policies to enhance innovation and to “construct advantage” in an uncertain competitive landscape. Finally, the actors in innovation include not only individual scientists and inventors but also the organizations that employ them, such as universities and firms. It is entrepreneurs who largely determine how innovation is exploited. The fruitful concept of the knowledge filter and the role of entrepreneurship and the geography of entrepreneurship provide clues to the patterns seen.

20.1 Introduction

Innovation is fundamental to economic growth and to variations in economic development across space. Innovation is a dynamic process – bringing about creative destruction and shifting the locus of innovation across industries and among locations. Innovation is a broader concept than technical (or technological) change alone; it includes ideas and knowledge that precede actual innovation, the learning that takes place through experience, and the synthesis of knowledge and complementary assets to utilize them profitably. Our understanding of the geography of innovation, however, has become too narrowly conceived as the topic has attracted a flurry of research attention from economists.

This chapter reviews what we know from the work of economists as well as from geographers. It begins with the simple world as grasped by patent data and models based on those data. Second, it examines what we know about innovation as a dynamic and complex – even messy – process. Third, this dynamic, complex messiness is seen in the location of innovation and of innovative capability: the geography of innovation at the global scale, which is itself the outcome of several distinct flows and forces. Fourth, the chapter reviews briefly the degree to which policy can influence the geography of innovation.

20.2 The Standard Model: Innovation as Knowledge Production

The standard economic view includes a knowledge production function, in which innovative output, typically measured as patents, results from innovative inputs, specifically research and development (R&D) by firms. Within regions, knowledge spills over from universities and industrial R&D, and these spillovers decline with distance. Griliches (1990: 1669) acknowledged “a whole host of problems” with patent data: “Not all inventions are patentable, not all inventions are patented, and the inventions that are patented differ greatly in ‘quality,’ in the magnitude of

inventive output associated with them”. However, most researchers have been persuaded by his conclusion that “[i]n spite of all the difficulties, patent statistics remain a unique resource for the analysis of the process of technical change. Nothing else even comes close in the quantity of available data, accessibility, and . . . detail” (p. 1702). Consequently, there has been a flood of research using patents as the principal – and often the only – measure of innovation and its geography.

Reviewing the literature since Griliches (1990), Nagaoka et al. (2010) conclude that patent data alone are not sufficient for understanding the mechanisms of either a knowledge production function or knowledge spillovers. Too many important flows are not captured by patents, including other means of appropriability, inventions not patented, and patented inventions not used. More common means of firms to protect their innovations include secrecy, lead time, and complementary capabilities (Nagaoka et al. 2010).

Notably, other knowledge – particularly tacit knowledge – is ignored or assumed to spread as seen in patent citations. The importance of tacit knowledge is that it is not readily transferred, and therefore, transfers are difficult unless the parties are colocated (permanently or temporarily) in a locality (Asheim and Gertler 2005). The growth of publications by firms also can be seen as an attempt both to find new access to external knowledge and to signal the existence of tacit knowledge and other unpublishable resources. Publishing allows a firm’s researchers to become involved or take part in academic activities, with access to the epistemic communities of researchers. In return, the firm expects access to the tacit knowledge of academics in the field.

Not all industries are the same. High-technology, or high-tech, industries have received a great deal of attention, and they have informed our knowledge of how innovation occurs in those sectors. Innovation is managed differently across industries: fast-changing industries may be more creative but also less efficient, whereas slow-changing industries emphasize efficiency over creativity.

Patenting is not typical in all sectors; the pharmaceutical industry is particularly dependent on patent protection. The glamour of biotechnology and blockbuster drugs has led to an overemphasis on the importance of patenting. We know a great deal about biotechnology, in part, because the industry fits the R&D-based model of prevailing theory and, in part, because it is relatively small and localized in few locations. We know that patents generally are highly concentrated in large cities.

Those who study innovation at the scale of the firm, rather than the region, have noted the evolution from the development of something new to a process of creativity to a process dependent on knowledge. A similar evolution has taken place in the management of R&D within firms.

20.3 What Is Innovation?

As a result of the broadening of definitions and of ways to measure innovation, broader views of innovation have become more widespread. They have developed largely within Europe, particularly in the context of Organisation for Economic Co-operation and Development (OECD) and European Union (EU) policy documents

(Mytelka and Smith 2002). The OECD definition of an innovation includes more than merely a new or significantly improved product (good or service) or process, but also the implementation of a new marketing method, or a new organizational method in business practices, workplace organization, or external relations.

Products and processes – some of which are patented – have been the object of research on innovation for decades; services, marketing methods, and organizational methods are more recent. The series of Community Innovation Surveys conducted in (an expanding number of) EU member states have added to our knowledge of how firms innovate. Similar surveys are now conducted in several countries outside Europe, with the United States conspicuously not among them.

To this list can be added *soft innovation* – new products offering aesthetic rather than functional appeal as well as those goods and services with a distinctly intellectual appeal (including books, films, art, or computer games). Soft innovation builds on the increased importance of aesthetic content in products. Aesthetic improvements, the outcome of soft innovations, are a principal source of product differentiation but generally cannot be patented. “Whereas patents require novelty and copyright requires originality, the counterpart for a trademark is distinctiveness. . . . Whereas patents are not available for aesthetic innovations, such innovations may be trademarked” (Stoneman 2010: 262). In addition, copyright protects material such as literature, art, music, sound recordings, films, and broadcasts, and design rights (or design patents) protect the appearance or visual appeal of products (Stoneman 2010). Trademarks and copyrights remain underappreciated and understudied aspects of innovation.

Many have focused on tacit knowledge, implicitly in tune with the idea of technologies as recipes. However, a great deal of tacit knowledge is needed beyond the technological procedures in any codified recipe. Tacit knowledge flows through many channels, such as the multitude of interactions and knowledge flows between economic entities such as firms (customers, suppliers, competitors), research organizations (universities, other public and private research institutions), and public agencies (technology transfer centers, development agencies) (Asheim and Gertler 2005). Organizational means for absorbing, integrating, and transforming knowledge have been a major focus of research.

Just as inputs beyond R&D (and of outputs beyond patents) are important in innovation, more than a patent is necessary for a firm to appropriate and profit from the gains from an invention. Even an imitator can outperform an innovator if the imitator has assembled a better set of critical complementary assets. It also is the case that R&D has purposes beyond only patentable innovations, on which more below.

20.4 Two Faces: The Multidimensional Nature of Innovation

Binaries and dichotomies are simple solutions to complex problems. Dichotomies are found in studies of knowledge and innovation, shedding light but also obscuring the actual workings of knowledge production and innovation. Knowledge is more complex than merely codified and tacit.

One of the more useful binaries is the observation that R&D has two faces; that is, firms invest in R&D not only to generate innovations but also to learn from competitors and knowledge sources outside the industry, such as university and government labs (Cohen and Levinthal 1989). To a large degree, subsequent research has followed either one path or the other. The first flood of research has focused on patents and linkages between patents through citations.

A second body of research, largely unconnected, has focused on learning by people and firms and on types of knowledge. Not all knowledge is used (nor perhaps even useful) immediately and is retained and accumulated for future use. This store of knowledge is to the individual's – and the firm's – absorptive capacity. Firms differ widely in their knowledge search strategies, with impacts on their absorptive capacities.

Other motivations for R&D beyond the need to build an absorptive capacity include the following: an intention to maintain the firm on the technological frontier, the search for reputation, building and signaling its competences, and entrance to networks, which are among the main incentives for firms to invest in R&D.

Systems integration, like R&D, also has two faces: the internal activities of firms as they develop and integrate the inputs they need to produce new products and services and the external activities of firms as they integrate components, skills, and knowledge from other organizations to produce ever more complex products and services. Complex systems of technologies (e.g., automobiles, aerospace systems, iPhones) require the integration of knowledge from many sources – technological as well as geographical. Systems integration and the skills required to translate and interpret across disciplines, jargon, language, and technologies – and to synthesize these into forms and routines usable within the organization – are neither easy nor straightforward.

Knowledge as created and used is not identical but differentiated. Three types of knowledge bases have been outlined by Asheim et al. (2011): *analytical* (science based), *synthetic* (engineering based), and *symbolic* (arts based). Alternative typologies are based on whether knowledge is codified or poorly articulated, spillovers are intentional or unintentional, and incentives to reveal and to capture knowledge are strong or weak. Once again, biotechnology (with few other industries) stands out as unusual.

A key debate in the literature concerns whether specialization or diversity within an agglomeration is most beneficial for spillovers. The consensus had begun to shift toward diversity, but the current consensus is swayed by research which shows that *related variety* is best (Asheim et al. 2011; Boschma and Frenken in Cooke et al. 2011; Iammarino in Cooke et al. 2011).

A recent addition to the roster of binaries is the distinction between local and nonlocal (or extralocal) knowledge sources. The impact of local “buzz” is particularly important in the creative and cultural industries, where symbolic knowledge, performance, and events perhaps outweigh the importance of codified, cumulative knowledge. A useful literature has grown on types of proximity – not only geographical, but also organizational, cultural, technological, cognitive, institutional, and social (► Chap. 26, “*Networks in the Innovation Process*” by Tranos). The summary by Moodysson and Jonsson (2007: 15) concerning Swedish biotechnology firms is appropriate more widely: “The convenience of local collaboration can never replace the extreme requirements of specialized knowledge, which forces them to seek collaborators on a global arena.”

Nuanced views deconstruct the meaning of proximity to an even greater extent: However, proximity has a different influence depending on the size of the city. The concept of *temporary clusters* also reflects the complexity of proximity: it need not be fixed in place or permanent to be beneficial. Crevoisier and Jeannerat (2009) develop a richer framework to understand the simultaneous need for both local and nonlocal sources. “The concept of ‘from elsewhere’ is now differentiated: the places are clearly identified, as are complementary and/or competing ones” (p. 1235). In other words, the globalization of knowledge does not reflect an amorphous “elsewhere.” It reflects known places where specialized knowledge is as great, or greater, than in a given locality.

Clusters do not necessarily have links to knowledge pools elsewhere (Vale 2011). Even when a region’s knowledge networks include pipelines to distant knowledge, that knowledge needs to be “anchored” and integrated with the regional knowledge base (Crevoisier and Jeannerat 2009; Vale 2011).

20.5 How Innovation Works: Linear or Complex?

The bottom line is that innovation flows from knowledge and ideas, broadly viewed, rather than from R&D, even if broadly defined. This point is implicit in the new growth theory, which results in positive-sum growth based on ideas. The recent criticism by Steinmueller (2010: 1190) is that “unlike the old growth theory which produced a central result, the ‘golden rule’ of accumulation, the new growth theory is still evolving” with considerable variety in its outcomes. The broader conception of knowledge and innovation is more explicit in the recent shift seen from innovation systems to knowledge systems.

Early work was based, explicitly or implicitly, on the *linear model*, which postulates that innovation begins with basic research, adding applied research and development (all still under the umbrella of R&D), followed by production and diffusion. A standard of innovation studies for decades, the linear model captures the temporal sequence of activities in innovation, is easily monitored in data gathering and appeals to policymakers because of its simplicity and logic. The linear model fits biotech and other science-based industries because of a key feature of the linear model – linearity – the fact that not everything occurs simultaneously. Regional analyses based on the linear model and on patent data are still common.

20.5.1 Entrepreneurship as Innovation

The linear model has been extended to encompass entrepreneurship. Ideas lead not only to new products and services but also to new firms and, in some cases, to clusters of new firms in new industries. Indeed, research and policy interest in entrepreneurship grew largely out of interest in technology-based clusters (Mason 2008).

The entrepreneurial process within the innovation process is captured best by the *knowledge filter*, a key element in the knowledge spillover theory of

entrepreneurship (Audretsch and Keilbach 2007; Acs et al. 2009). The knowledge filter is the set of barriers to converting research into commercialized knowledge.

The knowledge filter for academic research is (besides the challenge of converting basic science into applied knowledge) largely an institutional filter. It consists of organizational barriers, university policies, attitudes among faculty and university administrators against commercialization of research, and lack of incentives to pursue commercialization. Additional barriers within the academic knowledge filter reflect an inability to convert inventions into intellectual property (primarily in the form of patents) and to commercialize that intellectual property through licenses and start-ups.

Similar filters for industrial R&D reflect the difficulty in business organizations to convert research into intellectual property and to commercialize new products. Entrepreneurs are able to see a path and to assemble the networks necessary for commercialization. Many types of interfirm networks are needed, ranging from global to local and from formal links to informal networking (Lawton Smith 2008; Giuliani in Cooke et al. 2011).

20.5.2 Innovation as a Complex Process

What is missing from the dominant flow of the linear model are the feedbacks and interactions that are so crucial to innovation. Many interactions are contained within national boundaries or within regions (Asheim and Gertler 2005). These national and regional innovation systems are thought to largely define the institutions, cultures, and path-dependent strengths (and weaknesses) that vary from place to place. The idea of innovation as – and within – systems recognizes innovation as a complex and systemic phenomenon. Research on innovation systems also reflects this broad synthetic perspective (Fischer et al. 2001; Mytelka and Smith 2002; Soete et al. 2010; Wolfe in Cooke et al. 2011; ► Chap. 24, “Systems of Innovation and the Learning Region” by Cooke).

The spatial complexity of RISs and the operational complexity of learning have already pushed the linear model into the background. Caraça et al. (2009) suggest a multichannel interactive learning model that captures the complex flows and interactions among actors.

Work on innovation systems was at first national and technological. Subsequent research added sectoral systems and regional systems (Tödting and Trippel in Cooke et al. 2011). Research has begun to recognize the overlap and boundary relations between national, sectoral, and technology-specific innovation systems and between technological systems and sectoral systems of innovation. Crossing international boundaries highlights the distinctiveness of each national innovation system as nations compete to stay innovative and thereby wealthy. Regional systems link to those in other national systems, thereby forming international innovation systems (Crevoisier and Jeannerat 2009; Soete et al. 2010).

Regional innovation systems (RISs) have attracted the research attention of economic geographers and regional scientists (Asheim and Gertler 2005). The actual

workings, activities, and policies, as well as measurements of contacts and linkages, are sometimes easier to grasp within a regional or local context than at the scale of the nation. Several terms are used to describe such local territorial innovation systems, such as clusters, territorial production complexes, productive systems, territorial systems, milieus, and local systems (De Propriis and Crevoisier in Cooke et al. 2011).

The significance of RISs is that they represent “spatial knowledge monopolies” that attract investment and participation by transnational corporations (TNCs) (Cooke 2005). The central feature of the national and regional innovation systems is that while R&D activity still matters greatly, it is only one part of a larger system that includes education, training, government support, and linkages among sectors. Recent research suggests that regional clustering and networking (such as those found in innovative milieus) are less important than localized capacities to build global connections.

Intermediaries also can bring external knowledge to potential users. Knowledge-intensive business services (KIBS) are a particularly important source of innovative knowledge. Geographically, KIBS are highly concentrated at the top of the urban hierarchy.

Feldman and Kogler’s (2010) eight stylized facts in the geography of innovation focus on the importance of proximity and location to innovative activity. Although the geography of innovation comprises agglomeration and spillovers (Feldman and Kogler 2010; ► Chap. 22, “Knowledge Flows, Knowledge Externalities, and Regional Economic Development” by Karlsson and Gråsjö), it is also much more. Agglomeration or clustering alone does not provide the ingredients within RISs necessary for collective learning – institutions, social capital, and entrepreneurs (Capello in Cooke et al. 2011). The advantages of agglomeration are well established, providing opportunities for sharing, matching, and learning. In general, large urban areas are expected, *ceteris paribus*, to have higher proportions of skilled workers, higher rates of innovation, and more rapid adoption of innovations, smaller places. However, all large and/or dense cities are not alike; they vary widely in culture and in institutional infrastructure.

What is left out, of course, is the complex of social dynamics, captured in part by the concept of social capital, which is fundamental to the cohesion (or lack of it) in a community. Power – especially the power exerted by TNCs – is key to the actual dynamics in many regions, but is omitted from most analyses of RISs.

The ground-up, largely local view of how the geography of innovation is constructed is primarily an economic view rather than a bird’s-eye look at the changing geography of innovation. The following proceeds from the opposite direction: from the global to the local.

20.6 Global R&D

That R&D is global has been evident for over two decades. Through the 1990s, however, global R&D was largely triadic – distributed among (western) Europe, Japan, and North America. Since 2000, the “global landscape” of R&D has changed dramatically, reflecting major innovative effort in Asia outside Japan. The current

situation is a *global innovation system*, in which India, China, and the United States have leveraged the growing internationalization of innovation to offset weaknesses in their own national innovation systems.

The following focuses on two central shifts at the global scale: the location of innovative activity and the competition for talent. These shifts and the measures of them are tracked by a bewildering array of scoreboards of indicators.

20.6.1 Fact 1: Innovation Is Dispersing Globally

The geography of innovation used to follow the product cycle in a predictable manner, flowing from R&D, conducted only in high-income countries. The activities of TNCs and their global production networks have altered but not eliminated product cycle as an important concept at the global scale (Tichy in Cooke et al. 2011). The benefits of agglomeration economies appear to be greatest at the “birth” of new firms and diminish during the later stages of the industry life cycle.

During the 1970s – that is, before the rise of China – R&D had begun to globalize, becoming much more so during the 1990s to exploit sources of knowledge at the locations of customers and competitors. However, in-house R&D alone is no longer sufficient for a firm to be technologically competitive. In-house R&D must be complemented by external sources of innovation, which then need to be integrated into the firm’s structures and competences. These trends are captured in firms’ utilization of open innovation and the phenomenon of the double network.

The global innovative activities of TNCs are one force behind the shift from R&D being located only (or primarily) in rich countries. Another force is active efforts by firms – many state owned – in emerging economies to serve their own growing consumer markets. This means that in any industry, the number of pipelines a firm must maintain is increasing. As Crevoisier and Jeannerat (2009) stress, there are many knowledge sources, and links to them require effort to maintain rapport and productive contact. In short, research has increasingly become a borderless activity.

20.6.2 Fact 2: Places Are Competing for Talent and Brains

The global geography of innovation has been transformed primarily by the globalization of scientific and engineering talent, which Freeman (2010) suggests has proceeded rapidly along five related tracks. These are:

- Expansion of mass higher education worldwide
- Growth in number of international students
- Migration
- Non-immigration trips by academic visitors and conference attendees
- A rapid rise in international coauthorship and co-patenting

As these five changes have occurred, changes in national capabilities have taken place.

Migration is an important channel for the movement and spread of knowledge. Migration need not be considered a brain drain, but can be a *brain recirculation* as migration is less frequently permanent and as people construct multilocational careers and professional and personal lives. The term brain drain has been replaced by global competition for talent. In this ongoing competition or race for talent – and for highly skilled migrants – countries have implemented *competitive immigration regimes* as a new form of interjurisdictional competition.

There are benefits from such policies, seen the movement of the world's productive researchers toward nations with research infrastructure and strong R&D support.

At the level of policy, as opposed to theory, the geography of innovation primarily means the visible shifts in innovative capability, inputs, and outputs on the ground – the changing landscape of innovation. The new, more global pattern reflects the growing role of knowledge in the global economy, seen primarily in investments in tertiary education and R&D outside the OECD countries. Scientific publications are the result of creative efforts of people working in universities, government research institutes, and the R&D labs of private firms. The map of such knowledge-producing places is increasingly global, with prominent new nodes in China. Despite the diffusion of knowledge – and indicative of the peculiar nature of patents as an indicator of innovation – patents tend to be the most unequally distributed dimension of knowledge creation at the global level.

The dispersion of R&D has been a response to the location of both markets and talent, both of which have improved throughout much of the world as economic growth has taken place, particularly in Asia. As scientific and technological talent has improved in many places, the result on the ground is a range of capabilities, typically measured at the national level. Fagerberg et al. (2010) provide the most comprehensive review of how capabilities have been measured, incorporating one or more of several dimensions: science, research, and innovation; openness; production quality/standards; information and communication technology (ICT) infrastructure; finance; skills; quality of governance; and social values.

20.6.3 Keeping Track

A number of distinct efforts have been made to measure the technological capabilities of national economies, some for more academic interest and others for policymakers. Fagerberg et al. (2010) and Archibugi et al. (2009) compare many of these. Policymakers like such scoreboards for three reasons. First, they provide an “early warning system” for potential problems at a national level. Second, when used over time, national strengths and weaknesses can be monitored. Third, they help to focus firms, institutions, and government bodies on the same issues (Arundel and Hollanders 2008). Fagerberg et al. (2010) distinguish between several types of capabilities that indicate in various ways the capacity of the firms of a country to compete through creation of new technologies and to exploit existing knowledge from elsewhere.

It has become common for benchmarking and scoreboard reports to track the technological progress of national (and sometimes regional) economies. Indeed, there are so many scoreboards and sets of cross-national indicators that the EU produced its *Global Innovation Scoreboard* only in 2006 and 2008, now being content to publish only its *Innovation Union Competitiveness Report* and *Innovation Union Scoreboard* on an annual basis. All these measures are highly correlated – with one another and with gross domestic product (GDP) per capita (Fagerberg et al. 2010).

All of these address real – or imminent – technology gaps envisaged by the rise of China and other Asian competitors. All indicators and rankings are imperfect. Archibugi et al. (2009: 929) conclude, however, that “R&D intensity is less capable of explaining differences in innovative performance because *non-R&D factors* play an important role in differentiating national paths of innovation and performances”. However, there is a real risk that policymakers will drown in the flood of numbers from so many, especially annual, scoreboards.

20.7 Policy: Changing and Reacting to Changes in the Geography of Innovation

Here, policy refers to efforts at the national, regional, and local level to respond to – and to shape – the geography of innovation. Innovation policy has evolved from R&D alone to systemic – appreciating innovation as a systemic process. The OECD and, later, the EU have attempted to gather knowledge on the state of the art in policy and its empirical evaluation (Mytelka and Smith 2002). Policy continues to run ahead of theory (Steinmueller 2010).

20.7.1 Regional Innovation Policy: Constructing Advantage

Martin et al. (2011:566) provide convincing evidence that regional strategies based on one “best practice” model do not meet the very industry-specific needs of firms. In fact, these best-practice models . . . seem to be most well suited to industries that draw primarily on an analytical knowledge base”. Such sector-specific needs remind us of the importance of the nonspatial sectoral innovation systems. Any useful policy must include gatekeepers and other actors within a regional system who can interpret cross sectoral and technological boundaries. These interactions work best when they are informal, untraded interdependencies rather than formal, contractual links. It is plainly difficult to create policy structures that must be at the same time formal (enacted in laws, personnel hired and evaluated, accounted for to taxpaying citizens) and informal (flexible and adaptable to new circumstances and knowledge).

Regions compete and, more than in the past, they work to create advantage in a world where the ability to attract and keep capital and people requires attention to infrastructure, institutions, policies, and innumerable details (Asheim et al. 2011; Cooke in Cooke et al. 2011). At a minimum, regional advantage should be

constructed more on the basis of the unique capabilities of firms and regions and not primarily on the basis of corporate or regional R&D efforts. What is needed is “smart specialization” (Legendijk in Cooke et al. 2011). At worst, regions that fail to be attentive to these demands can become, or be perceived as, systemically innovation averse.

Constructed regional advantage, the current state-of-the-art regional innovation policy approach, takes into account three lessons from policy experience. First, *platform policies* represent “tailor-made policy strategies geared towards specific potentials and focused on tackling specific bottlenecks in regions that occur over time. As a result, regional policy needs to evolve, capitalizing on region-specific assets, rather than selecting from a portfolio of policy recipes that owed their success in different environments” (Asheim et al. 2011: 900; Cooke in Cooke et al. 2011; Harmaakorpi et al. in Cooke et al. 2011). Second, such a strategy must be based on *related variety*, rather than specialization or broad-based differentiation, to reflect shared and complementary knowledge bases and competences. The third element of this policy approach reflects that knowledge is distributed across traditionally defined sectors in distributed knowledge networks, and these knowledge bases are distinct and often incompatible with one another. Tura et al. (2008) illustrate several dimensions (structural, social, cultural, and intellectual) of *innovation platforms*, which reflect network-based innovative capability.

Policymakers, like firms, also face massive information overload. It appears that their ability to compete is made more difficult unless they use gatekeepers, such as consultants and service intermediaries who can help gather and synthesize knowledge from elsewhere. As with firms, the number of knowledge inputs to policy and the number of sources are increasing, and demands for data and synthesis – for example, for benchmarking – are common. Regional and national innovation policies now typically include university R&D, technology transfer, entrepreneurship, and spinoffs.

Regional absorptive capacity must be built and maintained, and it includes the absorptive capacities of firms located in the region, institutional features that promote knowledge exchange and learning in the region, and links to organizations elsewhere (Abreu in Cooke et al. 2011).

Vale (2011) dissects the standard policies related to clusters, which often downplay informal and untraded interaction among firms in an agglomeration. Further, he emphasizes that spatial localized learning processes are necessary but not sufficient for a successful cluster in a world where relevant knowledge is located in several – known and perhaps unknown – nonlocal and perhaps distant locations.

The complexity of innovation, not surprisingly, leads to complex frameworks for regional policy. Innovation policy generally is seen as messy and complex, with multiple levels and multiple actors including, in the European Union (EU), supra-national policy. In this sense, innovation systems – like clusters – may be too difficult for policymakers to grasp fully and to coordinate adequately. Numerous intermediaries are involved at several levels (Nauwelaers 2011). As policy continues to run ahead of theory, specific programs are evaluated, but it is uncommon for technology policy to undergo evaluation (Steinmueller 2010).

Recent proposals for policy focus on the *cognitive* dimension of territories (Camagni 2009, Capello in Cooke et al. 2011), whereby territories act as learning regions (Simmie in Cooke et al. 2011). Knowledge-oriented policies (KOP) for regions as well as for firms can help to build competencies and to participate in the codevelopment of knowledge at a global scale. This involves several types of networks (Lawton Smith 2008).

Uyarra and Flanagan (2010) believe that the regional innovation system has become a fuzzy concept – attractive to policymakers and a useful “boundary object” linking but at the same time preserving the integrity of academic and policy discourses. The use of the term “system” encourages a view of regional economies as more-or-less closed systems and allows for inclusion of emergent, functioning, and dysfunctional systems. It also focuses attention on structure at the expense of agency.

20.7.2 Policy in a World of Global Production Networks and Global Value Chains

Manufacturing, long derided as a blue-collar sector staffed by uncreative people, of course includes engineers and other innovative personnel. The now-distant capabilities related to manufacturing leave many firms as “head-and-tail” companies with no body – the only activities remaining in-house are research and branding. Dankbaar (2007: 272) asks two pertinent questions: “Is there any reason to assume that research can be maintained as an in-house activity in the long run, if development and manufacturing have been outsourced? What happens to research if knowledge and experience coming from manufacturing and development are no longer immediately available?” TNCs make location decisions with a short-term perspective, but ultimately weaken the knowledge base of their home economies as suppliers of advanced materials, tools, production equipment, and components – collective capabilities – are no longer utilized as they also move or are replaced abroad.

Within global production networks, there has been a “geographic dispersion of *cross-functional, knowledge-intensive support services* that are intrinsically linked to production”. As flagship firms have moved to global sourcing, an “*erosion of the collective knowledge* which used to be a characteristic feature of the flagship’s home location . . . may have migrated for good to the supplier’s overseas cluster(s)” (Ernst 2002: 51, emphasis in original). In response to the new global situation, current advice for innovation policy is to frame such policy as a knowledge-based economy strategy, within a complex framework that includes the whole of government.

20.8 Conclusions

This brief survey has emphasized the systemic, learning-based model of innovation favored by many geographers and evolutionary economists. This view of innovation is able to embrace what we know about how innovation actually works – as a messy

and highly varied process that defies model builders. The standard model has not provided adequate guidance for policy, and this is why policy runs ahead of theory: it must do so but the result is that we have little systematic knowledge about how and why policies actually work. Policymaking often takes its cues from politics and political pressures rather than from empirical knowledge. Changes in the geography of innovation at the global scale affect regions and localities, both through the changing location of R&D and flows among nodes in the global system of knowledge. However, global forces are much more difficult for regional – and even national – policies to influence, as they are the outcome of independent choices by TNCs and by national policymakers. Innovative capability also is more difficult for any actor to assemble as technology grows more complex, and the necessary knowledge is found in ever more places.

Abstract

Generation and diffusion of innovation are two distinct processes that are interlinked in several ways. First, innovation efforts of firms are stimulated by the diffusion of innovation ideas. Second, the market penetration of successful product innovations diffuse to user firms and consumers, providing users opportunities to adopt novel routines and to imitate new designs. Third, creative destruction develops when a novel product finds its way to customers and replaces earlier product vintages, and this phenomenon has the nature of

a substitution process. All these processes are supported by knowledge flows which vary in intensity and diversity across the innovation milieu of functional regions. It is concluded that the milieu characteristics which stimulate innovation also stimulate adoption of novelties.

21.1 Introduction

The economic growth literature has, since the contribution of Solow in the 1950s, attributed productivity growth to processes of technical change, where economy-wide technical change is based on the generation of innovations and their diffusion across firms and regions, although innovation processes were not modeled as endogenous until the late 1980s (e.g., Romer 1986; Aghion and Howitt 1992). As firms develop new routines for their operation and design new products for the market, they do so with the objective to increase their productivity. Following suggestions in Nelson and Winter (1982) – building on Schumpeter (1934) – we shall consider three broad categories of innovations: (i) new *product varieties* with novel combinations of product attributes, (ii) new *firm routines*, comprising novel production and administration processes and techniques, and (iii) new markets including novel links to customers.

The research approach in the field of innovation studies has changed in important ways during the past two decades, primarily as a result of new data sources which contain firm-level micro data sets, allowing researchers to observe for individual firms' (i) firm characteristics, (ii) innovation efforts, and (iii) location characteristics. With information about the location of each firm, it becomes possible to consider information about the innovation milieu associated with different locations. An example of new data sources is the *community innovation surveys (CIS)*, in which data from the EU member states are collected on a regular basis with harmonized information (OECD 2005).

The objective of this chapter is to develop and examine a view on how firms generate innovations and what consequences innovations can have on firm performance and heterogeneity. A second task is to describe how innovations diffuse from innovators to other (user) firms and thereby affect the performance of the latter as well as the entire economy. In this endeavor the chapter presents a theoretical framework in which lasting differences in firm performance are related to persisting differences in firms' innovation and adoption behavior.

In the subsequent exposé, it will be shown that *regional milieus* that favor the generation of innovations also facilitate diffusion of novelties. As an example we may observe that a firm's generation of innovations is positively related to the knowledge intensity of the firm's employees. Likewise, the knowledge intensity of a firm's labor force increases its absorption capacity, augmenting the probability that novel techniques and product-attribute information will diffuse to the firm. The regional aspect follows when we observe that knowledge-intensive firms are more frequent in regions with a knowledge-intensive labor force.

A firm generates innovations in a process of innovation activities, of which *research and development (R&D)* efforts may be a major part. Innovation activities bring about new knowledge while at the same time using inputs from the conjunction of internal and external knowledge sources. The combination of internal and external knowledge accession is cumulated into knowledge about (i) firm routines, (ii) product variety attributes, (iii) markets and customers' willingness to pay for product attributes, and (iv) routines for how to organize and perform innovation activities.

The presentation will concentrate on three major aspects, namely, firm characteristics, innovation milieu characteristics, and innovation activities. The additional question is as follows: how do the three aspects affect firm performance, where these effects can be subdivided into direct and indirect innovation consequences? Direct effects concern new patents, markets and products, and sales of new products. Examples of indirect effects are factor productivity growth, sales per employee, labor productivity, and profitability. The reader should also recognize that the output from a firm is products, comprising both services and goods.

As a way to amalgamate established findings in the literature, the presentation will focus on the following set of theses associated with making innovations and adopting innovation:

Thesis 1: Innovation and adoption activities are two interlinked and overlapping firm renewal phenomena. As a rule both activities require that the pertinent firm renews its routines. In all essence, such routine adjustments should be classified as routine or process innovations.

Thesis 2: Both innovation and adoption activities are fuelled by inputs from internal and external knowledge sources. Part of the external knowledge is disseminated according to classical diffusion.

Thesis 3: *Knowledge flows* reduce in volume and intensity as the distance between origin and destination grows. This form of spatial discounting implies that localized knowledge is a fundamental characteristic of a functional region. In the sequel each functional region will be categorized with regard to its accessibility to different knowledge sources.

21.2 Innovations and Heterogeneity of Firms and Places

In order to maintain its competitiveness, a firm has to renew itself over time. As emphasized in Thesis 1, such renewal has two forms. The first is more proactive and is based on R&D and innovation efforts, where the firm in the spirit of Schumpeter generates product and process (routine) innovations. The second form of firm renewal is rather reactive and consists of a firm's search for novel product ideas and for new technical solutions developed elsewhere in the economy.

Continued and repeated *firm renewal* is the key factor for a firm's survival and eventual growth. In renewal efforts firms develop and adopt new technologies, using knowledge components that are paid for as well as knowledge that pass by as unintended consequences of current economic activities. To facilitate the combination of internal efforts and external interaction, firms can establish *networks*

Fig. 21.1 Labor productivity cross tabulated against output of firms in an industry (OECD code 1) in productivity-descending order

for knowledge flows. The associated spillovers and organized knowledge flows stimulate innovation as well as adoption activities of firms and provide inputs to an ongoing process of firm renewal. Differences in firms' renewal intensity will cause heterogeneity among firms to sustain. Thesis 3 clarifies that proximity to knowledge sources matters.

Firms in the same industry or firms supplying product varieties belonging to the same product group have as a rule heterogeneous characteristics and display different performance in terms of productivity, profitability, or growth, and they differ in their R&D and innovation efforts. In established microeconomic theory, such differences are predicted to vanish over time, based on the argument that only the best practice can survive. Empirical observations do not support this view (Dosi and Nelson 2010). To a large extent, interfirm differences remain over long time sequences.

Differences between firms in a given industry (or group of industries) may be identified for a panel of firm observations over time. Such a panel will contain differences for each individual firm at different points in time as well as differences between firms that remain basically unchanged along time. With reference to Geroski (1998), we may then calculate the total variance for a performance variable like value added or gross profit per employee and then in a second step determine how much of the variance is due to the variation between years for each individual firm, referred to as *within variance*. The remaining variance can then be conceived as a persistent difference between firms, referred to as *between variance*. This between variance is typically 3–4 times larger than the within variance (Andersson et al. 2012). Such observations demonstrate heterogeneity among firms in most industries while at the same time showing that differences between firms persist over time.

Figure 21.1 provides a picture of the labor productivity (2006) in an industry supplying differentiated products (OECD code 1), based on Swedish data. The horizontal axis measures the cumulative output from firms in the sector when firms are ordered according to descending productivity. The figure illustrates how the quartile with the highest productivity has a productivity which is 3–4 times as large as the lowest quartile. Such performance differences provide a strong motive to examine firm characteristics when assessing performance. Among such characteristics the literature has considered firms' behavior with regard to efforts to innovate and

to adopt new technology developed by other firms. The first aspect associates with the process of generating innovation and the second with diffusion and adoption.

The presentation in this chapter makes use of a theoretical framework, in which lasting differences in firm performance are related to persistent differences in how firms generate their own innovations and how they adopt new equipment as well as current input flows. Thus, in a second perspective, we observe that there are also systematic differences between firms with regard to how large amounts of resources per sales and value added they commit to innovation efforts (R&D intensity). Such R&D shares display highly skewed distributions across firms, and the firm differences remain persistent over time (Klette and Kortum 2004). The picture that emerges is a system with different “species,” where a large share of firms is not engaged in innovation and R&D activities, where some firms are innovation active only occasionally, whereas firms in still another group remain persistently innovation active over a sequence of years. In addition, firms that display alertness in buying or imitating innovations developed elsewhere can be expected to have a higher *absorption capacity* than the average firm.

As firms are located in different regions, one may also investigate to what extent a firm’s local economic milieu affects its performance. Are there characteristics of a firm’s economic environment that influence firm performance both in terms of economic outcome and innovation results? Before that question can be answered properly, it is necessary to consider how a region is defined and identified. This presentation refers to the concept *functional urban region*, where the regional boundaries encircle an area within which frequent face-to-face interaction can take place with short notice and without travel planning. In most practical cases, this requirement is satisfied for local labor market regions, for which labor market commuting between intra-regional areas is much more intensive than between areas in two different functional regions.

Heterogeneity among firms is a result of different development paths, and these paths are consequences of how well each firm manages to carry out its own innovations and to adopt technological novelties developed elsewhere in the economy. Innovation efforts of firms combine with knowledge flows of various kind including interactive communication between the firm and other actors such as suppliers, customers, competitors, university researchers, and other knowledge providers. Knowledge flows are equally important for a firm’s efforts to acquire and adopt innovations. In the case of adoption, the driving incentive is to learn about new equipment and technical solutions as an input to making adoption decisions, and this makes knowledge flows vital. Similar observations apply to firms which imitate novel products with new attribute combinations.

Knowledge flows vary in content, diversity, and intensity between functional regions. In particular, the friction of knowledge diffusion and transfer is smaller inside a functional region than more long-distance flows. In this way we can explain the pronounced tendency of innovations and technology adoption to cluster in particular functional regions, caused by the heterogeneity of urban regions with regard to knowledge intensity of the labor force, the presence of R&D activities in firms and universities, the size of gross regional product (GRP) and level of GRP

Table 21.1 Illustration of urban region heterogeneity in Europe 2004

Rank order (GDP/cap)	Urban region	GDP/cap €	GDP €, million	Accessibility to GDP
1	Paris	67,500	146,000	823
2	Inner London	65,600	191,300	815
11	Copenhagen	38,300	46,100	178
33	Stuttgart	30,400	121,300	315
87	Glasgow	26,000	49,800	81
167	Skåne (Scania)	23,700	27,500	76

Remark: 640 NUTS 2/3 regions with PPS-adjusted GDP values (Eurostat)

per capita, the diversity of the region's export and import flows, etc. For the USA, such differences between urban regions are recognized and documented in, for example, Henderson (1997).

In their evolution urban or city regions remain different from each other and retain their idiosyncratic features including markedly different levels of income per inhabitant. As illustrated in Table 21.1, urban regions also differ in their human capital resources, which is reflected in the table by the knowledge intensity of the labor force, measured as the share of the labor force with at least 3 years' university studies. Three things are accentuated in the table. First, the *knowledge intensity* increases very fast between 1993 and 2007. Second, the relative difference between regions remains unchanged during the 14 years. Third, the larger the urban region is, the higher its knowledge intensity. Subsequently the presentation will emphasize a region's knowledge intensity as a determinant of its innovation as well as adoption intensity. High knowledge intensity is associated with two region features: (i) high absorption capacity of firms and (ii) intense knowledge flows and spillover phenomena, where pure spillovers are defined as unintended knowledge flows which occur free of charge.

21.3 Innovations, Diffusion, and Technological Development

As summarized by Mansfield (1987), technological change results in a change in the production function of an existing product (routine renewal) or in an addition to the list of technologically feasible products (product renewal). In practice both types of renewal may occur simultaneously. A firm's adoption of novelties may not be very different. As a firm purchases new equipment or imitates product innovations made by others, it may have to redesign its routines.

Figure 21.2 provides a stylized picture of how a firm renewal can affect firm performance and how a firm's innovation and adoption activities depend on:

- The characteristics of the firm which includes its innovation capabilities and innovation strategy
- The characteristics of the firm's *innovation milieu*, where the latter primarily corresponds to the possibility of knowledge interaction in the functional region where the firm is located

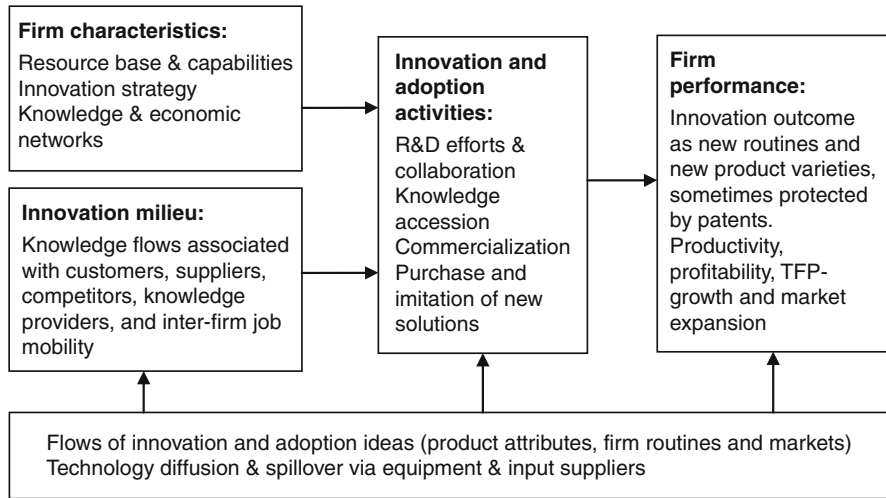

Fig. 21.2 Factors influencing the size and consequences of innovation and adoption activities

The figure illustrates the statements in the first and second theses of this chapter and attempts to connect the basic concepts for the analysis of innovation and adoption activities while putting the variety of diffusion processes in focus. First, as observed in the figure, diffusion of innovation and adoption ideas stimulates firms to make innovation efforts and to adopt new technical equipment. In addition, when a firm introduces a product innovation, then the market penetration of its new product can be modeled and analyzed as a diffusion process. Diffusion of new products that are sold to firms and households or imitated by user firms also represents economy-wide renewal which is usually labeled technological development. It also associates with *product cycle* dynamics (Vernon 1966).

21.3.1 Renewal Activities and Firm Performance

Figure 21.2 depicts how innovation activities can influence *firm performance*, subdivided into innovation outcomes and economic outcome. The first type of performance focuses on the innovation output of a firm, and the associated performance indicators comprise measures such as number of new products and patents, sales of new products, and sales of new export products. These are direct outcomes of renewal efforts to innovate and adopt novelties in the economic environment. The second type of performance refers to indirect consequences of renewal activities, measured by the economic result of the firm as reflected by the level and change in productivity and profitability, growth of total factor productivity (TFP growth), and increasing value of the firm and its market expansion. These are all different returns to renewal activities. As will be evident in Sect. 21.5 of this chapter, the economy-wide returns to an industry’s R&D are greater than the

returns to the typical single firm. As recognized early by Mansfield (1968), this is due to the role played by technology diffusion and spillovers between firms and industries as firms buy improved equipment and intermediaries.

An important message in this presentation is that a firm's development is the result of its *renewal activities* which include innovation and adoption. These two phenomena overlap without a clear demarcation line. We first observe that a firm that introduces new product varieties also has to adjust its production processes and thus make a routine innovation, indicating that product and process innovations are complementary (Nyström 2006). Such routine innovations are equally probable, irrespective of whether it is a matter of a product innovation or an imitation. Moreover, the adoption of new technical solutions in the form of new equipment also stimulates the firm to make routine innovations. Hence, innovation and adoption are intermingled. This reflects the chapter's second thesis saying that innovation and adoption activities are part of a firm's overall renewal efforts, and this view is reflected in the CIS specification of innovation efforts, which includes the following list of innovation and adoption activities: (i) internal R&D work, (ii) external R&D work, (iii) acquisition of new equipment and associated cost, (iv) accession of external knowledge, (v) allocation of time for human resource development and training, (vi) marketing and commercialization efforts associated with new products, (vii) product development and design, (viii) development and maintenance of links to external actors for R&D collaboration, and (ix) scanning external knowledge sources for innovation and adoption efforts (OECD 2005).

A firm's possibilities to carry out renewal activities depend in a critical way on the resource base and associated capabilities of the firm. These are durable and difficult-to-imitate capacities. The literature in this area (e.g., Teece 2010) emphasizes the capability of an innovating firm to develop, maintain, and orchestrate its resource base to adapt in an ever-changing business environment. The *knowledge intensity* and the firm's experiences from previous innovation and adoption efforts are the core determinants of firm renewal. The associated knowledge assets are based on learning how to organize and establish *routines* for conducting innovation activities.

21.3.2 Characteristics and Performance of Firms

Firm characteristics can be organized under the headings *strategy*, *renewal capabilities*, and *networks*. The characteristics influence what the firm is capable of doing but also what it intends to do. Intentions and objectives may be reflected by the firm's innovation strategy which comprises the firm's commitment to systematic R&D and its ambitions to develop capabilities and networks for knowledge flows over time. Recent studies suggest that firms display permanent heterogeneity that can be grouped into no, occasional, and persistent engagement in R&D and other innovation activities. With persistent engagement, the firm is rewarded with learning routines for how to conduct R&D, and this leads to firm knowledge and experiences that improve performance. Another strategy aspect is the size of innovation expenditures, often proxied by R&D intensity.

R&D intensity is usually calculated as the ratio between R&D expenditures and sales or between R&D expenditures and value added. In studies of the impact of R&D on firm performance, the measure R&D intensity controls for size. With this approach heterogeneity is revealed by the observation that as much as half of the variation in R&D intensity is explained by fixed firm effects. In view of this, one may remark that the two most widely used indicators of firm characteristics – cash flow and the degree of diversification – explain much less of interfirm differences in R&D intensity. Thus, the fixed firm effects indicate strongly that differences between firms' innovation efforts have a tendency to remain invariant over time. This can also be interpreted as a finding saying that firms employ different innovation strategies.

Having reached this point, one may ask: what about Schumpeter's suggestion that firm size affects its innovation intensity? Cohen and Levin (1989) and many other survey contributions suggest that it is difficult to reject the hypothesis that R&D efforts are proportional to firm size. Andersson and Johansson (2010) argue in a model with product variety innovations and multiple export markets that firms are large as a consequence of variety and market innovations in the past, not the other way around. Instead, cumulated innovation experiences affect a firm's probability of innovating in the future.

In order to develop its *innovation capabilities*, a firm has to invest in such capacities, and as a consequence we find that firms with a large share of knowledge-intensive employees spend more than average resources on innovation activities, and they do this in a more persistent way than the average firm. A firm with an offensive and sustainable strategy of this kind may also have more favorable economic outcome than average. Obviously, this also reflects dynamic interdependencies with ambiguous causation. In cross section as well as panel data analyses, one can observe that the likelihood of making innovation efforts is associated with the same variables as those which are associated with the economic result of these efforts. Such variables which correlate with higher innovation intensity and higher returns to innovation include (Andersson et al. 2012):

- Knowledge intensity of the labor force (human capital).
- Physical capital.
- Repeated innovation efforts.
- The firm belongs to a multinational company group.
- Market extension and export experiences.
- Import intensity and import links to foreign suppliers.

Instead of extending the review to consider other ways of relating firm performance to characteristics of firms, the presentation will focus on the conditions enumerated above to examine their association with location characteristics and innovation milieu of the innovating firm. Empirical observations suggest that the intensity and composition of knowledge flows are basic in explaining a firm's innovation engagement and economic return to its efforts. Table 21.2 provides an overview of different knowledge sources, of mechanisms influencing generation and transfer of knowledge of various character, and of spatial aspects of these mechanisms.

The table traces a broad set of *knowledge sources*, including knowledge exchange with collaborators' purchase from knowledge providers, pure knowledge spillovers as a side effect of ordinary transactions, knowledge that moves from one firm to another

Table 21.2 Knowledge intensity in the private sector of the economy. Sweden 2007

Functional region	The entire private sector 1993, %	The entire private sector 2007, %	Inhabitants 2007 (region average)
Stockholm metropolitan region	17.3	28.1	2.3 million
Göteborg – Malmö regions (average)	13.6	23.8	1.0 million
Medium-sized urban regions	10.3	18.6	0.2 million
Country average	8.6	14.7	0.1 million

Remark: Knowledge intensity is the share of the labor force with at least 3 years of university studies.

Source: Elaborations from Statistics Sweden (Johansson et al. 2010)

when persons switch from one employer to another, entrepreneurs that leave employment and start new firms, active search for *knowledge-accession* possibilities, and knowledge flows in long-distance networks such as internal links inside a multinational corporation. Many of these phenomena can be understood as diffusion of creative ideas, and we can identify network externalities when firms establish network links to carry both intended and unintended knowledge flows.

21.3.3 Proximity and Networks

While relying on its cumulated resource base and associated knowledge assets, the innovating firm is characterized by its capacity to exploit in-house knowledge in conjunction with external knowledge sources. The latter are characterized in [Table 21.3](#), from which it is obvious that a firm's proximity to external knowledge affects the opportunities to acquire useful inputs to the firm's innovation activities.

As outlined in Johansson and Quigley (2004), there are two principle ways that can simplify and stimulate knowledge interaction and exchange of associated information. The first principle is the *proximity advantage*, which is based on the fact that the frequency of face-to-face (FTF) interaction between two or several parties decreases as the (time) distance between the location of the parties increases. This principle implies that an innovating (and adopting) firm benefits from being located in an environment with rich and diverse knowledge flows and with a multiplicity of relevant knowledge sources and knowledge exchange actors like R&D-intensive firms, knowledge-intensive producer services, and research organizations, including universities.

The second approach to facilitate knowledge exchange between two parties is to invest in links (communication channels) between the parties. According to this principle, a firm can invest in links and entire networks of interaction links to reduce the friction and costs of interaction over long distance. This opportunity may be termed *network advantage*. Thus, when a proximity solution is not at hand in a given location, then a firm can choose to invest in links to distant collaborators (such as suppliers, customers, and other knowledge providers) as a means to compensate for

Table 21.3 Origin of knowledge flows that are inputs to a firm's innovation activities

Origin or source of knowledge flows	Generation and transfer of knowledge	Spatial aspects and co-location in the same region
Knowledge interaction	Collaboration with customers, suppliers, universities and other knowledge providers	The interactive efforts are facilitated when partners are co-located in the same region
Purchase of knowledge (e.g., from knowledge-intensive producer services suppliers)	Knowledge transactions may require links of trust between buyer and seller	Location proximity facilitates the establishment of contract-like links between actors
Spillovers from normal transactions between a firm and its customers and suppliers	The firm's interplay with customers, suppliers and other actors open up for unintended knowledge flows	A firm's transaction links extend across region and country borders, but intra-region links are more likely to establish in large urban regions
Job mobility bringing the firm new labor embodying knowledge achieved in previous job(s)	Recruitment inflow to a firm may be the basic source for unintended spillovers. Such flows decline with increasing distance	The frequency of job switching is more frequent (i) among knowledge-intensive labor and (ii) in large urban regions
Scanning and searching for knowledge accession opportunities	Renewal in the form of innovation and adoption is fuelled by the conjunction of internal and external knowledge	Firms located in urban regions which host many and diverse knowledge sources offer the local firms external knowledge advantages
Internal knowledge flows between units of a company group, especially multinationals	The internal networks of a multinational company group can overcome long distance and protect knowledge from leakage	The multinational subsidiaries can engage in knowledge accession and local networks in selected global set of nodes
Investment in R&D collaboration networks locally and globally	These networks include strategic alliances as well local links based on trust	Collaboration links reduce the friction of knowledge exchange and the payoff becomes higher and longer the planned interaction frequency is

the lack of feasible proximity options. In many cases lumpy investments in long-distance links complement investments in links for short-distance interaction. The advantage of a location in an agglomeration is that (i) the need for lumpy link investments is smaller in an urban agglomeration, while such investments at the same time are more easy to establish inside an agglomeration. In particular, when two actors are located in the same functional region, the cost of forming an interaction link should generically be smaller than when the same actors are more distant from each other. This conclusion can be motivated in the following way:

Consider that two actors strive to develop a mutual interaction link which has the form of an implicit contract underpinned by trust (based on positive experiences) and a joint capacity to communicate complex messages in a reliable way. We can assume that such relations require repeated face-to-face (FTF) contacts between the two parties as an input to the link formation, while maintenance

comes naturally as a consequence of using the link. In this view, a link is less costly to establish for firms which are colocated in the same region than for firms hosted in different regions.

A firm can be defined as *innovating* for periods during which it is engaged in innovation activities. Innovating firms have an advantage from being located in a large agglomeration with many opportunities to interact and many opportunities to establish local interaction links. This observation opens questions about the geography of diffusion, which is a field where a major contribution was made by Hägerstrand in the beginning of the 1950s. Hägerstrand (1967) used a huge set of observations to demonstrate the statement in the third thesis of this presentation. This statement stresses that ideas, production methods, and new products diffuse across geographical areas in spatial processes exhibiting clear regularities, where the novelties diffuse faster along short distances from the original source. In this sense the Hägerstrand model has been considered to stress neighborhood effects in the spreading process while observing that large and dense places represent a greater potential of neighborhoods.

Hägerstrand investigates several alternative explanations of innovation diffusion processes. For example, one may assume that (i) the entire population (of potential adopters) becomes informed about the innovation simultaneously, whereas acceptance of the novelty occurs in a random order of precedence. This may be varied by considering unevenly distributed capacities to accept the novelty, and this may in turn be associated with the presence of “innovation centers” and followers ordered in a hierarchy. From this we may conclude that (i) if receptiveness or propensity to adopt is unevenly distributed, spatial diffusion will unfold accordingly, and (ii) if the generation of novelties is more frequent in certain places, neighborhood effects will affect the *spatial diffusion* pattern.

21.4 Innovation, Regional Milieu, and Networks

Empirical observations suggest that innovation is spatially concentrated. Innovation combines invention and commercialization, and this may explain why innovation is more concentrated than invention and more concentrated than production. However, the basic observation in this section is that knowledge is spatially sticky. In every particular case of *knowledge diffusion* (spillover as well as commercial transfer), the friction cost will vary because of communication distances. This friction is augmented when knowledge is complex (Beckmann 2000) and when it is tacit (Polanyi 1966). In both cases messages are difficult to encode and decode, and the tool to overcome this obstacle is frequent *FTF interactions*. This makes knowledge spatially sticky (von Hippel 1994).

21.4.1 A Functional Region Is an Arena for Face-to-Face Contacts

In previous sections of this chapter, the presentation argues that an innovative firm has to rely on both internal knowledge workers and the presence of knowledge-intensive labor in the environment. A firm’s accessibility to knowledge intensity in its nearby

environment can benefit the firm in two different ways. First, a large local supply of labor with university education facilitates the matching of supply and demand with regard to qualifications and competence profiles. The second aspect is that a region with a wide spectrum of knowledge resources provides rich opportunities for knowledge exchange and creative interaction with other actors in the urban region.

The above observations refer to both pecuniary and other knowledge flow externalities. First, transaction costs for recruiting employees with a desired profile reduce in a large urban region. Second, transaction costs also reduce in processes of knowledge accession. Third, pure *knowledge spillover* can be expected to increase as the size of an urban agglomeration expands. A large urban region can afford diverse and frequent FTF contacts at low costs, and this explains the reduction of knowledge transaction costs and the augmented likelihood for spillovers.

Ohlin's early discussion of urbanization economies was reemphasized in the contributions by Jacobs (1969), where large urban agglomerations are depicted as places with diversity in competence, ideas, product innovations, and variation-rich import flows. Such milieus, Jacob argues, foster creativity and innovation activities, especially since they concretize Schumpeter's vision of *novelty by combination*.

If urbanization economies obtain in a milieu of complex diversity, localization economies may be characterized as a milieu with a spectrum of input suppliers and other support factors that are designed to improve collocated firms in the same industry, firms supplying varieties that belong to the same product group or firms which share the same categories of customers and suppliers. Cluster milieus with localization economies may be considered as the agglomeration phenomenon that can develop in small- and medium-sized urban regions, whereas urbanization economies is a characteristic of large urban (metropolitan) regions. In Capello (2002), it is argued that industry clusters are prevalent in large urban regions, while observing that in a metropolitan region there can be many types of clusters, making the economy a "cluster of clusters."

Especially for *cluster* phenomena, the literature has stressed the role of communication links between firms extended to complex networks for knowledge exchange among firms in the same cluster. A prerequisite is of course that the pertinent firms must have enough knowledge to exchange. In this view the network is rather an infrastructure for product and process development activities.

Firms belonging to a multinational company group have the internal network of the group as an infrastructure for knowledge interaction. First, such company group networks are especially designed to protect knowledge from leaking to competitors in undesired ways. Second, the global location of subsidiaries makes it possible for individual firms in a group to tap knowledge from different knowledge centers around the world.

21.4.2 Urbanization and Localization

Agglomeration of firms can theoretically be divided into two forms. The first case is obtained when several firms in the same industry collocate or cluster in the same urban region. In the second stance, agglomeration refers to collocation in the same

urban region of firms that belong to different types of industries. Clustering of similar firms is assumed to bring about localization economies with diversity within a specialized field, whereas agglomeration of firms adhering to a variety of industries is assumed to cause urbanization economies, where size and diversity of demand are expected to attract a diverse supply. This distinction between localization and urbanization economies was made by Ohlin (1933) and was later studied by Henderson (1997) and many others.

When a set of firms in the same industry are colocated in the same functional region, they benefit from *localization economies* due to mutual stimuli to improve production routines and to develop novel products. The consequence of such colocation can be augmented productivity of the pertinent firms. Localization economies are often thought of as an externality generated by colocation of several firms that have similarities with regard to markets (customers), intermediary inputs, technology and equipment, distribution systems, and the like. Having much in common, those colocated firms can mutually exchange and spill over adoption and innovation opportunities and technical knowledge. This phenomenon can be expected to have a significant role to play in smaller (urban) regions which may develop an environment of interlinked firms and their specialized suppliers of services and other inputs and associated institutions like trade associations and universities.

Obviously, a successful regional cluster may in the long term be affected by negative lock-in effects, such that they develop into mutual stiffness while evolving along a life-cycle path, starting with a juvenile period of expansion, followed by stagnation and eventually decline. In contradistinction we observe that large urban agglomerations in principle are protected against this phenomenon by having a broader spectrum of specialized fields and diversification as its basis. As emphasized by Jacobs (1969), the urban diversity constitutes an environment that boosts creativity and opens an avenue that facilitates the cross-fertilization of ideas. A very similar view was put forward by Vernon (1966) when he suggested that new product cycles frequently are initiated in metropolitan regions with rich knowledge sources, intense knowledge flows, and competent and demanding customers side by side with alert input suppliers. In this view innovations are generated where *urbanization economies* prevail and foster communication externalities.

A long range of empirical studies can be summarized by suggesting that large urban agglomerations are more innovative while at the same time being among the most productive places. These studies also suggest that metropolitan-region advantages are caused by economies of scope. These regions attract talented persons with creative occupations to migrate into metropolitan regions, and hence it becomes troublesome to which extent higher productivity and higher wages are caused by a metropolitan region's productive milieu or by a selective in-migration of skilled persons.

21.4.3 Accessibility to Knowledge Sources

Consider an economy which consists of a set of urban regions, $r \in R = \{1, \dots, \bar{r}\}$, as specified earlier in this chapter, and assume that each region consists of one or

several urban areas, $i \in r$, where each such area, however small, represents a spatial concentration of economic activity. Many early studies have examined how aggregate knowledge sources and R&D activities inside an urban region generate spillovers and affect innovation activities and innovation outcome of firms located in the region. The conclusion from many of these contributions is that knowledge flows and *spillovers* are spatially bounded in the sense that the likelihood of knowledge flows reduces as distance between origin and destination grows.

Let G_i be the amount of a knowledge resource located in urban area i , and consider that we can measure the time distance, t_{ij} between any two pairs of locations i and j . Let λ be a parameter reflecting the time sensitivity of FTF contacts between the two locations, and assume that $\exp\{-\lambda t_{ij}\}G_j$ is a measure of the potential for knowledge flows (including spillovers) from knowledge sources in urban area j to area i . This formulation, which can be derived from a random-choice specification (Andersson and Gråsjö 2009), implies that the potential for knowledge flows on the link (i, j) reduces in value as the time distance increases. The total knowledge flow potential of firms in urban area i , A_i , can be calculated as

$$A_i = \sum_r \sum_{j \in r} \exp\{-\lambda t_{ij}\} G_j \quad (21.1)$$

while the intra-regional potential equals $A_i^r = \sum_{j \in r} \exp\{-\lambda t_{ij}\} G_j$. One may interpret A_i as the overall *accessibility* to knowledge sources of firms in urban area i , while A_i^r represents the intra-regional accessibility to knowledge sources for firms in area i in region r . The measure of A_i in Eq. (21.1) represents an alternative to using an aggregate G-value for an entire urban or metropolitan region. In particular, the A_i -measure is not based on an arbitrary (administrative) delineation of the boundaries of an urban region.

Andersson and Gråsjö, (2009) employ a model with a knowledge production function (KPF), with patent applications of firms representing output, whereas internal and external knowledge sources comprise the inputs. The knowledge production is assumed to depend on R&D activities (man years) in other firms and R&D activities in universities (man years). The influence from these external knowledge resources is discounted according to the principle described in Eq. (21.1), but separated into local, intra-regional, and extra-regional influences. The study demonstrates that such an accessibility approach takes care of the spatial interdependencies by including them in the model. The described approach demonstrates a way to model spatial *knowledge interaction* opportunities, and for each given place, it provides a measure of the potential for diffusion of ideas from the surrounding environment to the selected place – in line with the model contributions of Hågerstrand as presented in Sect. 21.3.3. With another econometric technique, Fischer and Varga (2003) also provide evidence in favor of Hågerstrand's conclusion about distance decay effects.

21.5 Diffusion of Ideas and Technical Solutions

Technological diffusion has primarily been studied in the narrow perspective of firms starting to use a new method of production or, in other words, the adoption of a new production technique. Mansfield (1968) observes that until the end of the 1950s, economists allocated little attention to factors that may determine the rate of diffusion of a new technical solution. Studies during the following decades brought a considerable amount of information about the rate of diffusion (see Batten and Johansson 1989). All these studies also confirm that the diffusion approximates a sigmoid pattern, which can be mimicked by a logistic equation.

Technological diffusion of the kind referred to above plays a prominent role in a country's economic development, since it spreads new technical solutions that are applied across firms and regions. The diffusion can have the form of an innovation that is commercialized and sold in the form of new machinery equipment, information and communication technology (ICT) routines for logistics and administration, etc. In this case the diffusion is partly the result of marketing and sales efforts made by the innovator. The innovation may also originate from a firm which makes an invention to be used in the firm's own operation, while this innovation diffuses to other users through imitation. In this second case, the diffusion may take place in spite of efforts from the innovator to keep the innovation secret.

21.5.1 The Diffusion Model

Technology diffusion is just one of several diffusion processes that have been studied. We may, for example, consider the "epidemic" diffusion of social norms and consumer behavior. In the sequel we will consider diffusion of innovation ideas, representing knowledge that can be input to firms' efforts to develop new product varieties. Moreover, imitation of new products across firms and regions also has the character of a diffusion process. Such spread processes include the establishment of Chinese restaurants in cities over the globe in the 1960s and 1970s, as well as Sushi bars in the following decades.

Irrespective of the nature of what is being diffused, empirical observations provide evidence that the process follows a similar pattern in almost all cases. To make this obvious, a share variable, z , can be introduced, where for each point in time, z refers to (i) the share of a firm's operations that makes use of a specific technique, (ii) the share of all potential users of a new technique (or a new type of current input) who are employing the new technique, (iii) the share of a specific market that a new type of product has managed to conquer, or (iv) the market share a firm has obtained for a specified product segment. Frequently the variable z is referred to as the share of adopters or the market penetration share.

Consider now the development of z as described by the following differential equation:

$$\dot{z} = cz(1 - z) \quad (21.2)$$

where $c \geq 0$ is a given constant that describes the speed of change and $\dot{z} = dz/dt$. When z is small, the share of non-adopters, $(1 - z)$, is large, thereby providing opportunities for the novelty to “randomly” find potential adopters. As z grows and becomes larger, the uncertainty about the novelty is reduced and the propensity to adopt goes up, although the share of non-adopters, $(1 - z)$, is gradually becoming smaller. The outcome is the well-known sigmoid curve in Fig. 21.3, as depicted by graph A.

The Verhulst equation in Eq. (21.2) describes a logistic growth path of, and it can be solved to obtain $z/(1 - z) = \exp\{c(t - \tilde{t})\}$, where \tilde{t} denotes the time it takes for $z(t)$ to reach the value 0.5. Rearranging once more, the share at time t has the value $z(t) = [1 + \exp\{-c(t - \tilde{t})\}]^{-1}$.

For the model of technology *diffusion*, $z(t)$ can for an industry reflect the share of all potential adopters which at time t have already started to use the new technical solution. For the individual firm, z may instead measure the ratio between how much the firm has installed of the new technique relative to a complete installment.

In a seminal study by Griliches (1957), the diffusion of hybrid corn during 1932–1956 is shown to follow *S-shaped* paths for each of five states in the so-called Corn Belt of the USA. Moreover, the introduction of this novel hybrid seed method took place in a sequential order, with Iowa as the initiator or forerunner and with other states following with different time lags vis-à-vis Iowa. The study provides clear indication that the introduction started earlier for states in which the new method had higher profitability, and it also spread at a faster pace in places with higher profitability.

21.5.2 Technology Diffusion and R&D Spillovers

A firm’s production is based on internal resources and on inputs (equipment and intermediaries) bought from other firms. Typically the intermediaries account for at least half of the sales value, where outsourcing strategies of firms leads to an increasing share of intermediary inflows and a reduced share of value added. By means of its own R&D, the individual firm can increase its value added and reduce its cost of intermediary inputs. This type of change process improves the firm’s performance over time. However, there is a parallel process which also affects firm performance. Firms that supply inputs also spend resources to improve their deliveries, and these improvements have the capacity to affect input-buying firms’ performance. This secondary effect has been labeled R&D spillovers.

R&D spillovers refer to the direct knowledge gains of input-buying firms from the R&D of input-supplying industries. An early contribution to this form of analysis is from the 1960s, followed by studies that calculated measures of the amount of R&D embodied in customer firms’ inputs, based on information about capital purchases made by one industry from other industries. A step further was taken in the 1980s in studies using the product R&D made by input suppliers to obtain a measure of R&D spillovers.

Fig. 21.3 Market share development for (C) mechanical typewrites, (B) electrical typewrites, and (A) word processing equipment. Sweden 1970–1990 (Johansson and Karlsson 1991, p 21)

Wolff (1997) applies a measure of *embodied* technical change which is a weighted average of the TFP growth of the supplying industries, using the customer industry's input–output coefficients as weights. This can be referred to as direct productivity spillover and reflects the idea that spillover flows are proportional to inter-sector flows. The same study indicates an even stronger effect on an industry's rate of technical progress when input flows are constrained to be equipment deliveries. Results of this kind seem to indicate that disembodied knowledge flows follow the same patterns as equipment-embodied technology diffusion.

Technology spillovers is a partly misleading notion since an important share of knowledge flows through the economy has the form of purchased knowledge, often embodied in equipment and systems that are acquired by and installed in user firms. Two aspects are important to contemplate. First, when new equipment and new types of current inputs are being developed, the purchasing firm has to find out which are the suppliers offering suitable solutions and which are not. In this context certain firms are more capable and have more advanced absorption capacity. This may be described as firms' search for input suppliers that offer the best practice. This type of knowledge search and accession is not R&D but has many characteristics in common with innovation efforts. In particular, when a firm assesses new equipment options, it may also have to consider new routines and technical solutions and add own innovation efforts.

Second, the opportunities to scan and collect information about input alternatives and novel equipment vary between each innovation milieu associated with a specific location, where innovation milieu signifies the localized knowledge-accession and innovation-collaboration opportunities in the environment of the location. In this context a location is identified as a particular urban region. In an environment of alert input suppliers, the likelihood of finding relevant input alternatives is generally higher than when information has to be collected from more distant sources. Proximity to suppliers brings greater opportunities to communicate and interact with established and potential suppliers. In this way *proximity* may lead to the formation of interpersonal communication networks that can facilitate learning and development. Adams and Jaffe (1996) found that the effects of parent R&D on plant-level productivity were diminished by geographic distance as well as with technological distance, providing further evidence in favor of Thesis 3 in this chapter.

In regional science the importance of the innovation milieu has been studied for a long period, with one strand focusing on cluster formation in smaller urban regions – also referred to as localization economies – and a second strand following the theory of agglomeration economies – also recognized as *urbanization economies*. The arguments for how cluster and agglomeration economies foster technology diffusion and adoption run parallel to those focusing on the generation of innovations. A *cluster* may be rich in specialized input suppliers in view of a particular industry. Agglomeration economies offer diversity of different categories of specialization and can, as a consequence, foster a richer variety of novel combinations.

As we have seen, the sources of technology diffusion and spillover can be fostered by a milieu of local suppliers that have clustered in the same functional region. An important contrast is that also imports bring technology spillovers as was recognized in Coe and Helpman, (1995), later followed by additional studies that avoid some of the econometric problems in the contribution by Coe and Helpman. The emerging understanding is that the more R&D intensive the imports are from other countries, the more can a region and a country accumulate of foreign R&D capital. Thus, import flows from countries with high R&D intensity seem to spur productivity growth in the importing country (and region) more than other imports. One may also distinguish import flows in general from imports of capital or equipment goods, and such studies indicate that the latter have a more distinct influence than overall imports. These different findings suggest that an individual firm benefits from knowledge embedded in import flows. Moreover, they suggest an advantage for functional urban regions in which firms collectively have rich and diversified imports from R&D and innovation-intensive origins. In these regions firms are positively stimulated in their renewal activities (Keller 2004; Andersson and Johansson 2010).

The basic idea of studies of technology spillovers is to find out how intra-firm (and intra-industry) R&D together with R&D of input suppliers combine to generate firm (and industry) *TFP growth*. As reported in Wolff (1997, 2012), the social rate of return to R&D is considerably larger than the direct *return to R&D*. These studies are frequently using industry level data and do not disentangle input-embodied innovation from knowledge flows in a more general sense.

21.5.3 Innovation Ideas and New Products

A product innovation leading to the marketing of a new good or service may have firms and/or households as major customer groups. Although the basic needs of consumers may be limited, there are myriads of changes occurring at the intermediate stages of production as well as in the individual choice processes of households. Regardless of whether we consider intermediate or final users, advancing sophistication and technological evolution consists mainly of substituting new means of consumer satisfaction for old ones. Under these circumstances the diffusion model has to be extended to take the form of a substitution model, recognizing

that the introduction of novelties generates the disappearance of established products. Ultimately new product attributes replace old attribute combinations (Batten and Johansson 1989).

Studies of knowledge flows and diffusion may focus on how such flows are more frequent and faster for certain types of product as well as process innovations, for certain types of firms, and/or for certain regional innovation milieus. Recent contributions emphasize that it is not enough to characterize firms and their capabilities and firm-specific networks. The innovation milieu and its knowledge flows play a fundamental role as innovativeness depends critically on a firm's possibility to combine internal and external knowledge resources.

A *product innovation* has to be marketed and commercialized. This part of the innovation effort brings us to product cycles that may be identified for a specific product group as well as for individual product varieties which belong to the same product group. As discussed earlier in this chapter, it is frequently claimed that product cycles with high frequency are initiated in metropolitan environments in which new product ideas are more prevalent and diverse than elsewhere. Large urban regions also host producer-service suppliers across a range of specialization, and these suppliers are important supporters in the commercialization process. As new products successfully penetrate domestic and foreign markets, they often reach a state of maturity in which knowledge intensity has a reduced role to play and many decomposed activities may be relocated to smaller urban regions or regions which have favorable factor prices for other reasons.

The diffusion phenomenon as described by Eq. (21.1) may be applied to depict a novel product's penetration of geographic markets. Penetration of this kind develops along an *S-shaped* curve like A in Fig. 21.3. For a given product or product variety, the exact curvature will vary with regard to trade links between a supply origin and relevant destinations.

The main message from Fig. 21.3 is that *market penetration* involves two interlinked processes, combining into a substitution process in which a novel product group B is substituted for an old one C. The oldest group in the figure is an aggregate of mechanical typewriter varieties which lose their joint market share as the new group of electrical typewriter varieties gradually gains an increasing market share. The third step is the simultaneous market share decline for electrical typewriters as these are replaced by word processing equipment. In addition, the reader already knows that the word processors rather quickly were replaced by personal computers (PCs).

21.6 Conclusions

Section 21.2 of this chapter has a discussion of the heterogeneity of firms. The conclusions will instead emphasize that functional urban regions are heterogeneous. However, we first have to stress that innovation is a firm activity and so is adoption of technical solutions. These activities rely on a firm's innovation strategy, its innovation efforts, and its renewal capabilities, where the strategy comprises

ambitions to develop capabilities, resources for innovation expenditures, and networks for knowledge flows.

The innovation milieu of the firm can be viewed as an innovation and R&D infrastructure, which facilitates the innovating firm's attempts to combine internal knowledge resources with knowledge sources in the firm's environment. The implicit suggestion of this chapter is that regions differ markedly in their supply of knowledge-intensive labor, knowledge exchange partners, knowledge-based producer services, and knowledge flows in general.

One may formulate a long list of characteristics of an urban region that make the region innovation supportive, providing the region's firms with favorable preconditions. With a shorter list, the regional innovation milieu can be advantageous in the following dimensions:

- The region can attract human resources (knowledge-intensive, creative, and talented individuals).
- The region can attract firms which benefit from access to knowledge sources and R&D activities in firms and universities in the region.
- The region can attract firms which are stimulated by an economic milieu where firms have extensive export networks and associated experiences.
- The region can attract firms that benefit from the regional presence of firms with well-developed import networks as well as import agencies and other firms specialized in selective import for local customers.

The enumerated (and related) characteristics create problems for empirical studies because of grave multicollinearity patterns. At the same time, they represent a particular form of "endogeneity": the composition of the firms which have the same region as a host constitutes the most essential attraction factor of the region. The result is a process of cumulative dynamics which maintain and develop favorable milieu characteristics in certain regions (in which the cumulative causation works in the desired direction), while the dynamics may cause milieu deterioration in other regions.

Abstract

New knowledge generated by an economic agent in a region will tend over time to flow to other economic agents in the same region but also to economic agents in other regions. It is quite common in the literature to use the concept of knowledge spillovers for such knowledge flows, irrespective of whether they are intended or non-intended. The potential for intra-regional knowledge spillover effects depends on the volume and character of the generation on new knowledge in each region as well as of the general characteristics of the individual regional economic milieu, that is, those location attributes, which are regionally trapped and which include how well integrated it is with other regions. The larger this potential, the higher the probability that firms dependent upon knowledge spillovers will locate there and the higher the probability that entrepreneurs will take advantage of this potential to launch innovations and to create new knowledge-based firms. To the extent that firms and entrepreneurs can enjoy these knowledge spillovers, they represent an externality or more specifically a knowledge externality in the regional economy.

Great importance is in the literature attributed to knowledge spillovers and knowledge externalities as drivers of regional economic development. Some authors, for example, claim that regional variations in localized knowledge spillovers are one of the main reasons behind regional variations in innovation performance. Against this background, the purpose of this chapter is, based upon a general characterization of knowledge flows, to analyze the character of knowledge externalities and, in particular, their sources, their economic nature, their recipients, their mechanisms and channels, their geographic reach, and their economic consequences generally and for regional economic development in particular.

22.1 Introduction

According to the new endogenous growth theory, cumulative processes characterized by either self-reinforcing decline or self-reinforcing growth drive regional economic development, which may last for long periods and which transform location patterns considerably. Knowledge accumulation is here a crucial factor for generating sustained regional economic growth. In the different functional regions, such dynamics are recognized as change processes involving location and migration of firms and households. Thus, a significant part of regional economic growth can be modeled as induced by changes in knowledge, technology, organization, and location, which are related to regional scale effects and durable, that is, slowly changing, regional characteristics. In particular, models of endogenous growth normally treat knowledge capital as an independent production factor, which, however, partly has the character of a public good. Hence, part of the new knowledge generated by an economic agent in a region will tend over time to flow to other economic agents in the same region but also to economic agents in other

regions. It is quite common in the literature to use the concept of knowledge spillovers for such knowledge flows, irrespective of whether they are intended or non-intended. A number of studies also provide evidence of the contribution of “knowledge spillovers” to economic growth. However, these studies have clear weaknesses. They, for example, do not clarify the mechanisms and channels through which knowledge spills over, that is, flows, and they assume that all economic agents equally benefit from the spillovers. However, to understand how knowledge flows affect regional economic growth and how regional policies can influence regional economic growth via measures that affect knowledge flows, we need to understand the role and function of different mechanisms and channels for knowledge flows, that is, we must apply a microeconomic perspective.

Knowledge can flow between economic agents (i) in the form of a knowledge transaction, where economic agents, for example, purchases a patent; (ii) as a by-product in connection with normal purchases of goods and services; and/or (iii) through other interaction between economic agents or their employees. When the knowledge flows are not fully compensated, we talk about knowledge spillovers. Griliches (1992) defined knowledge spillovers as “working on similar things and hence benefiting much from each other’s research,” but it is important to stress here that we do not restrict knowledge spillovers only to occur in connection with research, since knowledge also can be generated in other ways, such as “learning-by-doing.”

Intra-regional knowledge spillovers, that is, localized knowledge spillovers, may generate dynamically increasing returns in the regional economy and, thus, stimulate innovation and regional economic growth. Such increasing returns have long-term effects, since they create a tendency for any given ranking of the competitive positions of regions to persist over time. The potential for intra-regional knowledge spillover effects is a function of the volume and character of the generation on new knowledge in each region as well as of the general characteristics of the individual regional economic milieu, that is, those location attributes, which are regionally trapped and which include how well integrated it is with other regions. The larger this potential, the higher the probability that firms dependent upon knowledge spillovers will locate there and the higher the probability that entrepreneurs will take advantage of this potential to launch innovations and to create new knowledge-based firms. To the extent that firms and entrepreneurs can enjoy these knowledge spillovers, they represent an externality or more specifically a knowledge externality in the regional economy.

Great importance is in the literature attributed to knowledge spillovers and knowledge externalities as drivers of regional economic development. Some authors, for example, claim that regional variations in localized knowledge spillovers are one of the main reasons behind regional variations in innovation performance (Jaffe et al. 1993). Against this background, the purpose of this chapter is, based upon a general characterization of knowledge flows, to analyze the character of knowledge externalities and, in particular, their sources, their economic nature, their recipients, their mechanisms and channels, their geographic reach, and their economic consequences generally and for regional economic development in particular (cf. Johansson 2005).

This chapter is organized as follows: In [Sect. 22.2](#), we discuss the nature of knowledge and its effect on the economy. Knowledge flows are discussed in [Sect. 22.3](#). [Section 22.4](#) highlights aspects of knowledge externalities including their economic nature, the sources of knowledge externalities, the recipients of knowledge externalities, the mechanisms and channels of knowledge spillovers, the geographic reach of knowledge spillovers, and the consequences of knowledge spillovers. The relationships between knowledge externalities and regional economic development are discussed in [Sect. 22.5](#), which is followed up in [Sect. 22.6](#) with a discussion of policy conclusions. [Section 22.7](#) concludes.

22.2 The Nature of Knowledge

In order to discuss knowledge flows and the knowledge spillovers and externalities they may generate, we must first discuss the nature of knowledge and its effects on the economy. A natural starting point is to examine how to distinguish between information and knowledge. Information can be defined as messages or data, which can easily be codified and therefore transmitted, received, transferred, and stored at low costs. Of course, these messages can communicate statements about knowledge. Knowledge, on the other hand, consists of organized or structured information that is difficult to codify and interpret and thus to transform into useful messages, generally due to its intrinsic complexity and indivisibility. Thus, much knowledge is tacit because it is the cumulative output of long periods of learning, specific to a particular setting, and cannot easily be written down and become codified.

Focusing on knowledge that can be related to the activities of economic agents, we can distinguish between the following categories:

- Know-how, which is always embodied in persons or embedded in economic agents, such as firms and other organizations. It signifies expertise, skills, and practical attainments. Know-how can be present without codified instructions, generically based on experience and training and often so difficult (or uneconomical) to codify that it remains tacit.
- Know-why, which has the character of systematic and broadly accepted (scientific) explanations, which can be stored in codified form but which may require specific training and skills to be decoded and understood. It refers to a capacity to understand and explain. Know-why refers to science in the sense that it does not exist – by definition – if it has not been created and codified.
- Knowledge in the form of human capital, which represents a combination of know-how and know-why embodied in persons.
- Knowledge embodied in products (hardware and software) created by persons or economic agents by applying human capital, know-why, and know-how in some production process.

For knowledge spillovers and related externalities, it is essential to consider the degree to which knowledge is “rivalrous” and “excludable” (cf. Cornes and Sandler 1986). A rival good has the property that its use by one economic agent precludes

the use by another economic actor, whereas a non-rival good lacks this property. Excludability relates to both technology and legal systems. A good is excludable if the owner can prevent others from using it. Pure public goods are both non-rival and non-excludable. This creates a fundamental conflict in society, since an economic agent will only be motivated to carry out R&D if competitors can be excluded, whereas society will benefit if the knowledge (innovation) is allowed to diffuse to be used by many economic agents (cf. Arrow 1962).

What types of knowledge are then relevant from the perspective of an economic agent? The following primary types of knowledge can be considered:

- Knowledge about activity routines
- Knowledge about output varieties
- Knowledge about markets and customers' willingness to pay for different output varieties
- Knowledge about routines to develop activities and output development activities

Activity routines include techniques, methods, and approaches that to a varying extent are applied in production, administration, distribution, logistics, transaction, interaction activities, and for innovative economic agents also activity and output development activities including general search for new knowledge (cf. Nelson and Winter 1982). The routines are a manifestation of the know-how of an economic agent. From a related perspective, it is possible to identify the following three knowledge concepts: (i) scientific knowledge (principles), (ii) technological knowledge (blueprints), and (iii) entrepreneurial (business) knowledge. In this context, it seems important to remark that both scientists and engineers perform R&D activities, while making use of know-how about effective and feasible ways to conduct research. Attempts to codify such know-how are often quite primitive and superficial.

However, whatever knowledge concept we use, it is important to observe that knowledge is distributed across a large number of individuals and other economic agents in every economy and that this distributed knowledge must be combined in new ways to generate new knowledge and innovations. Thus, to generate new knowledge, economic agents are dependent upon both "inside" and "outside" knowledge, where the former refers to an economic agent's own investments in new knowledge, such as R&D, whereas the latter refers to knowledge production activities performed by other economic agents. Own investments in knowledge production can, from this perspective, be comprehended as a means to absorb and appropriate "outside" knowledge (Cohen and Levinthal 1989). This absorptive capacity is also a function of the employment of skilled and highly educated individuals by economic agents, since the presence of such employees seems to be a key channel by which knowledge is transmitted across economic agents.

Understanding how combinations of distributed knowledge generate new knowledge demands interactive models of knowledge creation and innovation which can be achieved within national, regional, and metropolitan systems of innovation. This implies that new knowledge is not created in some anonymous knowledge production process. Instead, new knowledge is the result of interaction between often identifiable individuals, who previously have accumulated

a substantial stock of knowledge in their specific fields of expertise but who also more or less constantly are keeping themselves updated through various knowledge channels to be aware of new knowledge created elsewhere. New knowledge is created when these individuals share their knowledge within a larger group of people, for example, at a university department or in a research institute or in the research department of an economic agent.

Once it is recognized that new knowledge and new ideas are often offsprings, variations, or combinations of existing knowledge, the significance of “outside” knowledge becomes clear. As knowledge as an input in knowledge production is non-rival and tends to diffuse and spill over despite various appropriability mechanisms, it is frequently maintained that there are increasing returns in knowledge production. For such returns to emerge, diffusion and spillovers of the accumulated and, in particular, the newly generated knowledge are central, as it must be accessible for other economic agents as an input in their knowledge production. However, we must acknowledge that knowledge is often extremely complicated and contains complex elements. This implies that it often only is accessible via interactions within either the economic agents’ innovation networks or general innovation systems that according to much of the literature in the field tend to be bounded by geographical proximity (Jaffe et al. 1993; Karlsson and Manduchi 2001).

22.3 Knowledge Flows

Knowledge flows can be described as a special sort of communication related to the diffusion of messages, products, individuals, or economic agents that embody new ideas, knowledge, concepts, blueprints, and so on (Rogers 1983). Such flows occur whenever an idea generated by a certain economic agent is learned by another economic agent and indicate a process where economic agents learn from another economic agent’s ideas and combine these with internally generated ideas and internally existing ideas, thereby developing and extending the internally existing stock of ideas (cf. Griliches 1992). However, this learning can occur through many different mechanisms, such as markets, publications, social networks, professional networks, education and training, and labor mobility, which indicates that the diffusion of knowledge is a complex matter to disentangle and to understand not least since it is also dependent upon formal and informal institutions and the level of social capital (Helpman 2008, Ed.). Concerns have been raised that, on the one hand, the role of knowledge diffusion is underestimated and that, on the other hand, the role of knowledge spillovers, that is, unpriced knowledge externalities, compared to normal market transactions of knowledge is overestimated in economic theory (Breschi and Lissoni 2001).

As the creation of knowledge is spatially concentrated, it is obvious that knowledge flows that diffuse knowledge spatially play a decisive role in regional economic development. Due to its character, a substantial part of the diffusion of more complex knowledge takes place through face-to-face interaction. Frequent face-to-face

interaction brings distinct information including persistent updates, planned and unplanned learning and the development of similar interpretation schemes, shared understanding of new knowledge and technologies, local institutions, and similar cultural traditions and habits. Developments within “cognitive science” have since several decades credited processes of face-to-face interaction a fundamentally important role for knowledge accumulation and knowledge generation among economic agents. Spatial proximity facilitates face-to-face interaction and, thus, tends to accelerate the transfer of knowledge between individuals and other economic agents. However, spatial proximity is not a sufficient condition for knowledge transfers to take place. Learning often requires trust and cognitive and social proximity, which of course may be facilitated by spatial proximity.

There is actually a long tradition in economics studying these knowledge flows in terms of knowledge diffusion and knowledge spillovers. However, it is in particular since pioneering work of Griliches (1992) that knowledge flows have been extensively analyzed in the micro-productivity literature but also in a growing literature on knowledge spillovers in a spatial context.

The study of knowledge flows has used a number of distinct approaches and techniques. What can be characterized as a technological approach has assumed that knowledge only flows between economic agents (firms) in the same technology group. Other studies use more innovatory measures of knowledge flows and define, for example, technological distance as a bilateral measure, which permits different flow intensities between different pairs of economic agents (Jaffe 1986).

Since the early 1990s, researchers have increasingly used patent citations to follow the path of learning. Patent citations in fact report the potential learning flows between the citing and the cited economic agent. The importance of distance for knowledge flows has been tested by means of patent data (Jaffe et al. 1993). Patent data has also been used for analyzing and comparing knowledge flows originating in universities, federal labs, and firms (Jaffe 1989).

22.4 Aspects of Spatial Knowledge Externalities

Knowledge externalities can occur in situations where the protection of proprietary knowledge is incomplete. To be able to disentangle the role of knowledge externalities in regional economic development, we need to distinguish between six aspects of knowledge externalities: (i) their economic nature, (ii) their sources, (iii) their recipients, (iv) their mechanisms, (v) their geographical reach, and (vi) their effects (cf. Johansson 2005). Knowledge externalities involve firms but also other types of organization, and to have a more general discussion, we use the more general term economic agents. Economic agents are characterized by two main types of activities:

- Ordinary production activities, that is, at each point in time an economic agent uses current and fixed inputs to produce output by means of given techniques (routines)

- Development activities, that is, the use by economic agents of part of the inputs to develop new types of outputs and/or new routines (including the development routines)

It is essential to distinguish between these two types of activities, since knowledge externalities have quite different effects in the two cases. Both ordinary production activities and development activities involve interaction with other economic agents – interactions that give rise to interaction costs, which increase with geographical distance between the actual economic agents and which are nonlinear with regard to geographical distance. Hence, proximity brings an advantage to economic agents.

22.4.1 Economic Nature of Knowledge Externalities

As regards the economic nature of knowledge externalities, we have:

- Pecuniary knowledge externalities that operate via prices, that is, via market links (intra-market knowledge externalities) or via interorganization links (quasi-market knowledge externalities), which we may term connected knowledge spillovers
- Nonpecuniary (technological) knowledge externalities, which operate outside the market, that is, extra-market knowledge externalities or if we like pure knowledge spillovers

In perfect markets, there are no contacts between economic agents. In principle, they do not know each other. Some markets are rather close to perfect markets. However, many markets are characterized by different forms of links between economic agents. A suitable starting point for understanding such markets is the microlevel of individual decision-making units. The decision-making unit can be an economic agent in the form of a firm or other organization or household or individual decision-makers within firms and other organizations. A basic presumption here is that firms and other organizations have internal networks for communication and coordination of production and development activities. Certain internal networks consist of links that are arranged for the flow of resources, while other internal networks function as channels for diffusion and exchange of information and knowledge. All internal networks are connected and governed in such a way that economic agents are coherent.

Attached to the internal networks of economic agents are links that extend beyond the boundaries of the economic agent. Such links connect various economic agents with each other and constitute what we can call interorganizational networks, which are used for flows of goods, services, and/or knowledge. Interaction in this kind of knowledge networks can lead to the development of hybrid forms of knowledge that are freely available only to the network members and thus neither public nor private in character. This hybrid knowledge becomes a kind of club good for the network members (cf. Buchanan 1965). Interaction between economic agents is based upon a formal or informal contract, which normally is long term if one or several of the economic agents involved must make investments that are transaction or link specific.

22.4.2 Sources of Knowledge Externalities

New knowledge is generated by economic agents through deliberate search for new knowledge in the form of R&D activities and through learning-by-doing when carrying through different activities. This search is directed toward different kinds of sources. The sources can be classified into two groups: (i) sources containing embodied knowledge, including individuals, economic agents, and products, and (ii) sources containing disembodied knowledge, including books, articles, research and consultancy reports, patents, and web pages. Since the knowledge-generating activities are localized, regional knowledge externalities have two main spatial sources: (i) intra-regional knowledge sources, that is, knowledge sources characterized by geographical proximity, which lower transaction costs and facilitates pure knowledge spillovers, and (ii) interregional knowledge sources, that is, knowledge sources in other regions, available via different interregional links. Proximity implies that transactions and planned interactions between economic agents become less costly and that the probability for non-planned interactions increases. More advanced types of interactions between economic agents are dependent upon trust, and proximity makes it easier to develop trust (Breschi and Lissoni 2001).

However, for proximity to be important, it must be proximity to something, in this case other economic agents with the relevant knowledge. One type of proximity is proximity to economic agents engaged in the same trade. Such clustering or colocation gives rise to a special form of agglomeration economies, namely, localization economies, where specialization is an important feature. Clustering or colocation of economic agents from different trades gives rise to another type of agglomeration economies, namely, urbanization economies, where diversity and size are essential features. Agglomeration implies that economic agents can benefit from mutual proximity, but whether a more specialized or a more diversified regional economic milieu is most favorable for existence and size of localized knowledge spillovers is still an open question. It is in this connection important to observe that knowledge generation activities are more highly agglomerated than most other types of economic activities.

Anyhow, even if proximity is no guarantee for knowledge spillovers between economic agents, it has two important potential effects. It affects both how economic agents can interact in the marketplace and how they can interact outside the marketplace and benefit from nonpecuniary knowledge spillovers. Thus, proximity influences intra-market and quasi-market as well as extra-market externalities. However, quasi-market externalities are different, since they represent a link between economic agents. Establishing a link to another economic agent is a means to reduce geographical interaction costs and thus to make proximity less critical, that is, links can function as a substitute for proximity. However, since the establishment of an economic link involves search and negotiation costs, we must consider that link formation within a region can be less costly than formation of a link to an economic agent in another region, which implies that proximity play a role for extra-market externalities also.

22.4.3 The Recipients of Knowledge Externalities

Knowledge spillovers across economic agents occur when the knowledge generated by one economic agent is “borrowed” by other economic agents. Here, we must distinguish between spillovers between economic agents in the same trade and spillovers between economic agents in different trades (Audretsch and Feldman 1999). One critical question here concerns whether the specific mix of economic activities undertaken within different regions matter for the extent and direction of knowledge spillovers, that is, do knowledge spillovers occur mainly within or between trades? This question, which concerns the recipients of knowledge spillovers, is very relevant, and a debate among researchers during the two last decades has focused precisely on how the knowledge externalities generated by knowledge spillovers are affected by the regional mix of economic activities. Despite a consensus that knowledge spillovers within a given region stimulate dynamic knowledge externalities, there is no agreement concerning which the recipients of these knowledge spillovers are.

Glaeser et al. (1992), which analyze the factors that influence innovative activities in urban regions, illustrate the controversy. The authors identify two relevant models in the economics literature. The first model is the so-called Marshall-Arrow-Romer (MAR) model, which formalizes the insight that the concentration of a particular trade within a specific urban region (Lösch 1954) promotes intra-regional knowledge spillovers across economic agents in that particular trade and therefore stimulates innovation in that particular industry. The basic assumption here is that knowledge spillovers, and thus knowledge externalities, mainly takes place across economic agents in the same trade.

The alternative view regards intertrade knowledge spillovers as the most important channel to diffuse new economically relevant knowledge. Not least, Jacobs (1969) argues that the agglomeration of economic agents from different trades in urban regions fosters innovations due to the diversity of knowledge sources located in such regions. The recipients of knowledge spillovers from economic agents in one particular trade are here economic agents in other trades. The assumption here is that the variety of industries within an urban region can be a powerful engine of growth for that region and that the exchange of complementary knowledge across diverse economic agents leads to increasing returns to new knowledge. The empirical studies in the field give no clear answer to the question whether MAR or Jacobs’s externalities are most important.

What must be observed is that the gains from knowledge spillovers do not apply uniformly across the economic agents in a region due to the heterogeneity among economic agents. They differ in terms of their history, age, size, knowledge and other resources, location, networks, ownership structure, routines, strategies, and behavior even if they belong to the same industry.

22.4.4 Mechanisms of Knowledge Externalities

Breschi and Lissoni (2001) argue that it is important to improve the understanding of the knowledge transmission mechanisms in addition to study knowledge

spillovers by a rather limited set of variables. The mechanisms conveying knowledge externalities include (i) formal and informal interaction between economic agents, where the formal interaction is based on an explicit contract, while the informal interaction is based upon an implicit contract; (ii) active knowledge search of economic agents; and (iii) mobility of economic agents.

The formal and informal interaction between economic agents can take many forms ranging from transactions of goods and services including R&D services to cooperation in the form of joint ventures and strategic alliances including R&D cooperation. It includes the interaction of employees of different economic agents privately and in social, civic, and professional organizations. Since much knowledge is embodied in people, it is natural to assume that knowledge spillovers are partly a function of the interaction between people with the relevant education, skills, and experiences. Relations to suppliers and/or customers are also potential channels for knowledge spillovers. Furthermore, trade with goods and services embodying knowledge is a further channel for knowledge spillovers and externalities (Grossman and Helpman 1991b). Lastly, we have public policy programs supporting the cooperation between economic agents, which can be potentially important channel for knowledge spillovers.

Active knowledge search involves what can be described as “business intelligence” and involves activities ranging from analyses of patent applications and academic publications to “reverse engineering” of products. Mobility of economic agents involves the mobility of labor as well as the mobility of firms and other organizations. The mobility of people between economic agents and between regions is a potentially important channel for knowledge spillovers. We may observe that there exist several more mechanisms, which support and facilitate the transfer and diffusion of tacit as well as codified knowledge and technology: (i) education; (ii) seminars, conferences, and trade fairs; (iii) interactive communication channels (E-mail, the Internet, video conferences, etc.); (iv) people specially designated to obtain and disseminate knowledge (e.g., gatekeepers); (v) knowledge management within and between economic agents; and (vi) imitation.

It is important to notice that even if each of these channels or mechanisms can be seen as partly independent of each other, they are often linked to each other in different ways. It is in this connection important to observe that international cooperation in both the private and the public sectors play an important role for knowledge diffusion. An increasing number of partnerships among firms, universities, and public research centers as well as between individual researchers and inventors is a clear indication of the growing importance of collaboration. Collaboration permits the partners to share and acquire the expertise of each other, thus enriching their overall know-how. It often functions as a positive sum game, where the advantages outweigh the disadvantages even if the advantages are not always equally shared among the partners.

We are now in a position where we can disentangle the mechanisms behind intra-market, quasi-market, and extra-market knowledge externalities. Starting with the intra-market knowledge externalities, it is obvious that location and urbanization economies will make it possible for economic agents to buy inputs embodying

knowledge with lower transaction costs and potentially also at a lower price due to proximity. We can here think of hardware as well as software embodying knowledge, but we can also think of knowledge-intensive business services as relevant here. In particular, we can here think of purchases that are made ad hoc or so seldom that it is not rational to invest in a link. Urbanization economies bring diversity as an extra dimension, which gives economic agents an opportunity to test different suppliers with a somewhat different knowledge base for the same type of basic delivery and generate what is known as Jacobs's externalities (Jacobs 1969). Localization and urbanization economies also make it possible for economic agents to sell knowledge-intensive outputs with lower transaction costs and potentially at a lower price due to proximity.

Quasi-market or transaction-link knowledge externalities represent idiosyncratic relations between economic agents that provide the participants with advantages that occur in a quasi-market setting besides the ordinary market, that is, these knowledge externalities are a kind of club good. A link between economic agents for the delivery of knowledge or knowledge-intensive goods and/or services reduces transaction costs.

Extra-market knowledge externalities concern information and knowledge spillovers that occur as by-products in the course of all types of interactions between economic agents but can also occur without any direct interaction between economic agents. The prime focus here is on research, development, and innovation activities that are assumed to be stimulated by such spillovers (Karlsson and Manduchi 2001).

However, we must also acknowledge that knowledge can spillover between economic agents without any direct interaction. Obvious examples are when economic agents analyze patent applications and academic publications to get inputs, in particular, to their own research, development, and innovation activities.

22.4.5 The Geographic Reach of Knowledge Externalities

A critical issue in analyzing the role of knowledge spillovers and thus knowledge externalities for regional economic development is the geographic or spatial reach of knowledge spillovers. We have many reasons to believe that knowledge is subject to spatial decay. Due to "the tyranny of distance," most human interaction takes place within the functional region and in particular the locality where people live and often work. The claim that geographical proximity matters for knowledge spillovers between economic agents is largely supported by the empirical literature (Karlsson and Manduchi 2001). Already Glaeser et al. (1992, 1127) maintain that spatial proximity facilitates knowledge spillovers, because "intellectual breakthroughs must cross hallways and streets more easily than oceans and continents." This is followed up by Audretsch and Feldman (1999, 410) who argue, "knowledge spillovers not only generate externalities, but the evidence suggest that such knowledge spillovers tend to be geographically bounded."

The statement by Audretsch and Feldman that knowledge spillovers "tend to be" geographically bounded indicates that knowledge spillovers also may occur

between regions. Actually, the authors themselves only 5 years later argued, “there is no reason that knowledge stop spilling over just because of borders, such as a city limit, state limit or national boundary” (Audretsch and Feldman 2004, 6). In this connection, it may be relevant to go back to Palander (1935), who observed that one of the most remarkable features of modern urban structures is the frequency and extension of the interactions between activities carried out in different cities. These interactions presuppose of course the possibility of communicating between cities. Possibilities that have multiplied many times since the 1930s due to, on the one hand, a telecommunications revolution that has lowered the marginal cost of information exchange between different locations to levels very close to zero and, on the other hand, the evolution of highway and air travel networks that significantly has reduced the travel costs and the travel times. Thus, the interregional interaction costs have been reduced substantially in recent decades creating the necessary foundations for a global knowledge-intensive network economy. Against this background, we may ask to what extent it actually is true that interregional knowledge spillovers are limited in scope and spatial reach.

If we first turn our intention to scientific knowledge, we can indeed claim that the interregional knowledge spillovers are both substantial and rapid between individuals with the relevant absorptive capacity. The reason for this is that the international scientific community is organized in big knowledge networks, relying, for example, on international scientific conferences and journals, and that rapid publication of new scientific results are important for the prestige of the individual scientists. Is technological knowledge then different? To a certain extent, it is, since the economic agent that developed new technological knowledge normally does not want to share it without compensation with competitors. On the other hand, the economic agent who has been able to develop an innovation based upon own-developed new technology is eager that it should be diffused rapidly among customers wherever they are located before any competitor imitates the innovation. Entrepreneurship knowledge in the form of business ideas probably diffuses between regions without major problems, since it normally is not proprietary, even if trademarks and logotypes can be protected. Thus, it might be the case that the claims that geographical knowledge spillovers tend to be geographically bounded underestimate the geographical reach of knowledge spillovers. Actually, there is abundant evidence that the information and knowledge networks that enhance the efficiency and innovativeness of economic agents can be and often are widely diffused geographically. However, we need to stress that a critical factor that we do not discuss here is the speed with which that knowledge diffuses between regions.

22.4.6 Consequences of Knowledge Externalities

The consequences of knowledge externalities appear in the following forms:

- Efficiency externalities, which generate static differences between regions with regard to productivity and unit costs of economic agents

- Innovation externalities, which are dynamic phenomena and appear as new knowledge inducing changing economic efficiency (new routines) but also in the form of new products, increased product characteristic diversity, and similar novelties

We may assume that intra-market knowledge externalities and thus proximity are of special importance for efficiency externalities (cf., Johansson 2005). However, we must observe that links, that is, quasi-market externalities can function as an alternative to proximity.

However, the focus here is mainly on innovation externalities. In recent decades, we have witnessed a substantial progress in the understanding of innovation processes both with regard to process and product innovations. In particular, this is true for the macro level, with the development of the endogenous growth models (Romer 1986; Lucas 1988). In these models, development of technology is an endogenous part of each model, and this endogeneity is coupled to assumptions about knowledge externalities.

Unfortunately, we must admit that the micro foundations for understanding innovation processes are less well developed. The micro-oriented research on innovation processes has had a much stronger empirical focus and has partly been centered on concepts such as regional innovation systems and innovative milieu.

22.5 Knowledge Externalities and Regional Economic Development

In this section, we turn our focus to the effects of knowledge externalities on regional economic development. How does knowledge flows generally influence regional economic development? Orthodox economic theory gives two answers:

- a. Knowledge affects regional economic development via the production functions of regional economic agents by improving their use of their inputs, that is, their productivity (Chambers 1988).
- b. Knowledge affects regional economic development via the value ladder of product varieties produced by regional economic agents (Grossman and Helpman 1991a).

However, orthodox economic theory says nothing about the knowledge generation and diffusion mechanisms in general and knowledge spillovers in particular. A natural starting point for an increased understanding of these issues is a simple endogenous regional growth model for an isolated region, since concepts related to knowledge generation, knowledge accumulation, knowledge appropriation, knowledge flows, and knowledge spillovers are prominent features of such models as well as in the literature on innovation systems (Lundvall 1995, Ed.). These models also provide a systematic approach to understanding the adaptive capacity of a regional economy. Endogenous growth models describe the growth process of the isolated region and suggest that continuous increases in knowledge (“technology”) due to investments in knowledge generation increase aggregated economic growth in the region (cf. Romer 1986, 1990). The basic idea behind such models is that part of

a region's resources is used to produce an output that can be used for consumption and investment, while the remaining resources are employed in producing new knowledge ("technology"). Since knowledge is treated as non-rivalrous and only partially excludable, these models exhibit increasing returns. However, imperfect competition is needed for R&D investments to be worthwhile for economic agents. The innovations generated through the R&D investments later become the intermediate inputs for other firms, and hence, the rate of innovation determines the overall rate of growth.

New (technological) knowledge is in this kind of models used in two ways in the regional economy:

- a. The economic agent in the region that developed it uses new knowledge in the production of a specific unique product. Other economic agents in the region are excluded from using the same knowledge by means of patenting.
- b. New knowledge increases the total stock of knowledge in the region but may spill over to other economic agents to be used in knowledge production by means of examination of patent documentation (Romer 1990). Thus, the knowledge production productivity in the region increases. It may very well be that the new knowledge benefits other economic agents as much or even more than the economic agent that created it.

One limiting factor of this original Romer approach is the assumption of general accessibility of the stock of knowledge in general and new knowledge in particular for all economic agents in the region. There are strong reasons to believe that in particular, new knowledge is not evenly accessible for economic agents in a region, since, for example, not all new knowledge is patented but instead kept as business secret and not all economic agents have the absorption capacity necessary to use the new knowledge. Another limiting factor is that knowledge is treated as a homogenous concept and that no distinction is made between different types of knowledge.

Due to their aggregated character, these models have limitations when it comes to understanding the relation between knowledge production and economic growth at different levels of identification: the level of economic agents, the level of industries, and the regional level. Knowledge is assumed to spillover between economic agents in the region and to generate knowledge externalities, but the precise mechanisms are not explicated.

Another problem with the single-region Romer model is the separation from all other regions. Economic agents trade with economic agents in other regions, and economic agents make direct investments in other regions. Furthermore, people travel and move between regions, so there are numerous mechanisms through which knowledge will diffuse from one region to another and have impact upon productivity and innovation and thus regional economic development in other regions.

An alternative type of endogenous growth model is the intentional human capital model, which stresses the critical importance of education, learning-by-doing, and knowledge spillovers. Technological progress is here the result of intentional research and education investments, and here, human capital is an element in the

aggregate production function. Here, investments in human capital generate knowledge spillovers, which increase the productivity of both physical capital and the general labor force.

Moving from a single-region to a multiregion framework leads to a number of complications, when we want to disentangle the extent to which knowledge externalities influence regional economic development. We must acknowledge:

- That regions are different not least in terms of agglomeration, industrial structure, and accessibility to and interaction with other regions
- That regional economic development is path dependent, that is, history matters
- That the capacity to adapt to economic, technological, and institutional changes varies between regions
- That self-organization prevails due to the actions of households and economic agents
- That knowledge and knowledge generation is not evenly dispersed but instead unevenly distributed and in particular concentrated in (large) cities
- That the distribution pattern differs for different types of knowledge and institutions

Thus, the development potential of different regions is dependent upon their historical development paths including the partly self-organized (dis-)accumulation of infrastructure, economic agents, knowledge, and institutions and the pertinent potential for intra- and interregional knowledge spillovers, which defines the potential development trajectory for each region. Certainly, those regions that offer larger knowledge and other externalities have *ceteris paribus* a larger development potential than other regions. The driver behind regional economic development is the initiation of new technologies, new product cycles, new industries, new infrastructures, and new institutions that over time complements or replaces old ones through processes with different speeds. Hence, the economic development in different regions hinges on their capacity to absorb, generate, and adapt knowledge and to generate and nurture such novelties. This capacity is, given our discussion above, dependent upon (i) the education level of the regional labor force and the incentives for individuals to participate in education, (ii) the incentives for economic agents to undertake R&D and to innovate, and (iii) the degree to which knowledge diffuses within the region and from other regions.

Endogenous growth models tell us that the regions that are most well equipped with resources are most likely to accumulate more resources and increase productivity more over time according to the principle of circular and cumulative causation (Myrdal 1957). However, this form of positive feedbacks is in general constrained, on the one hand, by the development of the demand of the region and its external markets and, on the other hand, by the existing capacities in the form of built environment, accessibility-based transport systems, production capacities, and labor supply. Anyhow, differences between regions may “accrue from the growth of industry itself – the development of skill and know-how; the opportunities for easy communication of ideas and experience; the opportunity of ever-increasing differentiation and of specialization in human activities” (Kaldor 1970, 340).

It is certainly beyond the purpose of this chapter to present a formal multiregional model that in a consistent manner integrates the effects of knowledge flows and pertinent knowledge spillovers on regional economic development. The discussion here is limited to a discussion of some of the factors that must be considered when modeling knowledge-based multiregional growth. We start with discussing new economic geography models and knowledge-based regional growth and continue then with discussing first the role of interregional knowledge on multiregional growth and then how knowledge flows influence the behavior of individual economic agents. New economic geography models combine economies of scale with reduced transport costs to explain why similar economic activities will tend to concentrate in the same locations. These locations will become densely populated and will also have higher levels of income (Krugman 1991).

22.5.1 New Economic Geography Models and Knowledge-Based Regional Growth

It is well known that the original new economic geography models are not suitable to model the role of knowledge spillovers and knowledge externalities in regional economic growth because Krugman originally refused to model technological externalities (Krugman 1991). However, the literature on innovation systems convincingly shows that:

- Knowledge generation is highly geographically concentrated and thus that regions differ substantially in their volume of knowledge production.
- Regions differ substantially in terms of absorption capacity and accessibility to external knowledge.
- Its own unique knowledge mix characterizes each region.

It also stresses that knowledge flows and pertinent knowledge spillovers are at the core of knowledge-based regional development. This implies that the location of knowledge generation and the structure of the spatial networks for knowledge flows and knowledge spillovers are fundamental factors in modeling knowledge-based regional economic development. In addition, it must be acknowledged that the potential of economic agents to absorb new scientific, technological, and entrepreneurial knowledge is facilitated by geographic proximity (Jaffe et al. 1993). The exchange of knowledge and ideas may generate such technological externalities that it influences the location decisions of economic agents and induces them to cluster at specific locations (Marshall 1920), generating differences in income and productivity across geographic space (Henderson 1974). It was first with the merger of new economic geography models and endogenous growth models that knowledge spillovers were taken into account in the new economic geography literature. The critical message here is that when human capital and other capital resources, including R&D competence, are located together in the same region, self-reinforcing processes can be obtained, that is, such concentrations have the power to further stimulate economic growth in these regions.

Large (and dense) regions offer special advantages in terms of knowledge flows and potential for knowledge spillovers, since they normally host research universities, private R&D facilities, and many industrial clusters, that is, industrial diversity. Small (and sparsely populated) regions on the other hand are normally characterized by a lack of research universities and private R&D facilities as well as by having only one or a few industrial clusters or being dependent upon large-scale industries. This suggests the possibility of formulating a model along the lines of new economic geography principles, which takes one of its starting points the favorable conditions for knowledge generation and large potential for knowledge flows and knowledge spillovers in large regions. When such a region for any reason has achieved an initial advantage in knowledge generation, it will attract knowledge-generating and knowledge-utilizing economic agents, since it offers opportunities to get advantages in terms of increasing returns in knowledge generation and knowledge utilization.

Although it is indeed true that it is economic agents and not regions that compete, there are important regional production and knowledge advantages being pursued by the many economic actors within large regions. This leads to an important premise about scientific, technological, and entrepreneurial knowledge and innovations in large regions. New knowledge and innovations emerge uniquely out of large regions not simply because one or the other was endowed with a certain initial stock of knowledge and factors of production but because many assets necessary for knowledge generation and innovations are created in the course of the ongoing knowledge generation, innovation, and production activities among economic agents. These assets include new scientific, technological, and entrepreneurial knowledge, which are prerequisites for novelty-by-combination processes, which generate new knowledge and innovations but which facilitate the exploitation of knowledge resources and the development of regional formal and informal institutional innovations to support and sustain intra-regional knowledge flows. Furthermore, many of these scientific, technological, entrepreneurial, and institutional assets are not easily transferrable between regions and thus may preserve regional advantages for a long time.

The size of the regional market potential influences the probability that new knowledge in the form of inventions is turned into innovations in the region. The underlying reason is that a large market potential generally increases the demand for knowledge-intensive products. The probability that inventions are turned into innovations increases with the size of the regional market potential, and this gives knowledge-creating and knowledge-utilizing economic agents an extra advantage of locating in large regions. In addition, when more of these economic agents locate in large regions, this makes these regions more attractive for knowledge workers, which fuels the cumulative process and makes the region still more attractive for knowledge-intensive economic agents. More knowledge handlers and more knowledge-intensive economic agents in a region increase its market potential and make it still more attractive. Thus, we may conclude that from an endogenous growth perspective, regions that have a first-mover advantage in terms of knowledge, technology, and innovation are likely to attract educated labor (and capital) from

other regions and thereby generating a cumulative self-reinforcing process of R&D and innovation leadership. This implies that the scarce and critical resources in knowledge-based regions are factors such as highly educated labor, education system, R&D system, knowledge flows and spillovers, and innovation capability.

When large innovative regions grow, the demand for land, premises, and labor increases, which tends to drive up their prices. However, these price increases are a necessary mechanism to secure that resources gradually are pressed out of maturing industries and made available for new growth industries. This implies that economic growth in large innovative regions is strongly related to the functioning of the relevant markets. Of course, a condition for long-term growth is that the advantages in terms of knowledge and other spillovers increase with at least the same speed as the agglomeration costs.

22.5.2 Interregional Knowledge Flows and Multiregional Growth

The discussion in this section builds upon an endogenous growth model introduced by Andersson and Mantsinen (1980). The model is centered on a production function for each region r , $Q_r = Q(K_r, A_r)$, where K_r represents the total production capital in region r and A_r the total accessible knowledge in region r . The knowledge resources in any region r are G_r , but region r can also benefit from knowledge resources in all other region s , G_s . Thus, A_r represents a compound knowledge consisting of knowledge within region r and accessible knowledge in other regions.

With the help of the above model components, it is possible in a stylized way to illustrate how regional and interregional knowledge resources influence regional economic growth. G represents here all types of knowledge as well as the capacity to develop new knowledge. Now, assume that knowledge can be treated as a spatial public good, such that G_s in any region s influences the accessible knowledge in region r via a distance-decay factor $f_{sr} = \exp\{-\lambda t_{sr}\}$, where λ is the travel time sensitivity and t_{sr} is the travel time distance between region r and region s . This implies that

$$A_r = \sum_s f_{sr} G_s$$

summarizing the total accessible knowledge in region r , where $f_{rr} > f_{sr} > 0$, for $s \neq r$. In this model, the accessible knowledge will change when any of the G -variables, travel sensitivities, and/or travel time distances change. Changes in the G -variables are the outcomes of knowledge generation processes, which can be illustrated by the following differential equation:

$$\dot{G}_r = H[g_r(A_r), \tau_r(Q_r), \theta_r(Q_r)]$$

where g_r is the R&D productivity in region r , which is a function of accessible knowledge in region r , A_r , τ_r is the share of output Q_r devoted to R&D in region

r and θ_r is the “learning-by-doing productivity” in region r , which is a function of total output in region r . The important message here is that regions do not only rely of their own internal knowledge and capacity to generate knowledge but also on their capacity to integrate knowledge generated in other regions. If we also introduce a second dynamic equation that describes the accumulation of production capital in region r , K_r , we get a simple model of multiregional development:

$$\dot{K}_r = s_r(1 - \tau_r)Q_r$$

where s_r signifies the investment coefficient in region r . We will not here discuss the equilibrium properties of this model. Instead, we limit our comments here to aspects of knowledge generation and knowledge flows.

We start with discussing the knowledge generation process in a region r , \dot{G}_r . It seems reasonable to assume that large and rich (and dense) regions will have advantages in terms of knowledge generation. They have a large output, can afford to devote large resources to R&D, have a larger capacity for learning-by-doing due to a larger output, and have normally larger knowledge accessibility due to a large intra-regional knowledge pool and a good accessibility to other large regions with a large knowledge pool.

What then can we say about knowledge flows and the potential for knowledge spillovers? It is obvious that the knowledge accessibility of a region is critical here. Regions with a high accessibility to knowledge-rich regions obviously have a higher potential for knowledge flows and pertinent knowledge spillovers. A high accessibility does not only imply a high probability for trade flows but also for direct investments and for interaction between people. These are all mechanisms that can generate knowledge spillovers and thus be a source for increasing returns in regional economic development.

22.5.3 Microeconomic Aspects of Knowledge Spillovers, Knowledge Externalities, and Regional Economic Development

Aggregated regional growth models offer general understanding of some of the basic factors that drive regional economic development. These models illustrate the importance of R&D, human capital investments, endogenous technological change, exports, agglomeration economies, and knowledge and other spillovers from a theoretical perspective, but they are too aggregated for empirical testing. This implies that these models do not have enough capacity to discriminate between different factors in terms of their importance for regional productivity and general regional economic growth. These models also have problems in identifying which the true exogenous factors are, that is, the factors that are of interest for regional policymaking.

Another problem with the aggregated models is that they assume that all economic agents are homogenous in all respects. Thus, these models fail to acknowledge that economic agents are heterogeneous in terms of their history,

age, size, knowledge and other resources, location, networks, ownership structure, routines, strategies, and behavior even if they belong to the same industry. Industrial and regional productivity growth and general economic growth are generated by a large number of different individual processes within the different economic agents, which are influenced by different internal and external. In every industry, there are economic agents that are persistently investing in R&D, while other economic agents invest now and then or not at all. The same is true for exports and imports. In terms of efficiency, we know that productivity distributions are characterized by a high degree of inertia and that the position that the different economic agents occupy in the distribution is highly persistent over time.

To overcome these deficiencies and to increase our understanding of how knowledge spillovers and knowledge externalities influence regional economic development, we need a model framework at the microeconomic level capable of accommodating different conditions and different behavior among economic agents within the same industry. Thus, we need a model framework capable of analyzing the factors influencing the behavior of different economic agents as well as the effects of differing behavior among economic agents in terms of productivity improvements and increased market shares. It is beyond the scope of this chapter to develop such a microeconomic framework with such a capability. However, in the sequel, we highlight some aspects that are critical for developing such a framework.

An externality in production emerges when the output from one economic agent is influenced not only by its own inputs but also from the outputs and inputs used by other economic agents. When the externality emerges within the region, where the economic agent is located, it has the character of a proximity externality. We talk about localization economies, if other economic agents in the same trade generate the externality. If economic agents in other trades generate the externality, we talk about urbanization economies. If the externality emerges from outside the region, we can talk about an extra-market or network externality. Assuming that economic agents are engaged in two types of production – the production of goods and services and the production of knowledge – we can formulate two functions that describe the two processes, the first being the production function for economic agent i , in industry j in region r :

$$q_{i,j,r} = A_{i,j,r}(c_{i,j,r}^q) f(x_{i,j,r}, y_{j,r}, z_{n,r}, E_s)$$

where q signifies output, $A_{i,j,r}$ the accessible knowledge for economic agent i , $c_{i,j,r}^q$ the absorptive capacity of economic agent i of production relevant knowledge, $x_{i,j,r}$ the inputs used by economic agent i , $y_{j,r}$ the accessibility to other economic agents in the region in the same trade as economic agent i , $z_{n,r}$ the accessibility to other economic agents in the region in other trade than i , E_s and the accessibility to economic agents in all other regions s . The above formulation implies that the productivity level in the economic agent i depends on its knowledge level, the size of the localization economies, the size of the urbanization economies, and the size of

the extra-market externalities. What about then the generation of knowledge by economic agent r ? Knowledge generation by economic agent i in trade j in region r is

$$\dot{g}_{i,j,r} = h \left\{ g_{i,j,r} \left[A_{i,j,r}, \dot{g}_{j,r}^A, \dot{g}_{n,r}^A, \dot{g}_s^A, \theta_{i,j,r}(q_{i,j,r}), c_{i,j,r}^g \right], \tau_{i,j,r}(q_{i,j,r}) \right\}$$

where $g_{i,j,r}$ is the research productivity by economic agent i , $\dot{g}_{j,r}^A$ is the accessibility to knowledge output from other economic agents in trade j in region r , $\dot{g}_{n,r}^A$ is the accessibility to knowledge output in other trades in region r , \dot{g}_s^A is the accessibility to knowledge output in other regions, $\theta_{i,j,r}$ is the “learning-by-doing productivity” in economic agent i , $c_{i,j,r}^g$ is the absorptive capacity of economic agent i of R&D-relevant knowledge, and $\tau_{i,j,r}$ is the share of the output from economic agent i devoted to R&D. The current formulation tells us that an economic agent combines its current knowledge with new knowledge developed by economic agents in the same trade and in other trades in the home region, new knowledge developed in other regions, and with knowledge gained from the own production experience. The three knowledge accessibilities included represent three potentials for knowledge flows and thus for knowledge spillovers. However, the probability of each economic agent to succeed in the knowledge generation game is among other things dependent upon their skills and capacity in interacting with other economic agents, including, for example, research universities, in the home region as well as in other regions. It is also dependent upon the extent to which the location offers suitable interaction infrastructures and meeting places and formal and informal institutions including both a potential to protect the newly generated knowledge and the necessary level of trust for successful interaction between economic agents. The formulation allows for intra-market, quasi-market, and extra-market spillovers in line with the earlier discussion in this chapter. Concerning the extra-market spillovers, we want in particular to stress the role that exports and imports play as potential channels for knowledge spillovers. These spillovers can be direct, but they might also be indirect coming via other exporting or importing firms in the region.

The framework illustrated above is only a very partial framework. One important aspect missing is the creative destruction along Schumpeterian lines, that is, the scale and causes of entry and exit of economic agents and the role of knowledge spillovers in this respect. Innovation may represent a vehicle for new economic agents to enter the market successfully. However, since new firms by definition have done no R&D of their own, spillovers of scientific, technological, and entrepreneurial knowledge provide an explanation for innovative entry by new economic agents. Different regions have varying endowments of knowledge and not least new knowledge, which implies that the potential for innovative entry differs between regions and that larger regions generally offer a higher potential since they also offer a larger market potential. Of course, individuals and groups of individuals differ in their capacity to discover, create, and exploit innovations, that is, to create new combinations, but since individuals in larger regions generally have a higher education, more varied work experiences, and more extensive personal networks, these regions have an advantage here too.

22.6 Knowledge Externalities and Regional Economic Development: Policy Conclusions

Regional economic development seems increasingly to be dependent upon internal network structures to exploit fully the internal knowledge base, while at the same time absorbing new knowledge from outside the region. Given the potentially large importance of knowledge spillovers for regional (and thus national) economic development, policymakers have strong incentives to partly shift their traditional focus on the share of GRP and GDP invested in R&D to measures that foster knowledge spillovers, intra-regional as well as interregional. Concerning stimuli to intra-regional knowledge spillovers, policymakers should first of all focus on increasing intra-regional accessibility by means of investments in transport infrastructure and public transport. It is also important to establish arenas and meeting places where economic agents in the region can meet and interact.

Even if one should not underestimate the importance of intra-regional knowledge spillovers, it seems in particular important to promote interregional knowledge spillovers. There are certainly many channels for interregional knowledge flows. Starting with academic channels, we claim that it is important to involve scientists from other regions and countries in advanced research programs and to encourage scientists to engage in interregional and international cooperation and coauthorships as well as being guest researchers at research universities and laboratories in other countries. With a rapidly increasing number of patents and academic publications, it becomes more and more important to support inventors in all fields with rapid updates on new patents and publications. In particular, small- and medium-sized firms might need support when buying patents and licenses from other regions as well as in finding the right consultants in other regions. A positive and supportive attitude to strategic R&D cooperation with economic agents in other regions is also important. The role of imports of high-technology and knowledge-intensive products for interregional and international knowledge flows is often neglected. For regions that want to maximize the potential for interregional knowledge spillovers, it is important to create good conditions for import activities, not least through a high interregional accessibility. The same is true for direct investments from other regions. Multinational firms play an important but probably underestimated role for interregional knowledge spillovers. Another important channel for interregional knowledge flows is the in-migration of highly educated and skilled labor. Not least is it important to create an institutional framework that makes it easy for in-migrants to find information about available jobs, to apply for jobs, to find housing, etc.

22.7 Conclusions

There exists today a large literature on knowledge flows mainly using the concept knowledge spillovers without often making any distinction between intended and non-intended knowledge flows. The literature is not clear of the relative role of

intended, that is, market-based, versus non-intended, that is, spillover, knowledge flows. This distinction is important, since it is only the latter type which generates any knowledge externalities. The discussion of knowledge externalities in the literature has had a focus on technological spillovers, but it is obvious that there also exist pecuniary knowledge externalities. Thus, there is a substantial confusion in the literature as regards the economic nature of knowledge externalities. A similar confusion concerns the sources of knowledge spillovers. Many empirical studies have analyzed the role of patent citations, but it is obvious that economic agents learn from many other sources but patents. Another controversy concerns who benefits from knowledge spillovers. Is it mainly economic agents in the same trade or is it mainly economic agents in other trades? In terms of the mechanisms and channels for knowledge spillovers, it is obvious that learning takes place through many channels but that most studies only consider one channel at a time. A hot topic is the spatial reach of knowledge spillovers. It is a common statement in the literature that knowledge spillovers are bounded in geographical space, a statement that needs to be seriously questioned in the time of the Internet with global air connections, satellite TV channels, and a high volume of international trade, direct investments, traveling, and labor mobility. Furthermore, the consequences of knowledge spillovers and knowledge externalities are not well understood, disentangled, and analyzed. This state of the art certainly complicates analyses of the role of knowledge spillovers and knowledge externalities for regional economic development. A central problem here is that the majority of the studies are done at an aggregated level assuming that there is only one type of knowledge and that all economic agents are equal and benefitting to the same extent from knowledge spillovers. This implies that researchers in the field today have all too little understanding to guide policymakers. What we need for the future are multilevel studies based upon microeconomic data for economic agents, who recognize that economic agents and regions are heterogeneous and that different economic agents use different types of knowledge, use different knowledge channels, differ in their absorptive capacity, etc.

Abstract

Over the last three decades, literature on industrial districts, innovative milieus, and industrial clusters has enriched our knowledge about endogenous factors and processes driving regional development and the role of the region as an important level of economic coordination. This class of stylized development concepts has emerged since the 1970s and attempts to account for successful regional adaptations to changes in the global economic environment. Each of these

concepts grew out of specific inquiries into the causes of economic success to be found in the midst of general decline by building upon the early ideas of Alfred Marshall in several ways. Neo-Marshallian districts found in Italy highlight the importance of small firms supported by strong family and local ties, while the innovative milieu concept places great emphasis on the network structure of institutions to diffuse externally sourced innovations to the local economy. Clusters have become far more general in scope, fruitful in theoretical insights, and robust in application, informing the work of both academics and policy-makers around the world.

23.1 Introduction

When one first becomes interested in the growth or development implications for local or regional collections of firms and industries, a bewildering array of possibilities presents itself. One learns that external economies of scale accrue to firms that colocate and thereby stimulate growth, for example, pecuniary savings and intangible flows of information arise automatically from agglomeration benefiting resident firms. External economies of scale are defined as economies that are external to the firm but internal to the region. External economies of scale can be divided into localization economies (benefits from collocation accruing to firms operating in the same industry) and urbanization economies (benefits from collocation accruing to firms operating in different industries). A robust and widely ranging literature of this tradition does exist, guiding the theoretically inclined or those who wish to examine empirical tests of important propositions.

Then there are the development practitioners, academics, or students who rely upon a family of more stylized models to formulate development prospects. Such models frequently adopt the concepts that are most widely accepted or formulated in their home territories, the bulk of which date from the 1970s. The emergence of these concepts can be documented by Google Ngrams for books published in English between 1800 and 2000 (<http://books.google.com/ngrams>). The 1970s was a period in which traditional production methods and their centers lagged but more peripheral areas, focused increasingly on better or higher technologies and market niches, began to prosper from the bottom-up. Italians are quite familiar with “neo-Marshallian industrial districts,” while the French and many Swiss prefer insights drawn from “innovative milieu,” and contemporary English or German speakers – and many others – are most comfortable with the ideas borne of “industrial clusters.” The concepts discussed in this chapter all go beyond a pure economic view on agglomerated industries (i.e., the argument of external economies of scale), drawing – although to varying degrees – attention to social and institutional factors that allow for coordination of economic actors. The preferred notions arose in specific contexts and circumstances, but are they essentially similar or are there elemental differences worth emphasizing?

In this chapter, we shall focus on both the common and distinctive elements of these concepts. To get under way, we shall first examine the core foundation on

which each of these rests, after which representative definitions will be drawn from the contemporary literature to distinguish between Marshallian and neo-Marshallian industrial districts, innovative milieux, and industrial clusters. We will then compare these with the definitions found in the emergence of their seminal literatures. Primary attention will be paid to features that reveal common overlaps and how each addresses these points, while also noting uniquely specific features that clearly distinguish among them. Finally, we will comment on challenges for future research and application.

23.2 Core Concepts

23.2.1 The Marshallian Concept

The English economist Alfred Marshall is seen as the “father” of the industrial district concept, and most contemporary work on agglomeration, localization, clustering, and the innovation-enhancing effects related with the geographical concentration of firms is explicitly or at least implicitly based on his writings. The key element in Marshall’s theorizing about “localized industries” (defined as industries concentrated in certain localities) is the notion of external economies of scale (see Sect. 23.1). It is these effects that enable small firms colocated with others in a district to compete successfully with large vertically integrated firms, which take advantage of internal economies of scale (i.e., benefits of large-scale production). There were ample examples of such geographical settings in the late 1800s in Britain such as cotton and textile in Lancashire, cutlery in Sheffield, pottery in Staffordshire, or straw plaiting in Bedfordshire.

Marshall’s writings contain both explanations for the rise of localized industries and their long-term “anchoring” in districts. According to Marshall, the initial localization of industries can have many sources such as the availability of raw material, the demand for goods of high quality or the immigration of people with specialized skills. However, once an industry is spatially concentrated in a particular locality, a set of agglomeration forces keeps it in place: “When an industry has thus chosen a locality for itself, it is likely to stay there long: so great are the advantages which people following the same skilled trade get from near neighbourhood to one another” (Marshall 1920, p. 225). These advantages are threefold, and they can be conceptualized as positive external economies of scale:

- (i) Knowledge spillovers: Firms benefit from local knowledge circulation and manifold opportunities for monitoring, learning from, and imitation of innovative actions set by colocated firms. Marshall (1920, p. 225) notes: “The mysteries of trade become no mysteries; but are as it were in the air, and children learn many of them unconsciously. Good work is rightly appreciated, inventions and improvements in machinery, in processes and in general organization of the business have their merits promptly discussed: if one man starts a new idea, it is taken up by others and combined with suggestions of their own; and thus it becomes the source of further new ideas.”

- (ii) Rise of supplier industries: Colocated firms operating in the same industry also take advantage from the growth of specialized supplier industries in their neighborhood, supplying the localized industry with raw materials, intermediate products, and services.
- (iii) Labor market effects: Localization of industries promotes the emergence of a highly specialized labor market that attracts both firms and workers. Employers benefit from the ready availability of highly skilled workers with the required special qualifications, and workers can take advantage of the rich employment opportunities, allowing them to find adequate jobs rather easily.

According to Marshall, the spatial concentration of firms of moderate size in districts was a widespread phenomenon – it was the typical form of industrial organization – of the English economy in the late nineteenth century, that is, a phenomenon that could be observed in many different industries and not merely a few.

Marshall's formulation of the industrial district concept contains a profound analysis of the linkages that knit collocated small firms together. His work points to knowledge spillovers, producer-supplier relations, and labor mobility among district firms and conceptualizes such relations as key factors underpinning the innovation capacity of localized industries. Marshall's work went beyond pure economic factors and considered also sociocultural and institutional assets to explain the economic vibrancy of industrial districts. A key notion in his writings is that of an "industrial atmosphere," that is, the presence of a collective identity and shared industrial expertise that gradually develops in industrial districts and facilitates interaction, localized knowledge circulation, and the creation and diffusion of innovation.

Marshall was also aware of the potential dangers of specialized local development, anticipating the downturn of many English districts in the first decades of the twentieth century as well as what has happened many years later in old industrial areas characterized by economic mono-structures (i.e., overspecialization in mature sectors such as shipbuilding, coal and steel industries). He considered districts that are dependent on one industry as being extremely vulnerable, pointing to the risk of depression, crisis, and decline in case of changing context conditions such as, for instance, a fall in demand for its products or changes in technology.

In the era of mass production organized within large hierarchical firms, Marshall's ideas lost importance. His work on localized external economies of scale was brought to new life from the 1960s onward. Kenneth Arrow (1962) and Paul Romer (1986) extended Marshall's reasoning on knowledge spillovers as key source of innovation and growth. Such positive localization effects resulting from collocation of firms belonging to the same industry (intra-industry spillovers) are now known as Marshall-Arrow-Romer (MAR) externalities in regional science (Glaeser et al. 1992). They can and should be clearly distinguished from Jacobs externalities, that is, urbanization effects which arise from the presence of firms operating in different industries (interindustry spillovers).

The MAR literature provides a pure economic view of agglomeration phenomena, decoupled from Marshall's accounts of the supporting role of social and

cultural factors referred to as “industrial atmosphere” in his writings. However, Arrow and Romer were not the only scholars who have rediscovered Marshall. In the 1970s and early 1980s, Italian researchers started to draw extensively on his ideas, extending rather than downplaying the weight of the sociocultural underpinning of localized specialized economic activity in their conceptual and empirical analyses.

23.2.2 The Neo-Marshallian Industrial District Concept

The end of the golden age of mass production and the crisis of the large hierarchically organized firm in the 1970s provoked a renewed interest in Alfred Marshall’s work on external economies of scale and industrial districts. His basic ideas were revitalized and further developed by a group of Italian researchers who studied the industrial development in the central and northeastern part of Italy (the so-called Third Italy with its main regions Emilia-Romagna, Tuscany, and Veneto). This group was dealing with a somewhat puzzling phenomenon, that is, the economic success of industries with seemingly outdated organizational forms (family-owned small companies) belonging to mature sectors with limited growth prospects (such as textiles, footwear, leather goods, furniture).

Giacomo Becattini is one of the leading exponents of research on neo-Marshallian industrial districts. He rediscovered Marshall’s concept of industrial districts and reformulated it for the specific context of the Third Italy. Becattini’s article “From the industrial ‘sector’ to the industrial ‘district’” (published in Italian in the journal *Rivista di economia e politica industriale* (Becattini 1979) and in English 1989 in a book edited by Edward Goodman and Julia Bamford) is usually considered as the “starting point” of scholarly work on neo-Marshallian industrial districts (Landström 2005). The international dissemination of the concept was essentially promoted by Michael Piore and Charles Sabel. In their book *The Second Industrial Divide* (1984), they drew heavily on the example of neo-Marshallian industrial districts in the Third Italy to support their thesis of a major transformation from the Fordist mass production toward a model of flexible specialization. Looking at the Tuscan economy, Becattini (2003, p. 17) noted: “To employ a concept much used by Alfred Marshall, the course of Tuscan history leads to a form, still incomplete but already clear in outline, of “industrial district” . . . which produces economies external to the single firm and even to the industrial sector defined by technology, but internal to the “sectorial-social-territorial” network.”

Becattini and other protagonists of the neo-Marshallian industrial district notion (such as Gabi Dei Ottati, Sebastiano Brusco, Marco Bellandi, and Patrizio Bianci to name just a few) reject a purely economic view on local industrial growth and an exclusive focus on the economic effects of agglomeration. They suggest a much broader perspective that takes into consideration the social, cultural, and institutional foundations of local development. Becattini has advanced the idea of neo-Marshallian industrial districts as complex socioeconomic settings and highlighted the relation between efficiency and competitiveness of production and the

sociocultural conditions prevailing at the regional level. Becattini (1990, p. 36) defines neo-Marshallian industrial districts as “. . . a socio-territorial entity which is characterised by the active presence of both a community of people and a population of firms in one naturally and historically bounded area. In the district, unlike in other environments, such as manufacturing towns, community and firms tend to merge.”

Neo-Marshallian industrial districts in the Third Italy are characterized by a set of common features (see also Landström 2005). First (and accordingly emphasized in the definition presented above), in these districts, production activities and the “daily life” tend to merge. This merger is the outcome of a pattern of intensive interactions between the community of firms and families in a variety of dimensions. Second, there is a high division of labor among small companies, which are specialized in specific phases of the production process and work together in flexible teams. The manufacturer of the final good (the so-called *impannatore*) usually leads these teams and interacts with the market. Third, a widely shared value system (e.g., a specific ethic of work, principles of reciprocity) shapes action and interaction in the local community. These values are diffused throughout the district by a dense network of institutions (such as the firm, the family, the church, the local government, business associations). Fourth, in Third Italy’s neo-Marshallian industrial districts, competition and cooperation tend to coexist. The firms are linked to each other by manifold relationships, competing in some fields and collaborating in other ones. Finally, neo-Marshallian industrial districts benefit from a credit system with locally and socially embedded banks, which have a deep knowledge about and close linkages to the community of the districts’ firms.

From the 1980s onward, one could observe a rise in importance of local and regional policy interventions in Italian industrial districts. Policy-makers supported the evolution of districts by providing infrastructure (industrial parks, real service centers) and collective services (financing, education, marketing) and by performing the role of “social coordinators” (bringing actors together to solve common problems).

The 1990s has seen a growing skepticism about the long-term competitiveness and growth dynamics of neo-Marshallian industrial districts. Radical technological innovation and the globalization of the economy have led many authors to raise doubts about the extent to which they are a superior and stable spatial configuration of industrial production (see, for instance, Guerrieri et al. 2001). Critics have pointed to the limitations of self-sustaining production systems dominated by small firms in the global economy. Furthermore, the attempt made by Piore and Sabel (1984) to draw from very unique (and hardly generalizable) cases such as the Third Italy to develop their notion of flexible specialization has been viewed with extreme skepticism (see, for instance, Storper 1997).

Over the past years, a rich body of empirical work (for a review, see Rabellotti et al. 2009) emerged, documenting and analyzing ongoing structural changes in Italian districts. Based on a review of this literature, Rabellotti et al. (2009) found that some districts disappeared as a result of crises in their area of specialization (e.g., textile districts in Lombardy and Veneto). In most cases, these districts were

specialized in low-cost production and failed to compete successfully with manufacturers in newly emerging countries. Other districts have changed specialization, shifting from the production of final goods to the production of the machinery required for their manufacture. There are also districts which have conquered international luxury markets by upgrading the quality of their products, while others have enhanced their technological capabilities. Interestingly, the typical small Italian industrial district firm seems to lose importance. Indeed, the evidence suggests that it is medium-sized companies and groups of firms which are now the most dynamic agents and perform as key driving forces of structural changes (Rabellotti et al. 2009).

23.2.3 The Innovative Milieu Concept

The decline of many traditional industrial centers throughout Europe in the 1970s coupled with the subsequent rise of technological advances in industry and the emergence of innovative peripheral regions prompted serious rethinking of centrally directed and supported industrial development poles, often French in origin, in favor of innovatively driven indigenous growth. In the mid-1980s, Philippe Aydalot's hypothesized that there is "something" localized and intangible that permits innovation and dynamic development to proceed in certain regions and not in others (Crevoisier 2004). This observation set in motion a series of research efforts titled GREMI (Groupe de Recherche Européen sur les Milieux Innovateurs) to investigate and promote the dynamism seen in what became known as "innovative milieu." The concept of innovative milieu, however, has never ventured much beyond Francophone readers.

Research on milieus tends to be strongly focused on high-tech industries and on growth regions with extensive innovation intensity, although a few studies on conservative milieus in stagnating or declining traditional industrial regions and their restructuring processes also exist (see, for instance, Aydalot 1988; Maillat et al. 1997).

Definitions of innovative milieu vary, but most protagonists of this concept share the view that a milieu may be described as a set of region-specific rules, practices, and institutions that enhances the capacity of regional actors to innovate and to coordinate with other innovative actors (Storper 1997). In the writings of the GREMI group, the milieu is not always clearly distinguished from networks. As Storper (1997, p. 17) notes: "Many of the milieu theorists use the 'network' as their principal organizational metaphor. For some, the milieu is itself a network of actors . . . in a region. For others, the network concerns the input-output system; it is the network that is embedded in a milieu, and the milieu provides members of the network what they need for coordination, adjustment and successful innovation."

The directions taken by GREMI members reflect what Benko and Desbiens (2004, p. 325) "see as a genuine 'territorial turn' that can be characterized by a movement from economics toward geography; this renewal is influenced by the cultural turn...that has been expanded through the influence of traditional

economics and sociology.” This reorientation has profound implications for how one looks at regional development. Accordingly, the focus moves away from MAR externalities enjoyed by individual economic units or agents and their industrial interactions to instead gravitate toward an examination of the full pattern of structural linkages among institutions that diffuse and enhance the innovative potential of a territory. Rather than product, supply, labor, or material flows among firms that constitute a local economy, one looks to the overarching structure of institutional networks through which innovations and ideas – often external in origin – pulse and bring prosperity to regions.

For example, Camagni (1991a, p. 3) sees an innovative milieu as “the set, or the complex network of mainly informal social relationships on a limited geographical area, often determining a specific external ‘image’ and a specific internal ‘representation’ and sense of belonging, which enhance the local innovative capability through synergetic and collective learning processes. . . The attraction of external energies and know-how is exactly the objective we assign to innovative networks: through formalized and selective linkages with the outside world. . . local firms may attract the complementary assets they need to proceed in the economic and technological race.”

This network is not seen as passive or merely contextual, but rather as a robust, proactive, and enabling agent-like presence: “. . . it is often *the local environment which is, in effect, the entrepreneur and innovator, rather than the firm*. The firm is not an isolated agent of innovation: it is *one* element within the local industrial milieu which supports it” (Aydalot and Keeble, 1988, p. 9). Despite considerable research from subsequent GREMI investigations, the question of how desirable externalities arose initially remains unclear; Simmie (2005, p. 793) concludes from his survey of the literature that “Explanations slip all too easily into the argument that innovative milieu assist innovative firms while at the same time the presence of innovative firms create the innovative milieu that are supposed to be assisting them.”

However one reads this literature, it would seem that firms and industries have become secondary or complementary components of a local economy, which rely upon the linked institutions of their innovative milieu to acquire key technological assets. Crevoisier and Maillat (1991) have traced some of the possible connections between the innovative milieu and the underlying markets, sectors, industrial organization, etc., giving rise to what has become more generally known as a *territorial production system*. However, the territorial production system (TPS) remains a largely unspecified “black box” of idealized categorical types (e.g., industrial organization), which does not clearly identify the agents, elements, or incentives that constitute a working local economy. Storper (1997) notes that one of the key shortcomings of the literature on innovative milieus is that it fails to identify the economic logic by which a milieu promotes regional innovation. Little is said about why localization and territorial specificity should promote technological dynamics.

Camagni (1991b) goes further in seeing the innovative milieu as an uncertainty-reducing mechanism that permits firms to better assess and deploy innovative

resources, although he does not refer to a TPS in specifying several gaps to be overcome. The innovative milieu concept first launched important ideas about how innovations are introduced and exploited in local economies, but it was eventually overtaken by other more convincing accounts of how innovation systems are populated and operate within regions.

23.2.4 The Industrial Cluster Concept

From the 1990s onward, the term “cluster” has become increasingly prevalent to denote spatial concentrations of firms. There are many different branches of this notion. As the term “cluster” is rather imprecise and meanings could differ, various authors have attached to it the adjectives “industrial,” “regional,” “business,” and “economic.” It is beyond the scope of this chapter to deal with all these variants (for an overview, see Iammarino and McCann (2006) and Cruz and Teixeira (2010)). In this chapter, we focus on Michael Porter’s cluster approach which has become the most popular one. In 1990, Porter published his highly influential book “*The Competitive Advantage of Nations*,” which introduced his *industrial* cluster concept broadly to business and policy officials, and he rapidly propelled awareness of the concept well beyond the previous academic audience in a subsequent outpouring of books and articles. Clusters are defined as “... geographic concentrations of interconnected companies, specialized suppliers, service providers, firms in related industries, and associated institutions (for example, universities, standards agencies, and trade associations) in particular fields that compete but also cooperate” (Porter 1998, p. 197). Porter claims that clusters are a dominant feature of the landscape, that is, they could be found in virtually all countries and industries. The concept is rather flexible as regards the types of firms involved. Some clusters are made up of small firms only, while other host both small and larger ones (Porter 1990).

Unlike the previous descriptive accounts of colocation from which causal factors might be inferred, Porter brings both normative and positive insights to his cluster definition from long experience as a theorist of corporate strategy at Harvard Business School. His cluster view essentially complements the importance of corporate strategies to remain prepared to dismantle and reinvest/relocate individual components of the corporate value chain (headquarters, distribution, production, etc.) in clusters of competitive and productive enterprises, which are comprised of similar or related firm components.

Porter’s main interest is in explaining the sources of enduring competitive advantages in a global economy. He argues that competitive advantage is strongly localized; it arises from clusters and is shaped by four determinants: (i) factor conditions (human capital, natural resources, infrastructure, etc.), (ii) demand conditions (sophisticated and demanding local customers), (iii) related and supporting industries (presence of capable suppliers and competitive related industries), and (iv) firm strategy, structure, and competition. These four determinants of competitiveness are interrelated and form a self-reinforcing system, the so-called diamond. Among all elements of the diamond, rivalry among cluster actors is seen

as the most important one because it has a stimulating effect on all others. Fierce rivalry promotes the development of highly specialized input factors, it upgrades domestic demand, and it spurs the rise of related and supporting industries (Porter 1998).

Vigorous competition among locally based rival firms is, thus, the main driving force in Porter's cluster model. However, he also states that clusters represent a combination of competition and cooperation, although the cooperative dimension of clusters is seen as less important compared to the competitive one. Porter's view on cooperation is rather specific. His writings reflect a deep skepticism when it comes to horizontal collaboration, pointing to a set of harmful effects that potentially arise from cooperation among competitors. Vertical cooperation (i.e., collaboration and knowledge exchange with suppliers, customers, and actors from related and supporting industries) in contrast is seen to be beneficial. Porter's work contains only some vague cues on the importance of social factors (more precisely, social capital) that facilitate interaction and collaboration between actors located in a cluster. Social (as well as cultural and institutional) features of clusters are clearly undertheorized in Porter's approach.

Other points of critique that have been raised (Martin and Sunley 2003) include – among other things – that Porter has failed to provide a clear specification of the geographical and industrial boundaries of clusters, related difficulties to identify clusters, and the uncritical reception of the approach in policy circles.

The undeniable attraction of Porter's cluster concept results from its twofold usefulness in providing answers to these questions: (i) What advice should a firm or corporate component consider in its corporate strategy to maintain maximum competitiveness when considering alternative business environments, and (ii) what advice should subnational regions consider when designing economic development policies aimed at providing attractive production sites and a sustainable employment base? Accordingly, many of the most ardent followers of this concept are business or economic development consultants and policy officials.

23.3 Similarities and Dissimilarities

It is already apparent from the brief outlines above that important differences but also similarities exist among the concepts considered in this chapter. To deal with these differences and overlaps more systematically and thereby reveal more about each, we will rely on a series of important features that are summarized in Table 23.1.

23.3.1 Geographies and Space

All concepts are based upon a specific understanding of space and certain geographic factors that help bound and define each in particular ways. The *Marshallian district* was essentially limited by distances that could be economically traversed

Table 23.1 Key features of concepts

	Marshallian industrial districts	Neo-Marshallian industrial districts	Innovative milieux	Industrial clusters
<i>Geographies and space</i>	Geographical distance/neighborhoods	Common political district occupancy	Relational “space” coextensive with network	MAR + globalized factors
<i>Core actors</i>	Small firms	Family/fluid firms, local officials	Social and political institutions, knowledgeable producers	Firms of all size + industry groups
<i>Agent motivation</i>	Profit maximization	“Mastery of craft” + place/product pride; consolidate high-value, luxury/income-elastic consumer markets	Growth, place/product pride; gain greater prominence in tech-based development initiatives	MAR + ROI, seize market and production opportunities afforded by globalization
<i>Interactions (relationships between actors)</i>	MAR	MAR, long-term, trust-based local networks	Informal social relations, collective learning within the milieu, formalized extra-local networks	MAR, supply/value chains, vertical forms of exchange, project alliances
<i>Industries, technological intensity of products, and markets</i>	All industries prevailing in the nineteenth century	Consumer discretionary/low-medium craft	High-tech intensive	Export-intensive industries/high-tech and low-tech
<i>Innovation</i>	Diffusion of ideas, localized spilling over of trade secrets	Craft refinement and perpetuation, flexible organizations, incremental innovation	Adoption of extrinsically produced innovations that can be regionally exploited	MAR externalities, pre-commercial joint ventures, knowledge sourcing
<i>Environment (cultural and institutional context, extra-economic factors)</i>	“Industrial atmosphere”	Strong family and community values / identity, blurred boundaries between business and community spheres	Shared values and visions – regional cohesion	Trust and social capital forms the “glue” that binds cluster actors together
<i>Competition and cooperation</i>	Mix of competition (driving force of districts) and cooperation (precondition for collective innovation benefits)	Complex mix of competition and cooperation/high importance of cooperation as coordination mechanism	(Poorly specified) balance of competition and cooperation	Fierce competition as key driving force/cooperation less important

daily by workers and suppliers in the late nineteenth century, the densities of which were sufficiently high and distances sufficiently short that districts could often be referred to as “neighborhoods.” The late twentieth-century versions of *neo-Marshallian industrial districts* found in Italy are bounded instead within small governmental units known as political districts. The political boundaries are not matters of definitional convenience or regulatory requirement; rather, the local unit of government is an active partner and facilitator in the functioning of a neo-Marshallian industrial district. *Innovative milieus* are defined not at all by frictions of distance that separate the factors from individual producers or by official boundaries but instead by the “relational space” enclosed within a specific networked pattern of contacts among key institutions engaged in promulgating innovative impulses. *Industrial clusters* have perhaps the most flexible geographies, although they build upon Marshallian and MAR principles of market interaction that – with recent transportation and communication improvements – have expanded outward to include the “daily urban system” of entire metropolitan areas and regions. Indeed, Porter even speaks of a “California wine cluster,” although this is almost certainly comprised of several smaller, distinctive clusters of wine producers organized around a particular “terroir” that can take advantage of California’s full resources.

23.3.2 Actors and Interactions

Small- and medium-sized independent firms are the core agents in *Marshallian districts*. They are essentially profit-maximizing market actors who find greater market advantages by being located in industrial districts than if located apart. The prototypical *neo-Marshallian industrial district* found in the Third Italy consists of multiple agents: small family firms that expand or contract in various business arrangements with other firms, employees who may switch or hold jobs in multiple firms, and the local political district that establishes policies and practices. Profit maximization is but one of several motivations, which it shares with a mastery of craft, pride of place, and external recognition by consumers of luxury and income-elastic products. Agents are more difficult to isolate in the case of an *innovative milieu* because its constitutive networks engage many different institutions in a structure where specific roles go unremarked, although such institutions are said to be motivated by pride in their region and their efforts to promote innovation. Individual market and political agents operating lower down, at the level of the local economy, are seen as part of a “territorial production system” that interacts with and depends upon the innovative milieu, but these generally go unacknowledged as its core agents. *Industrial clusters* are essentially populated by firms and firm branches of all size and forms of corporate organization as their principal agents. It is often the case that the cluster itself acquires agent status and takes on a loose organizational form of institutional governance to promote the cluster, but this varies widely with fewer cluster organizations in Anglo-Saxon and more in continental European and Asian clusters. Return on investment, productivity growth, and market shares are principal agent motivations.

Looking at interactions, one finds that *Marshallian districts* are knit together by supplier linkages and often unconscious flows of knowledge, ideas, and workers (i.e., knowledge spillovers) among firms located nearby. The *neo-Marshallian industrial districts* theory puts due emphasis on long-term trust-based collaborative networks of small firms (and supporting organizations) that promote an easy exchange of tacit knowledge, joint purchase of materials, or joint initiatives to get access to technical or financial services. The literature on *innovative milieux* stresses the importance of mainly informal social relationships at the regional level which promote collective learning and, thus, the innovation capacity of companies. Collective learning is based on three mechanisms of knowledge transmission (see, for instance, Keeble 2000): (i) intra-regional mobility of labor, (ii) spin-offs, and (iii) formal and informal networks. It is noteworthy that the milieu literature specifically considers the role of extra-regional linkages. Such links to the outside world are more often than not formal in nature and considered as crucial in order to get access to complementary knowledge, markets, and technologies that are not available within the limited context of the milieu. The *industrial cluster concept* considers links of companies to demanding customers, suppliers, and vertical forms of exchange and interaction among companies. Both input-output relations and flows of knowledge are discussed in Porter's conceptual cluster model.

23.3.3 Industries and Innovation

Marshall did not specify the full range of 19th century industries, products, or technologies expected in his industrial districts, but it seems clear that any industrial process under way in England during that period could benefit from being located in a district. In short, the market interactions in *Marshallian districts* apply to all industries. Contrast this to the *neo-Marshallian industrial districts* of the Third Italy, which are very highly focused on mature industries and a more limited range of goods, markets, and production technologies. High-quality personal or household goods, often fashion- and design-intensive products, are intended for international markets of discerning consumers. Such goods are often craft-based or limited in production, which requires highly skilled artisans and quality-conscious production that takes advantage of incremental improvements in basic technologies. In comparison, the very idea of *innovative milieu* hinges on the defining importance of high technology, whose reemergence in the 1980s was seen as necessary to revive old (Maillat et al. 1997) and propel new production centers. Apart from the stress placed on links between high technology and industrial innovation, there appear to be no specific industries or markets implied. *Industrial clusters* are considered relevant to any industry or product where competitive forces require producers to enjoy MAR or Porterian diamond advantages. These are most acutely felt by firms competing in international markets, although locally competing firms are also said to benefit from cluster advantages.

In his analysis of British industrial districts in the nineteenth century, Alfred Marshall is remarkably clear about the sources and types of innovation arising in

highly localized industries. Innovation in *Marshallian districts* is seen to be essentially underpinned by a rapid diffusion of novel ideas and best practice solutions, spillovers of trade secrets, and a large stock of industry-specific knowledge which is constantly further improved by combinations of ideas of colocated firms and intergenerational knowledge transfer. Interestingly, Marshall seems to employ a rather broad definition of innovation that encompasses not only new products and processes but also “inventions and improvements . . . in general organization of the business . . .” (Marshall 1920, p. 225), that is, organizational innovations. Innovation in the *neo-Marshallian industrial districts* of the Third Italy is mainly incremental in nature (Asheim 2000). Small firm size, specialization in traditional industries, and little investment in formal research and development are seen as the main reasons for modest levels of technological innovation activity and radical innovation. Firms in Italy’s neo-Marshallian industrial districts tend to rely more on improving product quality, upgrading, and incremental process innovation (Rabellotti et al. 2009). Innovation activities are highly collaborative in nature (see Sect. 23.2) and typically oriented on craft refinement and perpetuation as well as on enhancing flexible organization structures. Protagonists of the *innovative milieu* concept stress both the importance of local collective learning processes (see Sect. 23.3.2) and the inflow of extra-local competences and complementary knowledge about technologies and markets. Innovation in milieus is essentially – although not exclusively – about the regional adoption and exploitation of knowledge, technologies, and innovations generated elsewhere. Innovation in *industrial clusters* is the outcome of the working of MAR externalities and conscious actions undertaken by firms such as pre-commercial joint ventures and acquisition of knowledge from a variety of sources. Elements of the diamond are seen to have substantial innovation-enhancing effects. Demanding customers, for instance, force cluster firms to carry out permanent improvements and innovation. Knowledge exchange and joint development projects with supplier and related industries provide essential inputs for innovative activities, and strong local competitors perform a critically important role in generating a high pressure to innovate. Taken together, these factors and conditions are supposed to constitute a fertile ground for continuous improvements and more radical innovations of products, processes, and organizations.

23.3.4 Environment, Competition, and Cooperation

The concepts under consideration here share an emphasis of the role that the environment, or more precisely, the cultural and institutional context, can play in regional development, competitiveness, and innovation. Marshall employs the notion of “industrial atmosphere” to highlight the role of social and cultural factors in supporting localized knowledge flows and industrial development. Colocation of similar firms in the same community implies that in *Marshallian industrial districts* “the secrets of industry are in the air.” A strong local cultural identity and shared industrial expertise are seen to form essential institutional foundations of the

evolution of Marshallian industrial districts. The literature on *neo-Marshallian industrial districts* clearly supports this view. Soft noneconomic factors such as a set of shared values, norms, trust, and collective identity are seen as fundamentally important to the economic success of industrial districts. The boundaries between the local community and industry are porous and often difficult to identify. Social and economic relations tend to be highly interwoven. Mutual trust, the identification with the region, and the products of a district, etc. are regarded as utmost significant. These factors enable and stabilize different types of collaboration and allow for a fruitful combination of cooperation and competition (see below). In a very similar vein, the *milieu approach* stresses the importance of the sociocultural dimension of innovation and development. A set of common values and shared visions (such as an orientation on long-term development goals instead of a short-term profit) and a willingness to collaborate reflect sound levels of regional cohesion and underpin high rates of innovation. It is important to note, however, that potential negative effects of too much cohesion on long-term innovation and adaption capacities of regions are also considered in the milieu literature. The *industrial cluster concept* proposed by Porter does not totally ignore noneconomic factors, but they are much less emphasized in his analysis when compared with the other approaches. He notes that trust and social capital are prerequisites for close interaction of cluster actors: “Social glue binds clusters together, contributing to the value creation process. Many of the competitive advantages of clusters depend on the free flow of information, the discovery of value-adding exchanges or transactions, the willingness to align agendas and to work across organizations, and strong motivation for improvement. Relationships, networks, and a sense of common interest undergird these circumstances. The social structure of clusters thus takes on central importance” (Porter 1998, p. 225).

One finds strong differences between the key concepts under review in this chapter when it comes to determining the relative importance of competition and cooperation as coordination mechanisms and key source of competitiveness. *Marshallian industrial districts* rely on both competition and cooperation. In Marshall’s view, it is competition that is the key driving force of industrial districts, while district benefits in knowledge creation and innovation are a result of collaboration (Newland 2003). According to Marshall, cooperation can take two forms: it may be conscious and intentional (an example is the formation of industry associations) or unconscious and automatic (knowledge spillovers). In *neo-Marshallian industrial districts*, firms’ willingness to cooperate is of critical importance for innovation and competitive advantage. In Third Italy’s districts, “a complex mix of competition and cooperation” (Brusco 1990, p. 1) tends to prevail. “The efficient co-ordination of the district’s activities and the promotion of dynamic growth is not simply a product of the unfettered operation of classic competitive market principles; on the contrary, what is at work is a complex amalgam of both competitive and co-operative principles . . . co-operation is at least as important as competition for organizing the district” (Sengenberger and Pyke 1992, p. 16). Protagonists of the concept of *innovative milieu* also emphasize the balance between competition and cooperation. The nature of this balance is, however, not clearly specified, and in

most contributions to the milieu school, the cooperative dimension seems to be rated as more important than the competitive one (Newlands 2003).

The *industrial cluster* concept – at least Michael Porter’s version of it – does not emphasize the role of cooperation to the same extent. On the contrary, it is fierce competition and not cooperation that determines competitive advantage. Porter and Ketels (2009) even argue that a large number of cluster benefits occur simply due to collocation, that is, for most benefits to unfold, no conscious and active collaboration by cluster firms is required. This does not mean, however, that cooperation is completely unimportant in Porter’s analysis. He recognizes some advantages in vertical forms of exchange, while cooperation between competitors is seen as harmful. “Clusters clearly represent a combination of competition and cooperation. Vigorous competition occurs in winning customers and retaining them . . . Yet cooperation must occur in a variety of areas . . . Much of it is vertical, involves related industries and is with local institutions. Competition and cooperation can coexist because they occur on different dimensions and between different players; cooperation in some dimensions aids successful competition in others” (Porter 1998, pp. 222). While cooperation is important, it does not have the same significance as competition. This argument is clearly supported by the fact that cooperation is not part of Porter’s diamond, while competition performs as the most crucial element in the diamond model because of the supposed stimulating effect it has on the other ones.

23.4 Conclusions

In this chapter, we have provided an overview on what is known about neo-Marshallian industrial districts, innovative milieus, and industrial clusters. From the 1970s onward, protagonists of these three concepts have essentially enhanced one’s understanding of the main sources of regional competitiveness and innovation. In the concluding section, we want to move beyond presenting past achievements made by adherents of the three concepts, glancing at the potential future of the notions under consideration. In our view, two aspects of future development deserve attention. The first concerns theoretical challenges; the second one is about the applicability of the concepts to other contexts and environments than those from which they have emerged.

A key issue for future theoretical work on neo-Marshallian industrial districts, innovative milieus, and industrial clusters will be to provide a more dynamic view on spatially concentrated industries and their institutional underpinnings. Although efforts are under way to understand their evolution, the literature on clusters and neo-Marshallian industrial districts in particular have been criticized sharply for relying too heavily upon static analysis and saying little about the development of regional collections of firms and industries over extended time periods. Consequently, a proper conceptualization of the evolution and transformation of agglomerated industries is urgently needed and should be a core topic of future research.

What is the potential future of the three concepts assessed by their transferability to other regions and countries than those from which they have emanated? Given the fact that the cluster notion provides a broader framework that allows for

capturing very different forms of geographical concentrations, one might argue that it will have the edge over the neo-Marshallian industrial district and milieu concepts. We see the cluster concept as the most fruitful one for cities and regions in Europe, North America, and Oceania and continuing in the near future, but it is unclear whether it will apply as convincingly in the more distant future or to other rapidly emerging economies of Latin America, Asia, or perhaps Africa. Is it a foregone conclusion that clusters as we now know them will arise in clearly identifiable forms in East Siberia, Mumbai, Jakarta, Amazonas, or Szechuan by 2050? Or will local circumstances – as was the case for neo-Marshallian industrial districts, innovative milieus, or industrial clusters – produce a rich variety of stylized models of local economic development to meet new challenges? Emergent countries may eventually come to differ rather considerably from the so-called Western models that presently operate within a relatively narrow range of characteristic democratic and market institutions. As the world's economies struggle to adjust to new monetary regimes, altered financial regulations, and impending resource frontiers, one cannot be certain how the systems of global production and international markets may change or how their knock-on effects may require the further repositioning of urban and regional economies.

Abstract

In this chapter, an overview is presented of the three-phase evolution thus far of the regional systems of innovation perspective. The connected notion of the “learning region” is situated and subsequently re-situated in this account. The chapter begins by establishing the debate in the regional governance, learning, and policy contexts, especially with reference to the concept of “experimental regionalism.” Early reflections upon various critical responses to the 20-year literature on regional innovation represent the first main phase change, indicating the relative conceptual and empirical flexibility of the approach. Innovation in thinking about entrepreneurship is shown to have been at the heart of this first evolving perspective on regional dynamics. The most recent phase change represents the engagement of regional innovation systems, as a core subfield

of evolutionary economic geography, with key concepts in the complexity sciences. These are coevolution, complexity, and emergence. Each is shown to denote important new ways of thinking about regional innovation and evolution. The continuing relevance of the perspective to regional theoretical and policy application is underscored.

24.1 Introduction

There is now 20 years of solid theoretical and empirical research into regional innovation systems, and the concept is increasingly being applied in the world of policy analysis and practice. Regional innovation systems analysis has evolved through at least three versions (Cooke 1992, 2012; Braczyk et al. 1998; Asheim and Gertler 2005). The first phase change was from a Eurocentric, static, and manufacturing-led approach to a more flexible, dynamic and entrepreneurial approach. The second involved recognition of the importance of entrepreneurship in managing flows between knowledge exploration and exploitation (see below). The most recent phase change has been to fully recognize that regional innovation is an exemplary evolutionary process typical of complex adaptive systems as described by the likes of Kauffman (1993, 2000, 2008). This means a whole new vocabulary has to be comprehended that recognizes such processes as coevolution, self-organization, emergence, path dependence and path interdependence, relatedness, variety, and transversality. This is additional to but complementary with evolutionary economic geography terminology like related variety, search, selection and retention, mutation, speciation, and learning.

In what follows, an attempt is made to outline, critique, and elaborate key aspects of the above-mentioned phase changes in the evolution of a dynamic spatial research paradigm. It does this in a manner that intends to consider regional innovation systems in relation to the rather less-developed idea of “learning regions.” Both appear to have cognate origins, but a moment’s reflection shows the one to be proactive in its emphasis on innovation while the other looks reactive in its emphasis on learning somewhere else’s innovation. An effort is made in the chapter to reintegrate a more nuanced and advanced version of the learning concept. This is influenced by organizational practice based in complexity science. The classic regional innovation systems framework is constructed as follows. First, an open system architecture is proposed, which is the regional innovation system. Second, the system of innovation is composed of two subsystems: an *exploration* subsystem where research knowledge is both endogenously developed and imported and an *exploitation* subsystem where such knowledge is commercialized. Third, in-between is a “membrane” composed of intermediaries that may be “institutional” (mainly public, e.g., venture capital, incubators – expressed as an institutional regional innovation system or IRIS) or “entrepreneurial” (private services firms supplying such innovation support services – expressed as entrepreneurial regional innovation systems or ERIS). “Region” denotes the governance level between national and local. In any region, there is an assemblage of industries

that have distinctive technological trajectories and differential path dependences collectively referred to as the regional “paradigm.” Similarly, the region has an enveloping “regime” of hard and soft governance mechanisms influencing innovation as part of regional evolution.

In the section which follows, important aspects of the first phase change for understanding the regional paradigm or nexus of spatial economic processes are discussed. This heralded the emergence of the ERIS concept to balance the prevailing IRIS original. In the next section, some key implications of this for governance and learning at the regional regime or policy and regulatory level of analysis and activity are opened up. This moves the chapter into an assessment of the learning region notion, reasons for its apparent atrophy and a reassessment of its possible future role in a complexity-informed regional innovation systems (RIS) 3.0 model. Following this is a section that explores the foothills of Version 3.0 beginning with a critique of the industrial economists’ vertical, specializationist “framing” of economic processes. In this phase change the lateral concept of ‘platform’ is preferred to the vertical concepts of ‘sectors’ and ‘clusters’ for social agency involving innovation. Attached is an elaboration of a more appropriate, geographically informed ontology which is interested in horizontal interactions, knowledge recombination, and understanding innovation as involving “emergence” of novelty from unlike forms. This section, for which certain formulations are worked out for practice, is, like all good regional innovation systems research, theoretically informed and empirically tested with primary research data, but modeling is restricted to the conceptual level. This is because, on the one hand, modeling data are inappropriate in this context, but on the other, and more importantly, the complexity perspective, which actually derives from simulation modeling, has found that in the evolutionary sciences prediction – a prime justification for modeling socioeconomic systems – is impossible. Life itself, it concludes, is not subject to the predictive modeling achievements of physicochemical science precisely because humans are creative, innovative, social agents whose important future achievements cannot be predicted. Thus, evolutionary biological events can be understood *ex post* but not foreseen, except trivially, *ex ante*.

24.2 Regional Governance and Learning

Since the 1990s, a growth area in spatial analysis and practice has focused on regional innovation analysis and policy. To a remarkable extent, new problems and avenues for exploration emerge regularly regarding regional innovation processes and institutions, for example, intermediaries (Tödtling and Trippl 2011a, b; Nauwelaers 2011); variety, a key underpinning in respect of “relatedness”; and “conventions” – the soft institutions that inform culture and that are marked features of the new regional innovation challenge (Sunley 2011). These pose interesting tasks for modes of governance of regional innovation and demands for new kinds of learning, both more proactive than the “institutional borrowing” that characterized the supply-side era when markets became perceived as the solvents of

developmental dilemmas. Main results of the uncritical belief in the stability of markets in many countries have involved social polarization, financial market collapse, continued regional deindustrialization, if not industrial “desertification,” and dependence on now-eroding regional public sector employment to mitigate the resulting imbalances. Faced with the budgetary reckoning of this neoliberal experiment, regional governance, where it exists or survives, must perforce itself to become innovative.

Coordinated market economies (Austria, Germany, Nordic countries) have recognized this for some time, sustaining innovation support institutionally. The task was harder in liberal market economies, where injunctions that state intervention was the problem rather than the solution penetrated most deeply into the governance fabric. Heidenreich and Koschatzky (2011) reviewed the literature on regional governance of innovation, pointing to some fallacies and open questions about the manner of its conception and execution. These authors inhabit Germany’s coordinated market regime and are accordingly comfortable with federal norms that devolve some innovation and other knowledge responsibilities (e.g., universities) to the meso-level. They identify key efficiencies from knowledge recombination coordinated in regional institutions from the outset, primarily lower transaction costs, learning advantages from spatial proximity, and direct provision of “collective competition goods.” “Governance” moves beyond a region’s “soft institutions” such as conventions by addressing its “harder” government plus civic or associational governance regime. These can involve the nature of financial support for innovation (this can range from grants to loans); university coordination (e.g., regional mergers or centers of excellence); sectoral, cluster, or platform stimulus (see Harmaakorpi et al. 2011); training and skills formation; foreign direct investment; and regional promotion abroad, a nontrivial package of innovation instruments.

24.3 Regional Governance and Policy Learning

These authors, like many others, see building social capital as a target of regional governance. Variety in the interactions between paradigm and regime exerts a strong influence on the distinctiveness of regional governance idiosyncrasies, which extend to regional innovation system configurations. Although for complex systems to function effectively, there must be considerable system articulation, especially those involving multilevel regional-national-supranational strata; Heidenreich and Koschatzky (2011) also refer to studies that see considerable friction among such levels. This is caused by networks negotiating and bargaining about innovation according to distinctively layered democratic politics. Thus, although not hierarchically organized in a top-down manner, the supranational may still withhold resources from the national or regional levels if proposals to access policy funds infringe the “rules of the game” being targeted. Occasionally a region can reject national innovation policy inclination, clarify that it has reserved

powers, or move ahead with its own projects where the state has abdicated or allowed to fall into disarray, conceivably for ideological reasons, a national strategic responsibility. “Real service” provision to SMEs by Italian regional administrations was a case of the last named, which was subsequently forced into privatization by a hostile right-wing national government. “Regional experimentalism” after Sabel (2004) characterizes aspects of such friction resolution. In general, friction of the kind noted is a minority pastime.

Regional agglomeration and associated regional advantage arising from spatially proximate innovation, productivity, and growth also partly explain the success of ideas and practices promoting regional innovation governance. So does recognition by evolutionary social scientists and practitioners (for whom neoclassical theorems can seem otherworldly) of the difficult-to-measure value of social networking and “untraded interdependencies.” These constitute Storper’s (2009) regional “dark matter” measurable only by its gravitational influence. Enough is understood of these to at least see their effects in rapid regional mobilization that can swiftly translate identity into innovative action, showing a region has “got its act together.” Is this an immutable regional comparative advantage for some, or can it be “learned” for wider regional practice? The generic design for this is portrayed in Heidenreich and Koschatzky (2011) as dilemmas surrounding regional economic structure, regional networks, regional institutions, and regional policies. The “big shift” for new regional innovation policy is to attend to the content and multidimensional interrelationships of regional networks and institutions, in particular, rather than mapping structure directly onto policies and vice versa. Regional intelligence and policy learning thus suggest a more proactive, “catalytic,” or “orchestrating” role being required of regional innovation governance in future.

One crucial characteristic of the species evolution of regional innovation systems theory and empirics is that it has responded to the relatively few solid critical observations in an adaptable manner. Thus, as Tödting and Trippel (2012) remind us, what we may call regional innovation systems version 1.0 (e.g., Braczyk et al. 1998) can, in hindsight, be seen to be somewhat Eurocentric in its emphasis upon public regional innovation intermediation and static in its portrayal of regional innovation system circuitry. These were products of the emergence of a new subfield (in both *regional* and *innovation* analyses) that began with European comparative regional research utilizing European-derived conceptual categories and generating tailored primary research data of a comparative kind. An important step forward was to recognize that other regional setups, though actually globally relatively few, were less “institutional” and more “entrepreneurial” in the provision of intermediary services (i.e., markets for innovation services were more developed, e.g., as in California or Massachusetts, Cooke 2007). To some extent, as also recognized by Tödting and Trippel (2012), a dynamic element was introduced by returning for more longitudinal analysis 10 years later to re-research content for the primary regional innovation systems source book (Cooke et al. 2004). So this phase change we may refer to accordingly as RIS Version 2.0.

24.4 The Learning Region

One perspective that promised regional policy learning was “the learning region,” a concept developed by Florida (1995), adapted by Asheim (1996) and Morgan (1997) and recently reviewed by James Simmie (2011). Somewhat disappointingly the promise of this notion has not materialized, partly because as Simmie shows it got bifurcated into a normative idea, resting on the injunction that learning was a desirable end for regions to aspire to, on the one hand, and more empirically that it was a modest action line in regional innovation *strategy*, on the other. Accordingly, it has never developed analytically even though, as much of the regional innovation systems literature makes clear, there is evidently an acutely perceived need for better qualities of “learning” by firms and other innovation actors and for “regional policy learning” to tackle issues such as “cognitive dissonance” among corporate functionaries and entrepreneurs, “convention analysis” of regional production culture, policy mixing to stimulate “path creation,” and the hybrid skills to facilitate relatedness and transversality among policy functionaries. It will be shown below how in the evolution to RIS Version 3.0, learning techniques and instruments have been refined to facilitate it in both RIS and learning contexts.

Correctly, in its origins, in the work of Richard Florida in 1995, “learning region” is a response to the rise of the knowledge economy as is even more the case in a rapid follow-up article by Björn Asheim which grounds the notion in Lundvall and Johnson’s advocacy of building a “learning economy” to face the exigencies of the same phenomenon. Michael Storper did not write about “learning regions” as such but devoted research time to comparing “technological learning” in clusters with different convention sets or modes of untraded interdependence, which were probably the most fruitful theory and practice lines to follow. Finally, probably the most-cited variant of the “learning region” idea was Kevin Morgan’s paper of 1997. Here, Simmie shows the key to regional regeneration and improved social welfare lay in strengthening a region’s social capital and institutional capacity to support learning.

Critique of the concept has ranged from ascribing it the status of “fuzzy,” an “impressionistic neologism,” “unlikely,” “over-localized,” and challenged by “learning asymmetries” (see, e.g., Martin 2001). This is reminiscent of the many critiques aimed at the cognate concept of “organizational learning” in the large corporation. Here, problems concerning how to sample, from where, or from whom to learn, whether what might be learned was applicable, and indeed whether it was yesterday’s knowledge, meaning the learner would be engaged in a permanent failure to “catch up” were all raised. This all seems rather unfair to what – if the concept had been better specified, perhaps in terms of learning the region’s paradigm and regime uniqueness and how it might be “nudged” toward path interdependence – we now see to be a fundamental cognitive need in accomplishing regional innovation and growth. This seems to be the thinking in recent attempts to revisit the concept by Rutten and Boekema (2007). However, the kind of conceptual and policy instruments needed to achieve such endogenous regional change remain to be clearly specified. We shall see below how some progress in this regard has

been made from the viewpoint of complexity theory (Mitleton-Kelly 2006; 2011). One task of this chapter is to evaluate such progress from the viewpoint of RIS Version 3.0.

24.5 Regional Platforms, Methods, and New Innovation Policies

This task was begun in the early 2000s, culminating in Harmaakorpi et al. (2011) with their “platform” concept of regional innovation and renewal. The roots of this model are found in recognition of basic Schumpeterian insights into the nature of innovation as a product of cross-fertilization (recombination) of knowledge and ideas. This is something which the cluster idea, as the apotheosis of proximate specialization, obscured for academics and policy-makers alike for two decades or more. Accordingly, there has been a lack of policy measures to foster practice-based, networked innovation processes that combine diverse knowledge bases. It could be added that until recently, and in the process of being articulated into a synthesis here, there has been relatively little intellectual leadership of an alternative perspective either. One reason for this is Lundvall’s line that policy learning is for policy-makers not academics, which on a moment’s reflection is a little timid. For while it is always difficult to think out and design policy abstractly in the “ivory tower,” a thoroughgoing critique of the economist’s traditional vertical “framing” of spatial processes opens up significant opportunity for innovative policy guidance. Harmaakorpi and associates are by no means alone either in having the privilege of occupying both “worlds”: academia and innovation policy-making simultaneously. This enabled them to conduct “regional experiments” à la Charles Sabel. Out of this experience, a newly minted criticism they discovered of the “proximity” perspective is that it fails to explain how learning from knowledge spillovers actually happens and that the effect of these may be negative. They find the distance implied in the notion of variety more appealing because it avoids negatives like involuntary spillovers, opportunism, and lock-in. Accordingly, their aim is to create an efficient *balance* between the contradictory purposes of enhancing proximity and distance. The cluster model is seen to be suboptimal in this respect and accordingly inferior to a platform model of regional innovation policy.

The “platform model of regional innovation policy” displays the following key characteristics: Its network morphology is one based on *loose coupling* of weak ties engaging with “structural holes.” Structural holes are the spaces (sometimes “white spaces”) between industries or specialized clusters. As we shall see later, loose coupling is an essential property of innovation-inducing adaptive systems from a complexity theory perspective (Mitleton-Kelly 2011). These are areas where network interactions may produce innovations if the holes can be bridged with innovation discourse, action, and content; social capital is thus of the institutional “bridging” kind; knowledge production is transversal; knowledge conversion is by means of cross-fertilization; regional absorptive capacity is future-oriented; experience-based learning is favored over science-based learning; external economies

are those of “urbanization” rather than “localization” in kind; and innovation systems are regional and national. On this basis, structured experiences of challenges and change of conventions, competences, and capabilities are induced by articulation of discourses among firms and stakeholders combining related knowledge from inside and beyond the region. The aim of this rendering of RIS 3.0 is to create a regional platform based on relatedness and supported by platform policies that optimize it to optimize innovation.

Facilitation of the required articulation of discourses that may valorize or change conventions and build up firm and intermediary competences and capabilities is intended to instigate a structure of learning institutions and processes in the region. The key spatial process aims here are as follows: to clarify the nature and forms of regional-related variety; to facilitate the *recombination* of knowledge; to identify the “structural holes” or “white spaces” where innovation opportunity may lie; and to evolve regional platforms that combine knowledges, clusters, and sectors for purposes of innovation. Complementing these in a new regional innovation systems perspective are four policy concepts. First, “enlightenment” may be diffused through the deployment of dramaturgy, literally acting out scripts of representative “convention sets” under challenge; second, assistance comes from having a mode of “orchestrating” dramaturgy and other learning facilities, such as “ideas incubators,” “living laboratories,” and “improvisation sessions.” Orchestration here implies promotion of such assets and conducting their articulation into a coherent narrative. Third, innovation system integration comes from achieving “transversality” or the cross-pollination of intercluster or sector-cluster innovation potentials within and beyond the region, and finally, of key importance is evolving methodologies, such as technology or creativity matrices to concretize commercializable innovation actions and outcomes. The exemplar of this is engineering-rich Bavaria, but it is also practiced in the design-driven innovation context of Lombardy and its creative and innovative design-intensive domestic furnishing, lighting, and kitchenware clusters as described by Verganti (2006). Here, the innovation paradigm is changed relatively frequently and radically in the “episodic” sense by articulation of discourse that changes conventions through changing the meanings prioritized in the prevailing “sociocultural regime.” This demands inputs both from expert “circles” inside and well beyond the region and within and well beyond the specific cluster. It requires strong articulation of regional firms and stakeholder institutions, and it is “orchestrated” in ways that “propose” innovations to markets. It can thus be vulnerable to overestimation of the market appeal of new lines, but such “practical reasoning” is also built into the articulation of discourse process.

Accordingly, a new paradigm for regional innovation and growth has been evolved in ways that meet the criticisms of the weaknesses and *lacunae* of inherited models, rooted as these initially were in Eurocentric regions, statically described and under the influence of manufacturing supply chain thinking of the 1990s. This is by no means the only way forward, but it resonates completely with the main threads of the discourse from its Schumpeterian origins to the modern day. Accordingly, the new agenda for regional innovation policy is different from the old.

As others have noted, endogenous innovation policy with the regional agency in a more catalytic role is now expected to replace the backstop functions of old. These had evolved in responding to market failures and welfare enhancement imperatives in the neoliberal, supply-side era. This is conceived as the appropriate posture in the context of a global knowledge economy regime assailed by seemingly intractable crises of economy and ecology. The region where innovation platform methodology was pioneered was a declining economy within Finland; the region where pulp and paper relatedness evolved to cross-media clustering is a relatively poor, peripheral region in Sweden; London and other metropolises may not be as innovative as presumed because they bask in conventions of entitlement, expectation, and privilege. Accordingly, the traditionally conceived “innovation paradox” in which least absorptive capacity is found in regions needing most innovation is clearly somewhat shaky and in need of measured reflection. This draws attention to the problematic nature of “smart specialization” as a “learning” response. Rather than implementing inappropriate initiatives from a supranational hierarchy, regional systems grow best by “emergence” of innovation from the recombination of their own paradigm and regime assets.

24.6 Regional Innovation Systems Version 3.0: Learning Dilemmas

One of the strong criticisms of the advocacy for “learning regions” a decade or more ago is that they were implicitly or explicitly modeled on an exemplar, usually Silicon Valley. The reason why this “framing” of the problem always produces disappointing results is aptly summed up below:

...The [organisational re-design] process was systemic and could not be reduced to individual parts or components or specific individuals on their own. That is part of the reason why “best practice” cannot be copied. The process is systemic, emergent and context dependent. It cannot be reduced to “building blocks” which can simply be re-assembled in a different context and give rise to an identical outcome. ... (Mitleton-Kelly 2011, 49)

This criticism is expressed from a complexity science perspective, which is wholly compatible with the kind of regional innovation system analysis and practice described in the preceding section. In order to explore the new take on regional innovation systems further, the following sections will explore the analytical and policy relevance of the approach by focusing on three of its master concepts: coevolution, complexity, and emergence. The revitalized role of “learning” in regional development is considered in the section on complex policy learning.

24.7 Coevolution

A good example of a coevolutionary analysis is Murmann (2003) who compares the evolution and institutional interactions involved in the separate fates of the British,

German, and American chemical industries. He finds that the coevolution of science and industry in Germany was a crucial coevolutionary series of events in that industry's success. However, in recent years, coevolutionary thinking came to the fore in the eco-innovation field. Here the intellectual effort was devoted to trying to understand and facilitate the transition of global society from its traditionally carbonized energy systems toward a non-carbonized, renewable energy future. Of special spatial interest has been why rising global concern with climate change issues produces national and regional policy responses that vary from the concerned and enthusiastic to the apparently unconcerned and apathetic. The idea of coevolution, and its absence is germane to such variable outcomes, a conclusion of Unruh (2000) who described a politico-economic institutional regime that has produced worldwide "carbon lock-in" as much for institutional as economic reasons. The US sub-prime financial crisis demonstrates negative coevolution (or systemic positive feedback) perfectly. Accordingly, the political subsystem, the consumer subsystem, the construction subsystem, the financial subsystem, and the energy subsystem were all coevolving in a particular, "dominant design" modality. Elsewhere, things were different, and a region like North Jutland and its country, Denmark, had simultaneously begun to express their "emergence" away from "carbon lock-in" through eco-innovation, initiated in the regional paradigm, whereby agro-engineering capabilities (milk cookers and turbofans) "emerged" into wind turbines, giving the innovating region the status of a "transition region." This meant it could innovate away from "carbon lock-in" by recombining a well-developed regional eco-innovation paradigm. Being home to former agro-engineering firm, *Vestas*, the world's leading wind turbine producer, *Grundfos*, a leading photovoltaics (solar energy) exporter, *Velux* (insulated windows), its owner *Arcon* (a leader in biogas energy production), and numerous green engineering SMEs allowed dynamic knowledge capabilities to be recombined in sustainable combined heat and power (CHP) design and construction. This capability was embedded in a pervasive "green" sociocultural and consumption regime supportive of local renewable energy networks (Cooke 2010). One complementary way to understand this process is according to a coevolutionary transition model (Geels 2006).

Coevolutionary transition theory, even with its multilevel perspective (MLP) is intellectually interesting on the one hand but frustrating on the other. The intellectually interesting level concerned is the process whereby globally significant innovation rose to prominence if not yet dominance at the level of the socio-technical system (STS). Theory suggests such innovation is destined eventually to become the dominant design (as hydro, solar, or wind power are for renewable energy today) and ultimately take over from carbon. Evolutionary economic geography theory also opened up this coevolutionary vein of research as evidenced by Martin and Sunley (2010a) who had critiqued classic path dependence theory as static and equilibrium orientated, opening up the prospect of a more dynamic perspective on regional development based on path *interdependence*. However, their approach lacked a convincing mechanism for bringing such novel states about. Similarly, the frustrating aspect of the earlier STS approach to transition was that it lacked a causal mechanism, change being seen as unproblematically arising from

market transactions or something akin to “enlightenment.” Reflecting upon this for path interdependence, it seemed primarily because, like much evolutionary economic geography, the nevertheless interesting and creative insight lacked a convincing theory of *innovation* as distinct from a vague notion of “technological change” as being somehow involved.

The key thing about a complexity analysis (which the coevolutionary transition model is not) is captured in the following observation by Eve Mitleton-Kelly that is relevant also to the broader project of evolving a richer theory of regional innovation and development:

...The distinguishing characteristic of complex co-evolving systems is their ability to create new order. In human systems this may take the form of new ways of working or relating, new ideas for products, procedures, artefacts, or even the creation of a different culture or a new organizational form. ... (Mitleton-Kelly 2006)

The way forward here is helped by “reframing” the theoretical problem as a transition from thinking of path dependence to one of conceptualizing path interdependence. This is integrated to another core concept in evolutionary economic geography (EEG), namely, “related variety” (Boschma and Frenken 2003; Frenken et al. 2007). These authors showed empirically that regions with industries in neighboring sectors (North Jutland’s eco-industries would be an excellent illustration) benefitted from a double “proximity effect.” The first of these is a *relational* advantage, which facilitates exploitation of “knowledge spillovers” because of the high lateral absorptive capacity potential of firms toward each other’s external economies of information. The second effect is in terms of the *geographical* proximity that facilitates by time-space compression the aforementioned *relational* advantage. This enriches information such that its elements of difference and surprise (“news”) may be communicated and factored into innovation calculations early, even before their full meaning has had time to be realized commercially.

This idea about the nature of information in innovation makes a significant contribution to RIS Version 3.0. It explains how coevolution of path-dependent processes can combine in order to branch into new path creation through facilitating path interdependence. The small but crucial addition that has to be made, from a spatial perspective, is that even though the relevant message may come from a great distance *geographically* or *relationally*, it has to be exploited in a particular space or place – the location of the innovation *design*. Such a location may take the form of a “transition region” as discussed above. Many innovations display this characteristic of combining or recombining information from widely different sources in a place that is nevertheless nonrandomly “selected” and explicable in terms of path dependence and path intersection of STSs. One of the key contributions the perspective makes is to expand the meaning of “related variety” beyond the narrow confines of neighboring industries such as electric and electronics, automotive and aerospace engineering, or banking and insurance. This means speaking of “relatedness” more generally, encompassing both routine and possibly surreal knowledge combinations for specific innovation. Information, even devoid of semantically precise meaning, is capable of making a *difference*. This means that

the unexpected interest or surprise that even *information* may provoke may help solve a problem related to the tendency to disorder (entropy) faced by the social agent seeking knowledge to innovate. The strong element of *surprise* involved here means that innovation prediction is impossible except in relatively trivial ways. Accordingly, “related variety” effects may be hypothesized *ex ante*, but they may only satisfactorily be understood *ex post*. This is called “revealed related variety” and captures the strong element of unexpectedness and unpredictability that seems to be associated with most innovation. This occurs with increasing frequency due to the expansion of “cocreated” variety in economic evolution, which means novelty becomes both more widespread and easier (Kauffman 2008, 151–154).

24.8 Complexity

There are clear resonances between the coevolutionary perspective that also incorporates key concepts like path dependence, related variety, and relatedness from EEG and the key findings of the complexity sciences (see, for an early economic geography approach to complexity, Martin and Sunley 2010b). One key difference between that treatment of the spatiality of complexity science and the present one is that this one relies significantly on complexity theory with an evolutionary biology inflection while, the other is informed by more of a physicochemical systems model. This is important because, as noted, Kauffman (2008) shows that evolutionary biological processes like selection, speciation, and mutation are unpredictable. By contrast, planetary and subatomic movements are largely predictable, albeit surprisingly often vitiated by data difficulties and even cavalier attitudes by scientists toward data where they do not fit the mathematics.

A second area of agreement between coevolutionary and complexity theory concerns the element of *difference* referred to above as being of such importance. This applies even in the analysis of the manner in which “mere” information, let alone meaningful *knowledge*, contributes to cognitive combinations and recombinations. The complexity science explanation of path interdependence is conceived of as occupying an imaginary topological landscape characterized by “strange attractors.” This is because complex adaptive systems are conceived to have an “ontogenetic” topology or “fitness landscape.” This fitness landscape can be rugged or sleek and variations in between. The sleeker the landscape, the more stable the system because there are few sources of perturbation and little opportunity for communication between system entities. This epitomizes the “wilderness” region with few sources of economic energy with which to interact. The more rugged the landscape, with metaphorical valleys and their tributaries acting as communication lines between centers of energy or potentially interacting entities, the more potentially unstable is the system. This is in the sense that it is prone to disequilibrating “collisions” of economic activities or their sub-elements that give rise to novelty. Some such interactions are considered to occur between “normal” attractors (or “routine”-related variety from an EEG viewpoint), but others involve “strange attractors” that are unexpected or surreal combinations that nevertheless

find ways to combine or recombine into innovative pathways. In Kauffman (1995), such centers of energy in complex adaptive systems are called “clusters,” and while these are different from the usage in economic geography, the latter are nevertheless a good illustration of the former. When such interactions are abundant, the system is said to be operating at “the edge of chaos.” This does not mean it is an utterly disorderly space but rather a condition in which the kind of system change, novelty, or innovation called for by Mitleton-Kelly (above) can occur. Finally, the complexity perspective also helps open the black box of innovation because of two core concepts introduced by Kauffman (2008), namely, “preadaptation” and “the adjacent possible.” These are options from within the complex adaptive system’s “normal” or “strange” attractor subsystem elements or “clusters” that are seeking novelty from the interactions that “the edge of chaos” has provided. In Kauffman (1995), he talks about these, naturally enough, although in complexity science it is, to be sure, a rare enough occurrence, in terms of communication between persons. Thus, interactions may initially take on the informal status of “gossip” between even lower-order employees of two incumbents (firms) in different entities (clusters or industries). Connectivity of this kind may reach middle managers in the strange attractor companies who might be *surprised* at the information passed on to them for semantic interpretation with senior executives interested in solving an innovation problem.

One direction such deliberations might take involves “preadaptation” whereby an innovative practice, product, or service implemented or marketed by a firm in one distinctive industry might already have within it sufficient information to allow it to be reworked in the other distinctive industry or cluster. This is both a not uncommon way in which usually incremental innovation actually occurs, and a strategy of how some “ahead of the curve” intermediary, innovation support agencies define their function in the regional innovation system. A good deal of such effort can involve “creative” activities like “sensemaking” of the kind Weick (1995) writes about, to “storytelling,” and even “critical theater” after Schreyogg and Hopfl (2004). This may seem strange to audiences unfamiliar with corporate change management practices or those of regional innovation agencies in countries that habitually make use of living laboratory learning and training settings. The second direction the innovative mind has the opportunity to follow is described as “the adjacent possible” where a step or steps into the unknown seeks to bridge the gaps where innovation potential might lie. This may lead to radical innovation where many sub-innovations may spin off an initial breakthrough, or it may be disruptive where some change in product status is induced in the appropriate market (online financial services, budget airlines, etc.), or it may be incremental but nevertheless an improvement to current practice. Evidence of both kinds of strategic innovation advice and practice are presented in the final brief section of this chapter that precedes the conclusions.

24.9 Emergence

This is a cognate concept to coevolution and complexity that provides theoretical interest but also gains additional practical meaning from its engagement with

regional innovation systems and practices. It has also usefully been reviewed by Martin and Sunley (2012) albeit from a fairly conventional top-down perspective. In “emergence” theory, the higher level tends to have been seen as the one responsible for qualitative change in elements that already exist in independent form at the lower levels of magnitude. But from an evolutionary biology perspective, the lower levels are usually determinant. Rarer is evidence of top-down causality. The examples of sugar or water existing at a superior level to that of the molecules that comprise them are often utilized as an illustration of emergence in the physicochemical world. The key point, however, is that “emergence” is caused by transversality rather than simple additivity. Transversality unites horizontally the properties latent in “relatedness” of natural or strange attractors. Thus, exploiting *difference* is actually at the heart of both “innovation” and “emergence”: Indeed they may, from a regional innovation systems perspective, be interchangeable.

In the economic geography literature, the question of “emergence” has been directed at, for example, the issue of cluster emergence (Fornahl et al. 2010). Hence, we might want to explain a cluster’s existence in terms of its agglomerative scale, which is a quantitative matter, but in terms of “emergence” the phenomenon under inspection is not scale dependent but relational. If collocated firms in the same field are working together on a regular basis, they can be a cluster. Accordingly, it is then a question of finding out why they find collaboration, collocation, and cocreation agreeable business strategies rather than how they simply came to agglomerate in space. The latter is an interesting question about *agglomeration* (which typically lacks collaboration and cocreation), but not especially about clustering. In other words, the cluster is “emergent” from the shared interests of the elements in higher-order economic activity; they could not achieve acting alone just as sugar is formed from but more than its constituent, lower-order molecules. Accordingly, it is as clear that the cluster elements collocate in space as the necessary sugar molecules do. The key point for regional innovation systems here is that when not interacting to create sugar, carbon atoms are available to bond with hydrogen atoms to make water or innumerable other chemical compounds used in everyday life. In other words, their “existence space” is the basis upon which their innovative recombination operates. Equally, some such atoms (or firms) may like to collocate, but not cocreate.

24.10 Policy Emergence and Learning

The exposition of RIS phase changes given above invites questions regarding the validity of its key propositions about coevolution, complexity, and emergence. A research project was, accordingly, implemented in Sweden, where complexity theory-derived measures were being deployed in two out of three regions studied. Thus, the research material alluded to in this section on policy was elicited from face-to-face interviews conducted with three regional development agency heads and some 12 cluster intermediaries in three Swedish regions during early 2011 (Cooke and Eriksson 2011). Briefly, the following case comparisons show instances both of “emergent” policies interlinking different activities at local level into

a grander synthesis at regional and even national levels. They also reveal, in one case, policy “learning” that leads to a complexity variant of “bifurcation” toward “clusters” of energy in a region that show more economic potential than the formerly path-dependent trajectory. Hence, the “emergence” perspective, informed by coevolution and complexity, begs some questions we hope to answer. At which system level does initial causality lie when, for example, the phenomenon under inspection is policy agency to seek mitigation from a planetary condition such as that of climate change? To what extent is top-down system hierarchy initiating or being influenced by lower levels? As will be seen “emergence” of a nonlinear kind was practiced in two Swedish regions (Västra Götaland and Skåne) under inspection and, more interestingly, learned by path interdependence in a third (Östergötland, centered on Norrköping and Linköping). In brief, one of the two regional agents, Västra Götaland, had by 2001 the outline of a regional eco-innovation strategy, preceding any EU member state, including its own, as well as the EU itself in this so much so that in 2001, it came to be known as the “Gothenburg Model of the Lisbon Strategy” (the EU’s competitiveness strategy). Over approximately a decade, a double feedback loop brought the EU’s advocacy of climate change strategizing back down to regional level in the *Europe 2020* (EU 2010) strategy document. However, long before then in the originating region, regional cluster initiatives inflected toward sustainability had “emerged” as practical actions. Moreover, such regional initiatives were “emergent” elsewhere in the same member state, and the member state itself was becoming more active. Thus such “edge of chaos” regional system adaptability was moving beyond the molecular level due to the exercise of *transversality* as regions and firms sought innovation by stimulating information flow and knowledge appreciation among unlike kinds of cluster. Nevertheless, eventually the EU resource-incentive narrative of “Grand Challenges” emanating from the highest system level gave a further degree of coherence to national and regional strategy discourse, expressing a third feedback loop (or “phase change”) in strategy emergence. A fourth will probably be added when *regional* policy emergence influences the formation of *national* strategy with its own resource-incentive discourse.

Skåne region is committed to giving greater identity and focus to its established and nascent industries by promoting its cluster policy which targets about eight fields. However, regime management builds upon transversal thinking and practice. These recognize the evident advantages of filling regional “white spaces” by stimulating the discovery of “revealed relatedness” and promoting transversal or interface projects and initiatives among clusters. As it stands, the clusters are mostly new and rather weak, except for life sciences, food, and film, but Skåne’s position on the Swedish periphery yet a Scandinavian core, due to its proximity to Copenhagen, means geographic proximity is important, something recognized in the status of the international Medicon Valley life science cluster between Skåne and the Danish capital. In this way, this region operates an “adjacent possible” innovation model inspired by two similar “Grand Challenges” as Västra Götaland in sustainable cities and healthcare but inflected according to regional expertise. Thus, recycling and eco-design are more pronounced elements meeting the national and EU aspirations for a concerted approach to tackling big issues.

Briefly instructive too is the way in which Ötsam, Östergötland's regional development agency, and particularly its optoelectronics research institute Acreo, branched away from a 30-year struggle to fit innovative printed electronics technology to a regional and national path dependence upon the packaging products of the pulp and paper industry. A low-intervention, "market-shaping" model here informed the strategy of stimulating the "emergence" of an indigenous supply chain to market the innovation. This failed because it was an overspecialized solution in search of a problem (consignment tracking in the logistics industry) that was already solved by more traditional and cheaper barcode methods. This led to thoroughgoing reversal (phase change) of policy methodology represented in a search for already "emerged" regional industry and clusters customers. These included renewable energy, biotechnology, and healthcare, where potentially appropriate applications of liquid polymer technology might evolve. As Juarrero (2000) observes,

... The precise path that the phase change takes can be explained only after the fact. Such explanation must take the form of a genealogical narrative that reconstructs the bifurcation... Phase changes embody essentially incompressible information... That is why fiction and drama... [are] better than deductions or formulas for explaining... transformations of this sort. (Juarrero 2000, 55)

Apart from our preference for factual over fictional narrative, as a justification for the kind of innovative change management approach explored in this chapter, this is difficult to improve upon. Accordingly, this review presents a rethought and empirically supported base for paying greater attention to the horizontal capacity and bottom-up capabilities of systems to stimulate innovation as an emergent property of interorganizational interaction. Recall this is a rebalancing act that underlines two-way and vertical as well as horizontal feedbacks or phase changes in multilevel process and policy systems.

24.11 Conclusions

Hypothetically, printed electronics began to be rethought once it was realized that its most successful innovative application had emerged in the touch screen controls of smartphones pioneered by *Samsung* of South Korea and early adopters like Taiwan's *HTC*. This looks to be a clear instance of multi-sectoral innovation "blindsiding," arising from technological path dependence since former Nordic leader companies in mobile telephony like *Sony Ericsson* and *Nokia* were locked-in to inferior proprietary and customized telephony system "frames." This can almost perfectly be framed by Mitleton-Kelly's (2011) comparative conclusions on the fate of two hospitals she researched, one that adopted a complexity learning format and one that adopted another approach:

... There was, however, no active learning from these [business process engineering] successes and the focus was very much on attaining financial balance. There was also little active feedback, and few opportunities for staff to get together to review performance and reflect in an open, relaxed and informal atmosphere. Reviewing was done formally in terms

of performance management. By restraining self-organisation and exploration and by not actively reflecting on the outcomes the learning environment was constrained... (Mitleton-Kelly 2011, p. 49)

Hence, we see a revitalized role for learning in RIS Version 3.0. It is that it should be the means whereby innovative organizational change can be motivated against a rather simple, linear model of change based, essentially on cost accounting with little employee engagement, feedback, or learning. Intellectually speaking, this is explicable in complexity science as the failing, cost accounting hospital having, as a system reached the “edge of chaos”:

... In complexity theory terms, changes in the ecosystem had pushed the hospital far-from-equilibrium in the sense that they could no longer operate under their existing regime using established norms and procedures. They reached a critical point and had to either do things differently or go downhill... (Mitleton-Kelly 2011, p. 51)

Of considerable influence is that we were able to show from selected examples recently studied that this way of thinking has, partly by a “design” approach broached in more detail in Cooke (2012) how regional innovation systems can be assisted toward optimal outcomes and evolutionary trajectories by utilizing insights from the theoretical material under discussion in this chapter.

Abstract

This chapter provides an overview of current theories and empirical research on cities and the knowledge economy. Two recent and interrelated streams of literature are discussed: the first focusing on agglomeration economies related to increasing returns and knowledge spillovers of firms in cities and the second highlighting the role of knowledge workers and creativity in identifying new and innovative growth opportunities in cities. We argue that analyses using knowledge production functions to capture knowledge flows in cities do not, as of yet, provide true insight into the generation and transfer of different kinds of knowledge. Only recently are various conceptualizations of distance and knowledge transmission channels able to address the heterogeneity of the actors and processes involved in capturing the respective role of cities in knowledge creation. We conclude that the mechanisms that create and diffuse knowledge in cities should be better embedded into both streams of literature. The current discourse on agglomeration externalities obviously needs such conceptual and

methodological views to address current impasses. In particular, evolutionary economic geographical concepts are promising in explaining the innovative behavior of growing firms and organizations in cities, carefully addressing the heterogeneity of the actors involved, spatial scale, selection and survival, as well as time and path dependency.

25.1 Introduction

In the 1980s, many people were convinced that cities as centers for social and economic dynamism were disappearing. Wealthier people wanted to live outside the cities, in larger villages, or in suburban areas. The widespread use of the car and the rise of information and communication technologies (ICT's), as well as the concentration of the socially and economically disadvantaged, made many observers think that we would see a complete transformation of communication, spatial configurations, and social and economic structures. The end of distance and spatial concentration seemed near (Gaspar and Glaeser 1998). The current view is completely different; today, views on urban development hold that distance still matters and that urban concentration still continues (Glaeser 2011). At first glance, it seems easy to understand why cities are increasingly the preferred mode of human settlement. They save on infrastructure, reduce trade costs, and enhance interaction. In developing countries, there's nothing particularly new about urbanization as an expression of development. At second glance, however, cities are associated with many costs – land, pollution, and other externalities. We once believed that suburbanization combined the primary advantages of urbanization with these lower land costs and other externalities, but density has returned to many parts of the world.

Examining the arguments behind this modern urbanization view, we find two major approaches. The first is based on the theory of agglomeration economies with increasing returns and easy access to knowledge (Jacobs 1984; Krugman 1995), and the second is based on the idea that (larger) cities are strong because they claim to be the physical concentration of skilled knowledge workers and the creative class (Glaeser 1999; Florida 2002). Both approaches lead to the hypothesis of an expected higher labor productivity. This raise of productivity seems to be the case, although the explanation can differ. In Europe, the largest urban areas, in particular the London-Randstad-Paris-Frankfurt-Milan axis, contribute much more to their national GDPs than could be expected judging by their population sizes (Ciccone 2002). The same conclusion was reached by Glaeser (2011) for the USA.

The question that can be raised is whether knowledge is a decisive factor in explaining (a) higher productivity and (b) the stronger attraction of knowledge workers, or more general, of the creative class. In urban economics, knowledge receives increasing attention as a source of growth. Apart from knowledge, urban growth is explained by many other variables, and by the concentration of creative people, with the expected concomitant development of new knowledge and innovations (Combes et al. 2008). Urban economics focus on properties associated with

agglomeration advantages, external economies of scale, increasing returns, and the development of a variety of producers and consumers. Knowledge, its generation, and its use in innovations are perceived as the principal variables. However, the concept of knowledge in itself is not entirely clear, and neither are the mechanisms of its impact on productivity. It can be seen as a separate production factor or as an attribute, in one way or another, linked to capital goods and labor. Most economic studies emphasize the second interpretation. In endogenous economic growth theory, knowledge is seen as an output of investment in research and development (R&D). This kind of investment can be defined more broadly, as knowledge-intensive inputs, such as in new capital goods and new labor, to increase R&D. To make things more difficult, in the aforementioned case, knowledge can be both an input and an output.

In this chapter, a (non-exhaustive) survey of theories and empirical applications on research focused on cities, knowledge, and innovation is provided. We structure the theories using two recent and interrelated streams of literature: the first focusing on agglomeration economies related to increasing returns and knowledge spillovers of firms in cities and the second highlighting the role of knowledge workers and creativity in identifying new and innovative growth opportunities in cities. [Section 25.2](#) provides an overview of historical and current conceptualizations of knowledge and knowledge diffusion. [Section 25.3](#) provides a discussion on knowledge production function methodologies applied to cities, and concludes, consistent with [Sect. 25.2](#), that future research should increasingly and explicitly focus on the transfer mechanisms of knowledge diffusion. [Section 25.4](#) focuses on the related literature of agglomeration externalities and its link to innovation and urban economic growth. [Section 25.5](#) confronts the central plea for a better embedding of knowledge transfer mechanisms in agglomerations with current agglomeration discourse and methodologies. Conclusions on new and necessary conceptual and methodological views are presented in [Sect. 25.6](#).

25.2 Knowledge Creation and Diffusion

A useful distinction is the one in “data” (facts or unstructured information), “information” (structured data and standardized knowledge) that can be easily transferred via markets, “practical knowledge” (dispersed over economic actors and belongs to particular individuals) that can be used in commercial activities or applied directly in production processes, and “scientific knowledge” that can be applied after further research and development. Knowledge is acquired through the interactive process of learning, based on the cognitive competencies and experiences of the actors. A distinction can be made between “tacit” and “codified” knowledge. Tacit knowledge can be defined as the person-specific knowledge that people have developed through a process of learning-by-doing or learning-by-using, meaning that a person is able to use it but is not, or is not yet, able to codify it in a transferable form, such as a book, patent, or a mathematical formula.

It has to be emphasized that these kinds of knowledge are not fixed. Nonaka and Takeuchi (1995) have emphasized that tacit knowledge and codified knowledge have to be perceived as dynamic attributes that can be transformed into one other. After a period of application, tacit knowledge can be codified and, vice versa; sometimes, codified knowledge can be developed further and can become tied to individuals. The ways in which learning and the transfer of knowledge across organizations and in spatial settings can be investigated and measured have triggered much debate and research.

Codified knowledge (like patents and books) can be transferred to other users and is most often sold in markets. Tacit knowledge is person and context specific; hence, it has to be transferred or sold connected to a person, as with labor mobility. In some instances, knowledge is transferred for free, as in certain teaching situations or in networks, based on friendship. Tacit knowledge can develop into codified knowledge. This happens when, through research, certain skills, feelings, or capabilities are formalized or defined by rules, as has been performed with chess programs and in medical research. The reverse also occurs when codified knowledge becomes “embedded” in behavior and becomes tacit through its implementation in new situations, through experience, or by sharing within a group. Recent questions on the subject involve the possibilities of transferring tacit knowledge not only via interpersonal contacts but also via modern tools such as TV, the Internet, and mobile phones. Another question is whether the use of knowledge for economic goals and its transfer are related exclusively to production and consumption. Additionally, the question arises regarding whether wider opportunities to increase welfare emerge, for instance, in the arts, or whether measures to increase the sustainability of cities are implemented (Glaeser 2011). Finally, the link between knowledge, skills, and creativity is important. The use of knowledge and, in a broader sense, creativity is not always directly related to economic goals of production and consumption. Creativity can be used for solving personal or family problems, or expressed in the arts. However, this also can lead to higher satisfaction or even to the rise of certain forms of consumption, through which the production of goods and services can increase. There are also many indirect links between creativity, knowledge development, and economic growth.

In endogenous growth theory, the generation of new knowledge and innovations is explained by increased investment in R&D. This concept was also described in Schumpeter’s 1942 book, in which he saw the entrepreneurial function of management replacing the risk-taking and innovative individual hero-entrepreneur. In this view, it is possible to create a knowledge production function (KPF), with investments in R&D as input and knowledge and patents as an output. Recent applications at the regional and urban level show that this line of thinking is fruitful for explaining urban growth differentials (Acs 2002; Breschi and Lissoni 2009). However, in this KPF approach, the important other causality, the line starting from the demand side, is often neglected. The failure to meet the preferences and needs of users has been consistently stressed as a major cause of unsuccessful R&D for over 30 years. This is especially important in urban agglomerations, as is emphasized in studies on consumer cities. In modern urban agglomerations,

consumers are increasingly seen as a source of changing demand and new ideas (Glaeser et al. 2001). However, it is not yet clear how the lines of knowledge generation and application can be connected to producers and consumers in urban contexts. It is particularly necessary to investigate the relative importance of markets (prices) and formal and informal networks as carriers of knowledge. Krugman (2009, p. 567) also emphasized the unclear role of spillovers: “it’s not at all clear how to think about the spatial limits of spillover. Do you have to be in the same city to reap positive externalities from other producers in the same industry?” However, for cities with a wide variety of different kinds of economic activities and international relations, this question becomes even more important. The analysis incorporating production functions does not provide us with insight of the generation and transfer of different kinds of knowledge (yet). The investigation of knowledge in cities, as well as other kinds of knowledge, such as scientific knowledge, practical knowledge, and Polanyi’s tacit knowledge, is in need of receiving greater attention. The generation and diffusion of these heterogeneous kinds of knowledge can vary and need to be considered as having different effects on urban economic variables. In turn, urban contexts can be perceived as having effects on the generation and diffusion of the various kinds of knowledge. Cities can cumulatively specialize in certain kinds of knowledge connected to different economic specializations (Duranton and Puga 2005).

It is generally accepted that geographical contexts, such as agglomerations, influence the generation and dissemination of knowledge, although other mechanisms besides markets are not always included in explanations of urban development. In urban economics, the role of geographical distance as such is reflected in transport costs (both in the old and in the new economic geography), in the impact on social relations, and in the availability of knowledge embedded in labor, as in the popular view on the development of industrial clusters. In theories of urban hierarchy, distance costs are seen as a decisive factor explaining the differences of the quality of services and amenities in centers of different size. Distance is generally translated in terms of costs or in missed opportunities, stemming from the failure to note chances to produce, sell, or purchase goods or services.

Boschma (2005) emphasized that the word “distance” can be interpreted in different ways. Geographical distance is not the only important factor; social and cultural distance can also be important. This distinction is especially relevant in analyzing the geographical sources of knowledge and innovation because in a globalizing world many researchers have connections with people in other places. Nevertheless, it seems that distance costs and perception barriers are important factors in the analysis of agglomeration advantages because closer distance, no matter how it is measured, seems to foster the development of knowledge and innovations (Breschi and Lissoni 2009). One of the strong attributes of closer distances is the easier transfer of knowledge. This is related to the uncertainties that are inherent to the economic process and to the rapid changes that knowledge development has shown in our time. Such changes in knowledge cause the need for continuous adaptations by economic actors and hence the tendencies to locate

generators of knowledge locally, such as in universities and other R&D organizations (Audretsch and Feldman 1996).

The dynamic properties of knowledge are associated with various forms of dissemination and with their applications as innovations, with concomitant changes in supply and demand conditions. Through this process, continuously disturbing effects on equilibrium exist. Markets have to respond quickly to rapidly changing contexts. Metcalfe (1998) even argued that capitalism is restless because knowledge is restless. Innovations can also change market structures by creating new monopolies, as in the case of radical new technologies, especially GPTs (general purpose technologies).

The consequences of the application of knowledge for innovations are important. However, it is also important to examine the sources of knowledge (or its generation), where the cognitive attributes of economic actors and the organizational capacities of entrepreneurs are decisive properties of a knowledge-enhancing urban society. Economic actors vary considerably in their cognitive capacities and other attributes. This heterogeneity is one of the strengths of cities and an important reason for their continuous creativity. Situations involving heterogeneous actors and conditions lead to continuous uncertainties, which offer “gaps in information” for the existent markets, and this, in turn, can give entrepreneurs opportunities for innovative actions. This is particularly the case when new knowledge leads to pecuniary external effects (Metcalfe 1998).

25.3 Mechanisms of Knowledge Production and Diffusion in Cities

Knowledge and innovation are closely associated. Knowledge is not just “given” but has to be generated. Schumpeter (1934) emphasized that the generation of knowledge is the result of a process of wider social significance. The generation of knowledge is important for the development of the quality of labor and capital goods and is decisive for innovation and economic growth. However, the direction of the causality of the relationship between knowledge, innovation, and economic growth is not always clear. Knowledge can be the result of investment in growing sectors of the economy, but it can also be developed by people with inquisitive minds, without the purpose of commercial application. Knowledge and innovation do not only start at the supply side with research and investment. Rather, the causality may sometimes start with changing demand because certain cultural developments alter the structure of demand through concomitant changes in sectoral structures. This can also happen if wealth increases due to the expansion of foreign markets with already-existing kinds of products. All types of change can lead to the demand of new knowledge, products, and production technologies. This section provides a discussion of production function methodologies and concludes by recognizing the need to explicitly focus future research on the transfer mechanisms of knowledge diffusion. The argumentation is neo-Schumpeterian in character.

Being that knowledge is hard to appropriate, as we argued in the previous section, it generates benefits to other agents through several spillover mechanisms. Understanding the geographical structures that underlie these spillover benefits is necessary for any evidence-based innovation policy to stimulate a region's (or collection of regions, such as Europe) transformation toward a knowledge-based society. Recent years have seen many macro studies on the effect of knowledge spillovers on innovation. Such studies generally apply a knowledge production function to differentiate regional innovation outputs from regional knowledge inputs, as well as from knowledge spillovers from other regions. The strength of interregional knowledge flows is generally assumed to decrease rapidly with geographical distance (Acs 2002), while others have attempted to measure spillovers directly by patent citations (Breschi and Lissoni 2009). Despite the fact that previous research has produced a certain degree of empirical coherence (Fritsch and Slavtchev 2007), it has proven difficult to distinguish between different channels of knowledge spillovers; this has subsequently led scholars to rely on specifications that are suggestive of knowledge spillovers without explicitly modeling the mechanisms through which they occur in practice. Understanding the mechanisms that are behind knowledge spillovers is obviously of the greatest importance for designing effective innovation policies.

The step forward to be taken in empirical research on knowledge production and diffusion in cities and city regions is to correctly model spillover mechanisms of knowledge (correctly). This means that, conceptually speaking, one should take into account via a single framework both geographically localized knowledge spillovers (by examining the extent to which regions profit from regions knowledge inputs nearby) and knowledge spillovers stemming from research collaborations (by examining the extent to which regions profit from network connections to other regions). Put differently, one can analytically distinguish between the "space of place" creating geographically localized knowledge spillovers and the "space of flows" creating spillovers in global networks (Castells 1996). In contrast to geographically localized channels of knowledge spillovers, such as spin-off dynamics and informal networking (Breschi and Lissoni 2009), two promising networked channels of knowledge diffusion come to the fore: research collaborations between firms and universities that are increasingly taking place over longer distances and the mobility of globally operating knowledge workers.

The presence of both private and public research organizations, such as universities and the laboratories of multinational corporations, is generally assumed to have a large impact on urban innovation due to their ability to attract knowledge workers and generate localized knowledge spillovers resulting from their research (Acs 2002). Various empirical studies have suggested the presence of localized academic knowledge spillovers for the USA and various European countries. It has been stressed that highly skilled workers can be regarded as carriers of knowledge diffusion and key drivers of regional innovation and growth. Individuals impact knowledge diffusion through two main and complementary channels: on the one hand, their ability to move from one place or one organization to another and, on the other hand, their ability to enter networks. The mobility patterns seem to be

predominantly local, though some evidence indicates that, due to the intrinsic universality of science, researcher's labor markets – in particular academic researchers' mobility – tend to be more international than other labor markets. Motivations for labor mobility could be related to scientific, economic, cultural, and personal factors. It is expected that nonpecuniary scientific factors, such as the quality of the university, the availability of research budgets, personnel and material research infrastructure, and institutional reputation, are more important than economic factors (Jons 2007). Due to the rising demand of specialized scientific labor, a reputation for scientific quality and openness is a critical factor for attracting excellent researchers. However, differences in wage levels, career opportunities, and concentration effects (talent is attracted by talent) are also thought to be relevant. There also exists a relation to soft factors, for example, language, cultural affinity, living environment, and personal motives (Florida 2002). In line with these insights, many countries have implemented regional innovation policies based on the presence of universities and research institutes in a city or region. In particular, initiatives have been set up to attract skilled workers and facilitate their movement. Systematic research on this kind of labor mobility and migration is lacking.

Besides the importance of local labor markets and spin-off dynamics, a growing body of research stresses the role of networks between individuals and between organizations as mechanisms for knowledge spillovers. Informal networking often takes place at the regional level and, as a result, knowledge spillovers are localized to the extent of these networks. Formal networks of research collaboration are an additionally important mechanism of knowledge spillovers; however, empirical research on the spatial dimension of these networks has suggested that they largely occur at the national or even international scale (Ponds et al. 2010; LeSage et al. 2007). The structure of collaboration networks thus needs to be taken into account to fully understand the impact of researchers' knowledge spillovers (Barber et al. 2011). Despite the increase in literature analyzing knowledge flows in different organizations and geographical contexts, little is known about actual knowledge circulation and its impact on community, as well as urban and regional knowledge creation, diffusion, and quality. At least two weaknesses in the existing studies stand out. First, most studies on localized knowledge spillovers claim that knowledge does not circulate freely across regional boundaries because it is tacit; on the other hand, these studies remain elusive on the specific mechanisms of diffusion of tacit knowledge (Audretsch and Feldman 1996). Studies of knowledge diffusion, with some exceptions, tend to focus only on codified forms of knowledge and on formal channels of transmission (i.e., patents, patent citations, publications, R&D). Second, studies on migration and mobility offer important insights into the motivational factors behind the decision of scientists to move. However, this literature is mostly based on anecdotic or only qualitative evidence. Quantitative evidence instead focuses only on selected groups of skilled workers (e.g., graduates, star scientists) and is limited to cases by country. Future research should shift attention from codified toward more tacit forms of knowledge and from stocks of knowledge toward flows and networks of knowledge.

25.4 Agglomeration, Variety, and Pecuniary External Effects

Agglomeration advantages have been connected with increasing returns to scale, external effects, and with the variety of producers and consumers (Combes et al. 2008). New knowledge changes markets, market structures, and production technologies (including organizational structures). Cities can be perceived not only as locations with agglomeration advantages but also as locations of interacting producers and consumers. Interaction occurs not only via markets but also via social networks, sometimes indicated with “buzz” (Storper and Venables 2004). Baumol (2002) argued that markets are predominant in the process of knowledge creation and diffusion, even when other mechanisms of dissemination also exist, such as social networks, labor mobility external effects (externalities), spillovers, and spin-offs. In various publications, the transfer of knowledge is assumed to be different from other goods and services, most often because it is perceived as a public good, freely accessible to anyone, or as given. In traditional growth accounting literature, “technological knowledge” was accepted as exogenous. Most often, the transfer of knowledge, especially codified knowledge such as books and patents, has a price and occurs via markets. This is also the case for labor mobility, where a higher wage is paid to newly attracted experts. The prices do not always completely cover the costs created by the generators of knowledge; subsequently, in many cases, we can highlight market failure or even more pecuniary external effects. In other cases, one could even address unpaid positive external effects; Alfred Marshall indicated this latter effect by asserting that “it is in the air.”

In the case of technological development and expanding or changing demand, new opportunities are created. This can change the relations between firms in different sectors, which are all confronted with an expanding or changing supply and demand. This requires new production methods and products, a good base for an endogenous process of increasing demand for new knowledge and innovations. Adam Smith and Alfred Marshall emphasized the interrelations between firms with the division of labor and industrial districts. In cities, changes could have their origin in new (technological) knowledge, increasing wealth, or new trade relations, leading to new supply and demand and hence to a larger economic base. As Adam Smith said, “the size of a town depends on the size of the market.” The interrelations between trade, the differentiation of consumers, different kinds of firms, and the development of increasing returns have experienced a resurgence in new trade economics and new economic geography. The economic process is influenced by these factors, but in cities, we can also observe the special influence of positive and negative external effects, which in economic theory has been defined as market failures. However, in the case of increasing market size (growing demand within cities and regions through increasing wealth and trade effects) positive pecuniary external effects are related to increasing returns. This leads to the conclusion that pecuniary external effects are not merely market failures but dynamic opportunities for innovators. Allyn Young (1928), then president of the American Economic Society, emphasized the positive impact of the interrelatedness of firms in the production process. In this structure of relations, as well as in the case of the

development of new technologies, pecuniary external effects could develop because entrepreneurs detect new opportunities for higher profits with new products or new technologies. He stressed that in this case, the opportunities to invest in new technology could result in pecuniary external effects and in increasing returns to scale for the entire structure of related firms. Pecuniary external effects offer new opportunities for entrepreneurs by creating “gaps” in the market. Entrepreneurs can establish new firms and produce new products (physical goods or services). Schumpeter (1934) emphasized that innovation is related to this entrepreneurial function of seeing the gaps in the relation of demand and supply by establishing new firms and improving the allocation of resources.

25.5 Knowledge Spillovers in the Urban Agglomeration Literature

Despite this complex and nuanced way of conceptually linking innovation – the introduction and the application of new or existing knowledge – with growth and cities, an ever-growing body of empirical literature on urban externalities remains rather inconclusive on the exact agglomeration circumstances that optimally enhance growth and innovation in cities. In such literature it is argued that externalities or spillovers occur if an innovation or growth improvement implemented by a certain enterprise increases the performance of other enterprises without the latter benefiting enterprise having to pay (full) compensation. Spatially bound externalities are related to enterprise’s geographical or network contexts and are not related to internal firm performance. All discussions of spatial externalities can be linked to a twofold classification in which the sources of agglomeration advantages are grouped. *Localization economies* usually take the form of Marshallian (technical) externalities whereby the productivity of labor in a given sector of a given city is assumed to increase with total employment in that sector. In short, they arise from labor market pooling, the creation of specialized suppliers, and the emergence of technological knowledge spillovers. The strength of local externalities is assumed to vary, such that they are stronger in some sectors and weaker in others. The associated economies of scale comprise factors that reduce the average cost of producing commodities. External scale economies are applicable when the industry to which the firm belongs (rather than the firm itself) is large. An urban system is composed of (fully) specialized cities, provided that the initial number of cities is large enough; such systems occur contingent on further assumptions on crowding (congestion costs that increase with population triggers dispersion), perfect product, and labor mobility within and between locations, not to mention the influence of large agents. Once cities exist, *urbanization economies* that apply to all sectors become equally important. Urbanization economies are often interchangeably mentioned with Jane Jacobs’ diversity externalities, as (sectoral) diversity tends to be larger in cities than outside them. Frenken et al. (2007) showed that a distinction between variety and diversity externalities and urbanization economies is necessary. A large body of empirical literature has grown around testing

these types of externalities in relation to knowledge spillovers using sectoral specialization, sectoral diversity, and density data from cities. The assumption is that if knowledge spillovers are important to growth and firm dynamics, they should be more easily identifiable in cities where many people are concentrated into a relatively small and confined space where knowledge is transmitted more easily. This literature has evolved in a rather polarized discussion on the question of whether sectoral specialization (clusters) or sectoral diversity matter for economic growth and innovation in cities. Three recent meta-analyses and overviews clearly show the limitations of this empirical approach (De Groot et al. 2009; Melo et al. 2010; Beaudry and Schiffauerova 2009); the outcomes of the many empirical analyses using the Glaeser et al. (1992) framework on agglomeration externalities appear to be highly dependent on spatial scale, sectoral detail, time frame, institutional context, and the construction of indicators and variables. Twenty years of research have not convincingly answered the question “Who was right, Marshall or Jacobs?” (Beaudry and Schiffauerova 2009). The answer is ambiguous; both specialization and diversity are related to growth in different aspects and ways.

In principle, this answer is rather unsatisfactory scientifically for understanding the relation between urban growth, spillovers, and innovation. It is very plausible that the prevailing static urban economic modeling approach, confronting the Marshallian versus the urbanization externalities approach, falls short both conceptually and methodologically, and in its present form is unable to test this important issue satisfactorily. In its conceptual sense, this was previously noted by Lambooy and Van Oort (2005), who suggest four heterodox aspects attached to urban and regional economic growth that are currently (still) relatively unaccounted for in research and should be taken more seriously. These are (a) the importance of the life stages and time frames of firms, technologies, and sectors, or development paths of firms, sectors, cities, and systems of cities; (b) specific spatial networks not showing (clear) relations to the forces of contiguous economic agglomeration; (c) specific urban and regional factors explaining why and through which transmission channels agglomeration forces influence sectors and firms differently, depending on the period of economic development and the various technological trajectories; and (d) factors related to forces that cannot be explained using equilibrium approaches, for example, the relation with institutional structures, path-dependent development, the way selection works out for new technologies and firms, innovation, the rise of new technologies and new regional concentrations of firms, spillover mechanisms, and (co-)evolution. These four heterodox aspects of economic theory and empirics are attached to evolutionary economic development trajectories in a wide range of cities, regions, and countries in the same manner (McCann and Van Oort 2009). In the evolutionary geographical research tradition, much more emphasis is placed on the interaction of the relevant urban and regional environment, with locational choices being made by individual firms and investors (Boschma and Martin 2010). In these traditions, a strong preference exists to allow for the differentiation of firms and types of behavior and locations, addressing the heterogeneity in actors and innovation in cities that were signaled in the previous section. The concept of related variety, indicating that successful sectors in regions diversify over time, though mostly in relation to existing competences and

specializations, is an important exponent of new conceptualizations in the agglomeration, innovation, and growth discussion (Frenken et al. 2007).

Together with these conceptual issues, methodological issues arise as well. More emphasis on a firm or consumer's personal agglomeration circumstances requires a modeling approach that takes firms and consumers as starting point. Duranton and Overman (2005) and Combes et al. (2008) argue that many measures of concentration use arbitrary spatial units (such as provinces, municipalities, or postcodes), which may be problematic, as they may lead to biases. Continuous space specifications of agglomeration circumstances of individual firms therefore become more important in present and future research, avoiding the problems of modifiable areal units signaled in the three review articles. Furthermore, issues of causality, endogeneity, selection, and sorting have to be addressed more thoroughly to ensure that the econometric analyses produce reliable outcomes. Both conceptual and methodological renewal are needed to investigate the nature and origin of knowledge creation and diffusion (transfer mechanisms and absorptive capacity of actors), addressing the central issue of heterogeneous actors as well as the varying contexts in the organization of sectors and networks.

25.6 Conclusions

We have provided an overview of historical and current conceptualizations of knowledge, knowledge diffusion, and innovation in cities. We have argued that knowledge is based on processes of learning as well as research and development, that it is both person specific as well as context specific, and that it can be codified and included in the quality of capital and labor. Recently, much empirical research has focused on the creation and transfer of knowledge across organizations in spatial contexts. We argue that analyses using knowledge production functions to capture these flows generally do not provide us with true insight into the generation and transfer of different kinds of knowledge. Only recently have various conceptualizations of distance and knowledge transmission channels been empirically related to knowledge creation and diffusion, addressing heterogeneity in related actors and processes, and capturing the role of cities in them. Our discussion of knowledge production function methodologies applied to cities has concluded that future research should increasingly and explicitly focus on the transfer mechanisms of knowledge diffusion. This is especially true for research on the mobility of (star) knowledge workers and on the evidently fruitful collaborations between firms and universities. To incorporate this in empirical modeling, econometrical knowledge and innovative applications are needed in this field of research. The chapter has further argued that markets remain the most important kind of interaction for economic actors, even in the case of knowledge. This nuances the large focus on nonmarket factors as put forward in the growing literature on urban competitiveness and innovation. We confronted the plea for a better embedding of the mechanisms that create and diffuse knowledge in agglomerations with current agglomeration discourses and methodologies. We conclude that to address the

apparent impasse on the measurement and interpretation of agglomeration externalities, new conceptual and methodological views are needed here as well. In particular, evolutionary economic and geographical concepts are promising for explaining the innovative behavior of growing firms and organizations in cities, carefully addressing the heterogeneity in the actors involved, spatial scale, selection and survival, and time and path dependency. For this, accompanying econometric tools have to be applied, such as continuous space modeling and causality analysis. The future of urban agglomeration research is thus in the interplay of conceptual and methodological renewal, in close relation to already-established insights: what is needed is renewed and related variety in conceptualization and testing.

Abstract

This chapter reviews the importance of networks in the innovation process from a spatial perspective. Such networks are part of different scale systems of innovation and are essential to the creation of knowledge externalities. It is well established in the extant literature that innovation does not occur in isolation, and furthermore, interorganizational networks facilitate innovation creation. Social networks, trust, and local embeddedness play key roles in the formation of such networks. In addition, relational perspectives, such as non-geographical proximities, are also vital factors for the creation of innovation networks, the main objective of which is knowledge creation. Important enough, the latter can be approached as crucial production factor in the frame of the knowledge economy. Moreover, scale is an important attribute of such networks, as both local and global links are important in the innovation process.

26.1 Introduction

This chapter aims to review the importance of network formations in the innovation process adopting a spatial perspective. The starting point for this journey is the systemic understanding of the innovation process: innovation does not occur in isolation but is the outcome of systemic interactions among various actors. The spatiality of such systems of innovation (SI) and more specifically networks of innovation is the main focus of this chapter. Unavoidably, such an analysis is underpinned to some extent by evolutionary processes, which capture the change of organizations, institutions, and their ties over time. Importantly, SI highlight the role of interactions between actors in the innovation process and the related feedback mechanisms. Thus, innovation activity is a collective process, which is based on actors interacting together to transfer, exchange, and create knowledge (Edquist 1997). Such knowledge is a necessary input for the *innovation* production. It needs to be stressed here that despite the great interest from academics and policy makers in understanding the mechanisms behind innovation creation, there is still not a commonly accepted definition for innovation. For the needs of this chapter, the following definition is adopted: “An innovation is the implementation of a new or significantly improved product (good or service), or process, a new marketing method, or a new organizational method in business practices, workplace organization or external relations” (OECD and Eurostat 2005, p. 46).

The systemic understanding of the innovation process was initiated by the introduction of the concept of national innovation systems (NIS). Pioneers in this conceptual formation were Christopher Freeman and Bengt-Åke Lundval, who introduced the idea that different innovation actors are linked together forming a knowledge exchange network structure. Such a systemic understanding of innovation is based on three components: (a) the actors of the innovation system, which are private (individuals and firms) and public organizations (universities or state authorities), the affiliation of which with the SI defines the boundaries of the system; (b) the relations and interactions among these actors for knowledge creation and diffusion; and (c) the attributes of the actors.

Soon after the systemic view on innovation was established, this approach was then transferred to a regional scale known as the regional innovation system (RIS) (Cooke 1992). This scalar change came as a response to empirical evidences that innovative activity is neither uniformly nor randomly distributed across geographical space. The main explanation is that knowledge, especially tacit – that is, the non-codified part of knowledge – can only be transferred via face-to-face interactions and within an atmosphere of trust. Thus, geographical proximity can act as a facilitator for the innovation production. However, as it will be highlighted later in this chapter, geography is not the only proximity dimension useful in this context. During 1990s, the RIS concept was developed as an analytical framework for policy makers and academic researchers to understand the innovation process in regional economies (Cooke 1992). RIS focuses on interactive networks of nodes

and linkages on a regional scale to understand a city or region's innovation performance. Thus, the spatiality of interactions among innovation actors becomes an important element of the innovation production.

The last point leads the discussion to the core of this chapter. Innovation is a systemic process, which is facilitated by networks of actors. The latter is a systemic representation of interactions among innovation actors. However, such systems are anything but *a*-spatial as spatial and territorial dynamics facilitate interactions and directly affect innovation actors. After analyzing the systemic nature of innovation in the introduction section, this chapter then focuses on further understanding innovation networks. Then, [Sect. 26.3](#) highlights the importance of networks in knowledge creation and in the frame of the knowledge economy. [Sect. 26.4](#) focuses on the impact of different proximities in network formations, and [Sect. 26.5](#) reviews the main current methodological challenges in modeling spatial innovation networks. Finally, the chapter ends with a conclusion section.

26.2 Networks and Associated Concepts

Owing to Cooke and Morgan's (1993) seminal work on the network paradigm, the importance of networks in regional economic growth is well established among academics and practitioners. Although the starting point was limited to the micro-scale, the spatiality of such links gained importance over time. Initially the focus was on interfirm links, usually representing buyer–supplier relationships. The dominant economic school of thought, grouped here for simplicity reasons under the term mainstream economics, incorporated space as “transaction cost.” Thus, proximity, mostly in terms of geographic proximity among actors of local production systems, can result in transaction cost reduction. Such a proximity effect decreases the locational disadvantage of peripheral, but still agglomerated regions when compared with the core urban areas, which represent the nodal points of the Fordist production system. A similar effect can be generated by the so-called Marshallian externalities. According to Alfred Marshall's argumentation on an *industrial atmosphere*, small and agglomerated firms in *industrial districts* can benefit by scale economies and the resulted cost decrease in human capital training, information and knowledge sharing, and the collective use of infrastructure (Marshall 1927).

However, the introduction of the *innovative milieu* concept by the French group GREMI (Groupement de Recherche Europeen sur les Milieux Innovateurs) turned the interest to more dynamic and territorially embedded conceptualizations of the innovation production. Indeed, proximity is in the center of the discussion around innovation production, not only because it decreases transaction costs, usually expressed in the form of transportation cost, but mostly because it eases information exchange usually through frequent face-to-face interactions and cultural similarity.

In more detail, there are two main characteristics of an innovative milieu. Firstly, a milieu, in order to enhance the innovation production, needs to be characterized by a *collective learning process*. Such an attribute improves local creativity, technological development, and adaptation and, in total, supports the innovation production. Secondly and in the same spirit, a local milieu reduces uncertainty as it enables a better understanding of firms' decisions given the easiness it provides in interpreting technological transformation (Camagni 1991).

At the same time, Porter (1990) introduced the notion of *clusters* and defined it as a group of interconnected companies from more than one industry and the related institutions, which are all located in geographic proximity. The notion of the industrial district differs from the regional cluster as the latter mostly consists of firms from the same or related industries as well as supporting institutions. Although he did not explicitly focus on networks, the distinctive point of his conceptual proposition was the interconnectedness of regional actors and how such network-like structures can benefit firms. The mechanism behind this argument is summed up by the following: once a specialized industrial cluster is formed, then demand for suppliers and other supporting services is generated. This demand acts as an incentive for suppliers and service producer firms to locate within the cluster to take advantage of the emerging economies of scale and the lower transaction and transportation costs. Consequently, dense transaction linkages should be expected within a cluster (Bathelt et al. 2004).

In total, various closely or less closely related concepts have been introduced in the new regionalism tradition including, apart from the innovative milieu and Porter's cluster notion, concepts such as local knowledge communities and learning regions. Even when the discussion moves to older conceptualizations such as Marshallian industrial districts, an important element for the success both of the firm and the district is the density of social networks among organizations. In both conceptualizations of local and regional networks, economic and social relations play a key role in innovation facilitation.

Therefore, given the wide acceptance of the above conceptualization, the spatiality of networks between actors came to the forefront of academic research, and in addition, such a network framework was further expanded to include non-firm actors. Examples include links between firms and other noncommercial organizations such as universities, research institutes, technology transfer agencies, and regional and governance bodies. Despite the different conceptualizations found in the literature, there are some common characteristics in respect to the mechanisms related with spatial innovation network formation (Giuliani 2011):

- Market relationships or *traded interdependencies* using Storper's (1997) terminology. Such networks are formed utilizing market mechanisms, and examples include user-producer links, spin-off companies, and highly skilled human capital mobility. Spatial proximity is an important facilitator of knowledge and most importantly tacit knowledge exchange.
- Social ties or *untraded interdependencies* (Storper 1997). More often than not, interpersonal networks provide the necessary basis to build market linkages. Examples include the importance of social relationships in the formation of

Italian industrial districts as well as their role in the success of Silicon Valley (Saxenian 1994).

- Policy-driven ties, which are the outcome of specifically designed (usually regional) policies, the main objective of which is to enhance the density of local interorganizational ties. The policy-related discussion around RIS tends to include such measures.

Despite the growing interest on networks, the relevant literature is still missing a universally accepted definition. As a summary of the above discussion, Tijssen's (1998, p. 792) definition is adopted here. According to him, a network is

an evolving mutual dependency system based on resource relationships in which their systemic character is the outcome of interactions, processes, procedures and institutionalization. Activities within such a network involve the creation, combination, exchange, transformation, absorption and exploitation of resources within a wide range of formal and informal relationships.

The discussion around networks is usually related with interfirm interactions. Firms benefit by participating in such regional innovation networks. Firstly, firms profit from the informal exchange of resources including knowledge and know-how, which is difficult to be facilitated by formal market mechanisms. Secondly, owing to an already adopted network perspective from a firm, the creation of new links is easier to take place, indicating a cumulative advantage. And thirdly, such networks carry trust and reciprocity – qualities that were usually excluded from mainstream economics, which enable the preservation of ties over long periods of time (Giuliani 2011).

Different typologies can be built for such networks. From a managerial perspective, innovation networks can be identified as the summation of interfirm linkages. Fischer (2006) distinguishes five different network types. *Supplier networks*, apart from intermediate goods purchase, reflect mostly subcontracting relationships between firms. The latter differs from the former as subcontracting relationships are ruled by formal contracts which define the order specifications, instead of simply obtaining final products from an upstream supplier. *Customer networks* represent the effort spent by companies to gain feedback from their customers to better customize their products and services. At the same time, the opposite direction of such a relationship is also important as customers – in this case firms – need to obtain information for new products from their suppliers. *Technological cooperations* is the third type of interfirm networks. The main objective of such networks is to share scientific knowledge and the outcome of R&D processes as well as to facilitate joint technology production and process development. *R&D cooperation networks* represent a well-established framework for interaction between firms and other actors such as universities and research centers, the main characteristics of which are fundamental or applied research. What used to be depicted as informal networks between firms and universities, nowadays, is mostly reflected in formal agreements between such actors. Finally, *production networks and strategic alliances* represent interfirm collaboration agreements for joint production. The main motivation for such agreements is the achievement of economies of scale and also surplus or scarcity in production capacity. While the first two types

of interfirm networks can be characterized as vertical networks, the last three represent horizontal collaborations (Fischer 2006).

From a functional point of view, interfirm networks can fulfill three different corporative needs: (a) problem solving by assistance networks; (b) lack of information such as whom to contact for specific reasons through information networks; and (c) entrepreneurship and product development (Mønsted 1993). The above networks are vastly based on interpersonal relationships and trust found in local communities. Although these networks are mostly interfirm networks, the driving force for such structures is interpersonal relations. In general, such regional innovation networks are always based on preexisting personal social networks which carry the necessary trust (Lechner and Dowling 1999). Thus, to the extent that such networks are related with regional innovation production as a necessary condition for firms to innovate and thrive, then trust, which is a necessary condition for the creation and maintenance of such interpersonal links, can be approached as an important mechanism for regional innovation processes. However, trust is a complex notion and can be approached as a socially embedded notion which is based on friendship, kinship, and repeated interaction (Boschma and Frenken 2010). Although such relationships are primarily social, they also carry information about potential partners, and because of this attribute, they increase the ability of organizations to get involved with innovation networks.

What also needs to be highlighted here is the interrelation between regional networks and regions per se. Regions do not only contain and shape network formation, but at the same time social interaction among actors in regional networks also affect its geography (Storper and Walker 1989). The above interrelation can be further intensified by the evolutionary nature of regional networks. For instance, the existence of large firms in the development stage of a region might prevent the development of extensive regional innovation networks or even an industrial district (Lechner and Dowling 1999). The explanation behind this influential role of large companies on regional networks is the power that large firms hold in terms of bargaining power against their supplies (Porter 1980). The utilization of such power has negative effects in developing interpersonal to innovation networks. A well-known example is the comparative discussion between Silicon Valley and Route 128. While in the former, the existence of one large firm, that is, Fairchild, supported the establishment of innovation networks, and the presence of multiple large firms in Route 128 prevented the creation of innovation links (Saxenian 1994).

26.3 Knowledge Networks in a Knowledge-Based Economy

Knowledge exchange is the main incentive behind the formation of networks. Knowledge production does not solely depend on isolated for-profit firms and nonprofit institutions. Knowledge comes as the outcome of unconstrained exchange of information between a plethora of actors organized formally or informally in systemic ways creating networks at different scales. Such networks tend to be more

and more inter-sectoral, interorganizational spanning over a variety of actors from firms to universities and also international (Autant-Bernard et al. 2007).

The importance of knowledge in the current economic framework is depicted in the discussion around the *knowledge economy*. Knowledge is directly linked to information because “knowledge is more than information as information is more than simply data” (Malecki and Moriset 2008, p. 29). The relation between these notions is hierarchical as one step higher in the hierarchy reveals a higher level of sophistication, codification, and consequently value. Leydesdorff (2006, 17; original emphasis) further explains the notion of knowledge and distinguishes it from information:

Knowledge enables us to codify the meaning of information. Information can be more or less meaningful given a perspective. However, meaning is provided from a system’s perspective and with hindsight. Providing meaning to an uncertainty [...] can be considered as a first codification. Knowledge enables us to discard some meanings and retain some others in a second layer of codifications. In other words, knowledge can be considered as a meaning which makes a difference. Knowledge itself can also be codified, and codified knowledge can, for example, be commercialized.

This last point is the key characteristic of the knowledge economy: knowledge, as a commercialized entity, has become a production factor, in advance of capital and labor (Drucker 1998). According to the OECD’s (1996, p. 7) definition, knowledge-based economies are economies “which are directly based on the production, distribution and use of knowledge and information.”

The notion of knowledge is tied with the notion of learning. The latter, as a collective ability of a society or a locale, appears to be central in the development process (Lundvall 1992). Advances in information and communication technologies (ICTs) resulted in the acceleration of codification and digitization of “codifiable” knowledge and thus in improvements in knowledge accessibility. These drastic changes in knowledge codification process resulted in the transformation of knowledge into a market commodity. The part of knowledge which is not codifiable is identified as tacit knowledge and is embodied in practices, people, and networks (Maignan et al. 2003).

Given the current knowledge economy framework, the importance of innovation and knowledge networks becomes more evident both at the micro- (firm) and meso- (city) level (for a city-level discussion around the knowledge economy, see Geenhuizen and Nijkamp 2012). *Knowledge spillovers*, which are defined as the positive externalities that a firm benefits from in terms of knowledge as a result of the environment it operates within (for a discussion, see Capello and Faggian 2005), are essential elements for knowledge generation and most importantly for the innovation creation process. Knowledge spillovers can be understood as incentives for the formation of formal and informal networks. Simply put, knowledge creation and innovation production are not just the product of one actor, but on the contrary are facilitated by spillover effects and efforts taking place outside the individual actor. Network structures support this process as they provide the necessary platform for utilizing such spillovers (Fischer 2006). Knowledge and innovation creation can be approached as interactive processes in which actors, which possess

different types of knowledge, interact together in order to overcome technical, organizational, commercial, or intellectual problems (Bathelt et al. 2004).

Of equal importance in understanding the role of networks in innovation process is the distinction between tacit and codified knowledge and how these different types of knowledge are tied to specific localities. The distinctive point between them is the easiness to be transferred. For instance, codified knowledge can be digitized and transferred through ICTs over long distances without the need for intensive interpersonal interaction. Especially nowadays, owing to the digital revolution and the pervasive character of ICTs, codified knowledge can be very easily transferred or even downloaded via digital networks. Therefore, the spatial ties of this type of knowledge are loose. However, this argument applies less for tacit knowledge. The latter is characterized by a higher level of sophistication and complexity which does not allow for its codification (It needs to be highlighted here that the borderline between codification and non-codification is not fixed and may change over time). As a consequence, tacit knowledge transfer is heavily based on interpersonal interactions. Therefore, tacit knowledge has a higher degree of local embeddedness as proximity is a crucial factor for transmission of such knowledge. The role that ICTs play in supporting distant, face-to-face interactions via teleconference applications needs to be highlighted here. Face-to-face communication can be divided into two components: the *conversation* and the *handshake*, with the former being the “metaphor for simultaneous real-time interactive visual and oral messages” while the latter for the physical co-presence (Leamer and Storper 2001, p. 4). ICTs can only lower the cost of the conversation component of the face-to-face communication, which enables up to a certain extent the transmission of tacit knowledge via global networks.

The above argumentation can be crudely summarized on the preposition that the more codified knowledge is, the less spatial dependent is. On the other hand, the more tacit characteristics knowledge has, the more its transfer is based on spatial proximity between the involved actors. This spatial distinction of knowledge and the knowledge transfer process also reflects the debate between global connectivity and local network intensity. The discussion in this chapter has been mostly focused on the latter, which refers to Marshallian externalities, clusters, and innovative milieu. All of these notions highlight the value of local networks in innovation generation and growth. What has not been yet discussed in this chapter is the value of global links in achieving the above objectives. Such global *pipelines* can be understood both as open channels and more closed conduits. The former approaches interorganizational links as open systems that diffuse knowledge to all the loosely connected actors in a way that facilitates knowledge spillovers. This type of linkages can be understood as weak links. The latter type of links functions in a more restricted way so that knowledge only flows among these connected actors that are part of the alliance. Such strong links are used to protect sensitive issues such as intellectual property rights. Based on this, it can be said that access to knowledge is not only the result of interactions among collocated actors in local or regional networks, but it can also be the outcome of partnership and linkages at an interregional or international scale (Owen-Smith and Powell 2004).

The interplay between local and global linkages can also be seen as the outcome of the transformation that our society is going through due to the extensive use of ICTs. From an urban perspective, the underlying new techno-economic paradigm is related with drastic social changes. The starting point for understanding these changes is the seminal work of Castells on the *network society* (Castells 1996), where he illustrated the emergence of a new spatial form due to the structural transformation that society is undergoing because of the extensive use of ICTs. He identified this new spatial form as *the space of flows*, and he defined it as the “managerial organization of time-sharing social practices that work through flows” (Castells 1996, p. 442). Such flows are “purposeful, repetitive, programmable, sequences of exchange and interaction” between detached socioeconomic actors (Castells 1996, p. 442). Castells presented this new spatial form as a three layer system. The first layer consists of the technical network infrastructure, upon which the flows of Castells’ network society are transported. Examples of such infrastructure include the digital infrastructure upon which the Internet function is based as well as aviation networks which are responsible for transfer of people between places. Most importantly from the innovation network viewpoint, the second layer refers to the nodes and the hubs of the space of flows. These are the real places with “well-defined social, cultural, physical, and functional characteristics” (Castells 1996, p. 443). These places – cities in reality – are interlinked through the first – infrastructural – layer of the space of flows upon which real flows, such as knowledge, are transported. From this perspective, global pipelines can be understood as part of the space of flows. Lastly, the third layer of the space of flows refers to “the dominant managerial elites” and analyzes the spatial organization of these privileged social groups, which are increasingly located in isolated communities, but at the same time in highly connected places (Castells 1996, p. 433).

What would be a mistake here is to approach the above discussion on the scale of interorganizational linkages as preference toward local or global links. The argument that innovation cannot occur in isolation is only valid from a multi-scalar perspective in the contemporary world economy. It is well established nowadays that local economies are dependent upon global corporate processes. Thus, localities cannot exist anymore as local and regional economies only linked with the global economic system via trade flows, following a Marshallian logic. From a policy point of view, strategies to support local economies using a Marshallian framework targeting only the intensification of local links ignore global interdependencies, and their success is anything but given (Amin and Thrift 1992). Such local strategies should be multi-scalar in nature and promote cross-fertilization between global and local links.

26.4 Innovation Networks and Different Types of Proximity

The discussion in the previous section took place on two axes. On the one axis, different knowledge types were analyzed. The focus was on tacit and codified knowledge and how these “distinct” types of knowledge flow between

organizations. On the other axis, the scale and the spatiality of interorganizational linkages, which facilitate these flows, were examined. As it was explicated, the range of such links varies from local to global links. Despite the importance of the above approach in understanding the mechanisms behind the formation of knowledge and innovation interorganizational links, it is still a simplification to assume an absolute correspondence between tacit knowledge and geographic proximity, on the one hand, and codified knowledge and long distance links, on the other hand. Firstly, the separation of both knowledge types is not always clear. Secondly, face-to-face interactions and geographic proximity are not the exclusive facilitators of tacit knowledge flows. For instance, ICTs, as mentioned before, can also play a role as such a facilitator. Most importantly though, it is important for innovative firms to establish links with nonlocal partners to obtain knowledge and ideas which are not accessible locally (Torre 2008).

In order to shed more light in this complex relation, this section takes a relational turn and introduces other non-geographic components of proximity. Thus, apart from the geographical proximity denoted by Euclidean distance, other relational proximities, including cognitive, organizational, and institutional proximity, will also be assessed. These proximities are defined in a *relational space* which can be defined as “the set of all relationships – market relationships, power relationships and cooperation – established between firms, institutions and people that stem from a strong sense of belonging and a highly developed capacity of cooperation typical of culturally similar people and institutions” (Capello and Faggian 2005, p. 78). The starting point for defining the different dimensions of proximity lies in the French school of proximity. The main objective of this group of industrial economists was to endogenize space in economic analysis and, more specifically, to incorporate space and other territorial proximity elements in a research framework, which aims to better understand the dynamics of innovation (for a review of the French school of proximity, see Torre 2008). A second development in further decomposing and analyzing the different components of proximity was studies related to innovation and territorial learning in the broader framework of evolutionary economic geography. In recent years, we have experienced an increased interest in factors which explain how firms and regions interact as part of a “collective learning process,” since learning and knowledge creation are an essential component of the firms’ and regions’ competitive advantage. The notion of proximity and its different components is juxtaposed with ideas about knowledge transfer and creation, tacit knowledge, and learning regions (Boschma 2005).

The common basis of these approaches is the importance of non-geographic types of proximity in innovation creation. Starting from the French school of proximity, two different types of proximity can be identified: geographical and organized (Torre 2008). The former type is more straightforward and usually represents physical distance and collocation. Nonetheless, different conceptualizations of geographic proximity could also be utilized, as physical proximity might be affected not only by Euclidean distance but also by the transportation cost between two places and their accessibility. In addition, the temporal continuity of

geographic proximity is also important. As Torre (2008) suggests, geographic proximity and face-to-face interactions are necessary only during specific stages of the innovation process.

Unlike physical proximity, organized proximity is a relational notion and refers to the ability of an organization to enhance interaction between its members. The main point behind this concept is that members of the same organization will interact together more easily than actors outside the organization. This is based on two different logics (Torre 2008): (a) adherence logic, according to which actors, who are close in organizational terms, such as a firm and network, are part of the same relational space, and (b) similarity logic, according to which the organizationally close actors tend to be alike. In a nutshell, while geographical proximity reflects separation in space regarding physical distance, organized proximity is considered as the overall framework in which different actors interact. In the same vein, Boschma defined organizational proximity “as the extent to which relations are shared in an organizational arrangement, either within or between organizations” (Boschma 2005, p. 65).

Building upon the French school of proximity findings, Boschma (2005) approached proximity as a five-dimension notion. Cognitive proximity is the point of departure for his conceptual framework and is defined as the level of similarity of the knowledge base of different organizations. Organizations collaborate and form links and networks using as criteria the knowledge background of the potential partners, as people and organizations, which share the same knowledge background and expertise, may learn from each other. The complexity of the learning process is reflected in the nonlinear effect of cognitive proximity in learning. In order for knowledge to be transferred, gained, or created, there is a need for optimal cognitive proximity, since too high cognitive proximity will eliminate any novelty from the interaction, while, vice versa, too high cognitive distance will result in communication difficulties (for a detailed discussion, see Boschma 2005).

Despite the effort spent in the relevant literature, cognitive proximity is still a rather fuzzy concept, and it is difficult to quantify. Strong links can be identified between cognitive proximity and technological similarity. While some authors distinguish these two, more often than not, these notions are used interchangeably in an empirical context. While cognitive proximity represents the similarity of the knowledge bases of two organizations or regions, technological proximity reflects the similarity between the technological knowledge among economic actors (Dangelico et al. 2010).

In addition, institutional proximity is also proposed as another proximity dimension. Following North's (1990) definition, institutions are the amalgamation of formal rules and informal constraints including behavioral and social standards, while organizations can be approached as a group of agents performing the same activity. Put simply, organizations define agents' practices and strategies in the overall context provided by the institutional ecosystem in which they are positioned (Kirat and Lung 1999). Therefore, one would expect that collocation in the same institutional environment would result in increased interaction.

The analytical value of the multidimensional approach of proximity is now well established in the relevant literature as a tool for understudying structurally interorganizational innovation networks. Apart from the above discussed proximity dimensions, different proximity components can be introduced such as social or linguistic proximity. Most importantly, in a quantitative framework, a multidimensional understanding of proximity will enable researchers to compare the impact of different proximity measures in the formation of linkages. Such a framework provides researchers with the necessary tools and flexibility to model the explanatory value of different proximity dimensions in network formation. For instance, it can be claimed that the different proximity dimensions in innovation networks are in reality substitutes rather than complements (Boschma 2005).

Despite the increased complexity that the inclusion of relational proximities introduces to the discussion on interorganizational spatial innovation networks, the above proximity components reveal interesting dimensions of organizational behavior. Thus, the inclusion of these relational dimensions of proximity should not be interpreted as a diminishing factor of the importance of the spatiality of interorganizational networks. It might be the case that geography, in terms of collocation and geographical proximity, is not the (only) determinant for the innovation networks formation, but on the other hand, the spatiality of the other relational dimensions of proximity might reveal interesting geographies as well. For instance, path dependency could explain organizational proximity between geographically distant actors. Although geography could not explain this phenomenon, a study of the spatiality of such networks and the underlying relational proximities, which do not correspond with the geographical one, could be of interest per se.

26.5 Innovation Networks: Some Methodological Approaches

The centrality of spatial innovation networks in economic geography and regional science can be depicted on the numerous different methodologies adopted by researchers in their effort to understand and model innovation activity and innovation networks in space. In this section, some recent methodological advances will be presented. On the one hand, “traditional” econometric modeling is enriched with spatial econometric concepts to understand innovation in space. Although this strand of research is less associated with network structures, it still provides insights on the spatiality of the innovation process and therefore is briefly presented here. On the other hand, the network structure of innovation activity is the key focus on studies having a starting point on *network science*. Despite the fact that space and geography is not the key focus of this field, recent developments incorporate this dimension as well in the search of the innovation networks driving forces.

A starting point for the first strand of methodological approaches is the *knowledge production function* which relates regional knowledge output with R&D by industry and university research in a Cobb-Douglas framework. The original work of Zvi Griliches and Adam B. Jaffe was further expanded by the developments in the spatial econometrics (for a discussion, see Anselin et al. 1997). The latter

enabled an in-depth investigation of the spatiality of knowledge spillovers. For instance, the work of Anselin et al. (1997) confirmed the significant positive relationship between university research and innovative activity, both directly and indirectly, through its impact on private sector R&D. Most importantly, the spatiality of university research spillovers on innovations was confirmed and quantified.

Moving to models addressing the relational character of interorganizational links, gravity models, an important model class in regional science, may be used to measure the impact of different types of proximity or distance on knowledge flows. These models typically rely on three types of factors: (i) origin-specific factors that characterize the ability of origin locations to generate knowledge flows, (ii) destination-specific factors that represent the attractiveness of destination locations to absorb knowledge flows, and (iii) origin–destination factors that characterize the way spatial separation of origin from destination locations constrains or impedes the interaction (Fischer and Wang 2011). Suppose that we have a spatial system of n locations representing network nodes, then the following (lognormal) knowledge flow model may be taken as a framework for the analysis:

$$\ln kF_{ij} = \alpha_0 + \alpha_1 \ln X_i^o + \alpha_2 \ln X_j^d + \alpha_3 D_{ij} + \alpha_4 BD_{ij} + \varepsilon_{ij} \quad i, j = 1, \dots, n \quad (26.1)$$

where kF_{ij} represents the knowledge flow (e.g., measured in terms of patent citations) from origin location i ($i = 1, \dots, n$) to destination location j ($j = 1, \dots, n$). X_i^o and X_j^d are origin-specific and destination-specific factors, respectively, and α_1 and α_2 denote the associated coefficients. D_{ij} is a continuous distance (proximity) measure, for example, geodetic distance or travel time from i to j , and BD_{ij} is a binary distance measure representing, for example, institutional proximity between the locations, with the corresponding distance sensitivity coefficients α_3 and α_4 . α_0 is the constant, and ε_{ij} is the error term, generally assumed to be identically and independently distributed. For model estimation issues, and econometric extensions of the lognormal gravity model to account for spatial or network dependence in flow data, see Fischer and Wang (2011, p. 47–70).

Finally, network science is shaping the latest developments in modeling the structure and the evolution of innovation networks, also from a spatial perspective. From a descriptive point of view, network analysis provides a plethora of metrics which can assist researchers to understand the topology of innovation networks. Examples include different *centrality* indicators, which depict the position of an actor and the roles it performs in the overall network, the *clustering coefficient*, which indicates the tendency of a network to create clusters of dense internal connections, and the *average path length*, which is a measure of network distance. From a modeling point of view, complexity science provides a plethora of tools to model innovation networks from a structural and evolutionary perspective. The distinctive point of this strand of research is that instead of adopting an explanatory modeling strategy as reflected in fitting regression lines in observed data (e.g., the gravitation family of models discussed above), stochastic models are utilized to

understand the underlying mechanisms of the network formation and to simulate the evolution of the (observed) network. A wide range of such modeling applications – from agent-based models to statistical physics and social network analysis – can be found in the book edited by Pyka and Scharnhorst (2009).

To sum up, spatial innovation networks are curved by a two-level complexity: a network level complexity which reflects the topological characteristics of k interacting actors and a spatial level complexity which represents the peculiarities of geographical space where innovation interactions are embedded. Despite the difficulty to model these mechanisms, studies focusing on such issues are currently at the forefront of regional science. Nonetheless, the incorporation of both level complexities is still a challenging task despite the developments in modeling presented in this section.

26.6 Conclusions

The objective of this chapter was to highlight the importance of networks in the innovation process. From the above discussion, it became apparent that innovation does not occur in isolation and that interorganizational networks facilitate innovation creation. Such networks are usually based on interpersonal relations characterized by a high level of trust. Moreover, these social networks are embedded in places. This reflects the importance of the spatiality of such networks. In addition, such innovation networks can be understood as knowledge networks and knowledge externality catalysts. Actors interact to gain knowledge, a crucial production element of the knowledge economy. Broadly speaking, two different types of knowledge and two scales of interaction can be identified: tacit and codified knowledge and local and global interaction. Although there is no absolute correspondence, it can be said that tacit knowledge is facilitated by geographic proximity, while codified knowledge can be easily accessed remotely. Counterarguments to the above statement are the increased use of teleconferencing applications via desktop computers and the necessity for firms to establish long-haul links to gain knowledge which is not available locally. These arguments advocate toward the adoption of a relative proximity perspective. The latter enables researchers to understand the determinants of innovation activity and networking not only in the Cartesian but also in relative space. Finally, effort was spent to approach innovation networks from a systemic perspective. Innovation networks are vital parts of multi-scalar systems of innovation, and this systemic attribute should also be reflected in attempts to model such networks as well as their dynamics.

To conclude, despite the inherent complexity for understanding and modeling such networks, especially from a spatial perspective, the research community should continue its efforts for two reasons. Firstly and from an analytical perspective, we are still lacking a generalized understanding of how actors interact together in order to innovate. From a spatial perspective, it is essential to understand the role

places perform in this process. Secondly, such analytical gains can be utilized to better design local and regional policies. In the current network society, it is important for policy makers to propose tools for increasing network intensity in a multi-scalar, targeted, and efficient way.

Abstract

Within location theory, classical models are typical abstract and formalized models, in which the main reasoning behind location choice of firms is driven by the *minimization of transportation costs* to achieve natural and intermediate production resources, and markets for final goods that are territorially dispersed. Classical models are similar in the question they want to reply to: what economic logic explains the location choices of firms in space? This topic is an important one.

Although in terms of time and financial resources, the performance of transport and communication has improved enormously, many economic activities have not become footloose to the extent expressed by the “death of distance.” Their location choice still remains anchored to a balance between a physical location generating economic advantages – in the form of agglomeration economies – and transport costs to intermediate or final markets, as explained by these models.

27.1 Introduction

Economic activity arises, grows, and develops in space. Firms, and economic actors in general, choose their locations in the same way as they choose their production factors and their technology. Location theory aims at explaining the economic rationale behind the choice of a firm to locate in a specific point in space and thus at interpreting the allocation of different portions of territory among different types of production, the division of a spatial market among producers, and the functional distribution of activities in space.

This topic is an important one; although in terms of time and financial resources, the performance of transport and communication has improved enormously, many economic activities have not become footloose to the extent expressed by the “death of distance” (Cairncross 1997). The location choice of firms still remains anchored to a balance between advantages that a physical location generates for firms – in the form of agglomeration economies – and transport costs, keeping the role of space in modern economies an important issue.

Within location theory, classical models are typical abstract and formalized models, in which the main reasoning behind location choice of firms is driven by the *minimization of transportation costs* to achieve natural and intermediate production resources, and markets for final goods that are territorially dispersed. Localization theory defines “transportation costs” as all the forms of spatial friction that give greater attractiveness to a location which reduces the distance between two points in space (e.g., production site and the final market, place of residence and the workplace, the raw materials market, and the production site). Transportation costs are essential to location theory, in general, and to industrial location choice models, in particular, for a very simple reason. The value of two production resources located in two different points in space can be directly compared only if the physical distance between the two resources is discounted. Transportation costs (i.e., the cost of movement of such inputs in space) represent the discount rate of *space*, as interest rates represent the discount rate of values in *time* (Isard 1956).

It is important to notice that in all location theory, transportation costs have a wider meaning than that of the economic cost of shipping goods (the pure cost of transporting and distributing them); they refer more in general to the opportunity cost represented by the time taken to cover the distance which could instead be put to other uses, by the psychological cost of the journey, by the cost and difficulty of communication over distances, and by the risk of failing to acquire vital information.

Transportation costs are even comprised in the concept of agglomeration economies, which denote all economic advantages accruing to firms from concentrated location close to other firms, namely, reduced production costs due to large plant size, the presence of advanced and specialized services, the availability of fixed social capital (e.g., infrastructures), the presence of skilled labor and of managerial expertise, and the presence of a broad and specialized intermediate goods market. If transportation costs were nil, there would be no reason to concentrate activities, because doing so would not produce any economic advantage. In this sense, agglomeration economies are “proximity economies”: they are, that is to say, advantages which arise from the interaction (often involuntary) among economic agents made possible by the lower amount of spatial friction in concentrated locations.

The logic behind classical location models is therefore the minimization of transportation costs between a production area and the market where goods are sold (von Thünen model), between place of residence and the workplace (Alonso model), and among production site, raw materials markets, and the final goods market, which together define a minimum transportation cost directly compared against agglomeration advantages (Weber model).

Classical models are similar in the question they want to reply to: what economic logic explains the location choices of firms? Their richness comes from what they, directly and indirectly, are able to explain. In replying to the question on where activities would be willing to locate their production in space, the von Thünen’s model indirectly interprets the formation of a land rent at different distances from a market place in a general equilibrium setting. Within the same framework of assumptions of von Thünen’s model, in a partial equilibrium approach, Alonso is able to explain the location choice of a new incoming firm in a city; moreover, in a general spatial equilibrium framework, Alonso is able to interpret the allocation of alternative types of activities in the urban space. In replying to the same conceptual question, i.e., “where do activities locate their production?” Weber is able to identify a location that reflects the two economic forces that organize activities in space and that push the location process in opposite directions: from one side, transportation costs, that – in conditions of perfect competition, perfectly mobile production factors, fixed raw materials and demand perfectly distributed across the territory – induce dispersion and, from the other, agglomeration economies that call for spatial concentration of production.

In what follows, the two main classical location theory models are presented. Firstly, the von Thünen-Alonso model is presented based on the assumption that the production site assumes a spatial dimension and extends across a territory, while the consumption site (the market) is punctiform. In this way, the model defines a “production area,” meaning by this the physical space (the land) occupied by an individual economic activity. Secondly, the Weber model is taken into account based on the assumptions that both the production and consumption sites are punctiform and that the minimization of the distance between them drives the identification of the minimum transportation cost location, directly compared

against a location generating agglomeration advantages. The models interpreting the identification of market areas, assuming that production develops at specific points in space and it supplies geographically dispersed markets, are left to the next chapter.

27.2 The Location of Activities in Space: Land Rent Formation

27.2.1 Accessibility and Transportation Costs

In the theories examined in this section, location choices are dictated by a specific principle of spatial organization of activity, namely, “accessibility,” and in particular accessibility to a market or a “center.” For firms, high accessibility means that they have easy access to broad and diversified markets for final goods and production factors, to information, and to the hubs of international infrastructures. For people, accessibility to a “central business district” and therefore to jobs means that their commuting costs are minimal, while at the same time, they enjoy easy access to a wide range of recreational services restricted to specific locations (e.g., theaters, museums, libraries) and proximity to specific services (e.g., universities), without having to pay the cost of long-distance travel.

High demand for accessibility to central areas triggers competition between industrial and residential activities for locations closer to the market or, more generally, closer to the hypothetical central business district (the city center).

The location choice models described in this section have an important feature in common: the *cost of land or land rent*. Assuming the existence of a single central business district, owing to high demand for central locations with their minimum transportation costs, land closer to the center costs more, a condition accentuated by the total rigidity, at least in the short-to-medium period, of the urban land supply. The models resolve the competition among activities on the basis of a strict economic principle: *firms able to locate in more central areas are those able to pay higher rents for those areas*.

These models envisage one specific factor organizing activity in space: land rent, this being the sole principle which explains location choices by all activities, whether agricultural, productive, or residential.

The strength of these models is the elegant and irrefutable logic with which they account for the distribution of productive, agricultural, and residential activities in a geographic space from which they eliminate every differentiating effect except for physical distance from the center. Given their assumptions on the structure of demand and supply in space, these models are particularly well suited to analysis of the location of industrial and residential activities in urban space. In an urban environment, in fact, it is easy to hypothesize the existence of a single business district (a city center) which, for firms, performs the function of collecting, distributing, and exporting the city’s products and, for households, is the place where jobs are available. These models are able to establish where an individual firm will locate.

The first model analyzing the spatial distribution of alternative production activities was developed in the early nineteenth century by Johann von Thünen. Only in the 1960s did pioneering studies by Walter Isard, Martin Beckmann, and Lowdon Wingo prepared the ground for Alonso's formulation of von Thünen's historical model applied to an urban context (Beckmann 1969; Isard 1956; Wingo 1961). The model of the monocentric city soon became a freestanding school of thought within location theory, where it was labeled "new urban economics." This corpus of theories endeavored to develop general equilibrium location models in which the main interest is no longer the decisions by individual firms. Instead, the main areas of inquiry become definition of the size and density of cities, and identification of the particular pattern of land costs at differing distances from the city that guarantees achievement of a location equilibrium for all firms in the city.

27.2.2 The Location of Agricultural Activities: The von Thünen Model

Johann Heinrich von Thünen developed the first location model based on the hypothesis of a continuous production space and a single punctiform final market (von Thünen 1826). His model has generated the entire corpus of theories on the urban location of economic activities.

Von Thünen's model is based on a set of assumptions which all subsequent theories would adopt:

- (a) There exists a uniform space where all land is equally fertile and transport infrastructures are identical in all directions (isotropic space).
- (b) There is a single center, the medieval town, where all goods are traded (i.e., there is a specific market place).
- (c) Demand is unlimited, an assumption which reflects the supply-oriented nature of the model: the location equilibrium depends solely on the conditions of supply.
- (d) The production factors are perfectly distributed in space: the allocation of land among alternative production activities does not derive from an uneven spatial distribution of the production factors.
- (e) There is a specific production function, with fixed coefficients and constant returns to scale, for each agricultural good; this assumption entails that the quantity of output obtainable from each unit of land and the unit cost of production are fixed in space.
- (f) Perfect competition exists in the agricultural goods market: farmers therefore take the prices of the goods they produce to be given.
- (g) Unit transportation costs are constant in space: the total cost of transportation depends on the distance between the production site and the town and on the volume of production. Transportation costs may vary according to the crop.

Assuming the existence of a certain number of farmers, von Thünen addresses the problem of how to determine the allocation of land among farmers working in

the area surrounding the market place. He bases his model on a concept of rent as a residual which comes from Ricardo's model and would also characterize subsequent models. Ricardo was the first to interpret rent as a differential rent (Ricardo 1971, original version 1817). In Ricardo, land rent is formed as a result of the productivity difference between agricultural lands (*decay of productive power*); if all agricultural lands had the same fertility, rent would be null. In von Thünen, lands are equal in terms of fertility but differ in terms of accessibility to the market; the difference in accessibility explains their different rent values.

In von Thünen, the price that farmers are willing to pay for land is the remainder left when transport and production costs, including a certain remuneration (profit) for the farmer, have been subtracted from revenues. In this logic, rent does not enter the formation of a good price, but is formed on the basis of the demand of products. If rent is high, it is because the demand for goods is high, and therefore the final price of goods is high; the high price of goods generates high profits and therefore high margins for rents. This means that rent is formed through the distribution of income rather than through income production. In the words of the classical economist Ricardo, "*corn is not high because rent is high, but rent is high because corn is high*" (Ricardo 1971, p. 98).

In von Thünen's model, in formal terms, if x is the quantity of a good per unit of land produced by a farmer, c the unit cost of production, p the price of the agricultural good, τ the unit cost of transportation, and d the distance to the market, then rent r is defined as

$$r(d) = (p - c - \tau d)x \quad (27.1)$$

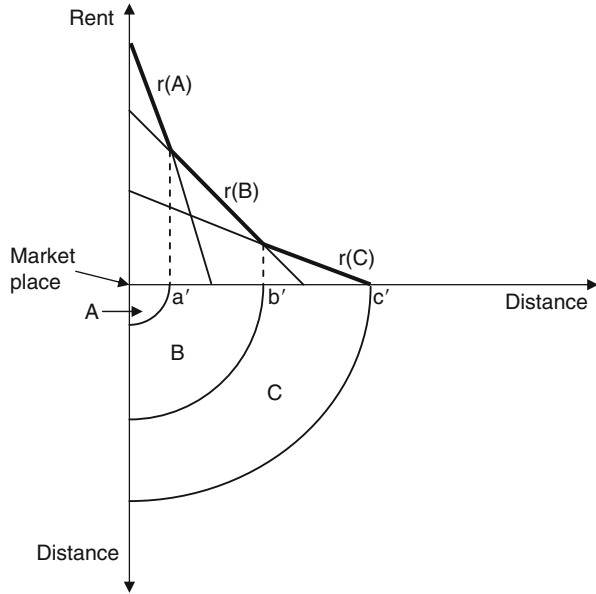

This equation states the levels of rent that farmers are willing to pay for land at different distances from the market place where goods are traded. It is represented graphically by a straight line, with slope $-\tau d$ and intercepts equal to $(p-c)x$ and $(p-c)/\tau$, respectively, denoting the maximum value of rent in the town and the maximum distance from the town, where land value is nil.

From Eq. (27.1) one can straightforwardly obtain the impact on rent due to a shift in space (e.g., of 1 km) by calculating the first derivative of rent with respect to distance:

$$\frac{dr(d)}{dd} = -\tau x \quad (27.2)$$

As Eq. (27.2) shows, the variation in rent is exactly equal to $-\tau x$: a shorter distance from the center generates a saving in total transportation costs equal to the increase in the rent required to occupy more central locations. This result is important because it has been obtained by all the models developed since von Thünen's. It states that rent is nothing other than a saving in transportation costs made possible by more central locations. From this follows the "indifference to alternative locations" condition, which is reached by an individual or a firm when a move in space costs nothing, i.e., when the saving in transportation costs

Fig. 27.1 Land allocation among three farmers: the Von Thünen model. Legend: $r(A)$ willingness to pay of farmer A, $r(B)$ willingness to pay of farmer B, $r(C)$ willingness to pay of farmer C, A area allocated to farmer A, B area allocated to farmer A, C area allocated to farmer C, a' maximum distance from the centre for which A offers a higher rent than farmers B and C, b' maximum distance from the centre for which B offers a higher rent than farmers A and C, c' maximum distance from the centre for which C offers a higher rent than farmers A and B

obtained by moving 1 km closer to the center equals the cost of the land that must be purchased to do so.

On the assumption that there are three farmers (A, B, and C), each of them producing a specific agricultural product with a differing degree of perishability, a rent supply curve can be constructed for each farmer. Because goods are perishable to differing extents, the rent supply curves assume different positions and slopes (Fig. 27.1).

The farmer who produces the most perishable good will have a productive process that uses the land in the most intensive and economically efficient way (geometrically, the highest intercept on the vertical axis, equal to $(p-c)x$), and he will be more willing to pay the rent charged for land 1 km closer to the town (geometrically, the steeper slope of the straight line, equal to $(-tx)$). As the farmers compete for the more accessible land, each unit of surface area will be allocated to the farmer willing to pay the highest rent for that land. As far as a' , the land will be allocated to farmer A, who offers the highest rent for the most central locations, from a' to b' to farmer B and from b' to c' to farmer C: the actual rent realized by the landowner from cultivation of his land is the envelope of the three rent supply curves.

This model strikes for its strong interpretative power. Assuming a homogeneous plain, with no economic activities located in this geographical space, the model is able to explain the formation of agglomeration by the simple distance from, or accessibility to, the town (expressed by transportation costs) which accounts for differences in land rent. Moreover, assuming equal fertility of land everywhere, the model departs from the classical Ricardian view that land profitability is explained by different degrees of fertility (Ricardo 1971;

orig. ed., 1817); simple distance from, or accessibility to, the town (expressed by transportation costs) accounts for differences in land rent in this model. By eliminating everything except the distance between land and the town from concrete geographic space, von Thünen defines a new type of space, namely, economic space.

27.2.3 The Location of Activities in a City: A Partial Spatial Equilibrium Approach

In the early 1960s, first William Alonso and then Richard Muth reconsidered von Thünen's model and adapted it to an urban context (Alonso 1960, 1964a, b; Muth 1968, 1969), thus paving the way for numerous subsequent studies. Alonso and Muth extended the bases of von Thünen's pioneering model, making it more specific to the urban case, but they also made it more general by abandoning the hypothesis that only transportation costs express spatial friction and the preference for more central locations.

The assumptions of Alonso's model are the same as those of von Thünen's model of agricultural activity described above. It envisages a city (no longer a plain) characterized by uniform space (homogeneous spatial distribution of the production factors) and endowed with infrastructures which cover the entire city in all directions (isotropic space). The city has a single center – the city center or business district – which is generically defined as the most attractive location for all firms. Given these assumptions, the city is analyzed along only one dimension: a radius comprising different distances from the city center to the periphery.

The base model addresses a problem similar to the one which preoccupied von Thünen. As firms compete for central locations, the model shows how the urban space is allocated among alternative types of production once the market cost of land at different distances from the center is known.

Also Alonso's model defines rent as the remainder left when the entrepreneur has subtracted production costs (including transportation costs) and a desired level of profit from the revenue obtained by selling the good. Formally, rent is expressed as

$$r(d) = (p_x - \pi - c(d))x(d) \quad (27.3)$$

where r denotes the rent, p_x the unit price of the good produced by the entrepreneur, c production costs per unit of land (including transportation costs) at distance d from the city center, π the profit per unit of land, and x the quantity of the good produced per unit of land at a distance d from the city center.

Because production costs include transportation costs, in the Alonso model, they depend on distance, as they do in von Thünen's model. However, unlike in the latter, revenues too depend on distance: a less suburban location gives greater proximity to broader markets and consequently access to higher earnings (consider the sales of a shop located in the city center compared to one in the periphery, especially if they sell luxury items).

Fig. 27.2 The bid-rent curve and the location equilibrium for firms. (a) Bid-rent curve. (b) Location equilibrium for the firm

Equation (27.3) expresses the “bid rent” or the rent (by square meter) that the entrepreneur is willing to pay at differing distances from the center, once costs and the entrepreneur’s intended profit have been subtracted from revenues. Profits remaining equal, a more central location implies a willingness to pay higher rent because the entrepreneur incurs lower transportation costs and obtains higher revenues. Likewise, a suburban location can yield the same profit if and only if less rent is paid for the land: the saving on land cost must offset the higher transportation costs and the lower revenues that less central locations entail (Fig. 27.2a).

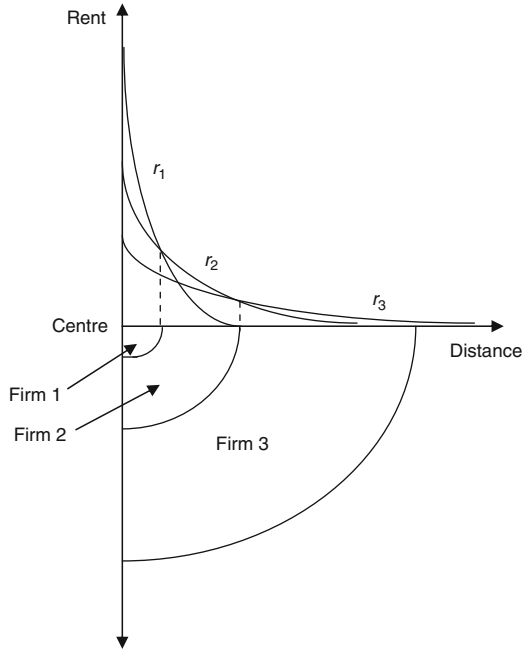

At every distance from the center (e.g., d_0 in Fig. 27.2b), if the firm wants to increase its profits, it must offer a lower rent. Vice versa, at the same distance, it can offer a higher rent if it is willing to accept lower profits. It is therefore possible to plot different bid-rent curves for an individual firm, all of them with the same slope and each of them defined on the basis of a different profit level which increases toward the origin (Fig. 27.2b).

In a partial equilibrium framework, which assumes as known the “market land rent curve” (i.e., the real market cost of land expressed by curve re in Fig. 27.2b), it is possible to define the optimal location for the firm. Along the market land rent curve (re), the firm will choose the location yielding the highest profit, which is expressed by the tangency of the market rent curve with the lowest bid-rent curve. In Fig. 27.2b, the location equilibrium is reached at point E and thus at a distance d_0 from the center and with a rent equal to $r(d_0)$ (Fujita 1985).

27.2.4 The Location of Activities in a City: A General Spatial Equilibrium Approach

If we discard the assumption that a city already exists (a market land exogenously determined) and therefore if we move away from the identification of an urban location for a new firm entering a city, we abandon a partial spatial equilibrium

Fig. 27.3 Location equilibrium for activities with different propensities for central location. Firm 1 = high propensity for central location. Firm 2 = average propensity for central location. Firm 3 = low propensity for central location. r_1 = rent bid by firm 1, r_2 = rent bid by firm 2, r_3 = rent bid by firm 3,

model and go back to von Thünen’s general spatial equilibrium framework, which entails an interesting interpretation of the allocation of the urban space between alternative production activities or between production and residential activities.

Suppose the existence of a point in space (a center) attracting firms because of the presence of a market for their goods. Firms compete for locating closest to the central location in a homogeneous space around the center. Let us assume that there exist firms with different propensity for central location. The slopes of the bid-rent curves will differ according to the different levels of propensity for central location; as the propensity increases, firms will be willing to pay more for houses in order to locate (one unit of distance) closer to the center (Fig. 27.3).

The three firms are distributed across the urban area as in von Thünen’s model: each area will be occupied by the firms that make the highest rent bid. Market land rent will be the envelope of the bid-rent curves at each distance from the center so that the city can be depicted as a set of concentric rings each containing the firm willing to pay the highest rent for that distance (Fig. 27.3).

But what determines the propensity for a central location? To reply to this question, a reasoning on the slope of the bid-rent curve, which expresses the variation in the cost of land due to a one unit of variation in the distance from the center, is helpful. The slope is given by

$$\frac{\partial r(d)}{\partial d} = (p_x - \pi - c(d)) \frac{\partial x(d)}{\partial d} - \frac{\partial c(d)}{\partial d} x(d) \tag{27.4}$$

Table 27.1 Taxonomy of activities with high propensity for central location

$\frac{\partial c(d)}{\partial d}$	$\frac{\partial x(d)}{\partial d}$	$p_x - \pi - c(d)$	x	Activities
Low	High	Normal	Normal	Commercial activities, shopping centers but also specialized shops, or luxury good shops
Low	Normal	High	Normal	Advanced service functions (e.g. lawyers, specialized doctors), or of activities that require a prestigious location
Low	Normal	Normal	High	Travel agencies, insurance brokers
High	Normal	Normal	Normal	Activities dependent on population and on other central activities
High	Normal	High	High	Financial intermediaries

Source: Camagni 1992

This shows that, at one unit of distance further away from the center, the rent offered to maintain the same profit level π diminishes because of increased transportation costs and decreased revenues. Equation (27.4) contains the four elements that, on their own or in combination, theoretically explain higher propensity of activities to central location; an activity will be in fact interested to locate in the center if:

- The costs of moving one unit of good toward the center ($\frac{\partial c(d)}{\partial d}$) are high.
- The influence of distance on the demand of goods ($\frac{\partial x(d)}{\partial d}$) is high.
- Extra profits ($p_x - \pi - c(d)$) are high.
- The value of activities per unit of land (x) is high.

Table 27.1 presents some examples of activities characterized by the major values of the slope of the bid-rent curve:

- (a) Activities oriented toward a high demand density, like commercial activities, shopping centers but also specialized shops, or luxury good shops, all characterized by a strong influence of distance on the demand of goods.
- (b) Advanced service functions (e.g., lawyers, specialized doctors) or of activities that require a prestigious location that can obtain thanks to their oligopolistic position (banks, insurances, public and private managerial functions), whose costs of moving one unit of good toward the periphery and the influence of distance on the demand of goods sold by unit of land are low but the extra profits of a central location are very high; through a central location, these activities abandon a perfect competition market and differentiate the product quality through the use of a traditional urban input factor, like information.
- (c) Travel agencies and insurance brokers, all characterized by a very high value of their activity per unit of land.
- (d) Activities that depend on a central market, with a high transportation cost of the final output: all industrial and service activities that depend on population and central activities.
- (e) Financial activities mostly linked to the stock exchange, whose propensity of a central location is the result of high transportation costs, monopolistic profits, and a high value of activity per unit of land.

Fig. 27.4 Location equilibrium for households and firms. Legend: $r(d_a)$ agricultural land value

These reflections provide already a first evidence of how these models, strongly abstract in their nature, are able to describe conditions which closely match actual reality.

The same logic of Fig. 27.3 can be applied for a simultaneous analysis of the location of firms and households. On the hypothesis that the rent gradient of firms is higher than that of households (i.e., firms are willing to pay higher unit rents in order to move one unit of distance closer to the center, as it is usually the case in the real world), the bid-rent curves for firms and households will be those shown in Fig. 27.4.

This model leads to two important results. The first is that it identifies the bid-rent curves of firms and households endogenously. Let us assume that at time t_0 , households choose a level of rent $r_0(d_0)$ characterized by a certain level of utility. For equilibrium to come about, the level of utility must be such that it determines an amount of population and a labor supply equal to the labor demand of firms. If households too have chosen a high level of utility and therefore make rent bids which are too low, the population located in the city (in the range $d_1 - d'_{max}$) may be insufficient to satisfy the labor demand by firms. The availability of work will attract new households into the city, with a consequent increase in demand for urban land which pushes the bid-rent curve up to $r_1(d_1)$ in Fig. 27.4. The city will expand (d''_{max}) until labor-market equilibrium has been reestablished at a lower level of utility.

The second important result of this model is that it divides the urban area between productive and residential activities. Urban land will be allocated to the activities able to pay a higher rent for each distance from the center – as in von Thünen’s model. In this case, the central areas will be occupied by firms, while households will be pushed toward suburban areas: a theoretical result which closely reflects what actually happens in reality.

As a final remark, although these models are highly abstract, owing to their unrealistic hypotheses (isotropic space, a city with a single center), they are able to

Fig. 27.5 Urban rent gradients in some major European cities (Rental values per sqm. per annum in euros – 2003) – Retail (Source: Capello 2007, p. 60)

describe conditions which closely match actual reality: an urban land rent gradient negative with respect to (business and management) broad suburban spaces for residential activities (Fig. 27.5).

27.2.5 Critical Remarks

Despite their logic, elegance, and economic rigor, these models have a number of theoretical elements which weaken their overall logical structure. One of them is the decisive role played by commuting in determining location equilibrium. If real behavior does not comply with the perfect rationality envisaged by the models so that commuting is of less importance for a person's utility, the entire theoretical-conceptual edifice collapses. However, this shortcoming can be partly remedied, however, if we acknowledge that the costs of transport to the center and the desire to reduce them may reflect other important aspects of an individual's utility function when she/he makes location choices, like accessibility to information, recreational services, and opportunities for social interaction.

A second shortcoming is more serious. These models concern themselves neither with how a city center is organized nor with what happens outside the city itself. They restrict themselves to interpreting locational behavior within the area extending between a hypothetical aspatial center and the physical boundary of the city. Moreover, when these models are used to interpret location equilibrium, not internally to a city but among cities, and therefore on the hypothesis that the city is part of an urban system and that firms may decide to relocate to other cities with attractively higher levels of utility or profit, they display a clear interpretative weakness. On the hypothesis that firms have equal production functions, there

can only be indifference to alternative locations in other cities if all these exhibit – in the logic applied here to describe them – the same bid-rent curve and the same boundary-rent curve and are therefore all of the same size.

If this is the case, there will be an urban system made up of cities which are all of equal size, but this circumstance is amply contradicted in the real world. In order to deal with this defect, the conceptual framework should be able to accommodate the hypothesis that locational advantages differ according to the size of the city and that rents – the monetary counterpart of the advantages that firms obtain from central urban locations – vary (distance from the center remaining equal) from city to city.

Only thus is it possible to conceive a location equilibrium with cities of different sizes. Yet this also requires acceptance of the idea that large, medium-sized, and small cities are structurally different and perform different functions in the overall economy and consequently have specific production specializations: a hypothesis at odds with the basic features of these models and which instead opens the way for the general equilibrium models discussed in ► [Chap. 3, “Labor Market Theory and Models”](#) of this handbook.

27.3 The Location of Industrial Activities in Space: Weber’s Model

27.3.1 Transportation Costs and Agglomeration Economies

The aim of other kinds of location models is to explain location choices of firms by considering the two great economic forces that organize activities in space: transportation costs and agglomeration economies. These forces push the location process in opposite directions since they simultaneously induce both the dispersion and the spatial concentration of production.

It is because of agglomeration economies that spatial concentration comes about. Widely used in regional economics, the term “agglomeration economies” denotes all economic advantages accruing to firms from concentrated location close to other firms and result from the concentration of economic activities in space. However, there are two forces which work in the reverse direction and give rise to dispersed location. The first is the formation in the agglomeration area of increasing costs or diseconomies, these being (i) the prices of less mobile and scarcer factors (land and labor) and (ii) the congestion costs (noise and air pollution, crime, social malaise) distinctive of large agglomerations. These diseconomies are generated above a certain critical threshold. However, the second factor – transportation costs – is of greater interest because these costs countervail the spatial concentration of activities whatever level of agglomeration has been reached. For in conditions of perfect competition, perfectly mobile production factors, fixed raw materials, and demand perfectly distributed across the territory, the existence of transportation costs may erode the advantages of agglomeration until activities are geographically dispersed and the market becomes divided among firms, each of which caters to a local market.

The way in which these two opposite forces can be taken at the same time into account is elegantly presented in Weber's model, described hereafter. As we will see, unlike the location models described in Sect. 27.2, which identify just one factor organizing activity in space (land rent), Weber's model envisages a different location equilibrium according to the spatial principle that patterns activities in space (agglomeration economies rather than minimum transportation costs).

27.3.2 Weber's Model

One of the first and best-known studies on the spatial concentration of industry dates back to 1909. In that year, the economist Alfred Weber constructed an elegant location model where the costs of transportation among production site, raw materials markets, and the final goods market (which together define a minimum transportation cost) are directly compared against localization economies (Weber 1929). The prevalence of one element over another determines the geography of industry location.

Weber's model is based on the following simplifying assumptions:

- (a) There is a punctiform market for the good (C in Fig. 27.6a).
- (b) Two raw materials markets, these too punctiform, are located at a certain distance from each other (M_1 and M_2 in Fig. 27.6a).
- (c) There is perfect competition in the market, i.e., firms are unable to gain monopolistic advantages from their choice of location.
- (d) Demand for the final good is price inelastic. Demand is said to be inelastic when the price of a good changes but the quantity of the good demanded (or supplied) varies less than proportionally or remains the same.
- (e) The same production technique is used in every possible location; production costs are therefore given and constant.

The location choice results from a complex calculation performed in two stages. In the first, the firm looks for the location that assures the minimum transportation cost between the production site, the raw materials market, and the final market for the good produced. In the second stage, the firm compares the advantages of agglomeration (localization economies) against the higher transportation costs that it would incur by choosing the new location instead of the one with minimum transportation costs.

The first stage of calculation identifies the location that assures minimum transportation costs. Let x and y be the tonnes of raw materials present, respectively, in markets M_1 and M_2 and required to produce one unit of output, and let z be the tonnes of the finished good to be transported to the final market C . Total transportation costs (CT) are expressed as a function of the weight of the good to be transported and the distance to cover:

$$CT = xa + yb + zc \quad (27.5)$$

Isodapane: geometric locus of points of constant additional cost of transportation with respect to the least-cost location

Fig. 27.6 Weber’s location equilibrium. (a) The locational triangle: choosing the location with the minimum transportation costs. (b) The agglomeration areas. Legend: x and y tonnes of raw materials, z tonnes of final goods, M_1 , market of one raw material, M_2 market of another raw material, C market of the final good, A , B , C and D ; different firms

where a , b , and c are, respectively, the distances in kilometers between the raw materials markets and the production site and between the latter and the final market and xa , yb , and zc represent the “forces of attraction” that push the firm, respectively, toward points M_1 , M_2 , and C (Fig. 27.6a).

The minimum cost location solution can be identified:

- At a point inside the triangle formed by joining M_1 , M_2 , and C if none of the “forces of attraction” exceeds the sum of the other two. In economic terms, this situation occurs when the cost of transporting the z tonnes of the good 1 km further away from the outlet market is less than the costs of transporting the x and y tonnes of raw materials 1 km further away from their source market.

- At corner C of the triangle, i.e., the final market, if the sum of the costs of transporting the x and y tonnes of raw materials 1 km further away from their market is less than the cost of transporting the z tonnes of final good produced one extra kilometer. This situation comes about because of the greater relative weight, in the composition of the finished product, of ubiquitous raw materials with respect to those that must be transported. Weber calls this condition “market oriented.”
- At a point closer to the raw materials markets if the sum of the costs of transporting the x and y tonnes of raw materials 1 km more is greater than the extra cost of transporting the z tonnes of the finished good. This situation can be explained by the lesser relative weight, in the composition of the final good, of ubiquitous raw materials with respect to localized raw materials and/or the product’s loss of weight during the manufacturing process. Weber calls this location “raw-material oriented.”

Weber provides a practical solution to the problem of identifying the minimum point. He hypothesizes a triangular board (the location triangle) in which three holes are drilled at the vertexes M_1 , M_2 , and C . Threads are passed through these holes (Fig. 27.6a), and their ends are knotted together on the upper surface of the board. Weights respectively proportional to x , y , and z are attached to the other ends of the threads below the board. The point at which the knot of the three threads lies on the upper surface of the board corresponds to the point of minimum transportation costs.

In the second stage of the location choice process, the firm compares the least-cost location with an alternative one where it can enjoy localization economies – for instance, the availability of labor at lower cost and/or better quality.

Assuming that P in Fig. 27.6a is the location point with the lowest transportation costs, Weber describes the “isodapanes”: curves along which the additional transportation cost that the firm must pay in order to cover a certain distance from the least-cost location remains constant. On the assumption that other firms operate in the same sector and that these firms obtain advantages from concentrated location such that they have a pecuniary advantage equal to v , the decision to relocate will be taken if and only if each firm’s isodapane measuring an extra transportation cost equal to the agglomerative advantage (v) intersects with the isodapanes of the other firms. In this case, in fact, within the area of intersection, the additional transportation costs are less than the advantages generated by concentrated location. In Fig. 27.6b, firms A , B , and C find themselves in this situation, and they relocate, but not so firm D , for which the agglomerative advantage is no greater than the additional transportation cost.

27.3.3 Criticisms of the Model

Weber’s model has made a permanent and major contribution to industrial location theory. Its principal merit is that it uses entirely rational modes of reasoning: for instance, comparison between the advantages of an alternative location and the

additional transportation costs that it would generate. Nevertheless, the model has a number of shortcomings:

- Its static nature. The model identifies the least-cost location on the basis of productive efficiency, but it ignores dynamic aspects such as innovation at the microeconomic level, while, at the macroeconomic one, it neglects changes in income distribution and in the relationships among agglomeration advantages, rents, and wages.
- Its transport-oriented nature. The cost of transportation defines first and foremost the most efficient location; only subsequently does it identify alternative locations. Some critics have claimed that this approach is less efficient than one based on the direct search for a point of minimum total production cost.
- Its abstractness, which makes the least-cost location difficult to calculate in real settings. It is rather unlikely, in fact, that the weight of raw materials in the final weight of the good can be calculated, distinguishing inter alia the weight of the raw materials to be transported from those present at the production site.
- Its nature as a partial equilibrium model which entirely neglects possible interactions among firms.
- Its supply-side bias. The criticism most frequently made of the model is that it is excessively oriented to the supply side: it makes no mention of demand factors, assuming that demand is unlimited and inelastic to price variations.

27.3.4 Strength of the Model

The main strength of the model is that for the first time it opened the way to reflections on the importance of agglomeration economies in location choices. The importance and power of agglomeration economies in the real world is evident. The number of concentrations of economic activity in space is very high. Local districts or clusters of SMEs denote a local area with a strong concentration of small- and medium-sized firms, each specialized in one or a few phases of the production process (or activities subsidiary to it) serving the needs of the area's principal sector. In this sense, they reflect Weber's concept of localization economies, i.e., those advantages stemming from the physical proximities of firms belonging to the same sector. In the real world, firms do not only cluster to achieve increased static efficiency of their production processes (i.e., an increase in firms' revenues or a decrease in their costs); firms get also *dynamic efficiency* in the form of increases in their innovative and creative capacity.

Cases in point are Silicon Valley in California, "Route 128" in the Boston area, Baden-Württemberg in the South of Germany, Jutland in Denmark, Småland in Sweden, and Sophia Antipolis close to Nice, to cite only some examples.

Weber's model does not explain the existence of agglomeration economies and gives them for granted. However, it has to be recognized that the intuition to highlight them as an important element in the choice of firms' location has opened the way to a long stream of theoretical reflections to interpret the formation of production agglomeration in space.

27.4 Conclusions

This chapter has surveyed the two groups of location theories developed to explain the determinants of location choices by industrial firms. First, it described models of a strictly neoclassical nature, which seek to account for the allocation of land between alternative activities within a spatial structure of uniform supply in space and a punctiform source of demand. High demand for access to central areas triggers competition among firms or between firms and households to obtain locations closer to the market, or more generally to a hypothetical central business district.

Land rent is the main factor that organizes activities in urban space. According to strict economic logic, competition for land closer to the center is resolved by its allocation to activities able to pay higher rents.

The virtues of these models are their rigor and their stringent economic logic. Their main weakness emerges when they set out to explain the location choices made by firms between cities with different levels of utility or profit. Indifference to alternative locations, which is the long-period equilibrium condition, is guaranteed if and only if cities offer the same utility and the same profit and therefore, according to the model's logic, if and only if cities are of the same size. Yet this implies the existence of an urban system consisting of cities which are all of the same size – a circumstance widely belied by reality. In order to understand the economic reasons for the existence of urban systems with cities of different sizes, consideration must be made of the functional characteristics of cities. This is an aspect which the models described thus far are unable to handle and which is instead addressed by the models discussed in the next chapter.

The second kind of models presented in this chapter is Weber's model. On the hypothesis that demand and supply structures are punctiform in space, the model elegantly and convincingly explains the existence of territorial agglomerations on the basis of two great economic forces which induce either the concentration or the dispersion of activities in space: agglomeration economies on the one hand and transportation costs on the other. Still today, these forces are components of more modern, and in certain respects more complex, models which seek to conjugate location choices with local growth dynamics (see ► [Sect. 5, "Location and Interaction"](#) of this handbook), and it is on the balancing of them that the geographical organization itself of activities depends.

Abstract

This chapter reviews some of major thematic approaches which have characterized urban and regional research over recent decades. Three broad schools of research are discussed, namely, the new economic geography, the new urban agenda, and the evolutionary and institutional school. The major assumptions underlying each of the schools of thought are outlined, and the broad areas of agreement and disagreement between the three schools of thought are highlighted. The changing economic realities on the ground in many regions, whereby the previously dominant large cities are no longer the key drivers of economic growth, pose major conceptual, analytical, and empirical challenges to all three of these schools of thought, schools which had emerged precisely during the period when major cities were reemerging as the drivers of growth.

28.1 Introduction

Recent developments in urban and regional economics have provided different discourses regarding the nature of regional and urban growth. These different discourses reflect different schools of thought, and these different schools of thought themselves can be interpreted in terms of what Lakatos (1970) defines as different “research programs,” programs which are built on self-contained sets of assumptions and their associated methodologies, programs which are largely internally consistent within their own assumptions, and programs which compete in terms of explanatory power with other research programs (McCann 2007). Over the last two decades, three major schools of thought can be identified in urban and regional economics, all of which arose initially in the late 1980s and early 1990s and which still continue to heavily influence urban and regional economic debates in rather different ways. Obviously, it is possible to categorize different research themes and schools diversely, but for the purposes of this chapter, the most parsimonious grouping is into three major research programs which can be listed as:

- (i) The new economic geography
- (ii) The new urban agenda
- (iii) The evolutionary and institutional school

These three research programs are in no way suggestive of an exhaustive listing of all regional science activities over the last two decades, nor are they entirely mutually exclusive of one another. However, they do, at least, capture many of the major lines of enquiry over recent years and also reflect many of the fundamental elements of agreement and disagreement between scholars regarding the workings of the interregional economic system and the lines for future required research. What these three research programs have done, however, is to reignite the debates regarding the role of cities and regions in national and international economic development and to reposition questions of geography back in the center of many wider debates about economic growth.

28.2 New Economic Geography

New economic geography, or NEG for short as it is known, arose initially out of the work of 2008 Nobel Laureate Paul Krugman, who applied the analytical approaches of new internal trade theory to questions of geography. In 1991, there appeared what is now widely regarded as being landmark publication (Krugman 1991) and which subsequently generated a wave of new analytical and empirical approaches to describing the geography of economics. Krugman’s early work with Masahisa Fujita and Anthony Venables (Fujita et al. 1999) has subsequently been extended and developed by such a wide range of scholars, to the extent that this research program has become a whole subfield of urban and regional economics in its own right.

As with all Lakatosian research programs, new economic geography is based on a particular set of assumptions. Although the models employed in this field can very quickly become rather complex and technical, in essence the models are based on very simple analytical framework, relating to the effects of variety, scale, factor mobility, and transactions costs. The first assumption concerns the relationship between size and variety, in that new economic models work on the assumption that the diversity of choices available to individual households and firms increases the welfare of those individuals and firms. As such the welfare effects of diversity are understood to operate primarily in two dimensions: firstly, the welfare of individuals and households is assumed to increase according to the range of consumers' choices and the consumption opportunities which are available to them; secondly, the profitability of a firm is assumed to be related to the variety of intermediate inputs among which a firm can choose to purchase supplies. In simple terms variety and choice increases (consumption or production) welfare, because it improves the quality of the matches between what the household or firm ideally wishes to consume and the opportunities to realize those choice preferences. In terms of geography, in new economic geography the primary setting where the elements of variety and size are naturally assumed to come together is in the context of a city or an urban area. The justification for this is based on the standard arguments relating to agglomeration economies, in that greater city size implies more variety of choices and better matching outcomes, for all individuals and firms in the city, as well as greater price competition and more efficient pricing outcomes.

The second element within new economic geography models is the question of factor migration. In early new economic geography models, labor is apportioned between employment in agricultural activities, which exhibit constant returns to scale, and manufacturing goods, exhibiting increasing returns to scale. The ability of factors (labor and capital) to move between sectors and places differs in different model specifications, based on the assumptions we make regarding the mobility or otherwise of factors. More recent models in new economic geography have also incorporated labor-commuting behavior and even knowledge and technological movements between places and sectors in their specifications.

The third and final element in the basic new economic geography framework is the specific way in which the distance costs are treated. New economic geography models specify distance costs or transport costs ways which are very different to traditional regional science approaches to these matters. Traditional region science models tend to specify product prices incorporating explicitly or implicitly transport costs in terms of functions which closely relate to f.o.b. (free on board) or c.i.f. (cost, insurance, freight) pricing schemes evident in transport economics, including ones that allow for frequency-optimization arrangements. In contrast, new economic geography models generally define transport costs or distance costs in a form known as an "iceberg" specification, whereby the value of the delivered good (or person in commuting models) falls with distance. The outcome of this iceberg specification is that the costs of distance are seen to increase at the margin with increasing distance. The reason for using this iceberg specification is to facilitate

the modeling of transport issues alongside the modeling of the other elements of the overall schema. This specification is loosely related to the von Thünen transport cost arguments, although the actual mechanics of, and justification for, adopting this approach are much less clear-cut and rather more problematic than is often assumed (McCann 2005).

In the new economic geography framework, a city is the natural setting where scale and variety come together. The production and consumption efficiencies associated with both scale and matching coincide in cities, and it is assumed that larger cities contain a greater variety of inputs and consumption choices, which provide the efficiency-scale effects. Taken together, these advantages therefore provide the “centripetal” forces which encourage factors to collocate together in cities, and the rate and scale of the collocation of factors depends in part on the mobility of the factors. In contrast, the iceberg transport costs, in which the costs associated with distance increase at the margin, provide the centrifugal forces favoring dispersion of factors. More recent new economic geography models also allow for localized congestion effects to provide another centrifugal force. While the centripetal forces encourage collocation and the formation of large cities which dominate their hinterlands, centrifugal forces allow more distance locations to maintain their own market hinterlands, rather than being dominated by the major urban centers. The overall observed spatial distribution of economic activities is argued to depend on the balance between these two opposing forces, with some regions in which economic activity is dispersed and other regions in which it is spatially concentrated.

There are numerous insights generated by new economic geography models, and more recently there are also new insights arising from the models which integrate new economic geography with new growth theory frameworks. However, for the purposes of this chapter, rather than trying to provide an exhaustive listing of all insights, it is useful to highlight a couple of key insights.

One of the most important new economic geography insights is provided by the model of Krugman and Venables (1995), in which two economies, one of which is large and contains a large agglomeration and one of which is small and contains only small urban areas, are increasingly integrated with one another due to falling trade costs, from a situation of having previously been largely closed to one another due to trade costs having been too high. In traditional neoclassical trade theory, such a process of mutual integration would have been assumed to provide standard factor price equalization-type outcomes, whereby factor movements and specialization and trade distributions would have continued until factor rewards are equalized in both countries. However, the Krugman and Venables (1995) model demonstrates that completely different results are possible. In particular, the benefits of the mutual trade openness are seen to generally favor the large economy.

The Krugman-Venables (1995) result, which is initially counterintuitive to many observers, is important in that it demonstrates the role played by geography in determining factor rewards. Specifically: when the two economies are largely closed to each other, they both exhibit similar production patterns, because the

high trade barriers encourage local production and a tendency toward autarky. However, as trade costs begin to fall, the greater agglomeration and home-market advantages of the large economy begin to tell, leading to an increasing center-periphery divergence in favor of the large economy. Moreover, this core-periphery pattern will be bolstered the greater is the mobility of the factors. In other words, falling trade costs will foster a greater concentration of activities in the larger economy, and these scale-productivity advantages of the large economy over the small economy will only disappear as trade costs fall toward zero, in which case colocation provides no advantages. Indeed, much of the evidence of falling trade barriers and falling communications costs over the last two decades suggests that exactly this type of process has taken place in many parts of the world, favoring core regions and large urban centers at the expense of other regions (McCann 2007).

A second key insight of new economic geography models is that the evolving spatial distribution of activities within a one-dimensional new economic geography framework (Fujita et al. 1999) can be seen to be broadly consistent with the types of hierarchical structures evident in both the urban-system patterns of Christaller and Lösch and also the rank-size rule pattern of urban size distributions. Moreover, the one-dimensional simulations of Fujita et al. (1999) have more recently been extended to two-dimensional simulations by Stelder (2005), and these clearly also demonstrate that clustering and dispersion are natural outcomes of spatial competition processes.

To say that the results of new economic geography models are largely consistent with the urban patterns and distributions generated by other rather more partial frameworks is not in any way to unequivocally demonstrate validity and veracity of the new economic geography models. Rather, what it does demonstrate is that the new economic geography models are well able to capture various different dimensions of the underlying mechanics of the interregional economic system and to do so in a manner which is reflective of a self-organizing economy operating in a general equilibrium type system. Indeed, the ability to capture these different dimensions simultaneously within the same schema represents both a major theoretical breakthrough on the part of new economic geography and also provides a major step forward in terms of how we frame questions about regional and urban issues, which nowadays increasingly start from the king of general equilibrium departure point of new economic geography models.

Having said this, it is also probably fair to say that the theoretical developments in new economic geography have been rather more significant than the empirical developments. Certainly, there are increasing numbers of spatial econometric models incorporating new economic geography frameworks into their analysis (Fingleton and Fischer 2010), but the primary impact of new economic geography has primarily been in terms of analytical insights. On this point, probably, the major empirical development in new economic geography relates to the ways in which the market potential can be estimated, and in particular to move beyond the standard market potential approach to one in which the impacts of competition, variety and wages are also included in market potential measurement (Redding and Venables 2004).

The weakness with these approaches is that they are seen to be very sensitive to the actual specifications employed (Bosker and Garretsen 2010), in which small changes in parameters and assumptions lead to major empirical changes.

28.3 The New Urban Agenda

The second major research program we discuss is what we will broadly define here as the *new urban agenda*, and this stream of research focuses on the investigation of the different mechanisms driving urban agglomeration economies (Glaeser 2011). In general, a major difference between this approach and that of new economic geography is that while new economic geography is overwhelmingly a theoretical research program with much more limited empirical elements embedded within it, the new urban agenda is fundamentally an empirical research program with some theoretical elements embedded within it.

The paper which is generally accredited with galvanizing the new urban agenda research program was by Glaeser et al. (1992), in which the role played by industrial specialization and diversity in fostering urban economic growth was examined empirically. The arguments in this chapter tend to center of the role played by economies of localization which are spillovers evident in the same sectors in the same places (or “MAR-externalities,” named after Marshall-Arrow-Romer) or economies of urbanization (or Jacobs externalities) which are spillovers evident between sectors in the same places. This seminal Glaeser et al. (1992) paper was followed by numerous other contributions since. More recent extensions of this approach also include the role played by cities as centers of consumption as well as production (Glaeser et al. 2001; Shapiro 2006), in which urban amenities are also considered as part of the attractor forces encouraging agglomeration. The overall conclusion from the US papers is that across all regions, sectoral diversity and urban scale appear to be better for fostering the long run growth of a region than sectoral specialization (Glaeser and Gottlieb 2009), and this conclusion clearly chimes with the basic assumptions of new economic geography. On the other hand, however, internationally there appears to be no such consensus on the growth-enhancing role of sectoral specialization or diversity, with some research pointing to the advantages of specialization and others to the advantages of diversification (de Groot et al. 2009). As such, it appears to depend somewhat on the context, whereby the degree of a region’s diversity or specialization may play a different role in different locations and different time periods.

Given the applied econometric focus of these papers, this research program has also highlighted the importance of having both good urban data and good data analysis. Various indices have been constructed in order to try to capture the extent of spatial clustering both within sectors and between sectors, as an indirect way of capturing different types of agglomeration effects. Such indices need to allow for the fact that some observations of clustering are likely to be entirely purely due to statistical reasons which are unrelated to actual firm location behavior or choices but rather to structural or cartographical issues. For example, several indices have

been developed to control for the fact that some observed patterns of employment clustering and dispersion may simply be the result of the distribution of firm sizes (Guimarães et al. 2007). Other indices have also been developed to control for the effects of the drawing of cartographical boundaries (Duranton and Overman 2005) and the effects of shared linkages between industries (Ellison et al. 2010). In each of these cases, the aim of these indices is to account for the degree of spatial clustering which occurs in addition from what would be expected on the basis of the definitions of firms, areas, or industries.

The new urban agenda research program has spurred the detailed econometric and theoretical work on the micro-foundations of urban areas (Duranton and Puga 2001). The role of cities as engines of economic growth has been emphasized, and, along with new economic geography, this research program has greatly helped to position geographical issues at the center of wider discussions of economic growth and particularly in the case of the USA (Glaeser and Gottlieb 2009).

One likely future change of emphasis, however, is being signaled by the recent work of the OECD (2009a, b, 2011), which shows that the growth-enhancing role of major cities in many countries has largely faded and that the growth contribution of such cities, while being important, is also nowadays largely unchanging. Increasingly, in many countries, national economic growth is more associated with smaller and medium-size centers than with the largest centers. At the same time, the concept of a “representative” region is actually declining, with regional heterogeneity increasing. Moreover, if smaller cities tend to be more specialized than larger cities, then this recent evidence would also appear to point in some cases to some reemerging advantages of urban sectoral specialization over diversification. These empirical findings also appear to be robust to different empirical specifications and are also broadly comparable across countries. Given that the new urban agenda research program emerged out of early-1990s empirical observations suggesting that urban scale and diversity were reemerging as a driver of economic growth, what these recent OECD empirical findings now imply in terms of shifting discourses regarding the role of cities remains to be seen.

28.4 The Evolutionary and Institutional School

A rather different research program to the two already discussed is that of the evolutionary and institutional school. This approach takes as its departure point the fact that places are not just by geographical distance, proximity, and accessibility but also by “knowledge,” distance, and accessibility (Boschma 2005) and that understanding the means by which knowledge is transmitted and mediated is critical. The argument here is that regions and sectors are related to each other according to various different dimensions which may not be best captured by the types of models and empirics adopted by either the new economic geography or the new urban agenda research programs. In particular, this research program stresses that many regions are “related” to each other in technological or institutional terms as well as geographical terms, and this has important

implications in terms of our understanding of how innovation and growth processes operate between regions.

Both the new economic geography and the new urban agenda frameworks can be linked to the earlier endogenous growth work, whereas the evolutionary and institutional school focus more on the insights of authors such as Aghion and Howitt (1992), who argue that economic growth is primarily driven neither by efficient factor allocation and pricing nor by competition, specialization, or variety. Slightly differently, the Aghion and Howitt (1992) framework is based on the assumption that growth is driven fundamentally by Schumpeterian processes of creative destruction, characterized by risk taking, entrepreneurship, and innovation. These Schumpeterian-type models do allow for the knowledge spillover, input variety, and human capital elements which are evident in other endogenous growth models and also in the new economic geography and new urban agenda frameworks. However, in these Schumpeterian models, competition is assumed to take place in an environment where technological change allows for major and fundamental shifts in the nature of competition. These shifts in competition, which are driven by innovation, imply that economic growth may follow quite different trajectories, depending on the technological breakthroughs which take place and the innovations associated with these breakthroughs. As such, there is not necessarily any preordained growth rate or growth trajectory to which the economy is assumed to converge, because it depends on how well positioned an economy is to take advantage of the newly emerging technologies. This line of research therefore emphasizes issues such as the diffusion of knowledge, the problems of technological “lock-in,” and the institutional capability of the economy, and in many ways these approaches mirror and build on the arguments put forward by Porter (1990) and Saxenian (1994).

When translated into the context of geography and regions, this line of reasoning implies that differences in regional growth are largely attributed to differences in the technological profile of different places, and these in turn depend on the interactions between history and geography. Such interactions are assumed to be the result of evolutionary processes, in which technologies and institutions play the equivalent role of genes in biology. These different technological profiles are assumed to lead to differences in the ability of regions to connect with, and to relate to, the newly emerging and most competitive technologies, and there are two aspects of this. Firstly, the ability of region to link with and exploit the technological developments in other leading regions is also argued to depend on the degree of technological congruence of the regions. Secondly, the ability of a region to take advantage of newly emerging technologies within its own productive capacity is assumed to depend on the region’s prevailing industrial structure.

On the first point, the assumptions of the evolutionary approach imply that the ability of one region to “learn” from another region depends on their degree of technological congruence between the regions. “Proximity” in terms of technological profiles facilitates knowledge spillovers and exchanges and thereby overcomes many of the problems associated with geographical distance. On the other hand, distance in terms of technology limits spillovers and knowledge exchanges, irrespective of the geographical distance.

A second, and arguably even more important insight of these evolutionary approaches, is that a region's ability to grow is conditioned by its own technological development trajectory – in other words, by its own technological history. More specifically, the argument here is that a region's growth potential is likely to be stronger if it aims to diversify into technological fields which are closer and more related to the region's current dominant technologies than in other largely unrelated technological fields. This is because such closely related technological shifts are assumed to better allow regional assets to exploit and build upon the region's existing skills and capabilities. This “related variety” (Frenken et al. 2007) argument, which is a combination of Schumpeterian and Darwinian thinking, therefore implies that the most promising trajectories or pathways forward for a region's growth are found by diversifying into technologies which are closely related to the existing dominant technologies, and there is now a large and growing body of empirical evidence to support this argument (Boschma and Iammarino 2009). Moreover, the evidence of this takes various forms in that both the inflows of new firms and also the founding of new local firms are found to be higher in related technological fields, while the outflows of firms or firm failures are also less likely in these same closely related sectors. Moreover, these effects prove to be even stronger at the regional scale than at the national scale. These Schumpeterian-Darwinian types of arguments all suggest that the clues to differing regional performance are related to questions of how knowledge flows are mediated and argues that technological profiles both reflect and also mediate the region's ability to acquire, generate, and process knowledge.

Other institutional approaches also adopt a similar line of reasoning regarding historical trajectories but from a slightly different point of view. Since the early 1990s, a great deal of new thinking about development and growth has emphasized the role played by institutions and governance systems in economic development. For many governance systems, an overreliance on a highly centralized state precludes the widespread engagement by local stakeholders (Barca et al. 2012), the result of which is only very limited endogenously driven local development. In contrast, an overreliance on decentralized systems often leads to coordination failures, rent seeking, duplication, and an absence of any coordinated strategy. Beyond this, however, it has become widely accepted that ability of an institutional system to facilitate growth and development is dependent not only on a “good” architectural design of the system but fundamentally also on the ways in which all of the system's actors, stakeholders, and interested parties interact with each other. In the case of institutions, one of the most important developments in our understanding centers on the role of what is known as social capital (Putnam 1993), whereby social capital relates to all of the social norms, social rules, and social conventions that operate within a society. Although the concept is almost a century old (Westlund 2009), it was reinvigorated by two seminal books written by Putnam (1993, 1996) which brought the arguments into contemporary mainstream economics and political science, and the arguments are particularly pertinent for urban and regional systems (Westlund 2009).

Putnam's (1993) initial work was based on the major development differences within Italy, which he ascribed to longstanding historical differences in the regional levels of trust in governance institutions. Putnam's argument is that these

historically determined levels of social capital have very long-lasting implications. Broadly, the less that individuals trust the protection to be afforded them from the formal legal and government institutions, the lower will be the levels of economic development, because weaker formal institutions make entrepreneurial activities increasingly risky. In contrast, high degrees of trust in well-functioning institutions mean that more people are willing to undertake entrepreneurial risks. As such, social trust and economic activity are argued to be highly correlated over time, and the long-term development of a region is therefore assumed to be closely related to the institutional history of the region.

As well as heavily determining a region's trajectory via the quality and efficacy of its institutional arrangements, however, social capital also plays a role in the ongoing development of region by influencing the ability of the region to adapt to changes (Putnam 1996). On this point, social capital can be understood in terms of two distinct types, namely, *bonding* capital and *bridging* capital, whereby bonding capital relates to the connection between people of similar types while bridging social capital refers to the ability of people to relate to other types of people. The former appears to be important in terms of keeping communities locally cohesive and may be an important element in ensuring that localities are "resilient" in times of adversity, whereas the latter appears to be important in helping localities to adjust to new economic realities.

In terms of our earlier arguments, it may well be the case that large and diverse urban areas display higher levels of bridging social capital, and this may facilitate greater knowledge flows and learning opportunities for adjusting and diversifying. Indeed, this may be one of the major economic advantages of diversity, a point also picked up on by Florida (2002). In contrast, smaller and more geographically peripheral centers may exhibit greater bonding social capital, which while being positive in terms of maintaining resilience in times of economic hardship, may limit the growth potential in stronger periods. The institutional and social history of the locality therefore becomes crucial for understanding the economic evolution of the region, and if these arguments are also linked to the related variety arguments, together the evolutionary and institutional school point to the technological, institutional, and social profile of the region as crucial for understanding its growth patterns, performance, and potential, over and above questions of variety, diversity, specialization, or scale, all of which are central to both the new economic geography and new urban agenda research programs.

28.5 Conclusions

The differences in approach between these different research programs or schools of thought do imply some differences in terms of how we think about the regional economy. On the one hand, the related variety, institutional, and social capital arguments tend to emphasize specific systemic factors within the local economic system as determining regional growth, and these themes closely mirror the themes picked up on by the work on new industrial areas, industrial districts, and clusters.

In contrast, the new economic geography and the new urban agenda approaches tend to see largely system-wide features as playing the dominant role. However, all three of these schools of thought, and in particular the new economic geography and new urban agenda schools, now face the challenge of responding to the recent empirical observations of the OECD (2009a, b, 2011) and MGI (2011), which suggest that the types of locations which these approaches emphasize, namely, the largest core cities, in reality may be rather less important for future economic growth than their analytical centrality implies. Moreover, the fact that both successful regions and struggling are becoming increasingly heterogeneous even within their own groupings (OECD 2009a, b) means that there is no simple typology describing an optimum structure. In reality, the actual outcomes in any particular region are likely to be a mixture of both region-specific and also the system-wide effects (Shearmur and Polèse 2007; Doloreux and Shearmur 2012). What is not yet clear is exactly how the balance between region-specific effects and system-wide effect, or between local influences and global influences, will change over the coming decades. The current literature was primarily forged during a period in which large cities were increasingly reaping the rewards of globalization, but in many countries this pattern nowadays appears to be changing (Barca et al. 2012), and this itself may warrant some changes in the lines of major enquiry.

Abstract

This chapter does not aim to survey what has been accomplished in new economic geography (NEG) since the publication of Paul Krugman's seminal paper. Rather, we provide an overview of recent developments in the NEG literature that build on the idea that the difference in the economic performance of regions is explained by the behavior and interactions between households and

firms located within them. This means that we consider NEG models which take into account land markets, thereby the internal structure and industrial mix of urban agglomerations.

29.1 Introduction

Ever since the publication of Krugman's (1991) pioneering paper, new economic geography (NEG) has given new life to spatial economics, which since then has made enormous progress by any previous yardstick. The very name "new economic geography" seems chosen to stir a debate: Is NEG economic geography proper or rather spatial economics? And is there anything really new in it? To the best of our knowledge, no economist before Krugman had been able to show how regional imbalances can arise within the realm of general equilibrium theory. To achieve this, Krugman has borrowed concepts and tools developed in modern economic theory, especially the Dixit and Stiglitz (1977) model of monopolistic competition, which is the workhorse of new growth and trade theories. As for transport costs, Krugman uses the iceberg technology: Only a fraction of a good shipped between two places reaches the destination, the missing share having melted on the way. This ingenious modeling trick, due to Samuelson (1954), allows integrating positive shipping costs without having to deal explicitly with a transport sector. Hence, Dixit, Stiglitz, and Samuelson form the trinity under which Krugman has combined increasing returns, commodity trade, and the mobility of production factors within his now famous "core-periphery" model.

In NEG, the distribution of activities emerges as the unintentional outcome of a myriad of decisions made by firms and households pursuing their own interest. Thus, *methodologically, NEG belongs to mainstream economics*. This is probably what distinguishes most NEG from economic geography proper. Our choice to focus on NEG only does not reflect any prejudice on our part. It is mainly driven by the need to stress how this approach can be used to highlight old and new issues. Being deeply rooted in mainstream economics, NEG has strong connections with several branches of modern economic theory, including industrial organization and international trade, but also with the new theories of growth and development. This permits cross-fertilizations which have been out of reach for a long time. We also want to stress that differences between alternative approaches are often overemphasized. Indeed, NEG and evolutionary economic geography share many common results (Jovanovic 2009). Furthermore, in terms of its subject matter, NEG cannot be considered alien to regional science and geography. Moreover, many ideas and concepts NEG builds on have been around for a long time, both in economics and regional science (Ottaviano and Thisse 2005). For example, the fundamental idea that the interplay between different types of scale economies and transport costs is critical for the way the space economy is organized, and so at various spatial scales (cities, regions, countries, continents), was known (at least) since the work of Weber and Lösch. It is fair to say, however, that those ideas were fairly disparate and in search of a synthesis.

It is now widely recognized that Krugman's main contribution was his entirely different and new approach to the origin of regional imbalance. Under constant returns, firms find it profitable to disperse their production to bring it closer to customers, as this will reduce transport costs without lowering productive efficiency. Such a space economy is the quintessence of self-sufficiency: If the distribution of factor endowments is uniform, the economy reduces to a Robinson Crusoe-type economy where each person produces for his or her own consumption. Under these circumstances, only differences in endowments of immobile production factors can explain the marked differences in the spatial distribution of activities and hence the need for interregional and international trade.

To a large extent, relying on first nature to explain the existence of large urban agglomerations and sizable trade flows amounts to playing Hamlet without the Prince. Krugman squarely tackles this problem by assuming that firms operate under increasing returns and imperfect competition on the product market. Such a combination is orthogonal to the standard paradigm of constant returns and perfect competition, which has dominated mainstream economic theory for a long time. Furthermore, to the trade-off between increasing returns and transport costs, Krugman (1980) has added a third variable: the size of spatially separated markets. The main accomplishment of NEG has been to highlight *how market size interacts with scale economies internal to firms and transport costs to shape the space economy*.

In NEG, the market outcome stems from the interplay between a dispersion force and an agglomeration force operating within a full-fledged general equilibrium model. In Krugman (1991) and Fujita et al. (1999), the dispersion force stems from the spatial immobility of farmers whose demands for the manufactured good are to be met. The agglomeration force is more involved and requires a more detailed description. If a larger number of manufactures are located in one region, the number of varieties locally produced is larger too. Then, manufactured goods are available at lower prices in the larger region because local varieties are cheaper than imported varieties. This in turn induces consumers living in the smaller region to move toward the larger region, where they may enjoy a higher standard of living. The resulting increase in the numbers of consumers creates a larger demand for the manufactured good, which, therefore, leads additional firms to locate therein. This implies the availability of more varieties in the region in question but less in the other because there are scale economies at the firm's level. Consequently, as noticed by Krugman (1991, p.486), *circular causation* à la Myrdal (1957) is present because these two effects reinforce each other: "manufactures production will tend to concentrate where there is a large market, but the market will be large where manufactures production is concentrated." The great accomplishment of Krugman was to integrate all these various effects within a unified framework and to show that the *level* of transport costs is the key-determining factor for the organization of the space economy.

When transport costs are sufficiently low, Krugman (1991) showed that manufactures are concentrated in a single region that becomes the *core* of the economy, whereas the other region, called the *periphery*, supplies only the agricultural good.

Firms are able to exploit scale economies by selling more in the larger market without losing much business in the smaller market. For exactly the opposite reasons, the economy displays a symmetric regional pattern of production when transport costs are high: Because the local markets are now protected by geographical separation, firms relax competition by being dispersed across regions. Hence, the core-periphery model allows for the possibility of convergence or divergence between regions, whereas the neoclassical model, based on constant returns and perfect competition, would predict convergence only. It is worth stressing that the dual structure made of a core and a periphery is brought about by market forces only as it is obtained in a setting formed by two regions that are *ex ante* identical. These results hold true in more general settings such as those discussed in great detail in Fujita et al. (1999) and Baldwin et al. (2003).

By focusing on the interactions between the product and labor markets, Krugman's work remains in the tradition of international trade. Although we recognize the limits of this approach, we believe it delivers a powerful framework which has proven to be very useful in dealing with a large number of issues. Yet, in this chapter, we do not discuss the canonical NEG models and their vast number of extensions. Rather, we provide an overview of recent developments in the NEG literature, which fits better the space economy of developed economies. In particular, we build on the idea that the difference in the economic performance of regions is, to some extent, explained by the behavior and interactions between households and firms that are located within them. *The focus thus shifts from the nation-state to the city region.* Therefore, we discuss NEG-like models in which the internal structure and industrial mix of urban agglomerations are determined in interaction with a land market.

To be precise, we start by focusing on the causes and consequences of the internal structure of cities because the way they are organized has a major impact of the well-being of people. In particular, housing and commuting costs, which we call *urban costs*, account for a large share of consumers' expenditures. For example, in the United States, housing accounts on average for 20 % of household budgets while 18 % of total expenditures is spent on car purchases, gasoline, and other related expenses which do not include the cost of time spent in traveling. In 2000, the total cost of people's journeys inside the Paris metropolitan area amounted to a staggering 34.3 billion euros, which is just over 8 % of the local GDP. As for housing, the price per square meter is, on average, 80 % higher in Paris than in the rest of France. This leads us to concur with Helpman (1998) for whom urban costs are the main dispersion force at work in modern urbanized economies.

In this alternative setting, an agglomeration is structured as a monocentric city in which firms gather in a central business district. Competition for land among consumers gives rise to land rent and commuting costs that both increase with population size. In other words, our approach endows regions with an urban structure which is absent in standard NEG models. As a result, the space economy is the outcome of the interaction between two types of mobility costs: the transport costs of commodities and the commuting costs borne by workers. The results presented in [Sect. 29.2](#) for a monocentric city differ from those obtained by

Krugman: *the evolution of commuting costs within cities, instead of transport costs between cities, becomes the key-factor explaining how the space-economy is organized.* Moreover, despite the many advantages provided by the inner city through an easy access to highly specialized services, the abyssal fall in communication costs has led firms or developers to form enterprise zones or edge cities (Henderson and Mitra 1996). We then go one step further by allowing firms to form secondary business centers. This analysis shows how polycentricity allows reducing urban costs, which in turn permits a large city to retain its dominant position by accommodating a large share of activities.

Another change of focus is on services rather than manufactures. The bulk of the NEG literature has concentrated on manufacturing sectors, although employment in modern cities is found mainly in firms providing nontradable consumption (b2c) services. While the Industrial Revolution fostered the emergence of manufacturing cities, services continue to show a taste for cities that manufacturing sectors no longer have (Bairoch 1985). As stressed by Glaeser et al. (2001), the success of a city depends more than before on its role as a center of consumption, that is, on the supply of local amenities and services. Even though NEG conveys the image of an economy formed by an urban core hosting manufactures and a rural hinterland specialized in agriculture, a pattern now obsolete in developed countries, recent contributions to NEG pay more attention to the role played by local services in urban development. In Sect. 29.3, we recognize that services (e.g., health care, restaurants, and movie theaters) are conditioned on precise locations and study their intercity distribution. We then add a new dimension to the above analysis by blending a service sector and a manufacturing sector in an economy in which workers display both sectoral and spatial mobility.

These ideas are presented through the lenses of a new framework. NEG being to some extent a collection of specific examples, we have no reason to apologize for using another specific model, that is, the linear model of monopolistic competition proposed by Tabuchi and Thisse (2006), which is much easier to handle than CES-based models. As for the transport cost, it is added to the production cost and measured in terms of the numéraire. This avoids imposing binding relationships between prices and shipping costs. By yielding linear equilibrium conditions, this model delivers a full analytical solution that captures in a simple way the pro-competitive effects associated with market size and market integration. To accomplish this task, we use a NEG-like model that takes into account the following fundamental aspects of urban development: (i) cities can be monocentric or polycentric, (ii) cities supply nonhousing services as well as tradable goods, and (iii) cities have heterogeneous demographic structures involving different types of individuals (e.g., workers and retirees) who are attracted by different location factors. Moreover, the framework we use displays enough versatility to tackle new issues which are difficult to cope with by using the standard framework of NEG. We are well aware that the reader accustomed to NEG might be surprised by our choice of menu. It is worth stressing that the basic model used in this chapter can replicate the main results obtained by Krugman and others. It thus belongs to NEG. The seemingly different approach followed here has been chosen in the hope

of convincing the skeptical regional scientist that NEG is a lively field that still has a high potential for future research.

The remainder of this chapter reflects the above methodological choices. The basic model is presented in Sect. 29.2, and the market outcome is compared to Krugman's core-periphery structure. We show how commuting costs and population density impact on the location of economic activities *between* and *within* cities. The subsequent section focuses on nontradable consumption services and their interactions with tradable manufactured goods. To illustrate the potential of NEG in the study of policy-driven problems, Sect. 29.4 addresses the implications of an aging population for the urban system and the environmental and economic consequences of compact cities characterized by a high population density. Section 29.5 concludes.

29.2 Cities and Manufacturing Firms

The economy is formed by two regions, labeled $r = A, B$, and populated by $L > 0$ consumers who are free to choose where to live and work. To ease the burden of notation, we choose the unit of labor for $L = 1$. Unlike the standard core-periphery model where regions are pretty much spaceless places, we recognize explicitly that any sizeable human settlement takes the form of a city where economic agents compete for land; cities are assumed to be anchored and separated by a given physical distance.

There is one manufacturing sector and three goods: land (housing), a produced good, which is differentiated and tradable, and an unproduced homogeneous good, which is the numéraire. Space is one-dimensional and the opportunity cost of land is zero. Each region can be urbanized by accommodating firms and consumers according to rules described below. Whenever a city exists, it has a central business district (CBD) where firms set up. Because NEG has nothing really new to add to the reasons explaining why CBDs exist, it is convenient to assume that CBDs preexist.

As discussed in the introduction, the main reason for the existence of cities is the presence of increasing returns. Under scale economies internal to firms, consumers have direct access to the locally produced varieties, the number of which depends on the size of the local market. When they display a love for variety or when the city population is formed by individuals having each idiosyncratic tastes for ideal varieties, consumers are also inclined to consume varieties produced in other places. This in turn prompts trade in differentiated commodities across spatially separated urban markets. As observed by Hicks (1969, p. 56): "The extension of trade does not primarily imply more goods. ... The variety of goods is increased, with all the widening of life that entails. There can be little doubt that the main advantage that will accrue to those with whom our merchants are trading is a gain of precisely this kind." However, foreign varieties must be imported at a positive transport cost, which tends to make them more expensive.

The standard thought experiment of NEG is well known: How do firms and consumers locate when the cost of shipping the manufactured good *between* regions/cities steadily decreases? Once we account for a description of the space economy that fits better the contemporary world, this thought experiment must be supplemented by another one, that is, the impact of commuting costs *within* cities. In sum, both the transport costs of commodities and the commuting costs of people must be taken into account to understand how economic activities are distributed across space.

29.2.1 Agglomeration and Commuting Costs

We assume that the lot size is fixed and normalized to 1 where the tallness (i.e., the number of floors) of buildings is given by $\delta > 0$ regardless of their location in the city. As a consequence, the parameter δ is the *population density* which also measures the city's compactness. Consequently, when the total population of city r is λ_r , the city is described by an interval of length λ_r/δ . At the residential equilibrium, all consumers reach the same utility level. If land is available on both sides of the CBD, the residential equilibrium involves a symmetric distribution of consumers around the CBD with city r 's right-hand side limit at

$$\bar{x}_r = \frac{\lambda_r}{2\delta}$$

A. Consumers. Consumers share the same quasi-linear preferences, which imply that the land ownership structure has no impact on our results. Denoting by n the total mass of varieties, the utility derived from consuming q_i units of variety $i \in [0, n]$ is given by

$$u(q_i) = \alpha q_i - \frac{\beta}{2} q_i^2 - \frac{\gamma}{2n} q_i \int_0^n q_j dj \tag{29.1}$$

The parameters α , β , and γ are interpreted as follows: $\alpha > 0$ measures the desirability of the manufactured good with respect to the numéraire and $\gamma > 0$ is the degree of substitutability between variety i and any other variety, whence a higher γ means that varieties are less differentiated. The parameter β expresses the desirability of variety i with respect to the total consumption: A high value of β means that a consumer aims at equalizing her consumption over the entire range of varieties. This parameter therefore measures the intensity of consumers' love for variety. Moreover, Eq. (29.1) shows that the marginal utility of variety i decreases with its own consumption as well as with the total consumption of the manufactured good.

Preferences are obtained by nesting the subutility Eq. (29.1) into a linear utility:

$$U(q_0, q_{i \leq n}) = q_0 + \alpha \int_0^n q_i di - \frac{\beta}{2} \int_0^n q_i^2 di - \frac{\gamma}{2n} \int_0^n q_i \left(\int_0^n q_j dj \right) di \tag{29.2}$$

where q_0 is the quantity of the numéraire. The lot size being fixed, there is no need to specify how housing enters into preferences. In what follows, we ease the burden of notation by adopting two normalizations which entail no loss of generality: The unit of the numéraire is chosen for $\alpha = 1$ and the unit of the manufactured good for $\gamma = 1$ to hold.

Each consumer supplies inelastically one unit of labor. Consumers commute to the CBD where jobs are located and earn an income w_r which is determined at the equilibrium. The unit commuting cost is given by $t > 0$, and thus, a consumer located at $x > 0$ bears a commuting cost equal to tx units of the numéraire. In addition, each consumer is endowed with $\bar{q}_0 > 0$ units of the numéraire, which is sufficiently large for the individual consumption of the homogeneous good to be strictly positive at the equilibrium outcome. Hence, the budget constraint faced by a consumer living in city r is given by

$$\int_0^n q_{ir} p_{ir} di + q_0 + R_r(x)/\delta + tx = w_r + \bar{q}_0 \quad (29.3)$$

where p_{ir} (q_{ir}) is the price (consumption) of variety i in city r and w_r the wage paid by the firms set up in city r 's CBD. In this expression, $R_r(x)$ is the land rent at x and thus $R_r(x)/\delta$ the price paid by a consumer to reside at x .

A consumer chooses her location and consumption bundle so as to maximize her utility Eq. (29.2) subject to the budget constraint Eq. (29.3). This yields the following demand for variety i :

$$q_{ir} = \frac{1}{\beta + 1} - \frac{p_{ir}}{\beta} + \frac{1}{\beta(\beta + 1)} \bar{p}_r \quad (29.4)$$

where

$$\bar{p}_r = \frac{1}{n} \int_0^n p_{jr} dj$$

is the average price prevailing in city r . The demand Eq. (29.4) captures in the very simple way the impact of competition on a firm's demand: A higher (lower) average price shifts upward (downward) the demand for variety i because local competition is softer (tougher), thus making variety i more (less) attractive to city r -consumers.

In what follows, we call "urban costs" the sum of housing and commuting costs borne by a city r -consumer residing at any location x :

$$UC_r(x) = R_r(x)/\delta + tx$$

Let $\Psi_r(x)$ be the highest price a worker is willing to pay to reside at location x in city r . Because there is only one type of labor, the equilibrium land rent is such that

$$R_r^*(x) = \delta \max\{\Psi_r(x), 0\}$$

The lot size being fixed, a marginal hike in the commuting trip must be equal to the decrease in the bid rent Ψ_r , that is, $\partial\Psi_r/\partial x + t = 0$. Hence, $\Psi_r(x) = k - tx$ where k is a constant. Since the land rent at \bar{x}_r is equal to the opportunity cost of land, here zero, we have $k = t\bar{x}_r$, and thus, $\Psi_r(x) = t\lambda_r/2\delta - tx$. Therefore, the price paid to reside at x is the mirror image of the corresponding commuting costs:

$$R_r^*(x)/\delta = t\left(\frac{\lambda_r}{2\delta} - x\right) \quad \text{for } x < \bar{x}_r \quad (29.5)$$

Hence, the price paid by a consumer to live at $\bar{x} > 0$ decreases with the population density since the average commuting is shorter.

The urban costs borne by consumers in city r do not depend their residential location within this city and are equal to

$$UC_r = \frac{t\lambda_r}{2\delta} \quad (29.6)$$

Because they increase with city size, *urban costs act as the dispersion force*. As expected, intercity differences in urban costs increase with commuting costs and decrease with population density.

It remains to close the model by specifying the structure of land ownership. Unless explicitly mentioned, we assume for simplicity that the aggregate land rent is distributed to absentee landlords.

B. Producers. Firms produce a differentiated and tradable good under monopolistic competition and increasing returns; for simplicity, they do not use land. A firm produces a single variety and any two firms supply two differentiated varieties. Producing a variety of the manufactured good requires a fixed number ϕ of labor units. Hence, the total mass of varieties supplied in the economy is given by $n = 1/\phi$ and the mass of firms producing in city r by $n_r = \lambda_r/\phi$. So a lower value of ϕ means a higher labor productivity. Note that λ_r is also the share of firms located in city r .

The manufactured good is shipped between cities at the cost of $\tau > 0$ units of the numéraire. Markets are segmented, that is, each firm is able to set a price specific to the market in which its output is sold (Engel and Rogers 2001). Because preferences and technologies are symmetric, firms sell their varieties at the same price in each city. Thus, we may disregard the index i and write the profits earned by a city r -firm as follows ($s \neq r$):

$$\pi_r = p_{rr}q_r(p_{rr})\lambda_r + (p_{sr} - \tau)q_s(p_{rs})\lambda_s - \phi w_r$$

where p_{rr} is the price set by the local firms and p_{rs} the delivered price charged by the foreign firms; q_r and q_s are the quantities sold by the r -firms and s -firms, respectively.

The average price in city r is given by

$$\bar{p}_r = n_r p_{rr} + n_s p_{sr}$$

Plugging this expression into Eq. (29.4) and solving the first-order conditions yield the equilibrium prices:

$$p_{rr}^* = \frac{2\beta + \tau\lambda_s}{2(2\beta + 1)} \quad \text{and} \quad p_{rs}^* = p_{ss}^* + \frac{\tau}{2} \quad (29.7)$$

Both prices p_{rr}^* and p_{sr}^* capture the pro-competitive effects associated with a larger number of local competitors and lower transport costs. In other words, the prices of local and imported varieties are lower in large cities than in small ones. This result runs against the conventional wisdom which holds that tradables are more expensive in larger cities because land rents and wages are higher therein. Note, first, that this argument overlooks the fact that, given the continual flows of new goods, the consumer price index for urban consumers almost completely ignores the quality improvements of existing goods and the introduction of new goods which allows consumers to substitute low-priced goods for high-priced goods. Controlling for these effects, Handbury and Weinstein (2011) use a dataset covering 10–20 million purchases of grocery items and find that prices for the same goods are indeed significantly lower in larger cities. This highlights a trade-off which has been neglected in the urban economics literature: *consumers bear higher urban costs in larger cities but the tradable goods are supplied at lower prices.*

Furthermore, Eq. (29.7) shows that trade exacerbates competition in each city though the consumer (c.i.f.) price of imported varieties is higher than that of domestic varieties because distant firms have to cover the cost of shipping their output. Therefore, consumption is biased toward locally produced goods. By contrast, the producer (f.o.b.) price of imported varieties is smaller than that of local varieties. There is freight absorption to facilitate the penetration of varieties produced in distant places. Last, for intercity trade to occur and its pro-competitive effects to become concrete, transport costs cannot be too high: $p_{rs}^* - \tau > 0$. This condition holds regardless of the spatial distribution of firms if and only if $\tau < \tau_{trade} \equiv 2\beta / (2\beta + 1) < 1$.

Urban labor markets are local while labor market clearing implies that the creation and destruction of firms is governed by the location of consumers. Specifically, the equilibrium wage is determined by a bidding process in which potential firms compete for workers by offering them higher and higher wages until no firm can profitably enter the market. Put simply, operating profits are completely absorbed by the wage bill. The equilibrium quantities sold are given by $q_{rr}^* = p_{rr}^* / \beta$ and $q_{rs}^* = (p_{rs}^* - \tau) / \beta$. Plugging the equilibrium prices and quantities into π_r and solving for w_r give the equilibrium wage in city r :

$$w_r^* = \left[\lambda_r (p_{rr}^*)^2 + \lambda_s (p_{rs}^* - \tau)^2 \right] / \phi$$

Ottaviano and Thisse (2002) have shown that w_r^* increases (decreases) as a decreasing (increasing) rate with λ_r when ϕ is large (small) as well as when τ is small (large). In other words, the equilibrium wage rises with the size of the local

market when the labor productivity is high, shipping goods is cheap, or both. This implies that a higher wage need not be associated with a larger city. Such a result conflicts with the widespread idea that a higher employment density is associated with higher wages (Combes et al. 2008; Puga 2010): Standard estimates of the density elasticity of wages typically range from 0.02 to 0.05. However, one should keep in mind that these estimates are averages across cities. Moreover, if the existence of agglomeration economies is well documented, the literature has not succeeded yet to identify the relative importance of the channels through which they percolate.

Last, observe that the size of the product and labor markets is endogenous when consumers are mobile. Indeed, when consumers move from one city to the other, they bring with them both their production and consumption capacities. As a consequence, both the numbers of consumers and workers change.

C. The Formation of Manufacturing Clusters. The locational choice made by a consumer is driven by the indirect utility level she reaches in a city:

$$V_r(L_r) = CS_r + w_r^* - UC_r + q_0^* \quad (29.8)$$

where CS_r is the consumer surplus evaluated at the equilibrium prices and q_0^* is the equilibrium consumption of the numéraire. Hence, when choosing the city where she lives, a consumer takes into account the income she earns, the level of urban costs she bears, and the consumer surplus she enjoys in the city. Thus, though the individual demands Eq. (29.4) are unaffected by income, the migration decision takes income into account. Everything else equal, workers are pulled by the higher wage region. The population becoming larger, the local demand for the manufactured good is raised, which attracts additional firms.

Although the present framework differs from Krugman's (1991), it captures the same effects. It also encapsulates the following fundamental trade-off, which is absent in Krugman: Concentrating people and firms in a small number of large cities minimizes the cost of shipping commodities among urban areas but makes work trips (as well as many other within-city trips) longer; when dispersion prevails, consumers bear lower commuting costs but goods are more expensive because each city produces a small number of varieties and shipping them to the other cities is costly. Thus, both configurations give rise to specific spatial costs.

The economy is in equilibrium when no consumer has an incentive to change place. Denoting by λ the endogenous share of consumers residing in city *A*, a *spatial equilibrium* arises at $1/2 \leq \lambda^* < 1$ when the utility differential $\Delta V(\lambda^*) \equiv V_A(\lambda^*) - V_B(\lambda^*) = 0$. When $\Delta V(1) \geq 0$, $\lambda^* = 1$, and thus, all consumers and firms are set up in city *A*. Thus, location choices exhibit strategic complementarity (substitutability) when the $\Delta V(\lambda)$ is increasing (decreasing). NEG models typically display several spatial equilibria. In such a context, it is convenient to use stability as a selection device since an unstable equilibrium is unlikely to happen. An interior equilibrium is *stable* if, for any marginal deviation away from the equilibrium, the incentive system provided by the market brings the distribution of consumers back to the original one. This is so if and only if the slope

of the utility differential ΔV is strictly negative at λ^* . By contrast, an agglomerated equilibrium is stable whenever it exists.

Replacing each term of V_r by its expression leads to the following utility differential:

$$\Delta V(\lambda) = - \left[\frac{t}{\delta} - \frac{A(\tau)}{\phi} \right] \left(\lambda - \frac{1}{2} \right) \quad (29.9)$$

where

$$A(\tau) \equiv \frac{\tau[4\beta(3\beta + 2) - (6\beta^2 + 6\beta + 1)\tau]}{2\beta(2\beta + 1)^2}$$

with $A(\tau) > 0$ because τ is smaller than τ_{trade} .

It follows immediately from Eq. (29.9) that $\lambda = 1/2$ is always a spatial equilibrium. This equilibrium is stable when t exceeds $\delta A(\tau)/\phi$. Otherwise, the manufacturing sector is concentrated into a single city. As a result, *when commuting costs steadily decrease, there is a transition from dispersion to agglomeration*. The intuition behind this result is straightforward. When t is large, urban costs are sufficiently high to prevent the emergence of a big city. By contrast, there is agglomeration when t is small because the gains from variety overcome the land market crowding effect. Note also that increasing the population density δ amounts to decreasing the level of commuting costs. Hence, a high population density, a high labor productivity, or both makes agglomeration more likely. This is because a larger city allows individuals to consume a wider range of varieties priced at a lower level.

Finally, note that the catastrophic nature of the bifurcation obtained both here and in Krugman (1991) is an artifact due to the assumption of identical consumers. Once it is recognized that consumers are heterogeneous in their migration behavior, the transition becomes smooth (Tabuchi and Thisse 2002). Therefore, the interest generated by the result of sudden urbanization is unwarranted.

Though very simple, the above model allows understanding the role played by commuting costs in shaping the space economy. Consumers having a love for variety, they are attracted by the city supplying the wider range of local varieties, which are cheaper to buy than the imported varieties. By moving to this city, consumers increase the size of the local market, which makes local competition tougher. However, migration flows crowd out the land market and raise the urban costs borne by consumers residing in this city. Eventually, market clearing and labor mobility balance these various forces and select a spatial pattern involving either two small cities or one large city.

Note the difference with Krugman (1991): Here low transport costs are associated with the dispersion of activities. Indeed, when τ is very small, we have $A(\tau) \approx 0$, which implies $\delta A(\tau) - t\phi < 0$. Consequently, firms and consumers are located in two small cities. This is because consumers have more or less the same access to the whole range of varieties but obviate paying high urban costs through dispersion. This means that lowering transport costs induces the (partial)

de-industrialization of large manufacturing cities and the relocation of manufactures in small cities or even in rural areas.

On the contrary, when τ is large and slightly smaller than τ_{trade} , $A(\tau)$ takes on its largest value so that $\delta A(\tau)/\phi$ is more likely to exceed t . Indeed, when transport costs are high, the agglomeration of the manufacturing sector allows consumers to have direct access to all varieties at a low price while firms are able to better exploit scale economies. In other words, high transport costs are likely to be associated with the agglomeration of activities.

To sum up, a drop in the cost of shipping commodities fosters the spatial decentralization of jobs and production: *Krugman's prediction is thus reversed*. This difference in results is simple to explain. In the above model, urban costs rise when consumers join the larger city, which strengthens the dispersion force. Simultaneously, lowering transport costs facilitates intercity trade. Combining the two forces tells us why dispersion arises. By contrast, in the core-periphery model developed by Krugman (1991), the spatial concentration of workers does not generate any cost in the core. Furthermore, the dispersion force stems from immobile farmers who live in what becomes the periphery. This force gets weaker when farmers can be supplied at a lower cost. Consequently, manufacturing firms choose to locate in the same region to benefit from a larger market. Krugman's conclusions thus hold in our setting provided that commuting costs are low and a sufficiently large share of consumers is immobile.

D. The Bell-Shaped Curve of Spatial Development. The above analysis suggests that the way the space economy is organized depends on the interplay between transport and commuting costs. Historically, it is well known that both costs have fallen at an unprecedented pace (Bairoch 1985). Therefore, what matters is the relative evolution of these two types of costs. For a long time, high transport costs have been the main impediment to trade. Even though the report of the "death of distance" is premature, it is clear that, within developed countries, the cost of shipping commodities has reached today a level which is much lower than commuting costs, which remain relatively high. As a consequence, the main dispersion force no longer lies in the cost of supplying distant markets, but in the level of urban costs. Under these circumstances, we may speculate that, though economic integration has initially fostered a more intensive agglomeration of economic activities, its continuation is liable to generate a redeployment of activities that could lead to a kind of geographical evening out. In short, one may expect the process of spatial development to unfold according to a *bell-shaped curve*.

To be precise, agglomeration occurs during the second phase of the integration process. The dispersion in the first and third integration phases emerges for very different reasons. In the former phase, the manufacturing sector is dispersed because shipping its output is expensive and, in the latter phase, because the smaller city has comparative advantage in terms of urban costs. Simply put, the relationship between economic integration and spatial inequality is not monotone: *while the first stages of economic integration exacerbate regional disparities, once a certain threshold is reached, additional integration starts undoing them* (for a more detailed discussion of the bell curve, see Combes et al. 2008).

29.2.2 The Decentralization of Jobs Within Cities

As seen above, globalization could well challenge the supremacy of large cities, the reason being that the escalation of urban costs would shift employment from large monocentric cities to small cities where these costs are lower. However, this argument relies on the assumption that cities have a monocentric morphology. The main point we wish to stress here is that decentralizing the production of goods in *secondary business districts* (SBD) may allow large cities to retain a high share of firms and jobs. Under these circumstances, firms are able to pay lower wages while retaining most of the benefits generated by large urban agglomerations. For example, Timothy and Wheaton (2001) report substantial variations in wages according to intra-urban location (15 % higher in central Boston than in outlying work zones, 18 % between central Minneapolis and the fringe counties). As they enjoy living on larger plots and/or move along with firms, consumers may also want to live in suburbia. Consequently, the creation of sub-centers within a city, that is, the formation of a *polycentric city*, appears to be a natural way to alleviate the burden of urban costs. It is, therefore, no surprise that Anas et al. (1998, p. 1442) observe that “polycentricity is an increasingly prominent feature of the landscape.”

For the redeployment of activities in a polycentric pattern to happen, firms set up in SBDs must be able to maintain a good access to the main urban center, which requires low communication costs. For example, about half of the business services consumed by US firms located in suburbia are supplied in city centers. By focusing on urban and communication costs, we recognize that both agglomeration and dispersion may take two quite separate forms because they are now compounded by the *centralization* or *decentralization* of activities within the same city. Such a distinction is crucial for understanding the interactions between cities and trade.

A. Polycentric Cities. We build on Cavailhès et al. (2007) and extend the above model by allowing manufacturing firms to locate in the CBD or to form a SBD on each side of the CBD. Both the CBD and the SBDs are surrounded by residential areas occupied by consumers. Because the higher-order services are still provided in the CBD, firms established in a SBD must incur a communication cost $K > 0$ so that the profit of a firm located in a SBD is given by $\pi_r - K$ whereas π_r is the profit of a firm established in CBD. In what follows, the superscript C is used to describe variables related to the CBD, whereas S describes the variables associated with a SBD.

Denote by y_r the right endpoint of the area formed by residents working in the CBD and by z_r the right endpoint of the residential area on the right-hand side of the SBD, which is also the outer limit of city r . Let x_r^S be the center of the SBD in city r . It is easy to show that these points are given by

$$y_r = \frac{\theta_r \lambda_r}{2\delta} \quad x_r^S = \frac{(1 + \theta_r) \lambda_r}{4\delta} \quad (29.10)$$

where $\theta_r < 1$ is the share of jobs located in the city r -CBD.

At a city equilibrium, each worker maximizes her utility subject to her budget constraint, each firm maximizes its profits, and markets clear. Individuals choose their workplace (CBD or SBD) and their residential location for given land rents and wages in the CBD (w_r^C) and in the SBD (w_r^S). The wage wedge between the CBD and a SBD is given by

$$w_r^C - w_r^S = t(2y_r - x_r^S) = \frac{t}{\delta} \frac{3\theta_r - 1}{4} \lambda_r \quad (29.11)$$

where we have used the expressions for y_r and x_r^S given in Eq. (29.10). In other words, the difference in the wages paid in the CBD and in the SBD compensates exactly the worker for the difference in the corresponding commuting costs. Moreover, the wage wedge is positive as long as $\theta_r > 1/3$, that is, the size of the CBD exceeds the size of each SBD. Note also that a larger population in city r raises the wage wedge. Indeed, as the average commuting cost rises, firms located in the CBD must pay a higher wage to their workers.

Within each workplace (CBD or SBD), the equilibrium wages are determined by a bidding process in which firms compete for workers by offering them higher wages until no firm can profitably enter the market. Hence, the equilibrium wages are related through the following expressions: $w_r^{C*} = w_r^*$ and $w_r^{S*} = w_r^* - K/\phi$. Given these equilibrium wages and the location of workers, firms choose to locate either in the CBD or in a SBD. At the city equilibrium, no firm has an incentive to change place within the city and no worker wants to change her working place and/or her residence.

Substituting w_r^{C*} and w_r^{S*} into Eq. (29.11) and solving with respect to θ_r yields

$$\theta_r^* = \min \left\{ \frac{1}{3} + \frac{4\delta K}{3t\phi\lambda_r}, 1 \right\} \quad (29.12)$$

which exceeds $1/3$ as long as $K > 0$. Clearly, the city is polycentric ($\theta_r^* < 1$) if and only if

$$K < \frac{t\phi\lambda_r}{2\delta}$$

The higher the communication costs, the lower the commuting cost, or both, the larger the CBD. In the limit, both SBDs shrink smoothly and the city becomes monocentric. In contrast, a larger population fosters the emergence of a polycentric city.

B. The Emergence of Polycentric Cities. The utility differential between cities now depends on the degree of job decentralization within each city. The indirect utility of an individual working in the CBD is still given by Eq. (29.8), but the urban costs Eq. (29.6) are replaced by the following expression:

$$UC_r \equiv \frac{t\lambda_r}{2\delta} \theta_r^*$$

Everything else equal, urban costs take on lower values when jobs are decentralized into the SBDs. As a consequence, the existence of SBDs allows the large cities to maintain their primacy.

The utility differential Eq. (29.9) becomes

$$\Delta V(\lambda) = - \left[\frac{t}{3\delta} - \frac{A(\tau)}{\phi} \right] \left(\lambda - \frac{1}{2} \right)$$

when both cities are polycentric and

$$\Delta V(\lambda) \equiv -2 \left[\frac{2t}{3\delta} - \frac{A(\tau)}{\phi} \right] \lambda + \left[\frac{t}{\delta} - \frac{A(\tau)}{\phi} - \frac{4K}{3} \right]$$

when only one city is polycentric ($\theta_1^* < \theta_2^* = 1$).

Unlike standard models but as in Cavailhès et al. (2007), the economy displays a richer set of stable equilibrium configurations: (i) dispersion with two identical monocentric cities, (ii) agglomeration within a single monocentric city, (iii) partial agglomeration with one large polycentric city and a small monocentric city, (iv) agglomeration within a single polycentric city, and (v) dispersion with two identical polycentric cities. Once communication costs are low enough, the economy traces out the following path when the ratio t/δ steadily decreases. By inducing high urban costs, a high t/δ -ratio leads to the dispersion and decentralization of jobs, that is, the economy involves two polycentric cities. When δ gets higher or t lower, urban costs decrease sufficiently for the centralization of jobs within one city to emerge at the market outcome. However, urban costs remain high enough for the equilibrium to involve two cities having different sizes and structures. Last, when the t/δ -ratio takes on very low values, urban costs become almost negligible, which allow saving the cost of shipping the manufactured good through the existence of a single city.

The multiplicity of stable equilibria has also an important implication that has been overlooked in the literature: *different types of spatial patterns may coexist under identical technological and economic conditions*. It should be no surprise, therefore, to observe different types of urban systems in the real world.

29.3 Cities and Services

In Sect. 29.2, as in most NEG models, consumers have access to the entire range of produced varieties. As observed by Handbury and Weinstein (2011), residents of larger cities have, *ceteris paribus*, access to more varieties than residents of smaller cities. The rising share of nontradable consumption services explains, to some extent, this fact. What distinguishes service cities from the manufacturing cities is that the cost of shipping local services are prohibitive. Consequently, consumers have access only to the varieties produced in the city in which they live.

29.3.1 Cities as Local Service Providers

To start with, we consider a setting with no manufacturing sector and focus on the impact of commuting costs on the spatial distribution of nonhousing services. The circumstances in which one large city or two small cities emerge are the issue discussed in this section.

Consumer preferences are given by Eq. (29.2), except that the set of available varieties in city r is now given by n_r instead of n . The profits earned by a city r -firm are given by

$$\pi_r = p_r q_r (p_r)^{\lambda_r} - w_r \phi$$

Because service firms compete only on their local market, the equilibrium price of a city r -variety is obtained by setting $\lambda_s = 0$ in Eq. (29.7):

$$p_r^* = \frac{\beta}{2\beta - 1} \equiv \mathbf{p} \quad (29.13)$$

which is the same in the two cities. Observe that a stronger love for variety yields a higher market price because service firms have more market power.

The consumer surplus generated by a single variety is equal to $S = (1 - \mathbf{p})^2 / \beta$, which is independent of the city size. Because the value of S does not play any role in the analysis undertaken here, we set $S = 1$. As for the total surplus, it is equal to the number $n_r = \lambda_r / \phi$ of locally produced varieties, which increases with both the city size and the labor productivity. Put simply, *consumers living in larger cities have access to more nontradable services*.

The urban labor markets being local, the equilibrium wage paid by firms established in city r is equal to

$$w_r^* = \mathbf{p}^2 \lambda_r / \phi$$

In other words, wages are higher in larger cities because the local market is bigger. Observe that this correlation does not reflect a difference in well-being. As expected, w_r^* also increases when workers are more productive because more firms compete on urban labor markets.

Replacing each term of V_r by its expression leads to the following utility differential:

$$\Delta V(\lambda) = - \left[\frac{t}{\delta} - \frac{2(1 + \mathbf{p}^2)}{\phi} \right] \left(\lambda - \frac{1}{2} \right)$$

As in Sect. 29.2.1, the symmetric pattern ($\lambda^* = 1/2$) is always a spatial equilibrium. However, when $t/\delta < 2(1 + \mathbf{p}^2)/\phi$, this equilibrium is unstable because the utility differential is positive for all values of λ . The market outcome therefore involves a single large city accommodating all consumers ($\lambda^* = 1$). Thus, *even in the absence of trade, consumers and firms may choose to be agglomerated within a single large city*. This is so when (i) commuting costs are low, (ii) the population density is high, and (iii) the array of local services is wide. The intuition is fairly

straightforward. By being agglomerated in a single city, consumers have access to all varieties. Furthermore, low fixed costs favor the entry of additional firms, which widens the range of varieties and increases consumers' utility who have a love for variety. As a consequence, the emergence of a large city is more likely to occur when the service sector is able to provide a larger number of differentiated varieties. Hence, labor-saving innovations such as the development of new information and communication technologies pushes toward the concentration of services in large cities.

By contrast, when $t/\delta > 2(1 + \mathbf{p}^2)/\phi$, the symmetric equilibrium is stable. This is because the gains from variety do not compensate consumers for the higher urban costs they would bear in the large city. In this case, instead of seeking variety, consumers aim to reduce urban costs, and thus, the population is equally dispersed between the two cities. Dispersion may even take the concrete form of a larger number of smaller cities, which are determined by the trade-off between urban costs and the gains from variety. To sum up, when commuting costs steadily decrease, a service economy shifts from dispersion to agglomeration because the latter allows individuals to consume more services and to earn higher wages.

29.3.2 The Size and Industrial Structure of Cities

We now take a broader perspective by considering a two-sector economy in which labor is perfectly mobile between locations *and* sectors. The objective is to determine the interindustry distribution of consumers as well as their residential location between and within cities.

The economy involves a manufacturing sector supplying a freely tradable good ($\tau = 0$) and another sector producing a nontradable service (other than land) for local consumption. Focusing on such an industrial mix allows revisiting the export base theory grounded in the assumption that the urban economy can be divided into two very broad sectors, that is, a basic sector whose fortunes depend largely in external factors and a nonbasic sector which depends on local factors. The tenet of this theory holds that the basic sector is the prime cause of local economic growth (Tiebout 1956).

A. The Export Base Theory Revisited. The manufactured good is denoted by 1 and the nonhousing service by 2. The utility derived from consuming q_i units of a variety i of good $j = 1, 2$ is given by Eq. (29.1). In other words, the parameters associated with the utility arising from consuming one variety of the manufactured product or of the consumption service are identical. This assumption does not affect qualitatively the properties of the spatial equilibria. Indeed, because good 1-varieties are available everywhere at the same price, the consumer surplus generated by the consumption of the manufactured good is the same regardless of the city in which consumers live. Furthermore, the profits earned by the manufacturing firms are the same regardless of the city in which they are located. Thus, the equilibrium values of the consumer surplus and wage associated with

good 1 do not play any role in workers' decision to move. As a consequence, assuming that the parameters of Eq. (29.1) are the same for goods 1 and 2 entails no loss of generality for the determination of the sectoral and spatial structure of the economy.

Preferences now involve two nonhousing goods and are given by

$$U(q_0; q_{ij}) = \sum_{j=1,2} \left[\int_0^{n_j} q_{ij} di - \frac{\beta n_j}{2(n_1 + n_2)} \int_0^{n_j} q_{ij}^2 di \right. \\ \left. - \frac{1}{2(n_1 + n_2)} \int_0^{n_j} q_{ij} \left(\int_0^{n_j} q_{kj} dk \right) di \right] + q_0 \quad (29.14)$$

where q_{ij} is the quantity of variety $i \in [0, n_j]$ of good $j = 1, 2$. Because good 1 is tradable, the total number n_1 of good 1-varieties is available in both cities, whereas n_2 is the number of good 2-varieties supplied in the city where the consumer lives. Consumers having a love for variety may vary between goods and services; the second term of Eq. (29.14) is weighted by the ratio $n_j/(n_1 + n_2)$. This captures the idea that a good supplied as a small range of varieties has more impact on the consumer's well-being than a good made available through a large array of varieties. Note that the following analysis can be extended to cope with different attitudes toward variety by assuming that $\beta_1 \neq \beta_2$.

Let λ_{ir} be the number of consumers working in sector $i = 1, 2$ and living city $r = A, B$. Labor being mobile between cities and sectors, the variables λ_{ir} are endogenous and determined in equilibrium. Labor market clearing implies

$$n_1 = \frac{\lambda_{1A} + \lambda_{1B}}{\phi_1} \quad n_{2r} = \frac{\lambda_{2r}}{\phi_2} \quad (29.15)$$

Labor being mobile between sectors, in equilibrium, it must be that $w_r = w_{1r} = w_{2r}$. Letting $\lambda_r = \lambda_{1r} + \lambda_{2r}$ be the population residing in city r , the budget constraint of a consumer residing in city r may be written as follows:

$$n_1 p_1 q_{1r} + n_{2r} p_{2r} q_{2r} + \frac{t}{\delta} \frac{\lambda_r}{2} + q_0 = \bar{q}_0 + w_r$$

where p_1 is the common price of a good 1-variety, p_{2r} the consumer price of a good 2-variety in city r , and q_0 the consumption of the numéraire.

It is readily verified that the individual demand for a good i -variety in city r is given by

$$q_{1r} = \left(\frac{1}{1 + \beta} - \frac{p_1}{\beta} + \frac{\bar{p}_1}{\beta(\beta + 1)} \right) \left(1 + \frac{n_{2r}}{n_1} \right) \quad (29.16)$$

$$q_{2r} = \left(\frac{1}{1 + \beta} - \frac{p_{2r}}{\beta} + \frac{\bar{p}_{2r}}{\beta(\beta + 1)} \right) \left(1 + \frac{n_1}{n_{2r}} \right) \quad (29.17)$$

Whereas the average price \bar{p}_1 is defined over the entire range of good 1-varieties because good 1 is tradable, \bar{p}_{2r} is defined only over the range of good 2-varieties produced in city r . Although this demand system involves no income effect, it displays a rich pattern of substitution via the relative number of varieties. Specifically, when the number of good i -varieties available in city r increases, the individual demands for good j -varieties are shifted upward because good j becomes relatively more attractive. In particular, the size and distribution of the service sector (n_{2r}) affects individual demands for the manufactured good in each city (see Eq. (29.17)). Unlike the export base theory which maintains that the industries producing tradable goods are the economic base of the urban economy, the model used here shows that *a growing service sector impacts positively on the local demand for the tradable good*.

Likewise, the size of the manufacturing sector (n_1) affects the individual demand for services in each city and, therefore, the spatial distribution of this sector. In contrast, the distribution of manufacturing firms has no direct impact on individual demands for good 1 because trading this good is costless. This suggests that manufacturing firms are indifferent between locations. But they are not because their workers are attracted by cities supplying a wide range of services.

Let

$$\pi_{1r} \equiv p_1[q_{1A}(p_1)\lambda_A + q_{1B}(p_1)\lambda_B] - \phi_1 w_r$$

be the profits earned by a manufacturing firm established in city r . As in Sect. 29.2.1, when choosing its own price, each firm treats parametrically the wage w_r as well as the average prices \bar{p}_{1A} and \bar{p}_{1B} . Setting $\tau = 0$ in Eq. (29.7) yields the equilibrium price of good 1, which is constant and the same in both cities: $p_1^* = \mathbf{p}$. When they are not agglomerated, manufacturing firms therefore make the same operating profits in both cities. This implies that they pay the same wage w_1^* to their workers. As a consequence, there is factor price equalization: $w_1^* = w_{1r}^* = w_{2r}^*$. In this event, the urban cost differential is exactly compensated by the difference in the number of nontradable services supplied in each city. Simply put, *consumers choose to live in a larger city where they bear higher urban costs because they have access to a wider array of local services*. Profits being zero in equilibrium, the wage paid by a manufacturing firm is equal to

$$w_1^* = \mathbf{p}^2 \sum_{r=A,B} \frac{n_r \lambda_r}{n_1 \phi_1} \tag{29.18}$$

where $n_r = n_1 + n_{2r}$.

The profits made by a service firm set up in city r are given by

$$\pi_{2r} = p_{2r} q_{2r} \lambda_r - \phi_2 w_{2r}$$

where p_{2r} is the price quoted by such a firm. Because substitution effects go through the numbers of varieties only, the equilibrium price of a good 2-variety is given by

Eq. (29.13). This in turn implies that the equilibrium wage paid by the service firms located in city r is

$$w_{2r}^* = \mathbf{p}^2 \frac{n_r \lambda_r}{n_{2r} \phi_2} \tag{29.19}$$

which varies with the size (λ_r) and the sectoral mix (n_r/n_{2r}) of the city. Note that the service sector is never agglomerated. Otherwise, w_{2r}^* becomes arbitrarily large when there is no service firms in city r ($n_{2r} = 0$).

Since $S = 1$, the welfare of a consumer working in sector i and living in city r is given by

$$V_{ir} = n_1 + n_{2r} + w_r^* - \frac{t}{\delta} \frac{\lambda_r}{2}$$

This shows how consumers' well-being depends on the spatial and sectoral distribution of jobs.

B. Urban Hierarchy. A *spatial-sectoral equilibrium* arises when no worker has an incentive to change place and/or to switch job. The stability of such an equilibrium is studied by using the myopic evolutionary dynamics (Fujita et al. 1999):

$$\dot{\lambda}_{ir} = \lambda_{ir}(V_{ir} - \bar{V}) \tag{29.20}$$

where $\bar{V} = \sum_i \sum_r V_{ir}$ is the average utility in the entire economy. Note that in Eq. (29.20), the choices of jobs and locations are treated in a symmetric way.

In what follows, we focus on the case in which the manufacturing sector is not fully agglomerated ($0 < \lambda_{1r}^* < 1$). In this event, we have $w_1^* = w_{2r}^*$. Using $p_1^* = p_2^* = \mathbf{p}$, the wage equality implies that $\sum_r n_{2r} \phi_2 = n_1^* \phi_1$. As a consequence, the labor force is equally split between the two sectors ($\lambda_1^* = \lambda_2^* = 1/2$).

The utility differential is now given by

$$V_{ir} - \bar{V} = \frac{2\delta - \phi_2 t}{\phi_2 \delta} \left(\lambda_{2r} - \frac{1}{4} \right) \lambda_s - \frac{t}{\delta} \left(\lambda_{1r} - \frac{1}{4} \right) \lambda_s \tag{29.21}$$

where λ_s is the city s -population (recall that w_{ir}^* is equal to the average wage). Solving the system Eq. (29.21) shows that there are two candidate equilibria (up to a permutation between A and B):

$$\lambda_{1A}^* = \lambda_{2A}^* = 1/4 \tag{29.22}$$

and

$$\lambda_{1A}^* = \frac{1}{4} + \frac{(2\delta - \phi_2 t)\sqrt{\Delta}}{4\phi_1 \phi_2 t} \quad \lambda_{2A}^* = \frac{1}{4} + \frac{\sqrt{\Delta}}{4\phi_1} \tag{29.23}$$

where

$$\Delta \equiv \phi_1^2 + 2\phi_1 \phi_2 - 2\phi_1 \phi_2^2 t / \delta$$

In both configurations, the total number of good i -varieties is given by $n_i^* = 1/2\phi_i$, and thus, the industrial mix $n_1^*/n_2^* = \phi_2/\phi_1$ in the global economy depends on the relative productivity of labor in the two sectors. By contrast, when the asymmetric configuration prevails, *cities differ not only in size but also in industrial structures*.

As in Sect. 29.2, the symmetric pattern Eq. (29.22), which involves two cities having the same size and the same industrial mix, is always a spatial-sectoral equilibrium. On the other hand, the asymmetric configuration Eq. (29.23) is a (stable) equilibrium if and only if $\Delta > 0$, that is,

$$\frac{t}{\delta} < \frac{\phi_1}{2\phi_2^2} + \frac{1}{\phi_2}$$

In other words, commuting costs (population density) must be sufficiently low (high) for a large city (A) and a small city (B) to coexist. Moreover,

$$\lambda_A^* - \lambda_B^* = \frac{\delta\sqrt{\Delta}}{\phi_1\phi_2 t} \geq 0$$

implies that a lower t or a higher δ gradually enlarges the population gap between the two cities. Though workers are identical, there is no catastrophic bifurcation: Small changes in commuting costs generate small changes in the location *and* the composition of economic activities. In other words, accounting for the possibility of changing jobs smooths out the process of migration.

A few remarks are in order. First, the existence of a nontradable service selects a well-defined distribution of the footloose industry 1. More precisely, except for fairly high commuting costs, the nontradable sector acts as a centripetal force that results in the (partial) agglomeration of the manufacturing sector. Second, as long as $t < 2\delta/\phi_2$ holds, the larger city supplies a wider array of varieties of each good than the smaller city ($\lambda_{1A}^* > 1/4 > \lambda_{1B}^*$ and $\lambda_{2A}^* > 1/4 > \lambda_{2B}^*$). In this case, the urban system displays a Christaller-like *hierarchy*: By supplying a larger array of services, city A attracts more consumers than city B . Though the demand for the manufactured good is higher therein (see Eq. (29.16)), this does not attract more manufactured workers because this good is shipped at zero cost. Thus, the process of circular causation comes to an end. Note, however, that the population gap between the two cities grows when the service sector becomes more productive.

Third, when $t > 2\delta/\phi_2$ holds, the larger city has a larger labor share in the service sector, whereas the smaller city has a larger labor share in the manufacturing sector:

$$\frac{\lambda_{1B}^*}{\lambda_B^*} > \frac{1}{2} > \frac{\lambda_{1A}^*}{\lambda_A^*} \quad \frac{\lambda_{2A}^*}{\lambda_A^*} > \frac{1}{2} > \frac{\lambda_{2B}^*}{\lambda_B^*}$$

In this event, the urban system involves *diversified but relatively specialized cities*. This is because the size advantage associated with the larger city no longer

compensates enough manufacturing workers for the higher urban costs they would bear there. This result is consistent with Ricardo's comparative advantage theory: The larger city has a comparative advantage in nontradables because it has a larger local market; the smaller city's comparative advantage is its lower level of urban costs. Note that a city's comparative advantage is not given; it emerges from market interactions and labor mobility.

Fourth, and last, the export base theory predicts that an increase in the local size of the basic sector induces a more than proportionate increase in the city size. It is readily verified that the equilibrium condition $V_{iA}^* = V_{iB}^*$ yields

$$\lambda_A^* = \frac{1}{2} \frac{\delta - \phi_2 t}{2\delta - \phi_2 t} + \frac{2\delta}{2\delta - \phi_2 t} \lambda_{1A}^*$$

where $2\delta/(2\delta - t\phi_2) > 1$ is the "regional multiplier." Hence, a shock that makes the basic sector larger (λ_{1A}^*) boosts a more than proportionate growth of the city size (λ_A^*) by attracting more services. However, a larger nonbasic sector also leads to the expansion of the basic sector, which means that the nonbasic sector can be an engine for urban growth.

Observe that the impact of the nonbasic sector on total employment is higher in the larger city because the service sector is relatively more concentrated in city *A* than in city *B* when $t/\delta < 1/\phi_2$. Indeed, $V_{iA} = V_{iB}$ implies that

$$\lambda_A^* = \frac{\phi_2 t - \delta}{2\phi_2 t} + \frac{2\delta}{t\phi_2} \lambda_{2A}^*$$

so that the regional multiplier of the nonbasic sector exceeds of the regional multiplier of the basic sector when $t/\delta < 1/\phi_2$, an inequality which is more likely to hold when the productivity in the nonbasic sector is high.

29.4 The Future of Cities

One may wonder how the kind of approach surveyed in the foregoing sections may help understand some of the main challenges faced by cities in the twenty-first century. In what follows, we consider two different issues which have important policy implications: (i) the growing share of retirees in developed countries, whose income does not come from labor, and (ii) the environmental impact of the rapid urbanization in emerging countries like China and India.

29.4.1 Cities in Aging Nations

The old-age dependency ratio (the ratio people aged 65 and older to people aged 15 to 64) is projected to double by 2050 within the European Union, with four persons

of working age for every elderly citizen to only two. This ratio is expected to be lower in the United States, with a rise from 19 to 32 %, but higher in Japan, with a rise from 25 in 2000 to 72 % in 2050. Such demographic changes are likely to have a major impact on cities because the retirees are driven by location factors that differ from those governing workers' residential choices. Workers' welfare depends on local services, land rent, and wages, whereas rentiers' welfare depends only upon local services/amenities and land rent. As a consequence, when the share of old people takes on a sufficiently high value, the process of circular causation *à la* Myrdal sparked by workers' location choice could well be challenged.

To study how the urban system might change as the old-age dependency ratio rises, we consider the model of Sect. 29.3.2 in which the population is split between two groups of consumers, that is, the *elderly* and the *workers* whose respective numbers are $\rho \geq 0$ and $1 - \rho \geq 0$. City *B* is endowed with an amenity $a > 0$, which is valued only by the elderly. We close the model by assuming that land is collectively owned by the elderly. The income of a retiree is, therefore, given by the aggregate land rent (*ALR*) divided by the total number of elderly (ρ). Workers and retirees have different unit commuting costs, t and θ , respectively. We assume $\theta > t$. The case where $t > \theta$ leads to more cumbersome expressions which do not affect the nature of our main results. What matters for our purpose is that a city's urban costs increase with the number of retirees residing there.

Let s_r be the share of elderly people living in city $r = A, B$. City r -population is then given by $\lambda_r = (\lambda_{1r} + \lambda_{2r})(1 - \rho) + s_r \rho$. Besides λ_{1r} and λ_{2r} , we have to determine s_r . If the elderly are those living close to the CBD, workers' urban costs borne are now as follows:

$$UC_r = t \frac{(\lambda_{1r} + \lambda_{2r})(1 - \rho) + s_r \rho}{2\delta}$$

which is equal to Eq. (29.6) when $\rho = 0$. It thus varies with the distribution of activities as well as with the way the retirees distribute themselves between the two cities.

Because of the asymmetry in the amenity supply, the elderly's equilibrium condition is given by $V_A^o - V_B^o = a$ with $V_r^o = n_1 + n_{2r} + ALR/\rho - UC_r^o$. The urban costs UC_r^o borne by the retirees are given by

$$UC_r^o = \theta \frac{s_r \rho}{2} + t \frac{(\lambda_{1r} + \lambda_{2r})(1 - \rho)}{2}$$

The equilibrium distribution of the elderly between cities is the same regardless of the spatial and sectoral allocation of workers:

$$s_B^* = \frac{1}{2} + \frac{a}{\rho(\theta - t)} \tag{29.24}$$

As expected, more elderly choose to live in the city endowed with the amenity advantage than in the working city. A larger share of elderly in the economy

increases the number ρs_B^* of old people living in city *B*. Likewise, the number of old people residing in city *A* increases, thus meaning that *the population of both cities gets older*.

When the share of the elderly people in the economy is not too high, the economy displays two stable equilibria. In the former one, the mobility of the elderly does not jeopardize the existing urban hierarchy, whereas it does in the latter one (Gaigné and Thisse 2009). This could explain why there are contradicting opinions regarding the evolution of urban systems in aging nations. The equilibrium in which the working city remains the primate city, while the other city accommodates the larger share of retirees, is the one that agrees with current empirical evidence (Chen and Rosenthal 2008). The corresponding equilibrium distribution of workers between sectors and cities is as follows:

$$\lambda_{1A}^* = \frac{1}{4} + \frac{(2 - t\phi_2)\sqrt{\Delta_a}}{4t\phi_1\phi_2} + \frac{a}{(1 - \rho)(\theta - t)} \quad \lambda_{2A}^* = \frac{1}{4} + \frac{\sqrt{\Delta_a}}{4\phi_1} \quad (29.25)$$

where

$$\Delta_a \equiv \phi_1(\phi_1 + 2\phi_2) - \frac{2t\phi_1\phi_2^2}{1 - \rho} < \Delta$$

Note that Eq. (29.25) boils down to Eq. (29.23) when $\rho = a = 0$.

Thus, *workers and retirees are not attracted by the same city*. Moreover, as shown by Eqs. (29.24) and (29.25), when city *B*'s local government improves its amenity supply, city *B* attracts a growing number of retirees, whereas the number of jobs in the working city rises. This provides a rationale for recent empirical evidence, which suggests that retirees and workers tend to live separately as the old-age dependency ratio increases.

Moreover, an aging population (a higher ρ) induces the dispersion of services at the expense of the working city while its effect on the manufacturing sector is ambiguous. In other words, an increasing share of retirees may challenge the performance of the working city. As a result, if the agglomeration of manufactures and services generates benefits not taken into account in the model, the economy will incur efficiency losses. In addition, employment in the working city decreases because the elderly city attracts more services. However, beyond some limit, the migration of retirees toward the amenity city raises the level of urban costs and/or decreases the supply of local services. This restores, to some extent, the attractiveness of the working city. Nevertheless, this need not be true for the services which still benefit from a big market in the elderly city. Regardless of old-age dependency ratio, the working city remains the larger one ($\lambda_A^* > \lambda_B^*$).

To sum up, though in an aging nation the relocation of consumption services weakens the supremacy of the working cities, these ones maintain their primacy. Indeed, as long as it is more profitable for the bulk of manufactures to congregate, a large share of services is prompted to set up therein. In addition, as the population gets older, cities diverge in their job and demographic structures. Yet, the supply of consumption services should prevent the complete spatial separation of workers and retirees.

29.4.2 Are Compact Cities Ecologically Desirable?

The transport sector is a large and growing emitter of greenhouse gases (GHG). It accounts for 30 % of total GHG emissions in the United States and approximately 20 % of GHG emissions in the EU-15. Moreover, road-based transport accounts for a very large share of GHG emissions generated by the transport sector. For example, in the US, nearly 60 % of GHG emissions stem from gasoline consumption for private vehicle use, while a share of 20 % is attributed to freight trucks, with an increase of 75 % from 1990 to 2006. Although new technological solutions will improve energy efficiency, other initiatives are needed, such as mitigation policies based on the reduction of average distances traveled by commodities and people.

A. The Ecological Trade-Off Between Commuting and Shipping Costs. We have seen that transporting people and commodities involves economic costs. It also implied ecological costs that obey the fundamental trade-off of Sect. 29.2.1: The agglomeration of firms and people in a few large cities minimizes the emissions of GHG stemming from shipping commodities, but increases those generated by longer commuting; dispersing people and firms across numerous small cities has the opposite costs and benefits. If cities are more compact (i.e., a higher population density δ), then, keeping population and firms fixed, the costs associated with the former spatial configuration (concentration) fall relative to those associated with the latter (dispersion) because people commute over shorter distances. However, when one recognizes that firms and people choose their location in order to maximize profits and utility, a policy that aims to make cities more compact will affect the intercity pattern of activities by fostering their progressive agglomeration, thus raising the level of GHG within fewer and larger cities. Therefore, the ecological effects of an increasing-density policy are a priori ambiguous (Gagné et al. 2012).

To illustrate how this trade-off operates, we consider the model of Sect. 29.2.1 and assume that the carbon footprint E of the urban system stems from the total distance traveled by commuters within cities (C) and the total quantity of the manufactured good shipped between cities (T):

$$E = e_C C + e_T T$$

where e_C is the amount of GHG generated by one unit of distance traveled by a consumer, while shipping one unit of the manufactured good between cities generates e_T units of carbon dioxides.

Because consumers are symmetrically distributed on each side of the CBD, the value of C depends on the intercity distribution of the manufacturing sector and is given by

$$C = \frac{1}{4\delta} (\lambda_r^2 + \lambda_s^2)$$

Clearly, the emission of GHG stemming from commuting increases is minimized when the manufacturing sector is evenly dispersed between two cities ($\lambda_r = \lambda_s = 1/2$).

Regarding the value of T , it is given by the sum of equilibrium trade flows:

$$T = \frac{\phi[4\beta - (4\beta + 1)\tau]}{2(2\beta + 1)\beta} \lambda_r \lambda_s$$

where $T > 0$ because $\tau < \tau_{trade}$. As expected, T is minimized when consumers and firms are agglomerated within a single city ($\lambda_r = 0$ or 1). Note also that T increases when shipping goods becomes cheaper because there is more intercity trade. Hence, transportation policies that foster lower shipping costs give rise to a larger emission of GHG.

Thus, E is described by a concave or convex parabola in λ , so that the emission of GHG is minimized either at $\lambda = 1$ or at $\lambda = 1/2$. Therefore, it is sufficient to evaluate the sign of $E(1; \delta) - E(1/2; \delta)$, which is negative if and only if $\delta > \delta_e$ where

$$\delta_e \equiv \frac{e_C}{e_T} \frac{(2\beta + 1)\beta}{\phi[4\beta - (4\beta + 1)\tau]}$$

As a consequence, the agglomeration of activities within a single city is ecologically desirable if and only if $\delta > \delta_e$. Otherwise, dispersion is the best ecological outcome. As a consequence, *agglomeration or dispersion is not by itself the most preferable pattern from the ecological point of view*. Contrary to general beliefs, large compact cities need not imply low levels of pollution. For agglomeration to be ecologically desirable, the population density must be sufficiently high for the average commuting distance to be small enough.

B. Does the Market Yield a Good, or a Bad, Ecological Outcome? As seen in Sect. 29.2.1, $\lambda = 1/2$ is a stable equilibrium if δ is smaller than $\delta_m \equiv \phi t / (\tau)$. Otherwise, the manufacturing sector is concentrated into a single city. Because $\delta_m = 0$ at $t = 0$ and increases with t , while δ_e is independent of t , the two curves δ_m and δ_e intersect once. As a result, *the market yields either the best or the worst ecological outcome*.

Specifically, there exists a unique value \bar{t} such that $\delta_m = \delta_e$. Consider, first, the case where t exceeds \bar{t} . If $\delta < \delta_m$, the market outcome involves two cities. Keeping this configuration unchanged, a more compact city (i.e., a higher δ) always reduces the emissions of pollutants. Once δ exceeds δ_m , the economy gets agglomerated, thus leading to a downward jump in the GHG emissions. Further increases in δ allow for lower emissions of GHG. Hence, when commuting costs are high, a denser city always yields lower emissions of GHG. Assume now that $t < \bar{t}$. As in the foregoing, provided that $\delta < \delta_m$, the market outcome involves dispersion while the pollution level decreases when the city gets more compact. When δ crosses δ_m from below, the pollution now displays an upward jump. In other words, when commuting costs are low, *more compact cities need not be ecologically desirable*.

Consequently, once it is recognized that consumers and firms are mobile, what matters for the total emission of GHG is the mix between city compactness (δ) and city size (λ), thus pointing to the need of coordinating environmental policies at the local and global levels. In other words, environmental policies must focus on the urban system as a whole and not on individual cities.

When it is recognized that the internal structure of cities may change with population density (see Sect. 29.2.2), the ecological effects of an increasing-density policy are even more ambiguous: More compactness favors the centralization of jobs at the city center. Gagné et al. (2012) point out that, unless commuting to SBDs generates a massive use of private cars, compact and monocentric cities may generate more pollution than polycentric and dispersed cities. By lowering urban costs without reducing the benefits generated by large urban agglomerations, the creation of SBCs would allow large cities both reducing GHG emissions and enjoying agglomeration economies.

29.5 Conclusions

The idea of spatial interaction is central to regional science. Broadly defined, spatial interaction refers to flows across space that are subject to various types of spatial frictions, such as traded goods, migrations, capital movements, interregional grants, remittances, and the interregional transmission of knowledge and business cycle effects. Though the NEG literature has for the most part focused on the mobility of goods and production factors, these issues are at the heart of NEG. Instead of writing one more review of the vast literature produced in the footsteps of Krugman (1991), we have chosen to highlight the role that NEG may play in understanding the process of urban development. Specifically, through several major trade-offs, we have covered a range of issues that highlight the working of urban systems. To do so, we have used very simple models, which vastly contrast with the heavy mathematical apparatus employed in the literature.

To a large extent, the lack of attention paid by economists to earlier contributions in regional science is unwarranted. Regional scientists and geographers have developed several models, such as those ranging from the entropy to the gravity and logit models, which have proven to be very effective in predicting and explaining different types of flows. By ignoring this body of research, economists have sometimes rediscovered the wheel and missed the opportunity of developing much earlier a sound theory of the space economy. But equally unwarranted is the acrimony expressed by many geographers soon after the diffusion of Krugman's work: They miss the importance of working with a fully consistent microeconomic model, especially the need of using a well-defined market structure and a precise specification of the externalities at work.

Cities of the twenty-first century face new and important challenges, such as climate change, aging population, crime, poverty, social exclusion, food security, the supply and management of transportation and communication infrastructure, and competition among the few world's largest cities. It is, therefore, fundamental to have sound theoretical models which can be used as guidelines in developing empirical research and designing new policies. Is NEG a useful tool? For many important urban questions, we believe the answer is yes. From the methodological standpoint, NEG has two major merits. First, the decisions made by firms and households are based on land rents, wages, and prices, which are themselves

endogenous and related to the size and structure of cities. Second, NEG takes into account the fact that households and firms may relocate between and within cities in response to major changes in their economic environment. NEG is connected with fast-growing economic fields that provide a set of tools and concepts, which can be used to tackle new and challenging issues.

Nevertheless, NEG suffers from a major drawback, which has been brushed aside in most of the literature: It is built on a two-location setting. Yet, it is well known that a firm's location is the balance of a system of forces pulling the firm in various directions. The new fundamental ingredient that a multilocation setting brings about is that spatial frictions between any two cities are likely to be different. As a consequence, the *relative position* of a city within the whole network of interactions matters (Behrens et al. 2007). Another key insight one can derive in a multilocation economy is that any change in the underlying parameters has in general complex impacts which vary in nontrivial ways with the properties of the graph representing the spatial economy. When there are only two locations, any change in structural parameters necessarily affects directly either one of the two cities or both. On the contrary, when there are more than two locations, any change in parameters that directly involves only two cities now generates spatial spillover effects that are unlikely to leave the remaining cities unaffected. More work is called for here but one should not expect a simple answer.

Last, the literature features two distinct models of competition in space (i.e., spatial competition à la Hotelling (1929) and monopolistic competition in Krugman-like settings). Each one seems to describe competition on two different spatial scales. Indeed, the former fits well competition “in the small,” which involves shopping malls, retailers, and service providers located within the same city; the latter provides a fairly good approximation of competition “in the large,” that is, competition among producers supplying several cities and countries. A theory encompassing both settings is needed to understand better how consumer prices are formed within different urban neighborhood as well as in cities having different sizes and morphologies. The industrial organization literature on vertical relationships linking upstream (global) and downstream (local) firms through carriers is a good point where to start.

Abstract

In this chapter we first briefly discuss how the new economic geography literature (NEG) follows from and builds on international trade theory. We then turn to the main empirical implications of NEG. We highlight that the main problem

This chapter is partially based on earlier work by the authors. We do not give detailed references to our own work but readers interested in further details can consult our book on geographical economics (Brakman et al. 2009) for more extensive and detailed discussions and references, see in particular ► Chaps. 3, “Labor Market Theory and Models” and ► 8, “Land Use, Real Estate, and Housing Markets”. We also make use of Brakman and Garretsen (2009)

with empirical applications of NEG is that a single test of the implications of the model combined is illusive because of the structure of the model. As a result the main consequences of the model are usually tested separately. And some of the implications of the model are also consistent with other models. We stress, therefore, that despite a real surge in empirical NEG inspired research, the empirical evidence is still rather sketchy and also that so far NEG-based policy advice is still mostly qualitative.

30.1 Introduction

The Nobel Prize committee that awarded the Nobel Prize in economics to Paul Krugman in 2008 stressed that the award was essentially given to him for his contributions in (mainly) three papers in two disciplines: international trade and economic geography (The prize committee of the *Royal Swedish Academy of Sciences* stated in its scientific background report (p.1): “*Traditionally, trade theory and economic geography evolved as separate subfields of economics. More recently, however, they have converged [to] become more and more united through new theoretical insights, which emphasize that the same basic forces simultaneously determine specialization across countries for a given international distribution of factors of production (trade theory) and the long-run location of those factors across countries (economic geography)*”). Krugman (1979) and Krugman (1980) deal with international trade (notably intra-industry trade), whereas Krugman (1991) extends the analysis of the first two papers by endogenizing the spatial allocation of economic activity. Both contributions became workhorse models for the two disciplines: the monopolistic competition model became the standard international trade reference for models incorporating intra-industry trade and the extension of this model, by allowing for factor mobility, became the core model of new economic geography (hereafter, NEG, also known as geographical economics).

In this chapter we will highlight the main characteristics of NEG, and in doing so we will not only explain the fundamentals of NEG and trace its origins to international trade theory but also mention some of the more recent developments. Next, we will illustrate the current state of affairs with respect to the empirical evidence for NEG and, related to this, the policy consequences of the model. Three features stand out. First, the combination of increasing returns to scale, imperfect competition and transport costs gives rise to the so-called home market effect. Second, the combination of the home market effect with interregional labor mobility endogenizes the location decisions of firms and footloose workers and hence the spatial allocation of both supply and demand. This setup allows for multiple equilibria, one of which is a core-periphery equilibrium. This explains why the model has also been used in urban economics to explain, for example, a system of cities. Third, despite a large and increasing literature on empirical evidence, a convincing test of NEG is still missing. This implies that policy advice based on the model should be handled with care and so far the basic policy contributions of NEG are of a qualitative nature.

In this chapter we will focus on the three aforementioned issues. A chapter like this is too short to provide a full survey, but the key issues will be introduced and explained (For extensive surveys or introductions to new trade theory, see, for instance, Feenstra (2004). For surveys of and introductions to the new economic geography, see the general references at the end of this chapter). In essence, by discussing the three topics, we will stress the most important contributions of NEG and explain the *tug of war* between the agglomeration and spreading forces that are active in the NEG models and their potential empirical and policy implications.

30.2 Increasing Returns and Intra-industry Trade

30.2.1 Basic Ingredients of the Model

During the 1970s, it became increasingly clear that the standard workhorse models of international trade were at odds with the facts. The Heckscher-Ohlin and the Ricardian model give a rationale for interindustry trade only. Empirical research (Grubel and Lloyd 1975), however, clearly showed that trade between (developed) countries was mainly in the form of intra-industry trade. The bulk of trade is in similar goods between similar countries, a puzzling phenomenon in neoclassical trade models. The theoretical challenge was to come up with a trade model that allowed for intra-industry trade. A possible explanation should center on the role of increasing returns to scale and on an imperfect competition in market structure. In Krugman (1979), a simplified version of the monopolistic competition model, as developed by Dixit and Stiglitz (1977), is introduced (see also Dixit and Norman 1980). The Dixit-Stiglitz model provides a fruitful way to model monopolistic competition. Almost instantly it became the preferred choice of researchers to model monopolistic competition, and it has become the benchmark model in various fields (see for a survey of contributions, Brakman and Heijdra 2004). We give a simplified version of the model below (The discussion in Sect. 30.2 is based on Brakman and Garretsen (2009)).

30.2.1.1 Demand

Household utility is characterized by a love-of-variety effect that assumes that each variety c_i , $i = 1, \dots, n$, enters utility, U , symmetrically as an incomplete substitute; H is a homogeneous commodity which can serve as a numéraire; and M is often referred to as manufacturing:

$$U = H^{1-\delta} M^\delta, \text{ where } M = \left(\sum_{i=1}^n c_i^\rho \right)^{1/\rho} \text{ and } 0 < \rho \equiv \left(1 - \frac{1}{\varepsilon} \right) < 1 \quad (30.1)$$

where δ is the Cobb-Douglas share of M and $(1 - \delta)$ the Cobb-Douglas share of H and ρ is the elasticity of substitution between varieties. If the number of varieties is (very) large, firms consider the elasticity of demand ε as given. Utility maximization of Eq. (30.1) subject to the budget constraint gives (For a step by step

derivation of this two-stage maximization problem, see, for instance, Brakman, Garretsen, and Van Marrewijk (2009, Chap. 3))

$$c_i = \frac{p_i^{-\varepsilon} \delta w L}{\sum_j^n p_j^{1-\varepsilon}} \quad (30.2)$$

where p_i is the price of variety i and n the number of varieties. The term in the denominator is related to the price index for the manufactured goods. In what follows we assume that there is only one factor of production, labor L , with wage rate w .

30.2.1.2 Supply

For the explanation of intra-industry trade, it is necessary that similar goods are produced in different places. Intra-industry trade follows immediately in a multicountry setting if all varieties are consumed by all consumers (love-of-variety effect). A simple way to introduce (internal) economies of scale and ensuring that each variety i is produced by a single firm is via the following labor cost function:

$$l_i = \alpha + \beta x_i, \text{ where } \alpha, \beta > 0 \quad (30.3)$$

Labor, l_i , is the only production factor, which earns a wage w . The parameters α and β determine the fixed and marginal costs, αw and βw , respectively (the fixed costs give rise to the internal scale economies). Equation (30.3) implies that average costs are decreasing in the quantity of variety i that is produced, and this warrants that in the competitive equilibrium a particular variety is produced by the firm that had initially the largest market share and thus the lowest costs per unit of production.

The full-employment condition describes that the summation of Eq. (30.3) over all varieties equals total labor supply:

$$L = \sum_{i=1}^n l_i = \sum_{i=1}^n \alpha + \beta x_i \quad (30.4)$$

Firms are defined symmetrically which implies that:

$$p_i = p; \quad x_i = x \quad (30.5)$$

for all i in equilibrium.

30.2.1.3 Equilibrium

The next step is to derive the market equilibrium. This gives the equilibrium output of each firm, x_i , the equilibrium number of varieties and hence the equilibrium number of firms, n , and it also yields the equilibrium price wage ratio, p_i/w_i . Profit maximization gives the familiar markup pricing rule, equating marginal costs to marginal revenue (dropping the index because of symmetry):

$$p = \frac{\varepsilon}{\varepsilon - 1} \beta w \text{ or } \frac{p}{w} = \frac{\varepsilon}{\varepsilon - 1} \beta \quad (30.6)$$

The zero profit condition implies that

$$0 = px - (\alpha + \beta x)w \Rightarrow \frac{p}{w} = \beta + \frac{\alpha}{x} = \beta + \frac{\alpha}{Lc_i} \quad (30.7)$$

Equations (30.6) and (30.7) together give the breakeven output, x , of a firm that is consistent with profit maximization and free entry and exit into the market:

$$x = \frac{(\varepsilon - 1)\alpha}{\beta}.$$

30.2.1.4 International Trade

The gains of international trade are present in the model outlined above but only in a rudimentary way. An increase in the available labor supply still shifts the average cost downward. This shift has implications for the number of varieties that are produced, which increases (see Eq. (30.4), $L/l_i = n$), but has no impact on other elements in the model. Consumers gain from trade because they consume more varieties than before international trade was allowed.

More interesting results can be derived by introducing transport costs. This is certainly true from a NEG perspective because the relevance of economic *geography* crucially hinges upon the presence of positive transport costs; without transport costs geography does not matter. The combination of increasing returns to scale (IRS) and transport costs implies that firms not only want to concentrate production in a single location (because of IRS) but they also care where in space they locate production (because of the transport costs). Firms prefer to locate where demand for the variety they produce is relatively large. This interplay between IRS, transport costs, and demand has become known as the home market effect, which is also the basis for NEG literature. Our discussion of the home market effect is in two parts: the more than proportional production of the increasing returns sector in the larger market (the volume effect, Sect. 30.2.2) and the higher wages of the increasing returns sector in the larger market (the price effect, Sect. 30.2.3). *The key issue is that with positive transport costs, the larger market offers location benefits that are absent in models that do not include transport costs.* We introduce this difference as the two versions have important consequences for empirical tests of the model that are not always taken into consideration.

30.2.2 The Home Market Effect (HME) as a Volume Effect

Iceberg transportation costs have the advantage that transportation costs can be introduced without having to deal with a transportation sector (For a critique of the iceberg depiction of transport costs, see Fingleton and McCann (2007)). Assume the iceberg costs are τ (with $\tau \geq 1$), that is, τ units have to be shipped in order for one unit to arrive in the other country. This raises the costs of imported varieties to $p\tau$.

Demand for a domestic variety now comes from two sources: domestic demand Eq. (30.8a) and foreign demand Eq. (30.8b). From Eq. (30.2), it are (where * indicates foreign variables)

$$x_i = \frac{p^{-\varepsilon}}{np^{1-\varepsilon} + n^*(\tau p)^{1-\varepsilon}} \delta w L \quad (30.8a)$$

$$x_i^* = \frac{(\tau p)^{-\varepsilon}}{n(\tau p)^{1-\varepsilon} + n^*(p)^{1-\varepsilon}} \delta w^* L^* \quad (30.8b)$$

Similar equations can be derived for the foreign country. From the discussion following Eqs. (30.6) and (30.7), we know that output per firm is fixed and equal to x in equilibrium. Goods market clearing in each country for the increasing returns sector gives, for the home country,

$$X \equiv nx = \frac{np^{-\varepsilon}}{np^{1-\varepsilon} + n^*(\tau p)^{1-\varepsilon}} \delta w L + \frac{n(\tau p)^{-\varepsilon}}{n(\tau p)^{1-\varepsilon} + n^*(p)^{1-\varepsilon}} \delta w^* L^* \tau \quad (30.9a)$$

and, for the foreign country,

$$X^* \equiv n^* x = \frac{n^*(\tau p)^{-\varepsilon}}{n(p)^{1-\varepsilon} + n^*(\tau p)^{1-\varepsilon}} \delta w L \tau + \frac{n^* p^{-\varepsilon}}{n(\tau p)^{1-\varepsilon} + n^*(p)^{1-\varepsilon}} \delta w L^* \quad (30.9b)$$

Note the additional τ multiplication terms in both expressions and also note that output level in both countries – for individual firms – is x . In Eq. (30.9a), part of the home exports to foreign melts during transportation, but it needs to be produced before it can melt, and similarly in Eq. (30.9b) for exports from foreign to home, hence the additional multiplication by τ .

Assume first that there are no transport costs with respect to the homogeneous sector, H , and second (as is standard in international trade theory) that labor is mobile between sectors but *immobile* between countries. It follows that wages in the H sectors in both countries are identical and because of perfect inter-sector labor mobility, also in the increasing returns sector. Equation (30.6) allows us to choose units such that $p = w = 1$.

This implies that we can simplify Eqs. (30.9a)–(30.9b) as follows (with $Z \equiv \tau^{1-\varepsilon}$) (In the new economic geography literature, $\tau^{1-\varepsilon}$ is known as the freeness of trade; see Baldwin et al. (2003)):

$$\frac{x}{\delta} = \frac{1}{n + n^* Z} L + \frac{Z}{n Z + n^*} L^* \quad (30.9a')$$

$$\frac{x}{\delta} = \frac{Z}{n + n^* Z} L + \frac{1}{n Z + n^*} L^* \quad (30.9b')$$

Fig. 30.1 Home market effect, the volume effect

We have two equations and two unknowns, n and n^* . In principle we have three possible cases (numbered a to c), namely, complete specialization in one of the two countries (cases a and b) and incomplete specialization (case c):

- a. $n = 0, n^* = \frac{\delta(L+L^*)}{x}$, from Eq. (30.9b’).
- b. $n = \frac{\delta(L+L^*)}{x}, n^* = 0$, from Eq. (30.9a’).
- c. $n = \frac{\delta}{(1-Z)x}(L - ZL^*), n^* = \frac{\delta}{(1-Z)x}(L^* - ZL)$, from Eqs. (30.9a’) and (30.9b’).

Concentrating on the home country, we can distinguish between these three possibilities. If we introduce the following notation, $s_l = \frac{L}{L+L^*}, s_n = \frac{n}{n+n^*}$ where s_l is the labor share and s_n the share of varieties or firms in home, we arrive at

$$s_n = \begin{cases} 0, & \text{for } s_l \leq \frac{Z}{1+Z} \\ (1-Z)^{-1}[(1+Z)s_l - Z], & \text{for } \frac{Z}{1+Z} < s_l < \frac{1}{1+Z} \\ 1, & \text{for } s_l \geq \frac{1}{1+Z} \end{cases} \quad (30.10)$$

The first entry in Eq. (30.10) follows from combining case a with case c (where specialization of all increasing returns production in foreign just becomes binding). Similarly, the last entry follows from combining cases b and c. Finally, the middle entry follows from solving case number c. The implications become clear if we depict these three possible cases as in Fig. 30.1.

What we see is that if the home country is large (small) enough in terms of labor relative to foreign, it will attract (lose) all increasing returns manufactures. What is important in our discussion of the home market effect (HME) is the slope of the curve in the area $\frac{Z}{1+Z} < s_l < \frac{1}{1+Z}$. From Eq. (30.10), we know that the slope of the line-piece is $(1-Z)^{-1}(1+Z) > 1$, which implies that the larger country in this area has a *more than proportional* share of varieties and hence firms compared to its share in labor. The reasoning is as follows. Suppose that from the point $(\frac{1}{2}, \frac{1}{2})$

a foreign firm (together with its workers) relocates to the home country that now becomes the larger market (the reason why this might take place is unimportant). This increases the market by the amount of workers that move, but it also increases the spending power of existing consumers who no longer have to incur transport costs resulting from importing the variety. This “double” increase in demand raises profits in the larger market and attracts more firms to the increasing returns sector. Points on the solid line indicate that the increase in the number of firms must be more than proportional than the number of workers (some workers come from the homogeneous sector) in order to restore equilibrium.

Why do not all firms move to the larger market in order to restore equilibrium? The reason is that additional firms also introduce more competition that reduces the (potential) profits in the larger market. To explore the thought experiment of making the home market larger, it is instructive to look at the denominator of Eq. (30.8a). A firm moving from foreign to home makes the denominator smaller (as the variety no longer has to be imported), and this implies more local competition. This competition effect is stronger; the higher are transport costs (high transport costs shield a market from foreign competition). So fewer firms have to move to reestablish equilibrium following the movement of a firm from foreign to home if transport costs are high (the slope of the line gets closer to the 45° line).

To sum up, countries or regions with a relatively large demand for a good are home to a more than proportional share of production of that good. Against this home market or market size effect, the competition effect acts to ensure that in equilibrium, and depending on the model’s parameters (notably on the level of transport cost index, Z), not all firms in the differentiated IRS sector need to end up choosing the larger market as their location. From an empirical point of view, the model gives rise to a testable hypothesis with respect to international trade flows: countries with a relatively large home market for variety i ceteris paribus are net exporters of this variety. In the trade literature (see, e.g., Davis and Weinstein 2003), this implication of the home market effect has been subjected to a series of tests (see below).

Three other observations are relevant concerning the home market effect. The first one is that the effect is quite sensitive to the underlying assumptions. If international trade in the homogenous good is also subject to transport costs, the home market effect ceases to exist (Davis 1998). Also, the analysis of the home market effect quickly gets quite complicated (or even muddled) for the case of $n > 2$ regions or countries. The second observation is that in the example of Fig. 30.1, a large home demand (here, a large s_L) leads to an influx of firms where the necessary labor to enable the additional production has to be released from the homogenous sector. Given that international labor mobility is still impossible (as we will see the main difference between Krugman (1980) and Krugman (1991)), the additional demand for labor by the firms in the differentiated IRS sector in home does indeed fully materialize in higher production because of an infinitely elastic inter-sector labor supply.

If labor supply is not perfectly elastic, at least part of the response in the larger market will be in the form of higher wages (Fujita et al. 1999, Eq. (4.42);

Head and Mayer 2006). As we will see next, with a less than elastic labor supply, a relatively large demand or a larger home market then translates (partly) into higher wages. A third and final observation is that demand across locations is given. This is a direct consequence of the fact that workers and hence consumers are immobile between locations. Any demand or market size differences are therefore exogenously given. What happens if one drops this assumption? What if not only (IRS) firms but also (some) workers are mobile and can choose in which country or location they wish to live? Answering this question leads us to the center of NEG, but first we present another manifestation of home market effect in terms of wages. The reason is that migration is determined by (real) wage differences between locations. So, we first need to derive an expression for (real) wages.

30.2.3 The Home Market Effect as a Factor Price Effect

In the example underlying Fig. 30.1, we, by construction, ignored any effect that market or demand size differences might have on wages. Labor was perfectly elastic between sectors but not between countries, which is the usual assumption in international trade theory. This enables us to focus on the number of varieties (firms). In Krugman (1991), an opposing case is introduced; the larger market does not attract more than a proportional share of firms, compared to its share in labor, but all benefits of a larger market now show up in terms of higher wages in the increasing returns sector.

Actually such a wage effect can already be seen as an outcome of the Krugman (1980) model, we only have to change one assumption: labor is not only immobile between countries but now also immobile between sectors. The implications are that we no longer have factor price equalization and that the number of varieties (firms) is proportional to the given quantity of labor in the increasing returns sector (so by assumption the HME of the previous section is absent). The setup of the model remains the same, but we can no longer take the steps to simplify Eqs. (30.9a) and (30.9b) to Eqs. (30.9a') and (30.9b'). At the same time it is true that location in the larger market offers benefits relative to location in the smaller market. Again, as in the previous section, location in the larger market implies that firms do not have to incur transport costs and that this increases the spending (real income) of consumers. How does it show up in this case? We can use Eq. (30.9a) to show this for the home country [and similarly for the foreign country using Eq. (30.9b)]. Note that as wages are not necessarily the same, prices also differ between countries. Furthermore, we have to be careful how to define income, Y and Y^* , in this case; see below. Taking care of these aspects results in

$$\frac{(\varepsilon - 1)\alpha}{\beta} = \frac{np^{-\varepsilon}}{np^{1-\varepsilon} + n^*(\tau p^*)^{1-\varepsilon}} \delta Y + \frac{n(\tau p)^{-\varepsilon}}{n(\tau p)^{1-\varepsilon} + n^*(p^*)^{1-\varepsilon}} \delta Y^* \tau \quad (30.11)$$

In Eq. (30.11), we have again used the fact that in the model markup, pricing together with the zero profit condition fixes the break even output of firms [see the left-hand side of Eq. (30.11) and the discussion following Eqs. (30.6) and (30.7)].

Using $p = \frac{\varepsilon}{\varepsilon-1}\beta w$, and $p^* = \frac{\varepsilon}{\varepsilon-1}\beta w^*$, we can rewrite Eq. (30.11) in terms of wages in the manufacturing sector (and do the same for the foreign country):

$$w = \rho\beta^{-\rho} \left(\frac{\delta}{(\varepsilon-1)\alpha} \right)^{1/\varepsilon} \left(YP_1^{\varepsilon-1} + \tau^{(1-\varepsilon)} Y^* P_2^{\varepsilon-1} \right)^{1/\varepsilon} \quad (30.12a)$$

$$w^* = \rho\beta^{-\rho} \left(\frac{\delta}{(\varepsilon-1)\alpha} \right)^{1/\varepsilon} \left(Y^* P_2^{\varepsilon-1} + \tau^{(1-\varepsilon)} Y P_1^{\varepsilon-1} \right)^{1/\varepsilon} \quad (30.12b)$$

where $P_1^{1-\varepsilon} = n(w/\rho)^{1-\varepsilon} + n^*(\tau w^*/\rho)^{1-\varepsilon}$, $P_2^{1-\varepsilon} = n(\tau w/\rho)^{1-\varepsilon} + n^*(w^*/\rho)^{1-\varepsilon}$, and Y and Y^* are the income generated in home and foreign, respectively.

These equations make sense in the following way. Wages in home are higher if it has a large home market in terms of real income, YP_1 , or if it is located near a large foreign market (large Y^*P_2 and low transport costs or, equivalently, a high freeness of trade, $\tau^{1-\varepsilon}$). The benefits of a large market are not reflected in a more than proportional share of firms relative to the labor share but in higher wages.

30.3 Adding Labor Mobility

30.3.1 Core NEG Model

It is now only a small step to make the model a full general equilibrium model that includes labor mobility (See Brakman and Garretsen (2009)). The only thing to add is the possibility of labor migration between regions. This implies that a region's market size becomes endogenous when migration is allowed to take place. In the 2-region setting of Krugman (1991), the equilibrium conditions of the model can be stated as follows:

$$Y = wL + 0.5L_H \quad (30.13a)$$

$$Y^* = w^*L^* + 0.5L_H \quad (30.13b)$$

$$w = \rho\beta^{-\rho} \left(\frac{\delta}{(\varepsilon-1)\alpha} \right)^{1/\varepsilon} \left(YP_1^{\varepsilon-1} + \tau^{(1-\varepsilon)} Y^* P_2^{\varepsilon-1} \right)^{1/\varepsilon} \quad (30.13c)$$

$$w^* = \rho\beta^{-\rho} \left(\frac{\delta}{(\varepsilon-1)\alpha} \right)^{1/\varepsilon} \left(Y^* P_2^{\varepsilon-1} + \tau^{(1-\varepsilon)} Y P_1^{\varepsilon-1} \right)^{1/\varepsilon} \quad (30.13d)$$

$$P_1^{1-\varepsilon} = n(w/\rho)^{1-\varepsilon} + n^*(\tau w^*/\rho)^{1-\varepsilon} \quad (30.13e)$$

$$P_2^{1-\varepsilon} = n(\tau w/\rho)^{1-\varepsilon} + n^*(w^*/\rho)^{1-\varepsilon} \quad (30.13f)$$

$$\omega = \frac{w}{P_1^\delta}, \quad \omega^* = \frac{w^*}{P_2^\delta} \quad (30.13g)$$

$$\frac{dL}{L} = -\frac{dL^*}{L^*} = \eta(\omega - \bar{\omega}), \quad \text{with } \bar{\omega} = \lambda\omega + \lambda^*\omega^* \quad (30.13h)$$

The model clearly builds (and even largely overlaps) with the international trade model of Sect. 30.2 but also includes some new elements of which interregional labor mobility is the most relevant one. Equations (30.13a) and (30.13b) are the income equations in the two regions or countries, home and foreign. The first term on the right-hand side indicates income earned in the increasing returns sectors that earn wages w and w^* in home and foreign, respectively. We assume that labor (in the increasing returns sector) is mobile between countries but not between sectors. The distribution of labor in the homogeneous (agricultural) sector is given and does not change. Total labor supply in this sector is L_H , and we assume – just for simplicity – that it is equally distributed over the two countries. There are no transport costs in this sector implying that wages earned in the homogeneous goods sector are equal in both regions, and we can use this sector as the numeraire sector, and wages in the increasing returns sector are relative to the wages in the homogeneous goods sector. It is important to note that we cannot do without this homogeneous goods sector in Krugman's (1991) core NEG model. It implies that even when labor in the increasing returns sector is completely agglomerated by being located in just one of the two regions, there is always a positive (residual) demand in the other region, and firms might want to relocate to this region in order to get away from the stiffer competition in the larger region.

Equations (30.13c)–(30.13f) are already familiar from earlier sections. Equations (30.13g) and (30.13h) give the dynamics in the model. Next, we define real income of a worker in the IRS sector in Eq. (30.13g). It is simply wages divided by the price index of all the commodities consumed (including the homogeneous good). As the increasing returns to scale sector comprises a share δ in the consumption basket, we want to correct for this in Eq. (30.13g) (Note that P_1 and P_2 are price indices associated with the CES sub-utility indices, which explains the somewhat complicated notation of these expressions; see Brakman, Garretsen, and Van Marrewijk (2009, Chap. 3) for a detailed discussion of these price indices). We also divide by the price in the homogeneous sector (raised to the power $1-\delta$, the share of the homogeneous goods sector), but this does not show up because the homogeneous good is the numeraire good (and the price equals one). Equation (30.13h) states that labor in the increasing returns sectors moves to the region with the highest real wage. Of course, in the real world migration, decisions are based on much more than just real wage differences. The model easily gets quite complicated because if labor moves, to say, the home country, this changes incomes [Eqs. (30.13a) and (30.13b)] which affects nominal wages

Fig. 30.2 The Tomahawk for the Krugman (1991) model

[Eqs. (30.13c) and (30.13d)] and also the price indices [Eqs. (30.13e) and (30.13f)], which subsequently affect the migration decision itself, and given the functional forms of the model, these effects are nonlinear.

Given the key model parameters, most importantly the value of transport costs, the balance between the agglomeration forces (home market effect, price index effect) and the spreading forces (competition effect) determines what the equilibrium spatial allocation will be. It turns out that the model has basically three (stable) equilibria: full agglomeration in home or foreign and perfect spreading. Interestingly, the model is characterized not only by multiple equilibria but also by path dependency. Figure 30.2 illustrates the model. The so-called Tomahawk depicted in Fig. 30.2 shows that for low *freeness of trade* $\tau^{1-\varepsilon}$ ($=Z$ in the previous section), that is, for high transport costs τ , footloose labor is evenly spread between the two regions, but if the freeness of trade gets high enough, that is, if transport costs get low enough, all footloose workers end up in either region one or two in equilibrium.

The solid lines indicate stable equilibria and the dashed lines indicate unstable equilibria. The arrows indicate in what direction the incentive for firms (and footloose labor) points, depending on the value of transportation costs.

What are the forces that determine interregional migration? Three forces matter in the Krugman (1991) model: the price index effect, the home market effect, and the extent of competition effect. The price index effect stimulates agglomeration in the larger market as fewer varieties have to be imported, and this saves on transport costs. This effect is magnified by the home market effect discussed above. If the home market effect results in higher wages (see Sect. 30.3.1), it makes the larger market more attractive. These agglomeration effects are counteracted and diminished by the extent of the competition effect, which acts as the spreading force.

If a firm moves to the larger market, the denominators in Eqs. (30.9a) and (30.9b) become smaller, which reduces the demand for an individual firm. The more firms (and workers) there are in a region, the higher the level of competition will be.

The balance between these three forces determines the direction of the arrows in Fig. 30.2. For low values of transport costs (high values of the freeness of trade), this competition effect is felt less as the price difference between markets becomes smaller. Note from Fig. 30.2 that there is not a gradual change from one stable equilibrium to another but instead a catastrophic change; the moment the balance tilts between these forces, it is either full agglomeration in one region or the other. Starting from an initial situation of a low freeness of trade (left part of x-axis in Fig. 30.2), the point at which this happens is the so-called *break point*, B; moving from high to low transportation costs, spreading is no longer a stable equilibrium (breaks) if transport costs are reduced further. One could also start with very low transport costs (high freeness of trade) and then subsequently increase transport costs (lower the freeness of trade) until agglomeration becomes unstable. This happens at the so-called *sustain points*, S, in Fig. 30.2. (Note that in the middle part of Fig. 30.2, there is some overlap as to the range of the freeness of trade for the agglomeration and spreading equilibrium which indicates that the model is characterized by path dependency, see Brakman, Garretsen, and van Marrewijk (2009, Chap. 4) for an explanation).

30.3.2 Model Extensions

The model described in Sect. 30.3.1 states the essence of the NEG model that was introduced by Krugman (1991). In the subsequent literature, many additions have been incorporated in this model. These extensions are often motivated to correct some of the more unlikely aspects of the model or to make the model more tractable.

- The model introduced above can be extended with an intermediate production sector. Assuming that labor is intraregionally mobile but interregionally immobile produces more realistic results than the extreme outcome as described in Fig. 30.2. Economic integration in this case results in real wage convergence between regions rather than divergence (The reason for this is that the peripheral region becomes more attractive for manufacturing production as transport cost decline, because wage differences start to dominate transportation costs [which decline during economic integration]). Most importantly, however, is the extension introduced by Puga (1999). The model introduced above predicts that small changes in the parameter values could result in sudden and dramatic changes (see the sustain and break points in Fig. 30.2) which seems unrealistic in practice. Puga (1999) extends the intermediate production model and assumes that the numeraire sector is no longer characterized by constant returns to scale but instead by diminishing returns. This implies that pulling workers out of the homogeneous sector raises marginal productivity and nominal wages in

this sector. This adds an additional spreading force into the model preventing a bang-bang solution as in the standard model. Puga (1999) shows that this additional force combined with the assumptions in Krugman and Venables (1995) and Venables (1996) is so strong that instead of the Tomahawk as depicted by Fig. 30.2, a bell-shaped curve appears, which suggests a more gradual change from full agglomeration to complete spreading. This aspect of the Puga (1999) model makes it a preferred model in empirical research (see below).

- Another extension is to allow for more factors of production. One can assume, for instance, that manufacturing production uses high-skilled and low-skilled labor in production. This makes the model more realistic. A surprising side effect is that the model becomes more tractable than in the standard case. If high-skilled labor is used in the fixed part of production (α , in Eq. (30.3)) and low-skilled labor in variable-cost part of manufacturing production (β in Eq. (30.3)), but also in the production of the homogeneous sector, we no longer have to solve for nominal wages (which also can be normalized) but only for high-skilled wages. The solution is relatively straightforward. So, besides introducing the more realistic assumption of more factors of production, we can now derive explicit solutions. This is not the only change to the basic model that results in analytical solutions. Ottaviano, Tabuchi, and Thisse (2002), for instance, drop the CES demand structure and introduce a quasi-linear demand structure.
- The Melitz (2003) revolution has also entered NEG. Firms in the standard models are all the same according to their cost structure, see Eq. (30.3). However, Baldwin and Okubo (2006) introduce productivity differences between firms. They show that firms line up for reallocation from a small to a large market in order of firm productivity levels; more productive firms can already relocate at transportation levels that would imply a loss for less productive firms. Models like these are important for empirical research as they point toward an empirical complication: do larger markets benefit from “agglomeration economies” or from the fact that they are home to the more productive firms?

30.4 Empirical Testing

Can we test the main implications of NEG? This seems a simple question, but it has turned out that this question is surprisingly difficult to answer. The model has interesting consequences, but a combined test of the main or, let alone, all aspects is still missing. Head and Mayer (2004, p.2616) identify five main characteristics – slightly restated by us below and compressed into three main testable implications– that are special for NEG and could be tested to explain the facts implied by Figs. 30.1 and 30.2 (Brakman et al. 2009, Chap. 5):

- (a) *The home market effect*: Large regions will be home to a disproportional share of the imperfectly competitive industry. Such large markets are, therefore, net exporters of industries characterized by increasing returns to scale. As we discussed at some length in Sect. 30.2, there are also two other possible testable implications from this effect:

- (a1) The *volume version* (recall Fig. 30.1): A large market potential induces factor inflows from the small to the large market. Footloose factors of production will be attracted to those markets that pay relatively high real factor rewards. This leads to a process of circular causality.
- (a2) The *factor price version* [Eqs. (30.12a)–(30.12b)]: A large market potential raises local factor prices in the core relative to the periphery. An attractive market with a strong home market effect will increase demand for factors of production, and this raises factor rewards.
- (b) *Shock sensitivity*: As we discussed with Fig. 30.2, changes in the economic environment can trigger drastic and permanent changes in the spatial distribution of economic activity.
- (c) At some critical level of transport or trade costs, and again see Fig. 30.2, a further *reduction in transport costs induces agglomeration by relocation of the footloose factors of production*. This implies that more economic integration should at some point lead to (more) agglomeration of the footloose activities and factors of production.

Characteristics (a1) and (a2) describe the consequence for factors of production or factor prices once the home market effect is established. As is explained in Fujita et al. (1999, p. 57), the equilibrium of the Krugman (1991) model implies the following equation: $\frac{dY}{Y} = \gamma_1 \frac{dw}{w} + \gamma_2 \frac{dL}{L}$, where Y is total demand for the footloose sector, w is the nominal wage rate in this sector, and L is employment in this sector and γ_1 and γ_2 are parameters (This equation also shows why the findings on the HME show a highly variable pattern of estimated coefficients: both wages and employment changes should be accounted for, not only employment changes as in the strict version of the home market effect). It shows that an increase in the demand (Y) for the goods from the footloose sector not only causes employment changes (the volume version of the home market effect) but also induces wage (w) changes (the factor price version of the home market effect).

In a series of papers, Davis and Weinstein (2003) have developed an empirical methodology that enables them “to distinguish a world in which trade arises due to increasing returns as opposed to comparative advantage” (Davis and Weinstein 2003, p. 3). In general they find some support for the volume version of the home market effect. As shown in Brakman, Garretsen, and Schramm (2006), however, both effects are typically at work. On balance it appears that the wage channel is the main route toward spatial equilibrium (Head and Mayer 2006). This explains also why most empirical work has focused on the wage equations, Eqs. (30.13c)–(30.13d). Despite the empirical evidence that supports the volume or factor price version of the home market effect, the question remains whether this evidence is a test of NEG as such; they are also a characteristic of standard trade models. We will return to this question at the end of the present section.

One of the key elements of NEG is the shock sensitivity. As illustrated by Fig. 30.2, small changes in parameters (in casu, the level of transport costs) can (but need not) have big consequences. It implies for instance that a small change in economic integration could lead to spectacular changes in the spatial

distribution of economic activity. If small changes already can have large effects, one would be inclined to think that permanent effects in the spatial distribution of economic activity can be found after large changes. The key issue is whether one can come up with real world examples of a large, temporary, and exogenous shock that can act as a testing ground for the shock sensitivity hypothesis. In a seminal paper, Davis and Weinstein (2002) use the case of the allied bombing of Japanese cities during World War II (WW II) as an example of such a shock. Brakman, Garretsen, and Schramm (2004) apply the Davis and Weinstein (2002) approach to the case of the allied bombing of German cities during WW II. In both studies the question is the same: did individual cities return to their initial, prewar growth path after WW II? The breakup of Germany in 1949 in the Federal Republic of Germany FRG (West Germany) and the German Democratic Republic GDR (East Germany) and the subsequent reunification of the two Germanies in 1990 after the fall of the Berlin Wall is another example of a large, temporary (40 years) shock. Redding and Sturm (2008) use this shock to test whether *West-German* border cities (close to the FRG-GDR border) experienced a substantial decline compared to non-border cities in West Germany. The evidence of these studies is somewhat mixed. Davis and Weinstein (2002) do not find evidence of long term effects, whereas the other studies – on Germany – do find such effects. In general it seems that economies show some shock sensitivity. Again, and notwithstanding this evidence on shock sensitivity, the ultimate question for our present purposes is whether these studies do provide a real test of NEG as such. Note for instance that the NEG model as depicted by Fig. 30.2 allows for shocks that can have permanent and nonpermanent effects. Also, it is clear that NEG is not the only location or spatial model to predict that shocks can alter the spatial equilibrium allocation of economic activity.

Finally, NEG models predict that changes in transportation costs could result in changes in the degree of agglomeration through the relocation of the mobile factors of production. To this end, we essentially need the full model, as described in Sect. 30.3. The long run equilibrium equation relates migration to real wage differences, which are determined in the model. For empirical research this is a challenging consequence of the model. First of all we have to find out where we are in terms of for instance Fig. 30.2. Is the economy that we are looking at initially to the left or to the right of the break point? This is important, because we like to know what happens if transportation costs change. In real world applications, however, we deal with a multi-region world and implicitly confront this multi-region model with break points from the Tomahawk diagram in a 2-region setting, which is problematic. Similar analytical solutions for break points in a multi-region setting ($n > 2$) only exist if all regions are at equal distance from each other. This assumption effectively means that the actual geography (where regions are located on a map) does not play a role and thus that space is neutral in that sense. Any real world application clearly violates this assumption.

How should we proceed to arrive at more conclusive evidence for our empirical hypothesis on transportation or trade cost-induced agglomeration? One option is to

drop the 2-region model, with its analytical solutions, and instead use multi-region model simulations in which key equations are based on multi-regional estimates of Eqs. (30.13c)–(30.13d). In Bosker et al. (2010), this is the preferred option. They show that, in a qualitative sense, the multi-region non-neutral space model gives rise to the same conclusions as the simple 2-region version of the Puga (1999) model, that is, the results show that the 2-region model carries over in the multi-region case. Given this result, the answer to the question “where on these curves are we?” can be answered in a simulation setting. Repeated simulations, using the estimated wage curves for different values of transportation costs, allow us to construct a multi-region version of Fig. 30.2. Confronting this curve with actual estimates for transportation costs gives us an idea where on the curve we are, and in what direction the economy is moving, toward further agglomeration or further spreading. But it is clear that evidence based on simulations is not the same thing as evidence based on actual estimations, while using the structural equations of the model and using real data, of the third NEG hypothesis.

How convincing is the empirical evidence for the NEG studies related to the three empirical hypotheses that were outlined at the beginning of this section? In addition to the comments made above for each of the hypotheses, four general problems for empirical confirmation of the geographical economics model stand out (see also Redding 2010):

- (i) Studies are not only consistent with geographical economics models but also with other theories of trade and location (the home market effect can, for instance, also be found in other trade models; see also discussion in Fingleton and Fischer (2010)).
- (ii) Applying two region NEG models like Krugman (1991) to a multi-region world makes conclusive testing difficult or even outright impossible.
- (iii) Causality: Are the empirical observations caused by NEG forces or not? The empirical evidence indicates that wages (left-hand side of the empirical specification of Eqs. (30.13c)–(30.13d)) are related to measures of market access. An important problem is whether this is a causal relation. Higher wages in regions with good market access may be caused by better institutions in surrounding regions or locational fundamentals instead of NEG forces, and the measures of market access might simply capture these more fundamental causes. This issue is more problematic for testing the home market effect (hypothesis 1) than for shock sensitivity tests (hypothesis 2, where cause and effect are more clearly distinguished).
- (iv) Using micro data: Virtually all empirical NEG work is based on the representative firm and consumer framework and ignores the extensive micro data sets that have become available over the past years. Using these data (as in the urban economics literature) may make it possible to determine if the agglomeration effects in the core are based on selection effects (truncation of the distribution) or agglomeration as such (rightward shift of the distribution); see Combes et al. (2008).

30.5 Policy Consequences

The NEG framework is widely used to discuss policy implications of (local or national) interventions. This holds, for example, for many (regional) studies performed on behalf of the European Union and for the recent *World Development Report 2009* by the World Bank (2008). A good summary of the six general policy conclusions based on the NEG model is provided by Ottaviano (2003); for a more extensive treatment of these points, see Baldwin et al. (2003):

- *Regional side effects.* One of the fundamental insights from NEG is that regions are connected and cannot be studied in isolation. Regional policy measures that, for example, affect economic integration, have consequences for all regions, not only the region at which the measure is aimed. Effects of regional policies are economy-wide.
- *Trade interaction effects.* Outcomes of the model depend crucially on initial levels of economic integration. A similar policy measure can have different effects, depending on the initial position of the economy (see Fig. 30.2).
- *Lock-in effects.* Temporary measures can have permanent effects. Suppose that a temporary subsidy takes an economy over the break point in Fig. 30.2. It is then possible that a new long run stable equilibrium is reached. The economy will remain there even when the subsidy is ended. Also history matters. If an economy finds itself in a stable equilibrium, strong policy measures might be needed in order to establish another equilibrium, in other words “history matters.”
- *Selection effects.* Figure 30.2 indicates that if transport costs are low, two stable equilibria are possible. Selecting one of the possibilities can have huge consequences from a welfare perspective. For example, the immobile workers in the core region benefit from being located in the core, but policy makers have to make up their mind that they indeed give welfare in the core region a greater weight in social welfare considerations than in the peripheral regions.
- *Threshold effects.* Policies measures can seem ineffective. The reason is that measures should take an economy over the break point in order to become effective.
- *Coordination effects.* NEG models are characterized by multiple equilibria. Especially in the overlap area in Fig. 30.2, expectations about the future of the economy can be important. If policy makers can convince firms/workers to relocate, this will start a self-sustaining move to a new equilibrium. A subsidy might take an economy toward a new equilibrium, but if policy makers can convince workers and firms that a specific region is the place-to-be, a subsidy is not required.

The list suggests that a world characterized by NEG offers policy makers many attractive options. However, some qualifications are in order. First of all which NEG model describes the world best, the stylized model depicted in Fig. 30.2 or one of the models that are extensions of this Fig. 30.2 model? The model in Fig. 30.2 is to a large extent driven by a few parameters, and it is highly unlikely that the real world can be described by only those few parameters, which are most likely

different for all sorts of economies or periods (Combes 2011). Furthermore, in general, core regions are always better off than peripheral regions. The Tomahawk Fig. 30.2 suggests that it is always possible, with the right measure, to pick a preferred equilibrium. Neary (2001) strongly argues against this “picking equilibria” role for the government, because, as we concluded at the end of the previous section, the empirical evidence for NEG is still too weak (see above), and that such a policy would bear the risk of strategic, and wasteful, rent seeking behavior from competing regions. Still, we think that one very strong policy measure results from NEG; regions are not free-floating islands in space, but they are spatially interdependent. All too often regional policies are addressed to deal with a specific regional issue – like low wages and lack of employment – and deal with such a region as if it is an island in space. Policy measures can have unexpected results. An investment in, for example, the regional infrastructure in this peripheral region might not stimulate growth in the periphery, but instead might strengthen the position of the core region because economic integration further strengthens the position of the core (see Fig. 30.2). This is probably – in a qualitative sense – one of the most important policy conclusions that can be derived from NEG.

30.6 Conclusions

We briefly discussed the structure of the NEG models to argue that the new aspect of this type of model is endogenizing economic size of a location. The economic aspect of the name refers to the economic tools used, while the geography part focuses on the crucial role of spatial interdependencies through transport and interaction costs. We then turn to the main empirical implications of NEG as summarized in a number of empirical characteristics. Despite the surge in empirical research in this area in the last decade, a number of crucial problems with empirically testing the NEG models remain. We list four of these, namely, (i) some effects can also be explained by other models, (ii) most tests in a multi-region world are only loosely based on a two-region basic model, (iii) causality problems are rarely adequately addressed, and (iv) we need to integrate locational phenomena at different scales by also using micro data. In view of our discussion of these shortcomings, the main policy implications (as discussed in Sect. 30.5) are still mostly qualitative, thus lacking a solid quantitative basis in most applied work.

Abstract

In the past decade, economic geography has encountered increasing interest and debates about evolutionary and relational thinking in regional development. Rather than comparing the two approaches, this chapter investigates how they can complement one another and be applied to specific research fields in economic geography. A comparison would be difficult because the approaches address different levels of the research process and are in a relatively early stage of their development. To demonstrate the potential of combining the two approaches, this chapter aims to conceptualize cluster dynamics in an integrated relational-evolutionary perspective. In recent years, research on clusters has experienced a paradigmatic shift from understanding their network structure to

analyzing dynamic changes. Within this context, inspired by relational and evolutionary thinking, a comprehensive tripolar analytical framework of cluster evolution is developed that combines the three concepts of context, network, and action, allowing each to evolve in interaction with the others. Through this, the chapter argues that, rather than viewing relational and evolutionary accounts as competitive approaches to economic geography, they can, in an integrated form, become fundamental guides to economic geography research.

31.1 Introduction

After vivid conceptual debate in economic geography in the 2000s, two approaches have received substantial attention in the academic community that will be discussed in this chapter: that is, relational and evolutionary perspectives. While some scholars compare both perspectives as competing conceptualizations (e.g., Hassink and Klaerding 2009), we believe that such a comparison is not easily possible. There are two reasons for this: First, relational economic geography is a broad term which encompasses a number of approaches that relate to different research traditions stretching out from critical realist and poststructuralist to actor-network theorizations – which makes it difficult to critique this work as a homogenous body of research – while evolutionary economic geography has more narrowly developed out of evolutionary economics. Second, relational perspectives address meta-theoretical aspects of how to position analyses in economic geography, which questions to ask and how to conceptualize specific problems. In contrast, evolutionary approaches are situated at the concept level and often involve a specific quantitative methodology to analyze a problem. Both approaches are also in a relatively early stage of their development.

Relational perspectives were designed as a multidisciplinary alternative to narrow regional science approaches which were primarily based on conventional neoclassical economics. Such work aimed to explain economic landscapes by introducing spatial variables into economic models. Although conventional analyses did not always strictly follow this line of thinking, much of the work was characterized by a meso-/macro-perspective, the treatment of spatial entities as if they were actors (while neglecting the real actors, i.e., individuals, firms, and other organizations), a neglect of wider social relations, and a lack of process analysis. Relational approaches instead view economic action as social practice, conduct a microlevel reasoning, investigate the way how institutions stabilize economic relations, explore social and economic processes, and analyze the effects of global production and the connection between local and global scales (e.g., Boggs and Rantisi 2003).

In the conceptualization of Bathelt and Glückler (2011), which provides the reference point for the arguments presented here, relational economic geography is a meta-conceptualization for formulating research questions and conducting research in economic geography. This conceptualization provides a bottom-up logic of how economic action unfolds in a spatial perspective and leads to wider spatial patterns that can differ from place to place. This includes a structural and an evolutionary component: The structural component refers to the role of *context*. Accordingly, economic

agents are situated in structures of social relations from which they cannot easily separate (Granovetter 1985). Firms in clusters and global value chains are, for instance, embedded in networks of knowledge flows and supplier-producer-user relations which are key when making decisions about product changes. The evolutionary component refers to the fact that economic action is *path dependent*. Past decisions and traditions of social relations provide preconditions for today's actions and thus impact contemporary decision-making. At the same time, the relational approach rejects the assumption that such patterns can be extrapolated to the future. Economic action is seen as fundamentally open-ended and *contingent*, since agents are free to deviate from preexisting structures and development paths. From this, it is suggested that the complex underlying structures of organization, interaction, innovation, and evolution in a spatial perspective are at the core of enquiries in economic geography.

Similar to relational perspectives, evolutionary approaches are based on a critique of conventional research that is mostly static. In contrast, evolutionary approaches to economic geography aim to analyze dynamic changes in economic landscapes, often based on conceptualizations from evolutionary economics (Martin and Sunley 2006). Focusing at the regional (or national) level, much of the work analyzes the effects of processes of selection, mutation, variation, and chance on the development of firm populations. Within this context, recent work investigates processes of establishing regional variety and selecting alternatives from this variety. The idea behind this is that "related variety" between local/regional industry sectors enables spillover processes, supports innovation, and produces regional advantage (Frenken et al. 2007). Over time, selection processes lead to specific regional development paths. While research on the establishment of new trajectories is still at an early stage, an older stream of the literature analyzes path-dependent regional development and potential lock-in processes (Grabher 1993).

Although offering new insights for studies in economic geography, both perspectives have shortcomings: Much of the empirical work using a relational framework aims at understanding why specific economic networks exist, what the nature of social relations is, and why this differs from place to place, while neglecting the dynamics of such structures. Vice versa, evolutionary approaches focus on regional economic dynamics and the identification of trajectories at a meso-/macro-level, while neglecting the underlying structures of socioeconomic relations. In fact, although evolutionary approaches are often based on a firm perspective, the actual analysis addresses aggregates, such as regional structures and developments, and derives general statements about, for instance, the persistence of regional distributions. These differences are illustrated further in the next section which directs attention to industrial clusters as the unit of analysis.

31.2 Segmented Cluster Paradigms

Arguably, empirical and conceptual analyses of industrial agglomerations and clusters have been at the core of much of the work in economic geography over the past three decades. Within this context, relational and evolutionary approaches

have developed in two successive stages of the discussions of industrial clusters: Initially, academic interest was attracted by the robust growth of certain industrial districts, clusters, or regional innovation systems. (This early stage of cluster research is, in fact, only partially relational since much of this work lacks dynamic components. This may explain why some scholars interpret relational approaches as static (Martin and Sunley 2006; Hassink and Klaerding 2009).) A consensus about the structure of these competitive regions was that they combine economic activities and culture at the local level through untraded (aside from traded) linkages, echoing with the social-embeddedness argument in economic sociology (Granovetter 1985). It was argued that networks of local agents, which are often associated with mutual trust, provide a third way of governing economic relations beyond the dual structure of market and hierarchy. They generate regional prototypes of tacit knowledge where new knowledge is constantly being created and successfully shared (Malmberg and Maskell 2002). In more recent research, due to changes in regional configurations, such as the Third Italy (Hadjimichalis 2006) and Silicon Valley (Saxenian 2006), a transition has taken place from a static to a more evolutionary view of clusters. This has given rise to a new evolutionary approach on clusters that focuses on dynamic changes, drawing inspirations from concepts such as path-dependency, lock-in, and industry life cycles (Frenken et al. 2007).

Until now, the two dimensions - network and evolution - have remained relatively unconnected in the literature on industrial clusters. In both perspectives, broader levels of change in social networks and local culture and their impact on cluster evolution have rarely been discussed. This chapter argues that a close linkage between network dynamics and cluster evolution needs to be established to develop a coherent conceptualization of clusters. Without changes in networks and conventions, regional renaissance would barely be a “flash in the pan,” induced by temporary increases in demand. Signs of recovery would not lead to a succession of the evolutionary path or life cycle of a cluster. Without an evolutionary perspective, regional success would be determined by the existing local manufacturing culture (Gertler 2004), which would also provide a partial understanding.

To bridge the gap between narrow relational and evolutionary perspectives in cluster research, this chapter formulates a tripolar framework for the analysis of cluster dynamics through contextualized theoretical construction (Li et al. 2012). The tripolar framework builds on the pillars of context, network, and action, integrating them in an organic way at the local/regional level. This is not an attempt to establish a global model of cluster dynamics. Rather, by contextualizing social networks, we emphasize the possibility of network dynamics and, hence, varied effects of networks on local agency over time. As such, contextualized networks help explain and understand deeper transformations inside clusters. Furthermore, by placing networks in dynamic context-action configurations, we indicate how new cluster paths can be created through structuration processes that are initiated by local agents (Giddens 1984).

Following this agenda, this chapter is structured as follows: The next section discusses relational cluster conceptions that focus on the network paradigm, drawing particularly from the knowledge-based buzz-and-pipeline model. Then, we

present an overview of evolutionary cluster conceptions. From a critique of both types of approaches, we develop a reconceptualization of cluster dynamics in an integrated relational-evolutionary way, before presenting concluding remarks.

31.3 Network Relations and the Knowledge-Based Conception of Clusters

Traditionally, work on industrial agglomerations or regional industry clusters has emphasized the role of cost advantages, especially low transportation and transaction costs and close material linkages within such settings. Krugman (1991), for instance, stressed the importance of cost incentives for suppliers to locate close to an existing industrial agglomeration and advantages of agglomeration from a labor market perspective. As contributions by Storper and Salais (1997), Malmberg and Maskell (2002), and others have emphasized, however, it is necessary to go beyond cost factors to more fully understand the processes underlying regional specialization and concentration. In drawing on “localized capabilities” and “untraded interdependencies,” broader conceptualizations of regional clusters acknowledge the importance of socio-institutional settings, interfirm knowledge flows and interactive learning in regional innovation and growth.

From this understanding, a research tradition has developed that stresses the importance of network linkages and producer-user relations in clusters. Focusing on local interfirm linkages, Malmberg and Maskell (2002) emphasize the vertical and horizontal dimensions and relationships in clusters. While the former relationships refer to firms that are linked through input–output linkages and value-chain-based relations, the latter relate to firms that produce similar products and compete against one another. They learn by monitoring and comparing themselves with other firms.

Although Malmberg and Maskell (2002) point out that, in order to establish a theory of clusters, it would be necessary to understand which factors support the continued growth of clusters and how they are reproduced, much of the existing work has not developed a dynamic or evolutionary perspective. This is also reflected in the buzz-and-pipeline model of clusters (Bathelt et al. 2004), which suggests that the growth of a cluster depends on systematic linkages between its internal networks, conceptualized as “local buzz,” and its external knowledge and market environment, referred to as “global pipelines.” Within the cluster, specific information about technologies, markets, and strategies is exchanged in a variety of ways in planned and unplanned meetings. Based on a shared institutional background, firms learn how to interpret local buzz and make good use of it. Participation in this buzz does not require specific investments, since the firms are surrounded by a tight web of opinions, recommendations, judgments, and interpretations (Storper and Venables 2004).

While local buzz supports internal coherence, a cluster’s competitive success and growth strongly depends on its external linkages (Owen-Smith and Powell 2004). Since access to global or trans-local markets and knowledge is not free, considerable search efforts have to be undertaken to find the right

partners – a process that entails high investments and uncertainties. External relationships also require building trust, which is a timely and costly process. The buzz-and-pipeline model suggests that the local information and knowledge ecology is of only limited effect in the absence of trans-local connections (Bathelt et al. 2004). The more strongly the actors in a cluster are involved in establishing and maintaining external partnerships, the more information about new markets and technologies is pumped into the cluster's networks (Fitjar and Rodríguez-Pose 2011). Without this influx of external knowledge, there is a danger that firms miss out new opportunities or pin their hopes on the wrong technologies. Vice versa, without local buzz, the cluster's external pipelines are also of little use. Local buzz enables firms to rapidly filter out from the mass of external information those elements that are particularly important for the development of technologies (Bathelt and Glückler 2011).

Although related cluster approaches often draw on dynamic concepts, such as growth and reproductivity, they are mostly static in character. Such approaches focus on network aspects and do not conceptualize the genesis and evolution of clusters (Maskell and Malmberg 2007).

31.4 Regional Path Dependence and Cluster Life Cycles

The growing interest in cluster dynamics originates from the failure of conventional static models in explaining local crises and structural changes. A dilemma of such research is that localized benefits are expected to happen once clusters exist. The question of how cluster structures emerge in the first place is neglected in this work or viewed as an “individualistic” process. Since the factors that support a cluster's genesis may differ from those that support its ongoing growth (Bresnahan et al. 2001), a systematic conceptualization of clusters requires a dynamic component.

One strand of the literature on cluster dynamics focuses on the concepts of path dependence and lock-in related to evolutionary theories. A conceptual challenge when applying metaphors from evolutionary economics or evolutionary biology to economic geography is, of course, to justify the transferability of path-dependence explanations – originating from microlevel analysis of organizational behavior – to the aggregate local/regional level. A natural way of justifying the use of evolutionary ideas at the local level is to demonstrate that geography matters in the realization of path-dependent processes. Such processes – be it related to technological lock-in, externalities, or institutional inertia – do not occur in a spaceless world. The idea that a firm's interactive learning processes, strategic choices, and organizational routines are shaped by the local cultural and institutional environment has been repeatedly pointed out in the network tradition of cluster research. In this view, path dependence is associated with a place-dependent evolutionary process (Martin and Sunley 2006). Various empirical studies add to this argument by illustrating that regional path dependence can persist over a very long time period (Grabher 1993; Saxenian 2006).

Further theoretical exploration of evolutionary thinking in economic geography goes beyond preliminary claims of regional stability. History matters but does not determine future trajectories of clusters (Bathelt and Glückler 2011). Related to this, it appears that path dependence overaccentuates the continuity and stability of regional developments while discontinuities and structural crises, which are equally if not more important, are rarely conceptualized. To conceptualize structural change and path dependence in a consistent manner requires a different interpretation of clusters.

The traditional path-dependence model treats clusters as homogenous entities that form the unit of analysis. Even though social relations of firms are acknowledged in the localization process of a new path, the central focus is the overall intensity of local networks rather than their internal structure, let alone changes in the network structure of social relations. Since the position in a network impacts the kind of knowledge an agent can receive, a diversified set of agents is likely associated with more diversified structures of local knowledge flows and networks. Therefore, new path creation of clusters – an outcome driven by the interaction between agents – is more likely to occur in regions with varied structures (Frenken et al. 2007; Boschma and Iammarino 2009). The focus on the heterogeneous and diverse nature of regions revitalizes evolutionary thinking in economic geography. In a transformational context, therefore, re-bundling processes in a region without diversified networks may lead to the development of hollow instead of renewed clusters (Bathelt et al. 2004). By viewing regions as composite systems and drawing inspirations from evolutionary ideas in political science, Martin (2010) puts forward an alternative model of path dependence to highlight dynamic path processes. By inspecting interactions of agents in different network positions, Sydow et al. (2010) make an effort to combine conceptions of path dependence with Giddens' (1984) structuration theory, thus trying to disentangle the underlying agency processes of new path creation in clusters. The tripolar framework, developed in the next section, draws from a similar conceptualization.

Although contributions to new path creation complement interpretations of clusters as quasi-permanent structures, evolutionary perspectives are, thus far, still limited by a relatively narrow focus of analysis. In views of path dependence, singular interpretations dominate, whereby cluster dynamics are restricted both theoretically and empirically to industry, technology, or institutional structures. In contrast, aspects of the coevolution of interrelated economic, technological, institutional, and sociocultural arenas – “a key issue for further research” (Martin and Sunley 2006, 413) – are remarkably under-conceptualized. Singular views of evolutionary dynamics are also strong in regional analyses. In conventional studies, the evolution of clusters has primarily been explained at the local level, leading MacKinnon et al. (2010) to criticize evolutionary economic geography as neglecting social structure, labor relations, and capital accumulation at a broader macro-level. In globalized competition, especially in capital-intensive industries, influences at the national and international scale are indispensable to understand evolutionary processes. To go beyond a regional theorization of cluster evolution is also propelled by international technical communities that promote cooperation and competition between clusters (Saxenian 2006).

Other conceptualizations of cluster evolution draw on industry or product life-cycle theories (Klepper 1997). Industry life-cycle theories suggest that a dominant product design does not exist during the early stages of industrial development and that new technologies only flourish in selected areas. With increasing maturity, markets become more stable, knowledge gets codified, and dominant technologies emerge. Since communication of tacit knowledge and technological innovation are key features of innovative clusters, a natural corollary of life-cycle theories is that innovative clusters most likely develop in an early rather than a mature stage of industrial development (Iammarino and McCann 2006). The point of this argument is that the evolution of clusters corresponds with and follows from the technological paradigm of those industries that form their bases.

Cluster life cycles are often a regional version of industry life cycles. Strong emphasis on the role of technology in cluster dynamics in these approaches, however, adds an element of determinism to the explanation. When using technological paradigms to explain the rise or failure of industrial clusters, there is a danger of a posteriori reductionist reasoning. It is easy to explain technological changes of an industry when looking back, but difficult to foretell what will happen in the future. Accordingly, only after clusters succeed or fail can the rationality of a technology regime be fully understood. In practice, however, a change in technology is not an external factor that determines the cluster's evolution but the outcome of the interconnected nature of the firms' choices and actions along the dynamics of cluster development. Cluster-, industry-, and product life-cycle theories predict technological change in a deterministic manner rather than explaining the origins of technologies as resulting, for instance, from cluster innovation.

Other cycle conceptualizations are different in that they presume that cluster life cycles are existent rather than constructed. Related research pays attention to uncovering the characteristic forces at each stage of a cluster cycle. Accordingly, different forces have been identified, through which clusters move from one stage to another (Maskell and Malmberg 2007; Menzel and Fornahl 2009). Early discussions of this type of cluster cycles implied that clusters experience a unidirectional stage-to-stage development. To free clusters from such deterministic reasoning, Menzel and Fornahl (2009) add feedback loops allowing clusters to jump back to earlier stages during the sustainability or decline stages. However, such relaxation of stage rigidity only alleviates the mechanical characteristics of cluster cycles. It is problematic to assume that a single life cycle could cover the diverse trajectories of clusters in different real-world contexts. Even Martin and Sunley's (2011) recent attempt to conceptualize cluster dynamics as an adaptive-cycle model drawing on evolutionary ecology does not fully overcome the idea of a "natural" development trajectory. They suggest that cluster evolution proceeds through different stages that can lead to continuous cyclicity but also get stuck in stages of ongoing adaptation, stabilization, reorientation/renewal or decline and disappearance of existing clusters.

Although evolutionary and life-cycle conceptualizations of cluster dynamics draw from different origins, they share two aspects in their theoretical construction. First, in both discussions cluster dynamics are typically conceptualized from model

assumptions rather than derived from within their regional or national contexts. Forces driving cluster evolution are, in many models, situated at aggregate levels beyond the individual agent. Such a way of conceptualization risks overabstraction, potentially losing sight of interesting insights happening “on the ground.” Studies may thus dismiss the diversity of trajectories of cluster development.

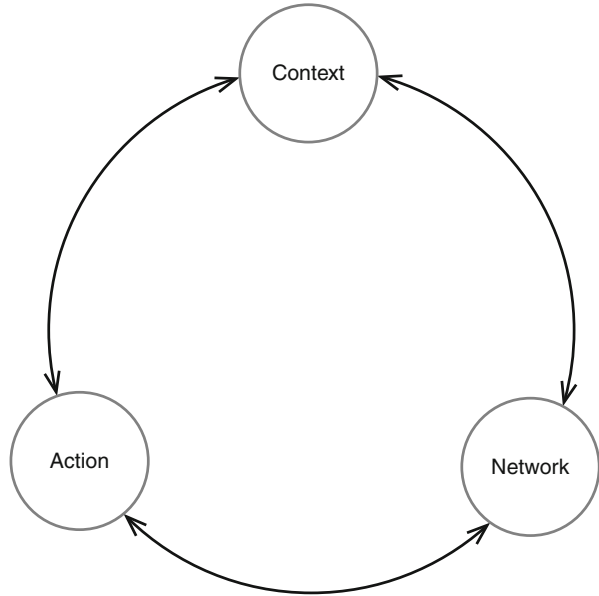

Second, there is an inclination to disregard changes in the underlying social structure. In cluster life cycles, different stages are mainly distinguished by observable indicators, such as firm size and number of employees, or by indicators that are less easily measurable, such as technology and diversity of local knowledge pools. In terms of the institutional dimension, it is institutional inertia rather than reforms of institutions that are captured by lock-in processes. Local business culture and social networks, which have been extensively discussed in the network paradigm of clusters, are deliberately excluded in these theoretical frameworks of cluster dynamics. It is suggested that path-dependent evolution leads to long-term stability in or irreversibility of spatial industry patterns (e.g., Boschma and Iammarino 2009). The problem of this view is that the seeming stability of aggregate patterns hides changes in the social structure and network relations underlying these meso-macro patterns.

As significant as evolutionary and life-cycle conceptualizations may be, their concentration on normative descriptions of cluster dynamics draws away attention from the analytical concerns of cluster theories. In a different approach, the theorization developed in the next section aims to frame the relationships of those forces enabling and shaping diverse trajectories of clusters. Based on observations of the economic agents’ behavior at the local level, as well as beyond, this conceptualization aims to extract key influences of cluster dynamics in the long run. Instead of asking how clusters will evolve, our analytical framework gives priority to the question of why clusters change. This does not presume the existence of a general theory that extracts the critical forces behind the dynamics of clusters.

31.5 Toward an Integrated Relational-Evolutionary Model of Cluster Dynamics

Any conceptualization of clusters presumes an interpretation of what a cluster is. In our view, a cluster is neither an organism, which can grow and decline per se, nor an entity, which can be described by a single rationality or technology. In the tripolar framework, a cluster is a group of agents and firms that are bound together geographically, technologically, and relationally. In this vein, trajectories of clusters are aggregate – planned as well as unanticipated – outcomes of the individual choices and actions of local agents, as well as the synergies that derive from them. Analytical frameworks of cluster dynamics need to be formulated in relation to the actions and motivations of local agents. From the contingent, relational, and accumulated characteristics of the local agent’s behaviors (Bathelt and Glückler 2011), three important pillars are identified as central analytical categories in the tripolar framework. These are context, network, and action, bound together in a reflexive manner that stimulates an evolutionary dynamic (Fig. 31.1).

Fig. 31.1 A tripolar analytical framework of cluster evolution (Source: Li et al. (2012, 133))

Context. Actions of local agents are contingent, which makes it hard to predict such actions. Contingency is directly related to the first pillar of our framework: the specific context in which actors are situated. By context, we mean the economic and institutional structures influencing local actors in the process of making and fulfilling decisions. This influence also includes the results of previous actions of other agents. The economic structure of clusters involves industry and market characteristics, technological patterns, intra-firm organization, and the dominant interfirm linkages inside and beyond the region. The institutional structure, in turn, refers to the local and nonlocal political regimes, routines, conventions, and value and belief systems. The economic and institutional settings, which are structured by the division of labor and the geographical distance between activities (Storper 2009), influence the local actors' knowledge base and their interaction. When applied to cluster evolution, the economic and institutional dimensions of context are often blurred since long-term interfirm connections can form powerful interest groups, stabilizing the local institutional context (Grabher 1993).

Context both constrains and enables action in clusters. From a psychological and pragmatic perspective, Storper (2009, 13) proposes an informational interpretation of context, the structural component of which "is defined by the division of labor in which the actor finds himself, which has a decisive influence on the information environment for the individual, hence his 'input' structure of cues and reference points." In this sense, context has an impact on the ways how actors find and apply information and knowledge, leading them to choose certain actions over others. The relationship between context and action is neither predetermined nor normative. A specific context does not determine what actors do but limits ways of coordinating actions in a given situation. In other words, there are different frameworks of action

in possible worlds of production, yet, in a certain context, some coordinated collective actions are more likely than others (Storper and Salais 1997). The effects of context on performance are not predetermined as they can be positive or negative (Storper 2009). On the negative side, the practical environment of actions restricts what kind of knowledge local actors may receive. On the positive side, context enables what agents in clusters can do by creating a bias toward certain kinds of knowledge. Therefore, for local agents, the question is not how to escape restricted contexts and/or enter more beneficial environments, but how to reflexively interpret practical situations and make appropriate adjustments. Context becomes an important influence once it has been internalized into the actors' motivations and behavior. In sum, the constitution of context reflects the duality of structure, both as a medium and an outcome of the agents' practices (Giddens 1984).

From a structural perspective, actions are structured by contexts. At a particular time for a specific local actor, context is a given constraint. Over a long time span, however, contexts are constructed by actions and are thus variable. Routines and conventions of doing business are formed based on foreseeable expectations about the mutual behavior of others as an outcome of recursive interaction. Ongoing interfirm relations are consolidated through the successes of series of transactions. Competitive patterns of industries are shaped by the choices and practices of actors in comparison with those of their competitors. Context is thus not a predestined background against which agents make choices and take actions; rather, it is constructed and sustained by ongoing practices of *all* agents. This means that the context, in which all agents are situated, usually cannot be controlled by single or exclusively local agents. At the cluster level, actors can modify their context in several ways, but there are also important components that are out of the hands of local agents. Although firms in clusters may engage in collective action to alter the supply conditions of a specific industry, they cannot easily change the demand of customers directly or influence national macroeconomic policies, legislative frameworks, and education systems.

Network. Network refers to the contextualized social relations of agents and firms within, but not limited to, the local production system. The wider structure of input–output linkages of firms also becomes part of the economic context of agents in clusters. In practice, social and economic relations are inseparable indicating that traded and untraded interdependencies (Storper and Salais 1997) are closely interwoven. As to trade linkages, the incompleteness of contracts leaves room for the development of trust (or distrust) between related partners in the negotiation and during the course of economic transactions. Mutual trusted relations become indispensable for traded interdependencies. Social networks in some places also originate out of economic rationales. Although not originally part of economic transactions, new personal relationships may be established over time through repeated economic transactions. In the end, however, it is the compellability and inspiration of personalities that trigger the formation of new social networks at a person-to-person level. Economic transactions offer opportunities for interaction and communication based on which some personal relationships develop, and not others. At the regional level, personal social networks may exist before the

formation of clusters. Such networks can become a key mechanism in the diffusion of market and technology information and develop into a cluster later on.

Changes in value and belief systems, advances in telecommunication technologies, and the intensification of interfirm competition can trigger a transformation of personal interaction toward a broad societal level beyond the region. In reflecting trust and ontological security systems between different societies, kinship relations can be viewed as providing a stable mode of organizing personal relations in the premodern societal context. These relations have been substituted by relationships of friendship or emotional intimacy in modern society. It is thus reasonable to assume that for clusters in developing or transitional economies, structures of social networks at the personal level will also change in the modernization process. Such a change of basic personal networks also impacts strategic actions within clusters, yet to maintain personal relations requires regular interaction and communication. Networks in this sense are “as much process as they are structure, being continually shaped and reshaped by the action of actors who are in turn constrained by the structural positions in which they find themselves” (Nohria 1992, 7). By viewing networks as dynamic connections within heterogeneous contexts that are shaped by actions, the context-network-action framework conceptualizes deeper changes in the socioeconomic structure of clusters.

Action. Even though context and network offer powerful insights into the behavior of local agents, action still needs to be treated as a separate pillar in our framework because experience from action develops in a cumulative fashion, and agents learn based on their absorptive capability (Cohen and Levinthal 1990). At both the individual and organizational levels, prior related knowledge helps and directs agents to use and assimilate new knowledge. The more specialized knowledge agents have previously acquired, the faster they can learn within their context or network. The role of absorptive capability of agents suggests that learning is a cumulative and path-dependent process with self-reinforcing characteristics. A conceptualization of cluster evolution without action would bear the risk of overemphasizing exogenous variables. Action refers to the individual level of decision-making that depends on specific personal and internal organizational structures, as opposed to the external context.

In our framework, context, network, and action are equally indispensable. Conceptualizing cluster dynamics without recognizing all three pillars provides only a partial understanding. Merely emphasizing the role of stable networks in local actions risks failing to understand diversifying patterns with transitional or developmental background. Conceptualizations, which limit themselves to emphasizing the importance of external contexts for actions, conversely neglect the role of human agency in regional practices (Scott 2006). Also, the theorization of actions that are withdrawn from the agents' network and context would lead us to view clusters as organisms or groups of unrelated agents, neither of which would reflect real-world structures.

In sum, the tripolar framework offers a systematic way of studying and interpreting the evolution of clusters. At the regional level, it is the interaction of these pillars that explains the evolution of clusters, yet the framework does not

Fig. 31.2 Evolutionary dynamics in the tripolar cluster conception

produce ideal-type cluster visions since the dynamics of the three pillars can work in both vicious and virtuous ways:

- a. *Vicious Cycles*. We refer to interrelationships between the pillars as being vicious if they produce lock-ins and result in regional decline, as illustrated by the contractive interactive movement of the three pillars in Fig. 31.2. In the literature, economic crises in industrial districts are often explained by changes in economic contexts, such as a sharp drop in demand or the appearance of new technologies. But a transformation of the external environment accounts for only one part in the overall stagnation of clusters. Weaknesses within the networks of a region can also be responsible for the rigidity of old industrial areas. Reasons for regional failure can be classified as different forms of lock-ins (Grabher 1993), which are consequences of interrelationships between the three pillars. First, decades of cooperation (action) in infrastructure projects and subsidy programs may stabilize intensive relations between people and firms (network) in an industry and corresponding policy field, thus strengthening a local conservative regime (context) that constrains further adjustment of local agents. The ossified institutional context may result in “political lock-in.” Second, long-term personal networks of local agents can result in similar reactions (action) to demand changes and technological opportunities. A homogeneous view of the world caused by intensive social networks in clusters may be the consequence of “cognitive lock-in.” Third, the stable demand for products may fixate the localized social division of labor and support a rigid economic context. The enduring fragmentation of activities among firms can result in shortcomings in the local agents’ learning processes and investment decisions regarding R&D. By exclusively concentrating on certain activities, the local agents’ accumulation of knowledge becomes biased and absorptive

capabilities with respect to new knowledge may become more restricted. In Grabher's (1993) classical typology, this rigidity of interfirm connections (economic context) generates "functional lock-in."

- b. *Virtuous Cycles*. In contrast to the above, virtuous interrelations between the three pillars can develop that have positive effects, as illustrated by the expansive interactive movement of the three pillars in Fig. 31.2. Agents with overlapping knowledge bases are, for instance, motivated to cooperate and communicate. Through the action and interaction of diversified agents, knowledge circulates in clusters, ideas collide, and innovation becomes more likely. In turning innovative ideas into business successes, the agents' relationships (network) that have been established in previous interaction are reinforced. Some commercialization of innovation may fail but there are also successes, which may reorder the existing industrial structure (economic context) and change the existing cluster path. Successful cooperation of agents not only results in economic returns to innovation but may also establish new interpretations of the context within which the agents are situated while producing important knowledge about their strengths and weaknesses. Agents with enhanced reflexive capability with respect to their context are more likely to act in anticipation of, rather than react to, future changes.

At the regional level, clusters with pre-active agents across different networks are characterized by high adaptability. This can lead to dynamic processes of path creation. Along with dynamic interactions of agents, mutual expectations regarding the coordination of actions may turn into unconscious routines and norms (institutional context), which become new components of the overall intangible regional assets. In the long run, these regional assets – both social networks and routines of doing business – are thus constructed, sustained, and altered through social reproduction. In Giddens' (1984) sense, the interaction of context, network, and action in virtuous cycles actively drives a regionalized structuration process.

31.6 Conclusions

This chapter started by discussing recent relational and evolutionary perspectives in economic geography, arguing that it is useful to integrate both approaches to combine their strengths rather than discussing them against one another. Applying these approaches to the study of regional industry clusters, it is suggested that both have shortcomings if used in isolation: While relational conceptualizations that focus on the social relations and structural dimensions of clusters tend to neglect aspects of cluster dynamics, evolutionary approaches do not sufficiently understand the underlying structure of social relations in clusters. To overcome this, we suggest a *tripolar framework of cluster evolution* that presents a combined relational-evolutionary perspective. Some elements of this framework are also reflected in the adaptive-cluster model described by Martin and Sunley (2011) – albeit at the

expense of assuming a predefined natural cycle. We believe that the tripolar approach provides important insights about network dynamics and cluster evolution in a spatial perspective:

First, the concept of *network* is relational in nature and should be interpreted in a contingent way (Bathelt and Glückler 2011). Research on networks in clusters has focused on the intensity of existing linkages, generally assuming that such ties are responsible for regional success or failure. Be the ties strong or weak, a relational-evolutionary perspective is skeptical of whether such a static interpretation of network can account for multifaceted regional developments. In the tripolar framework, network is only one pillar of the entire system and changes over time in interaction with the other pillars of context and action. One has to consider the dynamics of the *whole* framework to be able to properly evaluate the impact of strong or weak ties on cluster evolution. A specific network structure, for example, that supports a cluster's growth in one instance may turn out to be detrimental to regional competitiveness in a different setting.

Second, local traditions of action and interaction need to be evaluated in the specific *context* in which they matter for cluster evolution. Contextualized interpretations provide a perspective to understand why history matters in a nondeterministic way which is a thorny issue in evolutionary economic geography. With new political-economic contexts, for instance, new practices of interaction among individuals and organizations can form and become new elements of local structures and traditions. But not all practices of interaction develop into key elements of "regional assets." The degree to which a regional path can be established by local action depends on the specific context within which the local agents are situated (Storper 2009).

Third, the evolution of clusters is shaped by the aggregated *action* of local agents, as well as the unintended consequences of this action. Since some contexts are out of the hands of local agents, action may have unintended effects that shape future settings and affect individual and collective action in the next round. Consequently, the integrated relational-evolutionary framework rejects a normative model of cluster evolution or cluster life cycles, especially since there are also unexpected strategic actions that may, in the end, significantly alter the trajectory of clusters.

In sum, the tripolar framework conceptualizes cluster evolution through systematic interrelationships and ongoing feedbacks between context, network, and action. Focusing on the interdependencies of these important pillars, the framework demonstrates the value added of combining relational network-focused and evolutionary approaches in cluster research. A relational component in the tripolar framework helps explain *why* clusters evolve, thus avoiding deterministic elements in previous cyclical and evolutionary approaches. Further, an evolutionary perspective serves to extend the interpretation of local relations from a traditional static to a dynamic level of analysis. As an illustration of relational-evolutionary theorization on a specific topic, the tripolar framework reveals the potential of combining these different approaches to deepen our understandings of turbulent regional worlds. Therefore, this chapter may be regarded as an invitation to an integrated relational-evolutionary theorizing in economic geography.

Acknowledgements This chapter, to which both authors have contributed equally, is based on a more extensive conceptual and empirical study (Li et al. 2012). We would like to thank Andres Rodríguez-Pose for his encouragement and Manfred Fischer and Peter Maskell for thoughtful comments.

Abstract

The concept of path dependence has rapidly assumed the status of a “fundamental principle” in the new paradigm of evolutionary economic geography that has emerged over the past few years. This chapter reviews the interpretation and use of this concept within this new field. The dominant interpretation has been that of “lock-in,” by self-reinforcing mechanisms, of particular (equilibrium) patterns of industrial location and regional specialization. This model is somewhat restrictive, however, and does not capture the full repertoire of ongoing path-dependent evolutionary trajectories that can be observed in the economic landscape. To respond to this limitation, the chapter suggests a “developmental–evolutionary” model of path dependence that includes “lock-in” as a special case, but which is also more general in its application and relevance.

R. Martin

32.1 Introduction

In recent years, the concept of path dependence has assumed a key explanatory role in a wide spectrum of social sciences and is now part of the standard lexicon of any approach that has pretensions to being “evolutionary” in orientation. Any evolutionary perspective on the socioeconomy starts from an elementary but important fact, namely, that, in each period, a socioeconomy inherits the legacy of its own past. Once this is acknowledged, we are faced with the possibility that “history matters.” The notion of path dependence is intended to imbue this idea with some degree of conceptual and explanatory rigor and hence go beyond simple narratives that merely describe historical effects. The idea of path dependence in its modern form was first developed by economists Paul David and Brian Arthur in the 1980s and early 1990s (David 1985, 1986; Arthur 1989, 1994) to explain technology adoption processes and industry evolution. Arthur’s discussion of the concept is particularly interesting, since he made explicit reference to the importance of path dependence in shaping the location of industry (Arthur 1994), a point also emphasized around the same time by Paul Krugman, who argued that:

If there is one single area of economics in which path dependence is unmistakable, it is in economic geography – the location of production in space. The long shadow cast by history over location is apparent at all scales, from the smallest to the largest. (Paul Krugman 1991, p. 80)

Although an early use of path dependence ideas to explain regional development was Grabher’s (1993) study of the Ruhr in Germany, it has only been over the past decade or so that the notion has really been taken up by economic geographers. In particular, the concept has assumed central importance in the theoretical and empirical contributions to the new paradigm of evolutionary economic geography that has emerged over the past few years (see Boschma and Martin 2007, 2010; Martin 2010a) and has come to be regarded as a key “organizing concept” for understanding how the economic landscape evolves over time.

The reason for this take-up of the concept of path dependence in evolutionary economic geography is not hard to explain. As evinced by David and Arthur, path dependence refers to a particular type of process that leads to the asymptotic convergence of an economic form or structure to a stable, “locked-in” configuration that can only be changed or “de-locked” by some sort of external shock or disturbance (see also Castaldi and Dosi 2006). Likewise, geographers argue, industrial location patterns and regional economic specializations show a similar process of self-reinforcing “lock-in.” We know that regional industrial structures, local economic specialisms, urban locations, and geographical patterns of development do not suddenly spring up over night, but have their origins in the past, and are built up over time, in many cases spanning several decades. Neither, typically, do spatial economic structures and configurations change suddenly. It is clear that any one point in time, the spatial structure of an economy is very similar to, and highly influenced by, the structure in the immediate and even less immediate past. The economic landscape we observe at any point in time has been shaped by the

historical adjustment path taken to it: it reflects its past development. Put another way, the economic landscape evolves as a consequence of its own history. In this sense, as Krugman argues (in the quote above), it is possible to argue that history casts a “long shadow” over industrial location patterns.

Yet, intuitive and appealing though this invocation of path dependence as a process shaping the spatial economy might be, it is not a straightforward notion. Even a “lock-in” definition can be given different interpretations and representations, and “lock-in,” if present, can be considered to be a positive feature or a negative one (see Martin and Sunley 2006). Further, different authors have used different formal models to represent path dependence, and these imply somewhat different definitions of the process. More generally, in the last few years, the frequent definition of path dependence as “lock-in” has itself come under increasing scrutiny, especially in political science, historical sociology, and management and organization studies. In these fields, there has been a growing reaction against the original model of path dependence as articulated by David and Arthur. Critics of this conceptualization argue that “lock-in” implies stability, stasis, or no change, or at the very least a particular form of evolution, namely, one in which long periods of stability are separated by periodic phases of rapid and disruptive change, whereas in reality many social and political structures and product and process technologies within business organizations evolve more or less continuously, yet still display path dependence. Accordingly, these writers have put forward alternative or revised models of path dependence that they believe more faithfully capture the actual varieties and patterns of path-dependent development observed in socioeconomic and technological systems. These alternative models may not produce the very “strong” form of path dependence associated with “lock-in,” but rather depict path dependence as an ongoing or “unfolding” process of adaptation whereby purposive behavior by individual agents, drawing on the structures and outcomes inherited from the past, actively reshapes those structures and outcomes: path dependence and path adaptation become inextricably linked.

Economic geographers and regional analysts do not seem to have been fully appreciative of these debates, yet they have important implications for how the concept of path dependence can be used to understand how regional and local economies evolve (see Martin and Sunley 2006; Martin 2010a, 2012). And here, additional issues also intervene. Regional and local economies are complex, heterogeneous, and highly open systems, often encompassing several different industries and activities, or subsystems, and are unlike the singular technologies, institutions, or products that are so often the subject of path dependence analysis in other disciplines. This complexity begs the question of what it is in regional and local economies that is path dependent. In addition, and potentially of critical importance, is the question whether path dependence is simply a general process or dynamic that shapes geographical economic outcomes, or is itself a process that is shaped by geographical context: in other words, is path dependence to some extent place dependent (Martin and Sunley 2006)? Still further, how does the concept of path dependence relate to our existing theories of (uneven) regional development? One of the criticisms leveled at the expanding paradigm of

evolutionary economic geography is that its advocates seem more intent on constructing a separate perspective than on integrating their evolutionary ideas and concepts with existing approaches, some of which, it is claimed, already take history seriously in one way or another (Mackinnon et al. 2009; Coe 2011; Oosterlynck 2012). This issue would seem to apply a fortiori to path dependence. Should the aim be to construct a distinct “path dependence theory” of regional growth and development, and what would such a theory look like? Or should the objective be to explore both the implications of the concept for existing regional theories, and what those theories imply for the idea of path dependence?

It is certainly not possible to take up all of these issues in detail in this short review of the “state of the art,” and what follows is necessarily somewhat selective and partial in coverage. I begin by summarizing the “canonical” interpretation of path dependence as “self-reinforcing lock-in,” and how far and in what ways this model is applicable to the spatial economic landscape. I then move on to examine some of the alternative views of path dependence that have been emerging in certain social and historical sciences, and what these interpretations imply for how we might think about the idea of regional path dependence. Building on this discussion, I then suggest what might be called a “developmental–evolutionary” view of path dependence, an interpretation that, while capable of including the basic “lock-in” model as a special case, allows for a much wider repertoire of evolutionary outcomes.

32.2 Path Dependence as Self-reinforcing Spatial Economic “Lock-in”: What Does It Mean and How Common Is It?

At least four formal models (and associated interpretations) of path dependence can be identified from the economic literature (see Table 32.1). One attempt to characterize the process of path dependence mathematically is in terms of a dynamic system which can be reduced to a difference equation in some key dependent variable, say X , which possesses a unit root, which means that the value of X_t in any period t embodies “memory” of its previous values and is thus dependent on its entire prior adjustment path. Such a unit root system does not converge to any equilibrium value or state: instead, the “long-run outcome” is defined as such by virtue of the temporal distance from some initial starting state, that is, from X_0 . Such an interpretation begs the question, of course, of what the “carrier of history” is that imbues the system or characteristic X with path dependence. Secondly, some authors (e.g., Setterfield 1998, 2009) provide this mechanism in terms of Kaldorian-type recursive cumulative causation models of national and regional growth, in which technological and institutional dynamics also play a key role. Again, in these structural difference equation models, no long-run equilibrium solution or state is implied. Thus far, models of this sort have not figured in economic geographers’ studies of spatial or regional path dependence, even though they would seem to offer a potentially useful avenue to explore. Instead, economic geographers have tended to rely almost entirely on the original notions of path dependence developed by David and Arthur.

Table 32.1 Four formal models of path dependence

Formal model representation	Typical application
1. <i>Path dependence as an absorbing Markov chain process</i> , in which a system has a probability transition matrix with more than one absorbing states ($p_{ii} = 1$), so that the system converges on a final distribution across states that depends in the initial (starting) distribution	Model implied in David's writings on the "lock-in" of technologies or institutional standards to historically fixed and unchanging forms, which may or may not be the most (market) efficient
2. <i>Path dependence as a nonlinear Polya (urn) stochastic process</i> in which the probability of an outcome of a given type in a given period increases the probability of generating that same outcome in the next period (a "proportions to probability" mapping). Model converges to an equilibrium distribution that is dependent on the initial (random) distribution	Model used by Arthur to generate the progressive "lock-in" of locational distributions of industries or cities to long-run stable spatial patterns that become self-reproducing
3. <i>Path dependence as a unit root process</i> in which a dynamic system can be reduced to a difference equation in the key dependent variable, say X, which possesses a unit root, which means that the value of X in any period t embodies "memory" of its previous values and is thus dependent on its prior adjustment path	Model used by various authors to study short- and long-run macro-dynamic phenomena. Such unit root models do capture at least one key aspect of path dependence, namely, the propensity for transitory random events shocks to have permanent effects
4. <i>Path dependence as a recursive cumulative causation process</i> in which recursive feedbacks among the structural components or relationships of a system reinforce a given trajectory or pattern of development. No long-term equilibrium is implied	Model used to generate Kaldorian-type, export-driven models of national and regional growth, with recursive dynamics (see Setterfield 2009), for example, $X_t \rightarrow Y_t \rightarrow Z_{t+1} \rightarrow X_{t+1}$ and so on

Basic to David's and Arthur's interpretations is the argument that rather than assuming an economy converges to a unique (pre-given) equilibrium irrespective of where it starts from – the approach taken by conventional economic theory – the nature of the (long-run) equilibrium an economy reaches depends on the process of getting there, and this will depend on some happenstance event in the past which then becomes selectively and progressively "locked-in" by some form or other of "self-reinforcing" mechanism. Thus, instead of a single equilibrium, there are multiple possible equilibria and which one the economy ends up in will depend on contingent events in the past. Here is David on the issue:

Small events of a random character—especially those occurring early on the path—are likely to figure significantly in 'selecting' one or other among the set of stable equilibria, or 'attractors.' (David 2005, p. 151)

The elaboration of theories around the core concept of path dependent dynamics...encourages and enables economists to entertain the possibility that, in place of a unique equilibrium-seeking dynamic, they should envisage a process that is seeking an historically-contingent equilibrium. (David 2007, p. 2)

Both David and Arthur conceptualize path dependence in terms of the limiting distributions of non-ergodic stochastic processes (see Table 32.1). In David's

Table 32.2 Processes-generating path-dependent lock-in

David's model ("Network externalities")	Arthur's model ("Increasing returns effects")
1. <i>Technical interrelatedness</i> (the reinforcing effects of complementarity and compatibility among the different components of a technology and its use)	1. <i>Large initial fixed setup costs</i> (in effect the inertia of sunk costs)
2. <i>Economies of scale</i> (the benefits associated with the increasing use of a technology – such as a decline in user costs – as the technology gains in acceptance relative to other systems)	2. <i>Dynamic learning effects</i> (learning by doing or using and learning by interaction tend to entail positive feedbacks)
3. <i>The quasi-irreversibility of investments</i> (the difficulties of switching technology-specific capital and human skills to alternative uses)	3. <i>Coordination effects</i> (which confer advantages to going along with other economic agents taking similar actions)
	4. <i>Self-reinforcing expectations</i> (when the increased prevalence of a product, technology, process, or practice enhances beliefs of further prevalence)

Based on Martin (2010)

accounts, path dependence is likened to a Markov chain process with one or more absorbing states. Which absorbing state (long-run limiting equilibrium distribution) such a system will end up in will depend on where it started – “history matters” – but once in that state, the system cannot escape: it becomes “locked” into that particular equilibrium outcome. In Arthur’s formalization, path dependence is represented by a nonlinear Polya urn process, which possesses a multiplicity of possible stable fixed (equilibrium) outcomes (structures) of which one will be dynamically “selected” and “locked-in”:

Often there is a multiplicity of patterns that are candidates for long-term self-reinforcement: the cumulation of small events early on ‘pushes’ the dynamics into the orbit of one of these and thus ‘selects’ the structure that the system eventually locks into. (Arthur 1994, p. 33)

Arthur uses this model to show how industrial location can be interpreted as a path-dependent process that progressively “locks into” a stable, fixed distribution (of shares) of firms across regions. It is assumed that the autocatalytic or self-reinforcing mechanisms that generate path dependence (see Table 32.2 for the mechanisms identified by David and Arthur) have a spatial dimension, in that firms choosing where to locate are attracted by the presence of other firms in a region. Arthur describes two such models. In the “spin-off” version, the path-dependent geographical distribution of industry occurs through a process of local firm “spin-offs” from parent firms: This type of birth mechanism is argued to have characterized the US electronics and car industries. In the “agglomeration economies” version, if one region by chance gets off to a good start, its attractiveness and the probability that it will be chosen will be enhanced, further firms may then choose this region, and it becomes yet more attractive because of the emergence of various agglomeration economies and externalities, and the concentration of firms there becomes self-reinforcing. If such agglomeration economies are unbounded, then the model predicts that all of the firms in the industry will eventually end up in

one region: Arthur suggests Silicon Valley as a possible example of this sort of “locational monopoly.” A not dissimilar similar idea of self-reinforcing “lock-in” of a spatial economic structure into one of a number of possible multiple equilibrium patterns is to be found in NEG models. However, since such models are basically comparative static in nature and spatial agglomeration as one possible equilibrium outcome occurs instantaneously (for given assumptions about transport costs, wage functions, etc.), the often-made claim that these models incorporate “history” and “path dependence” is questionable (see Martin 2010b; Garretsen and Martin 2010).

The point about both David’s and Arthur’s models is that according to chance (combined in some cases with necessity, such as the spatial distribution of raw materials or natural resources), a different path-dependent spatial outcome might have been obtained with some other region becoming dominant. Thus, with different initial conditions (chance, random, or contingent events) combined with self-reinforcing path dependence effects, a multiplicity of possible equilibrium spatial economic structures can result. Which particular equilibrium (long-run) spatial economic structure becomes “locked-in” is assumed to remain fixed until such time that it is “de-locked” by a disturbance of one kind or another. (Likewise, in NEG models, a shock – such as a reduction in transport costs or a policy intervention – can “de-lock” one equilibrium spatial distribution of economic activity and move the system to a different equilibrium pattern, what NEG theorists refer to as “locational hysteresis.”) Construed in these terms, then, the economic landscape evolves by the emergence and “lock-in” of historically contingent, long-run equilibrium locational patterns of industrial activity and specialization that are periodically disrupted and, eventually, replaced by the path-dependent development of new historically contingent equilibrium patterns: in essence, an evolution characterized primarily by “punctuated equilibria” (David 2007, p. 187, explicitly aligns his path dependence model with this view of economic evolution).

How far does this version of path dependence capture real-world patterns of regional economic development? To some extent, this depends on what it is we are looking at. Many industrial location patterns and local industrial specializations, once established, often do seem to be subject to, or to give rise to, “self-reinforcing” mechanisms and processes that “lock” those patterns in (Table 32.3). However, this conception also raises several questions (Martin 2010a). For one thing, the model predicts a progressive “lock-in” to a long-run equilibrium stable state – in the sense of a stable pattern of localization of an industry or pattern of local sectoral specialization. Indeed, David (2005, 2007) actually refers to “path-dependent equilibrium economics.” But just how long is the “long run”? The problem with using a formal stochastic model (such as an absorbing Markov process or a nonlinear Polya urn process) to define path dependence is that there is no correspondence between the (logical) “convergence to equilibrium time” in such models and the real history of actual real-world processes of economic activity and development. Nor do real-world economies necessarily ever reach equilibrium states, even of a “historically contingent” kind. The idea of an equilibrium, or of multiple equilibria, is an imposed assumption, not a proven fact. As Setterfield (2003) argues,

Table 32.3 Some possible sources of regional path dependence

Source	Features
1. <i>Natural resource based</i>	Regional development path shaped and constrained by dependence on a particular raw material or resource
2. <i>Sunk costs of local productive, physical, and infrastructural assets</i>	Durability and quasi-irreversibility of local specialized capital equipment, infrastructures, or built forms
3. <i>Local external economies of industrial specialization</i>	Marshallian-type dynamic externalities, and both traded and untraded interdependencies associated with specialized local industrial districts or clusters
4. <i>Local technological lock-in</i>	Development of distinctive local technological regime or innovation system through local collective learning, cognitive inertia, knowledge transfers, and imitative behavior
5. <i>Localized “spin-off” firm birth process</i>	Local parent firms are sources of “spin-off” firms in similar or related activity, possibly supplying the original parent firms, leading to the buildup of a local industrial specialization or cluster
6. <i>Agglomeration economies</i>	Generalized self-reinforcing economies associated with spatial concentration of activity, including product and labor market effects, thick networks of suppliers, services and information
7. <i>Interregional linkages and interdependencies</i>	Development path in one region shaped by and dependent on development paths in another region, for example, because of interindustry linkages (such as acting as a specialist supplier of inputs to, or dependent on inputs supplied by, an industry in another region)

Based on Martin and Sunley (2006)

the very process of an actually existing economy approaching a stable long-run equilibrium position or state is itself likely to stimulate individual behavior – “innovation,” as he calls it – by economic actors to change their activities and thus prevent that economy from becoming fully locked into that particular equilibrium state. This is the sentiment expressed in another way by Metcalfe et al. (2006), who argue that because knowledge is constantly changing, capitalism can never be in a state of long-run equilibrium, but is instead in a state of constant “restlessness” in which some sort of innovation and structural change occurs more or less continuously. To be sure, such innovation and structural change may at times be slow and incremental, or at other times may occur in fits and starts, but the idea of an economy being in any type of stable or fixed equilibrium, essentially a state of stasis, is incompatible with the nature of capitalism as a dynamic, evolving system, as a process of continual “creative destruction.”

In what sense, then, is it possible to talk of spatial or regional “lock-in”? As mentioned above, from one vantage point, the *locational patterns* of industry and specialization can be viewed as being characterized by a certain degree of “spatial equilibrium” or “lock-in.” However, the longer, in historical time, the “long run” is specified or permitted to be, the less the spatial structure of the economy is likely to remain in a stable, unchanging state. Moreover, even if the *spatial patterns* of

industries across regions and locations are stable (“locked-in”), this need not suggest that the particular industries and specialisms *within* individual regions and locations are necessarily in a state of stasis or stability, with no product, technological, or organizational change. However, this is precisely what Krugman (1991) ignores in his discussion of the path dependence and “persistent dominance” of the US Manufacturing Belt. While US manufacturing has long been concentrated in a relatively small area of the North East and East North Central regions, the nature of the manufacturing activity conducted there has evolved considerably over time. The geographies of production may shift and change relatively slowly, but the firms and industries in a region may be characterized by significant ongoing endogenous change. Competition from other producers in other regions, or from other producers within the same region, is a constant source of pressure on a given region’s firms to upgrade and modernize their products, to introduce new variants or ranges of products, and to improve their productive efficiency through innovation. If a region’s firms fail to upgrade and innovate sufficiently, they face losing competitiveness and market share and even going out of business. This process need not occur suddenly: economic landscapes are littered with industrial districts and clusters that have undergone slow and protracted decline. Some such districts and clusters may eventually disappear altogether. Others, however, may survive and even undergo renewed success, sometimes much smaller in size and serving specialist niche markets, and in other instances undergoing renewed expansion based on shifting into related or complementary specialisms (for a discussion of the different evolutionary trajectories that clusters may undergo, see Martin and Sunley 2011). A “punctuated equilibrium” model of path-dependent regional “lock-in” may not in fact fit many actual regional and local experiences.

Yet further, unlike a singular technology or institutional standard (of the sort favored by David and many others in their discussions of path dependence), a given industry in a region (even if it is the only industry) is typically composed of numerous firms, among which there is bound to be heterogeneity, of products, production methods, innovativeness, business strategy, and so on. This heterogeneity or *variety* – or “composition” effect – also suggests that the idea of a regional industry becoming “locked” into a stable equilibrium state, a state of stasis, is unlikely to be the norm. Very specific local circumstances are required for this sort of outcome to occur, such as a local industry based entirely on a local natural resource, or when the firms in a local industry are closely linked by a very high degree of technological interrelatedness – for example, a form of production involving a detailed horizontal interfirm division of labor – such that a change in one firm would require a change among all or almost all other firms, which might prevent any one single firm from changing in isolation. Such examples do obviously occur. But in most cases, the “lock-in” of locational patterns of industrial specialization *across space* by no means implies or leads to the technological or product “lock-in” of the firms *in individual places*.

The technological and product bases of firms, and thus industries, can and do change and develop over time, and the trajectories along which such development occurs can and do display path dependence, in that the improvements, innovations, and adaptations that firms make to their products and technologies invariably build

upon and are shaped by their existing products and technologies, which in their turn evolved out of previous versions. Essentially, then, as Page (2006) points out, it is possible to distinguish between two main types of path dependence: path dependence in which long-run *equilibria* depend on history, and path dependence in which *outcomes* are history dependent. Equilibrium path dependence is where the long-run distribution over outcomes depends on past outcomes: it is all about the historically contingent selection and self-reinforcing convergence to one of a number of possible limiting distributions over outcomes and links directly to the idea of progressive “lock-in.” Outcome path dependence is where the outcome in a period depends on past outcomes. Equilibrium path dependence implies outcome dependence, since if the long-run equilibrium distribution over outcomes depends on the past, then so must the outcomes in individual time periods. But outcome dependence does not imply equilibrium dependence: history matters in that current outcomes can be related, to some degree or other, to previous outcomes, and thus different previous outcomes are likely to have led to different present outcomes – the process is path dependent – but the path of outcomes over time need not converge to any long-run equilibrium or stable outcome. What this opens up is the possibility of a wider interpretation or conceptualization of path dependence, in which “lock-in” is only one, and a particularly “strong,” possibility, and in which pathways of technological, industrial, and regional development themselves evolve and unfold over time, in an outcome-dependent manner. This suggests the need for a wider conception of path dependence.

32.3 Rethinking Path Dependence: From “Lock-in” to Ongoing Path Evolution

Over the past few years, an increasing number of political scientists, historical sociologists, and management scientists have begun to explore what form(s) such a wider conception of path dependence might take. The “lock-in” model of path dependence has been frequently adopted in these disciplines to describe how political systems, social institutions, management practices, and the like evolve over time. But a growing corpus of empirical work has indicated that the evolution of these systems, structures, and organizations may in fact be much more ongoing and incremental than the “canonical” path dependence model would suggest. Put another way, it is argued that the standard path dependence model overemphasizes stability at the expense of ongoing change, mutation, and adaptation.

In historical sociology and political science, three main mechanisms have been suggested that operate at the micro-level to impart ongoing change to path-dependent institutional evolution: “layering,” “conversion,” and “recombination.” In a *layering* process, an institution or other such system changes gradually by the addition and accretion of new rules, procedures, or structures to what already exists. Each new “layer” (rule, etc.) constitutes only a small change of the institution as a whole, but this process can be cumulative over time so that while path dependent, the institution also evolves, leading to the mutation or even transformation of the institution’s fundamental nature. Not only does the addition of a new rule or

procedure to an institution depend on there being existing network externalities for its success, but this addition changes those externalities incrementally – and sometimes more substantially – in the process. Continuous incremental institutional change is thus both path dependent *and* path evolving.

A second process by which ongoing path-dependent change may occur in political and sociological systems is “conversion,” that is, the reorientation of an institution or other such system in terms of form or function, or both. Conversion can occur in two ways. First, the addition of new “layers” (new rules, procedures, and so forth) is itself a source of institutional conversion or reorientation, since the addition of new rules or procedures typically arises from the need or desire to alter an institution to serve new functions, roles, or imperatives. And the addition of a new layer may arise from, lead to, or necessitate the removal of an old layer. The second source of conversion is when the existing structures and arrangements of an institution are reoriented to serve new purposes, in response to external pressures or developments, or as part of a learning process by which existing rules are improved. No new rules or procedures as such need be added; rather, existing rules and procedures are realigned or modified. In some cases, however, the conversion of an institution may be possible only by means of a layering process. Although the recent political science literature has proposed that layering and conversion processes are separate and distinct mechanisms of incremental path-dependent institutional change, in reality they frequently coexist and interact. Moreover, while these mechanisms can be argued as alternatives to explanations couched in terms of path dependence mechanisms, they are in fact consistent with such mechanisms – indeed, they depend on them for their adoption and success. But unlike the canonical model of path dependence, layering and conversion processes need not lead to “lock-in”: Rather, they may well prevent “lock-in” from occurring.

Thirdly, other writers have proposed what they call a “recombinant” path dependence model. The basic idea is that any particular existing social–political–economic structure is, in effect, a system of resources and properties that actors can recombine and redefine, in conjunction with new resources and properties, to produce a new structure. Such a recombination is a source of path dependence in that what resources exist shape to some degree what changes can be made. The degree and nature of the “structured variety” that characterizes a socioeconomic system may thus be of some importance, since it will condition the range of resources that can be recombined. This recombination of existing social and institutional resources can be incremental but even plays a role at times of radical change.

In the management sciences, too, interest has focused on deriving alternative conceptions of path dependence that escape the restrictions of the canonical “lock-in” model and allow for ongoing evolution of a path. A key argument in this strand of literature is that standard path dependence models say little about *agency*, about how economic and other actors *create, recreate, and alter* paths (Garud and Karnøe 2001; Garud et al. 2010). The complaint is that the standard perspective on path dependence is that of an “outsider’s ontology”: the emphasis is on unpredictable contingencies, external increasing returns effects, and self-reinforcing nonlinear dynamics, which determine the behavior of actors who, once locked-in, cannot

escape unless some exogenous shock occurs. It is as if (local) economic actors are subject to some “higher-order logic” or “master plan” we call path dependence, over which they have no control. In contrast, it is argued, there is a need for another perspective on path dependence that embraces an “insider’s ontology,” that is, one which recognizes and assigns central importance to the purposive actions and behavior of actors. Purposive action is not only often responsible for the initial creation of a new path – which in the standard path dependence model is typically regarded as a happenstance or random event, “outside the knowledge” of the observer, or as Arthur (1994, p. 17) puts it, “beyond the resolving power of his [sic] ‘model’ or abstraction of the situation” – but also for how that path develops over time. Actors mobilize and draw upon the past (previous outcomes and experiences) in order to shape and fulfill their aspirations for the future: they may wish to repeat the past (to continue a particular form of activity) or to improve or move on from the past (by changing activity and behavior in some way). As Garud et al. (2010, p. 769) put it, “different visions of the future will lead to the mobilisation of the past in different ways. And these images of the future and mobilizations of the past will galvanise specific actions in the present.” Rather than “lock-in,” these authors argue, there is ever the possibility of creative destruction, with agents proactively innovating in order to move their activity forward under the pressure of competition and new opportunities. At the very least, economic agents learn, and contrary to the assumption made in the standard model of path dependence that learning leads to progressive imitation and to widespread adoption (i.e., “lock-in”), the assumption made by Arthur, learning can equally lead to more or less continual evolution of a path.

Although some, including Garud and his coauthors, want to go as far as to argue that path creation and path dependence should be regarded as distinct, others (such as Sydow et al. 2009) view path dependence and path creation as complementary and argue that any process is driven by a mix of the two. This opens up the possibility of different forms and degrees of path dependence, according to the balance of this mix of processes. Even “locked-in” states depend on agents’ decisions and actions – in this case, to change nothing and continue as before; whereas in many instances, there will be at least some agents, or groups of agents, whose intentional actions (entering into business, withdrawing from business, undertaking innovation, upgrading or redeveloping products, and so on) have the net effect that an industrial or technological or local economic path will mutate over time. In other words, the heterogeneity of decisions and actions among heterogeneous actors is very likely to prevent “lock-in” from occurring and instead lead to the ongoing adaptation of a path.

32.4 Toward a “Developmental–Evolutionary” Model of Path Dependence in the Spatial Economy

Elsewhere, I have suggested that these explorations into alternative perspectives on path dependence are highly suggestive for how we should think about the idea of

path dependence as a model of spatial economic evolution (Martin 2010a). I am not arguing that the processes operating in local or regional economies are identical to those shaping the development and evolution of institutional forms, merely that there are analogous processes at work in the former that resemble those in the latter, and that these are worth exploring and elaborating (see Martin 2012a). In the first place, while strong increasing returns effects may make for a self-reinforcing movement toward the “lock-in” of a particular industrial path in a local or regional setting, other mechanisms analogous to “layering,” “conversion,” and “recombination” may make for mutation and adaptation of that path over time. New firms are created or added more or less continuously as a local industry grows and develops; they may be spin-offs from existing firms, entirely new ventures, or implants from outside the locality. At the same time, some existing firms fail or move out of the locality. The addition and subtraction of competing entities and the consequential change in the relative frequency of different entities in a system are key forces that generate variety, and variety is a fundamental principle of evolution. New firms in an industry are likely to employ more advanced techniques, offer competing and perhaps different variants of the industry’s product or products, have different productivity and innovation profiles, and so on. The balance between entry, exit, and survival of firms may vary, of course, as the industry develops, and will be driven by a selection process that is determined, in large part, by the relative competitiveness of the firms in their relevant external markets.

Like “layering,” the idea of “conversion” also has an immediate relevance in a local industrial context. Changes to the characteristics of existing entities of a system are a key evolutionary mechanism. In the economic geographic case, it would refer to the ongoing innovation by firms in the local industry – in terms of new products, techniques, business organization, and the like – in response to market opportunities, competitive pressures, knowledge spillovers, and similar stimuli. The entry of new firms that employ newer techniques, different variants of products, and so on, by adding new elements to the local economy (i.e., “layering”), may, in turn, exercise a demonstration effect or spillover effect on existing firms leading to the “conversion” (reorientation) of their activities. As in the case of institutional evolution, these local industry “layering” and “conversion” processes interact, and “conversion” may well entail “recombination”-type processes, whereby firms are able to draw upon some aspects of existing local economic resources, capabilities, and externalities (such as skilled labor, technology centers, and the like) to reconfigure and reorient their activities. To the extent that mechanisms of these sorts operate, the technological and product “portfolio” of the local industry as a whole can change more or less continuously over time. Furthermore, as these changes cumulate, then the network externalities that support and benefit the local firms in the industry will also change. The skills of the local labor force, the range of intermediaries, of suppliers, of local supporting institutions – in fact, the whole gamut of local network externalities – may slowly evolve as the industrial path evolves. And driving the scale and direction of this evolution, of course, are the aspirations, reactions, and decisions of local actors, in firms, institutions, and other organizations.

This perspective on path dependence also allows for processes of “branching” to occur, whereby new, related sectors of activity emerge from and develop alongside, and perhaps even eventually replace, existing activities. The nature of such branching, itself a mechanism for creating variety or diversity in the local economy, will be path dependent to the extent that the new activities draw on competencies, technologies, and knowledges transferred from existing firms and activities. There is growing evidence that local economic diversification, the emergence of new activities and specializations, is often shaped by the existing industrial structure of an area, both in terms of influencing the scope for such diversification and the form it takes. In this sense, some local economic structures may be more “enabling” environments for branching and diversification to occur than others, which might be “constraining” in this regard. The point is that not only may a given local industrial path evolve and adapt over time but that a local economy’s entire economic structure may evolve in a path-dependent manner.

Conceptually, this can be thought of as a “developmental–evolutionary” model of path dependence in which there is a recursive relationship between the sectoral, technological, and institutional structures of a local economy, on the one hand, and the processes that drive economic evolution as these operate within and upon the local economy, on the other (see [Fig. 32.1](#)). At any one moment in time, a local economy will consist of a particular population of firms and businesses in specific sectors of activity and specialization, characterized by a range of technologies and processes, employing workers with certain skills, and linked to and regulated by, to varying degrees, local institutional arrangements. This local industrial–technological–institutional ecology provides the setting, the context, within which various processes of economic evolution operate. These processes depend on the conditions and circumstances obtaining in the local economy itself but also on various external factors, such as competitive pressures, new market opportunities, linkages to extra-local firms, external technological developments, regulatory norms, economic policies, and the like. The range of such external factors and developments that are relevant to and the particular effect they have on a local economy will itself also depend, in part at least, on that locality’s existing economic and technological structures. In combination, these local structures and external factors will stimulate, influence the scope for, shape the direction of, and constrain the mechanisms that make for change versus continuity within the firms and industries in the locality (the processes akin to “layering,” “conversion,” and “recombination” referred to above, namely, the local entry and exit of firms, the pace and direction of innovation by local firms, and the emergence of new or related activities). As the local economy’s sectoral and technological structure changes in response to these evolutionary processes, this then alters the ecology within which those processes operate, which then produces further change (or continuity) in the local economy’s development path, and so on.

The recursive model set out in [Fig. 32.1](#) is obviously a highly simplified representation of what in reality is a highly complex set of processes that can operate at different historical speeds across different firms and sectors, and at different spatial scales. But the key idea behind this model of path dependence is

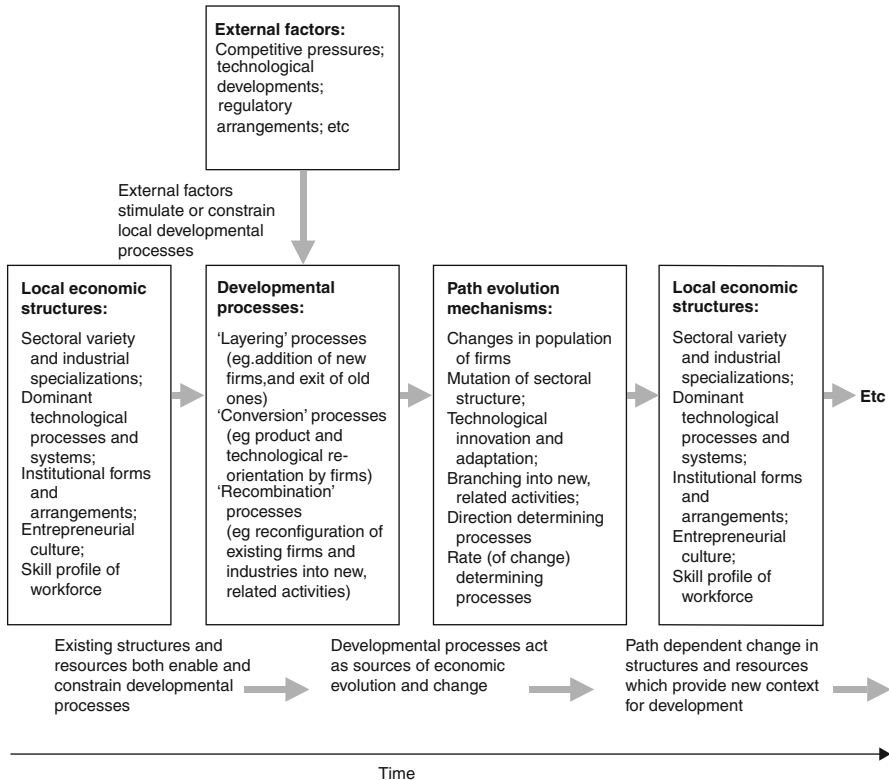

Fig. 32.1 A “developmental–evolutionary” model of local economic path dependence

that existing local economic and associated structures condition and influence the scope for and nature of developmental processes, which in turn shape the pace and direction of change in those structures, which in their turn feedback to condition and influence local economic developmental processes. Such a system is recursive and path dependent, but also potentially evolutionary. As such it offers a wider interpretation of path dependence than the “lock-in” model while encapsulating the latter as a special case (see Table 32.4).

Not only the scope for but also the pace at which local industrial paths evolve will obviously vary from one industry to another and from place to place. The slower the process, the more it is possible to describe the path or locational pattern as conforming to the standard “lock-in” model of path dependence: the research task in such cases is to determine why a local industry has failed to adapt and evolve. The faster the adaptation process, the less the notion of “lock-in” seems appropriate, the more the path will mutate in one way or another, and the more it is possible to describe the process as one of “developmental–evolutionary” path dependence. Allowing for purposive and intentional action by economic agents,

Table 32.4 The “lock-in” and “developmental–evolutionary” models of path dependence compared

	“Lock-in” model	“Developmental–evolutionary” model
1. <i>Initial conditions</i>	Inherited market and local economic and technological conditions assumed unimportant for creation of paths (“virgin market” assumption and “windows of locational opportunity” assumed open)	Inherited and constructed. Preexisting market and local conditions can enable or constrain new economic and technological possibilities. Previous and existing paths condition possibilities for new ones
2. <i>Contingencies</i>	Exogenous and manifest as unpredictable, nonpurposive, and somewhat random events	Emergent and serving as the embedded contexts for ongoing action by agents
3. <i>Self-reinforcing mechanisms</i>	Assumed key and given. “Systemic” mechanisms and processes that compel and constrain local agents’ decisions, which are largely beyond their control	May or may not be present locally. Not essential for path dependence and can be strategically manipulated by local (and extra-local) actors
4. <i>Lock-in</i>	Progressive convergence to a particular spatial distribution of an industry or local industrial structure or specialism, which is assumed to be an equilibrium state and unchanging until disrupted by an external shock	Lock-in (and equilibrium) is a special case. Most industrial location patterns and local industries undergo some form of ongoing change, adaptation, and evolution, both within industry (products, processes) and between industries (changing structural composition of local economy)
5. <i>Path plasticity</i>	While sometimes acknowledged (e.g., David 2001), lock-in to a stable outcome or path generally assumed to be the norm	Local industrial and technological paths can and do evolve incrementally. Actors constantly seeking improved and new product and process opportunities, and the cumulation of such behavior imparts mutation to an industry or specialism
6. <i>Path decline/destruction</i>	Assumed that some sort of (external) shock is necessary to “de-lock” a local industrial or technological path (state). Little discussion of gradual or long-run processes of decline of an industry or technology	Local industries and technologies display various types (and speeds) of relative and absolute decline. Causes of decline involve the complex interaction of exogenous and endogenous factors (e.g., failure or slowness of local firms to innovate and adapt in the context of changing market and competitive conditions)
7. <i>New path creation</i>	Not well theorized. What and where new industries and technologies emerge are contingent events	Constructed. New paths are typically the outcome of purposive and deviating behavior by agents, often influenced by or dependent on preexisting local conditions
8. <i>Model of economic evolution</i>	Punctuated equilibrium, whereby phases of stability (lock-in) are periodically disrupted by shocks (e.g., introduction of new technology)	Mutational and adaptive, allowing for incremental as well as discontinuous change

Note to table: In compiling Table 32.4, I have been influenced by Garud et al. (2010). However, their comparison is between the “lock-in” model of path dependence and what they regard as a distinctly different perspective on industrial and technological development which they call “path creation.” Since path dependence is an ongoing (re)creative process, driven by the activities and decisions of agents, these authors’ counterposition of path dependence and path creation is not perhaps that helpful. I prefer to follow Sydow et al. (2009) here, in seeing path dependence and path creation as inextricably interlinked and interactive, in an ongoing developmental–evolutionary process

for the normal ongoing processes of firm population dynamics, and for innovation, competition, and entrepreneurship sets a “developmental–evolutionary” model of path dependence apart from the standard conception. A “developmental–evolutionary” model is more admmissive of the complex range of actual evolutionary paths that are found among industries, technologies, and local and regional economies.

Such a model also provides a richer perspective on the issue of new path creation. The standard model of path dependence does not have much to say about how, or where, new industrial–technological paths come into being, other than ascribing the emergence of new industries or technologies, and their locational geographies, to random, happenstance, or serendipitous events. Witt (2003) has questioned the validity, or at least the generality, of this “virgin market” idea, the assumption that the emergence of a new technology, product, or industry, and any competition with other emergent rivals, takes place without reference to and uninfluenced by inherited market conditions. Likewise, a “virgin landscape” assumption, the idea that where a new industry or technology emerges is unrelated to preexisting regional industrial and technological structures, can be challenged. There is a curious contradiction in the standard path dependence model, in that path dependence seems to matter only *once* a new industry or technology has emerged but plays no part in influencing *where* it emerges. In fact, there is growing evidence in economic geography that the inherited, preexisting industrial structure of a region or locality often does have an influence on whether a new industrial path emerges or develops there. A “developmental–evolutionary” model of path dependence, by giving recognition to developmental processes such as “layering,” “conversion,” and “recombination,” and how these are the outcomes of the purposive and intentional behaviors of local economic actors, admits of several possible mechanisms by which new local industrial pathways of economic development can emerge from preexisting ones. New paths can emerge from old. Local new path creation may thus itself form part of the developmental–evolutionary path dependence process: local preexisting capabilities, competencies, technologies, and knowledges can provide a resource base for local actors to deliberately venture into new or related fields.

Similarly, a “developmental–evolutionary” model offers a wider perspective on how local industrial and technological paths come to an end. In the standard “lock-in” model, it is assumed that a path is broken by some unpredictable external “shock.” Although such shocks can and do occur, and can certainly undermine or disrupt a local industry, and perhaps lead to its decline and demise, to attribute the decline of an industrial or technological path invariably to the impact of some unexpected or unpredictable exogenous shock is not especially enlightening. To be sure, a local industry is not a closed system and is subject to a variety of external pressures (and new opportunities). But such pressures and challenges are more or less constant features of modern economic life and not necessarily spasmodic, infrequent events. What matters, therefore, is the nature of the pressures that impinge on a local industry, and how the industry reacts to them, which, in turn, depends on the industry’s resilience and adaptability

(Hassink 2010; Martin 2012b). Furthermore, the decline of a local industrial path may arise endogenously, for example, because of the exhaustion of innovation by local firms, which then become uncompetitive and decline, so the industry shrinks. It may also occur if local firms switch to a different, perhaps related, sector of activity on a new path that is perceived as affording more profitable opportunities. Martin and Sunley (2006) suggested a number of possible mechanisms by which a local industrial path may be disrupted, or even destroyed, most of which revolve around the interaction of exogenous and endogenous forces. Yet, their analysis, like that of Castaldi and Dosi (2006) and, indeed, like many of those in economic geography, was founded on the assumption that the problem is one of identifying the mechanisms by which a “locked-in” stable state can be “de-locked.” But if “lock-in” never occurs, clearly a different conceptualization is needed as to how industrial development paths lose momentum, atrophy, and decline.

In several respects, then, a “developmental–evolutionary” model of path dependence differs significantly from the standard “lock-in” model. Whether it be in terms of the initial conditions that influence when and where a new industry or technology emerges, or the mechanisms that give rise to its path-dependent development across space, or the processes by which new industries replace old, or the type of local industrial evolution that is implied, the “developmental–evolutionary” model would seem more encompassing of the range of local economic evolutionary trajectories actually encountered. Furthermore, it incorporates the standard or strict “lock-in” model of path dependence as a special case. Thus, the notion of path dependence should be seen as a complex process that can take varying forms and produce varying rates of local industrial–technological change and evolution. In fact, the “developmental–evolutionary” model focuses attention precisely on why industrial paths vary in their evolvability (capacity to generate variety, of products, technologies, and indeed whole new industries) and adaptability and why these processes vary from one local economy to another.

32.5 Conclusion

According to Boschma and Frenken (2006, p. 280–281), “evolutionary theory deals with *path dependent* processes, in which previous events affect the probability of future events to occur” (emphasis in the original). The original formulations of path dependence in economics focused on a model that defined the process as the progressive “lock-in” – to a stable state – of particular technologies. This model has been taken up in various disciplines, including economic geography, where it has been used to explain the emergence and self-reinforcing spatial localization of industries. However, the “lock-in” model represents a very restricted model of spatial economic evolution. In recent years, this restricted definition or interpretation has been increasingly questioned. In evolutionary economics itself, there have

been dissenting voices. Thus, Witt (2003, p. 124), a leading evolutionary economist, has argued that the notion of “lock-in” is antithetical to industrial and technological evolution:

[S]ome doubts should be raised about the plausibility of both the theoretical underpinnings of, and the empirical evidence for, technological or industrial ‘lock-in’... sooner or later there will always be new rivals who threaten the market dominance of a technology or variant. The erosion of market dominance under competitive pressure by new technologies supports Schumpeter’s empirical generalisation that an incessant process of creative destruction characterises modern industrial capitalism (Witt 2003).

The same argument must surely apply to local and regional economies. The issue, then, is whether the notion of path dependence should be narrowly restricted to and reserved for situations of true “lock-in,” as recently argued by Vergne and Durand (2010), or whether the concept can be meaningfully widened to incorporate processes and systems – including local economies – that display ongoing developmental evolution.

Adherents of the narrow, “lock-in” view will no doubt see this idea of a “developmental–evolutionary” model of path dependence as too broad and lacking definitional precision and analytical formalism, perhaps even not as path dependence at all. The problem with this reaction is not only that the empirical applicability of the standard or canonical “lock-in” model would seem to be limited, since many industries and technologies – and most local and regional economies – exhibit varying degrees of ongoing development and adaptation, but that such ongoing development is itself characterized by some degree of path dependence and thus requires conceptualization: we need a framework for analyzing how and why local economies differ in the rate and direction of path-dependent adaptation and evolution. What precise form such a framework will take is a task for future research, but it will entail linking path dependence much more closely with other evolutionary concepts used in economic geography. The “developmental–evolutionary” model proposed above offers considerable scope in this direction. It also entails methodological deliberation. One of the possible attractions of the standard “lock-in” model of path dependence, especially perhaps to economists, is that it can be given a formal (i.e., mathematical and equilibrium) representation (as outlined in Table 32.1 above). But formalism can come at a cost: it can close off (“lock-out,” one is tempted to say) empirical patterns and outcomes that do not fit the prevailing model yet which, if subjected to appreciative theorizing, could well suggest other interpretations and generalizations that are more relevant. The “developmental–evolutionary” perspective on spatial economic path dependence suggested here is intended to encourage greater appreciative theorizing from concrete cases in order precisely to widen the applicability of the notion. In this sense, future work on path dependence in the spatial economy might well resemble the new generation of “history-friendly” models that are being pioneered in evolutionary economics, in which it is explicitly recognized that industries and technologies can take a variety of evolutionary paths and where appreciative theorizing from concrete case studies is used to construct models that take full account of that variety (see, e.g., Malerba 2010).

Abstract

This chapter discusses the literature on agglomeration economies from the perspective of jobs and job dynamics. It provides a partial review of the empirical evidence on agglomeration externalities; the functionality of cities; the dynamic relationship between cities, jobs, and firms; and the linkages between cities. We provide the following conclusions. First, agglomeration effects are quantitatively important and pervasive. Second, the productive advantage of large cities is constantly eroded and needs to be sustained by new job creations and innovations. Third, this process of creative destruction in cities, which is fundamental for aggregate growth, is determined by the characteristics of urban systems and broader institutional features. We highlight important differences between developing countries and more advanced economies. A major challenge for developing countries is the transformation of their urban systems into drivers of economic growth.

33.1 Introduction

This chapter reviews the literature on agglomeration economies from the perspective of jobs and labor markets.

In cities, jobs are more productive because of agglomeration effects. These take place through a variety of channels: resource sharing, quicker and better matching, and greater knowledge spillovers. [Section 33.2](#) provides a discussion of these issues. The bottom line is straightforward; cities have a positive effect on productivity and wages.

More productive urban jobs however do not come in a void. [Section 33.3](#) broadens the discussion to job creation and firm dynamics in cities. More productive jobs in cities need to be created. Innovation, entrepreneurial activity, and firm growth all play a crucial role in this respect. Adding to this, more productive jobs do not remain more productive forever. This productivity advantage is constantly eroded and needs to be constantly re-created. The creative destruction process, that is, more firm entry and exit and higher portion of innovative young firms, is also fundamental.

In turn, the dynamics of firms and jobs in cities is shaped by the broader characteristics of urban systems. In [Sect. 33.4](#), we highlight major differences between cities in developing countries and more advanced economies. In short, the urban system of many developing countries acts as a brake on economic growth. A major challenge for the countries is the transformation of their urban systems into drivers of economic growth. More specifically, cities in developing countries appear to be far less functionally specialized than cities in more advanced economies. This hampers the dynamism of the largest cities in developing countries which are burdened by many ancillary activities. These activities add to urban crowding without adding to agglomeration benefits. Better infrastructure, in particular better transportation infrastructure, and a reduction in favoritism toward large cities may be a way to remedy these problems. Policies to foster job creations directly may be tempting, but their record in more advanced economies is unsatisfactory. In addition, developing cities also function less efficiently and face challenges that differ from those of cities in more advanced economies. An appropriate management of the transition to full urbanization, a strengthening of urban governance, a reduction in labor market duality, and a reduction or the full elimination of land market duality are key challenges that must be tackled for developing cities to take the full advantage of agglomeration effects and foster aggregate growth.

33.2 Cities, Worker Productivity, and Wages

Cities enjoy a productive advantage over rural areas, and this advantage is larger for larger cities. The positive association between various measures of productivity and urban scale has been repeatedly documented. That larger cities obtain higher scores on many productivity metrics from wages to output per worker, or the total factor

productivity of firms is now beyond doubt. Most of the studies reviewed by Puga (2010) find an elasticity of wages or firm productivity with respect to city employment or urban density between 0.02 and 0.10. As shown by Henderson (2005), these findings also hold widely in cities in developing countries.

More formally, this type of work involves regressing an outcome variable by location on a measure of agglomeration. In the early literature, the typical regression of choice involved using output per worker as dependent variable and city population as explanatory variable. In the early 1990s, authors often employed more indirect strategies and started to use variables such as employment growth or firm creation as outcome measures. More recently, the literature has moved to microdata and returned to more direct outcome measures, namely, the total factor productivity of firms and wages. More precisely, recent studies estimate a regression like

$$\log w_{ic(i)} = \alpha \log Pop_{c(i)} + \eta_{c(i)} + u_i + \varepsilon_{ic(i)}, \quad (33.1)$$

where c denotes cities and i denotes individuals or groups of individuals. The dependent variable is w the wage, and the explanatory variables are $\log Pop$ the log of population as a measure of urban scale, η a city effect (usually proxied through a number of control variables at the city level), and u an individual effect (often proxied through observable individual characteristics). Finally, ε is an error term. The estimated value of the coefficient of interest, α , is usually positive and significant. Similar regressions can be proposed for firm data using measures of firm level productivity and firm characteristics.

After Ciccone and Hall (1996), density has often been favored relative to population since it appears to yield more reliable results. The reason is probably that density-based measures of agglomeration are more robust to zoning idiosyncrasies. For instance treating Washington and Baltimore as one big consolidated metropolitan area or two separate cities makes a big difference to their employment count but only little difference to density.

After asserting this robust statistical association between productivity outcomes and agglomeration, the first question regards whether the estimated coefficient α in the regression described by Eq. (33.1) reflects the causal effect of agglomeration on wages. An examination of Eq. (33.1) reveals three possible sources of bias. They all come from the fact that, as highlighted by the notations in Eq. (33.1) above, the measure of agglomeration is indexed by $c(i)$, that is, the city c is *chosen* by worker i . Ideally, one would like to compare the same workers across the cities that they have chosen and those that they have not chosen. In absence of randomized experiments, this is not possible. Greenstone et al.'s (2010) quasi experiment on "million dollar plants" is what comes closest to this ideal for firms' location choices.

The first source bias is the possible link between city effects (which are not observed directly) and the variable of interest, city population, or density. Put differently, the "quantity of labor" may be endogenous, and it is reasonable to expect workers to go to more productive cities. A possible solution to this problem

is to use instruments for city population or density as Ciccone and Hall (1996). These instruments need to predict current population patterns but must be otherwise uncorrelated with city productivity. Deep historical lags such as population from 200 years ago or soil characteristics can do the job. Studies using this type of approach typically find that correcting for the endogeneity of population has only a mild downward effect on the estimation of the coefficient of interest α .

The second main identification problem in the estimation of Eq. (33.1) regards a possible correlation between the measure of city population and individual effects. That is, the quality of labor may be endogenous, and we expect more productive workers to reside in larger cities. A first possible solution to this problem is to control for an extensive set of individual characteristics. A more drastic solution is to use (whenever possible) the longitudinal dimension of the data and impose worker fixed effects as Combes et al. (2008). The endogenous quality of labor seems to be an important source of bias in the estimation of Eq. (33.1). The estimated value of α is typically reduced by 30–50 % using extensive individual controls or worker effects. This said, one needs to be careful. Imposing worker effects improves the quality of the estimation, but it is not a perfect solution since it assumes that mobility is exogenous.

Related to this last issue, the third source of bias in the estimation of Eq. (33.1) is the possibility of a correlation between the error term and the measure of city population of interest. If, for instance, workers move more easily from large cities to small cities than the opposite in case of a good external wage offer, this will create another source of bias which in this particular situation leads to an underestimate of agglomeration economies. No satisfactory solution to this problem has been proposed so far.

At this point, the conclusion of the agglomeration literature is that there is a causal static effect of cities and urbanization on wages in more advanced economies but that this effect represents only about half the measured association between city population or density and wages (or alternative measures of productivity). The rest of the association between population or density and wages reflects the sorting of more productive workers in larger and denser cities and, to a lesser extent, reverse causality and workers moving to more productive places. Recent investigations that tackle the concerns mentioned above find agglomeration elasticities around 2 %. They thus suggest rather modest static effects of cities on productivity. The literature from developing countries often uses less sophisticated approaches but finds results that are comparable and, if anything, indicative of moderately stronger agglomeration effects.

After questioning its causal aspect, the second key question about the estimation of agglomeration effects regards their sources. When asking about the “sources” of agglomeration, the literature frequently confuses two separate questions. The first is about which markets are affected by these agglomeration effects, and the second is about which mechanisms actually occur. Regarding the “where” question, it is customary to distinguish the markets for (intermediate) goods, the market for labor, and the (absent) market for ideas and knowledge. In terms of mechanisms, we often distinguish between sharing, matching, and learning mechanisms.

“Sharing” is about the many possible benefits from the mutualization of specialized input providers, the diversity of local goods, the division of labor, or the risks. “Matching” is about the greater probability of finding another party such as a worker, an employer, a supplier, or an investor and the greater quality of the match with that party. Finally, “learning” is about the better generation, diffusion, and accumulation of knowledge. The latter set of mechanisms is regularly referred to as knowledge spillovers.

Because of the wide variety of possible mechanisms and the markets where they can take place, the literature that investigates the sources of agglomeration benefits is much more heterogeneous than the literature that attempts to measure the overall benefits from agglomeration. The latter naturally coalesces around the estimation of Eq. (33.1).

First, there is a diversity of work which provides evidence of an association between some aspect of agglomeration such as a particular mechanism or market and measures of agglomeration such as city size. Let us take only a few recent examples (see Puga 2010, for a more exhaustive discussion). Taken together, these studies are suggestive that many of the agglomeration mechanisms described by the theoretical literature are at work in a variety of markets.

This conclusion must be taken cautiously, however. Establishing the direction of causality in this type of work is even harder here than when attempting to measure the overall effects of agglomeration. To understand this point and the pitfalls associated with this type of work, let us use the analysis of Charlot and Duranton (2004) on workplace communication. They show that communication is associated positively with city size and with wages. This leads them to conclude that communication spillovers could account for up to a quarter of agglomeration benefits. However, this finding could be explained in part by the greater sorting of good communicators in larger cities. This is the equivalent of the quality-of-labor bias discussed above. This worry can be reduced by comparing movers and stayers in cities as Charlot and Duranton (2004) do. It is difficult to eliminate it entirely though. In addition, one also needs to show that greater communication in cities is not the by-product of another agglomeration force. Workers in larger cities may communicate more because firms outsource more of their output. This requires some coordination. In such a case, the real source of agglomeration benefits may be input–output linkages, not communication spillovers. To go round this problem, Charlot and Duranton (2004), who use rich firm level data, suggest instrumenting workplace communication by measures of organizational changes such as a flattening of the hierarchy. These changes typically increase the need for horizontal communication. This type of instrument is nonetheless valid only if changes in organization are unrelated to other sources of agglomeration benefits such as labor pooling or input–output linkages. That firm reorganization affects worker communication behavior but has no direct effect on recruiting practices, or outsourcing is plausible but not certain. More generally, studies that focus on one particular source of agglomeration face a major missing variable problem: The other sources of agglomeration are absent from the regression even though they are expected to be correlated with both wages (or other productivity measures) and measures of agglomeration such as city size.

Given how difficult it is to measure many aspects of agglomeration and given also that the list of possible agglomeration sources is open, considering all sources of agglomeration in one regression is not a feasible option. A more reasonable path forward is, following Ellison et al. (2010), to consider several classes of agglomeration sources in the same approach. Ellison et al. (2010) assess how much labor pooling, input–output linkages, and spillovers account for co-agglomeration between industries in the USA. They use a measure of industry co-agglomeration and find more co-agglomeration among (i) industries that buy from each other, (ii) industries that use a similar workforce, and (iii) industries that share a common scientific base. To reduce the possibility that co-agglomerated industries end up buying from each other or using similar workers because of their proximity, they instrument their US measures of input–output linkages and labor pooling using corresponding UK data. Of course, if the biases are the same in the UK as in the USA, these instruments are of limited value. Another caveat is that input–output linkages are possibly more easily measured using input–output matrices than spillovers using patent citations. This can also lead to biased estimates since a positive correlation with both linkages and spillovers is likely to be picked up mainly by the better-measured linkage variable. This said, Ellison et al. (2010) confirm that the three motives for agglomeration they consider are at play with input–output linkages playing a more important role.

Even if we abstract from the uncertainty around those results, the notion that several mechanisms, each operating in several markets, contribute to agglomeration benefits is problematic for policy. At their heart, agglomeration benefits rely on market failures associated with the existence of small indivisibilities with sharing mechanisms, thick market effects with matching mechanisms, and uncompensated knowledge transfers with learning mechanisms. That is, there are possibly many market failures at play in many markets. In turn, this implies that there may be no hope of fostering agglomeration economies through a small number of simple policy prescriptions.

Before broadening the discussion, there are four further features of agglomeration that have implications for workers and jobs in cities.

The first is the issue of the sectoral scope of agglomeration and whether agglomeration effects accrue mostly within or across sectors. Agglomeration effects within sectors are referred to as localization economies and between sectors as urbanization economies. When estimating a more general version of Eq. (33.1) that accounts for both city size or density and the degree of same sector specialization, extant research has found evidence of both localization and urbanization effects. There are two interesting nuances. The first is the presence of significant heterogeneity across industries. This heterogeneity follows an interesting pattern as it appears that more technologically advanced industries benefit more from urbanization economies whereas more mature industries benefit more from localization economies. Second, the calculations of Combes et al. (2008) indicate that in France the benefits from localization economies are smaller than those of urbanization economies and mostly uncorrelated with local wages. Put differently, increased local specialization has only small benefits and does not contribute to making workers richer.

The second extra feature of agglomeration is the notion that not all workers benefit equally from urban scale. Equation (33.1) estimates an “average” agglomeration effect. As highlighted by, among others, Glaeser and Resseger (2010), agglomeration effects appear stronger for more educated workers in the USA. Higher returns in larger cities should in turn provide stronger incentives to more skilled workers to locate there. Hence, these results are consistent with the well-documented fact that workers in larger cities in more advanced economies tend to be more educated and better skilled (e.g., Combes et al. 2008).

Next, while not all workers benefit equally to agglomeration effects, it also appears that not all workers contribute equally to these effects either. There is a large literature on human capital externalities suggesting that workers enjoy higher wages when surrounded by more educated workers. Estimates of external returns to education are typically between 50 % and 100 % the corresponding estimates of private returns to education, in particular for university graduates. These findings are robust to a number of estimation concerns and suggestive of large effects. It is beyond the scope of this chapter to review this literature extensively. See instead Moretti (2004) for an in-depth survey.

Finally, there is also emerging evidence from US and European data that wage growth also depends on city size/density. To show this, one can estimate a regression along the lines of Eq. (33.1) but use wages in first difference instead of in levels as dependent variable:

$$\Delta_{t+1,t} \log w_{ic(i)} = \alpha \log Pop_{c(i)t} + \eta_{c(i)} + u_i + \varepsilon_{ic(i)t} \quad (33.2)$$

where Δ is used to note time differences between t and $t + 1$. Among a number of papers, De la Roca and Puga (2012) confirm that wage growth is stronger in larger cities.

Because the structure of Eq. (33.2) is the same as that of Eq. (33.1) for the static estimation of agglomeration economies, it suffers from the same drawbacks. First, the association between wage growth and agglomeration could be explained by the sorting of workers with faster wage growth in larger cities. This could occur because “fast learner” tends to locate in larger cities or because the wage of workers who are predominantly located in larger cities (such as more educated workers) tends to increase faster. Following the same sort of fixed effect strategy described above and applying that to a regression like Eq. (33.2), Freedman (2008) nonetheless shows that this type of result holds even after controlling for the fact that some workers may experience higher wage growth independently of their location.

Although the result that wages grow faster in cities is frequently interpreted as evidence about faster learning in cities and knowledge spillovers, the mechanisms that drive it are unclear. Just like regressing wages in levels on a measure of urban scale in Eq. (33.1) does not tell us anything about the sources of static agglomeration economies, regressing wage growth on urban scale in Eq. (33.2) is equally uninformative about the sources of agglomeration dynamics. Interestingly, Wheeler (2008) shows that young workers tend to change job more often in larger cities, while the opposite holds for old workers. This type of evolution is consistent with

a matching model where workers can find their “ideal match” faster in larger cities and then stick to it. Such mechanism could explain both faster wage growth and eventually higher wages in larger cities.

Evidence about learning in cities can come from the fact that workers retain some benefits from agglomeration after they leave their city. De la Roca and Puga (2012) confirm this on Spanish data. Their findings suggest the existence of both a level effect of cities on wages (of the same magnitude as those discussed above) and a dynamic effect. Over the long run, workers in large cities seem to gain about as much from both effects.

To sum up, this discussion of agglomeration economies which focuses mainly on workers and jobs reaches a number of interesting conclusions. First, larger cities make workers more productive. There is both a static and a dynamic component to these gains. A static elasticity of wages with respect to city population of 0.03 implies that a worker receives a 23 % higher wage when moving from a tiny city with population 5,000 to a large metropolis with a population of five million. Over time, dynamic effects could make this urban premium twice as large. While long-run gains close to 50 % are not miraculous, they are nonetheless sizeable.

In terms of policy implications, the temptation to “foster agglomeration effects” should be resisted. We are too far from knowing enough about the sources of agglomeration to implement any meaningful policy, not to mention the great heterogeneity in who gains from and who contributes to agglomeration gains. It remains nonetheless that the economic gains from urbanization are significant and urbanization should be embraced rather than resisted.

33.3 Firm Dynamics Within Cities

This higher productivity of jobs in cities is only one facet of the issue. Jobs are usually viewed as a veil when we model production in theoretical models. In practice, higher labor productivity is associated with doing different things and doing them differently. That is, to receive higher wages, workers need “better jobs.” Firm dynamics is often the vector of these changes. More specifically, let us examine several aspects of firm dynamics in cities: innovation, firm creation and growth, and factor allocation and reallocation across firms.

Starting with innovation, the first salient feature of the geography of innovative activity is that research and innovation is much more concentrated than production in most industries. Interestingly, this tendency seems particularly strong for industries that are more intensive in skilled labor and in research and development. It is also the case that this concentration of research and development typically takes place in large metropolitan areas.

These location patterns for innovative activity are consistent with the notion that cities have a positive effect on innovation just like they have on wages. More direct evidence can be found in Feldman and Audretsch (1999) and Carlino et al. (2007). To measure innovation, Feldman and Audretsch (1999) make a count of all new product innovations in US metropolitan areas for a broad set of technologies and

sectors in 1982. They find no evidence of urban scale effects but find that same sector specialization is strongly negatively associated with innovation whereas a diversity of employment in technologically related industries is strongly positively associated with innovation. They also find strong positive innovation effects associated with the presence of smaller establishments.

Using the number of patents per capita as dependent variable, Carlino et al. (2007) find evidence of strong agglomeration effects for innovative activity. Their estimate of the elasticity of patenting per capita with respect to employment density is 0.2. This is several times the estimates reported above for the corresponding elasticity of wages. Interestingly, Carlino et al. (2007) also find that this elasticity of innovation with respect to employment density or population size is not constant across the urban hierarchy. Patenting per capita appears to peak at around 5,700 jobs per square kilometer or a city population size slightly below a million.

While this evidence is highly suggestive that cities affect innovation, there is, to the best of our knowledge, no work which focuses on the effects of innovative activity in cities such as its effects on urban growth. Regressing urban population growth on innovative activity would raise some obvious identification concerns. In addition, simple theoretical argument suggests that the effect of innovation on urban growth need not be positive. Obviously, product innovation in the form of either an entirely new product or the capture of an established product from another location is expected to add to a city's employment. However, process innovation within a city can cut both ways. Employment will increase with process innovation only if greater productive efficiency and lower prices lead to a more than proportional increase in demand. In the opposite case, process innovation will imply a contraction of local employment. Remarkably, Carlino et al. (2007) show that Rochester, Buffalo, Cleveland, St Louis, and Detroit are all highly innovative cities. This suggests that, to some extent, the demise of these cities may be attributed to the fact that labor productivity increased much faster than demand in their industries.

Finally, innovative activity appears to change the nature of jobs in the cities where it takes place. As shown by Lin (2011), cities that patent more tend to have a greater proportion of what he labels "new work," that is, jobs that did not exist a few years before. New work is also fostered by a greater proportion of educated workers and a diversity of industries, two other attributes of large cities.

To conclude on the links between innovation and cities, extant literature supports the notion that cities affect innovation either because of their sheer population size or because of the (diverse) structure of their production activities. The evidence about the effect of innovation on cities is more complex. Innovation *within a given city* affects the proportion of workers in new work. Other effects are either ambiguous or poorly documented. As we show below, further insights about the effects of innovation on cities can be gained by looking across cities.

Entrepreneurship is also closely associated with cities in several ways. First, cities affect entrepreneurship just like they affect wages and innovation. In a comprehensive analysis of the determinants of employment in new manufacturing start-ups across sectors in US cities, Glaeser and Kerr (2009) generate a rich harvest of facts. The first is the existence of scale economies. As a city grows larger,

employment in new start-ups in this city increases more than proportionately. Depending on their specification, Glaeser and Kerr (2009) find an elasticity of employment in new start-ups per capita with respect to city scale between 0.07 and 0.22. City population, city-industry employment, and sector effects explain around 80 % of the variation in start-up employment across cities and sectors.

Glaeser and Kerr (2009) also find that the presence of many small suppliers has a strong effect on employment in start-ups. In addition, they also find evidence of mild Marshallian effects associated with input–output linkages, labor market pooling, and spillovers. Finally, city demographics only has a limited explanatory power just like their measure of “entrepreneurial culture.”

The other key feature about the supply of entrepreneurs is that there is a strong local bias in entrepreneurship. Entrepreneurs tend to create their start-up in the place where they were born and/or where they have lived and worked before becoming entrepreneurs. This important fact has been documented by Figueiredo et al. (2002) for Portugal and Michelacci and Silva (2007) for Italy and the USA. This finding has been confirmed by several other studies in developed economies. Figueiredo et al. (2002) also show that when entrepreneurs chose a new location, this choice is strongly governed by agglomeration economies and a proximity to large cities.

After looking at the urban determinants of entrepreneurship, we now turn to the effects of entrepreneurship on their cities. It has been shown repeatedly that entrepreneurship plays a key role in urban evolutions. The key fact here is that growth in a city and sector over a period of time is strongly correlated with the presence of small establishments in that city and sector at the beginning of the period. This fact was first documented by Glaeser et al. (1992) and has been confirmed for other countries and time periods by many other studies.

Just like with many of the correlations discussed above, the strong link between small firms and employment growth raises a key identification concern about the direction of causality. However, this issue has been neglected by the literature. This is perhaps because the standard regression uses growth over a period as dependent variable and establishment size *at the beginning of the period* as explanatory variable. However, using a predetermined variable as explanatory variable in a regression does not guarantee its exogeneity. Local entrepreneurs could enter in large numbers in a city and sector if they foresee strong future demand. That expectations of future growth should trigger entry today is only natural. That is the nature of business.

To resolve this identification problem, it is difficult to think of instruments that would predict establishment size in a city and sector but be otherwise uncorrelated with subsequent growth. To clarify the meaning of the relationship between small establishments and high subsequent growth, Glaeser et al. (2010) do something quite different. They look at whether the presence of many small firms in a city and sector is driven by the demand for entrepreneurship or its supply. To the extent that the demand for entrepreneurship can be captured by higher sales per worker, this does not appear to be the case. They also find limited evidence about the importance of lower labor costs or entrepreneurs sorting into high amenity cities. They find

stronger evidence about the importance of the proportion of university graduates (particularly in more skilled industries), but that still does not explain away the effect of having lots of small establishments. While still preliminary, this type of evidence points at some unspecified supply effects. More entrepreneurial cities happen to have a greater supply of entrepreneurs, and the literature has thus far been unable to trace this further.

Turning finally to factor allocation and reallocation, the literature that examines these issues makes two important claims. The first is that a large fraction of productivity growth at the country level can be accounted for by the reallocation of factors from less productive to more productive firms. A large share of productivity growth can be accounted for by a churning process where low-productivity firms are replaced by new and more productive start-ups. These important findings have been confirmed for many countries (Bartelsman et al. 2004).

The second important claim made by the reallocation literature is that “misallocation” can account for a large share of existing productivity differences across countries. To understand this point better, consider the influential work of Hsieh and Klenow (2009). They first note that, in equilibrium, the marginal product should be equalized across firms. If the demand for the varieties produced by firms has a constant elasticity of substitution, this implies an equalization of the product of their price by their “true productivity” (which is the ability of firms to produce output from inputs). This – price times true productivity – product is what is estimated as “total factor productivity” in most productivity exercises. We may call this second quantity “apparent productivity.” Obviously, the firms’ apparent productivities are never equalized in real data. Hsieh and Klenow (2009) interpret this as evidence of factor misallocation. Taking the highly dispersed distribution of manufacturing productivity in China and India, they calculate very large potential costs from such misallocation. Acknowledging that a perfectly efficient allocation may be impossible, they compute that the productivity gains for manufacturing in China and India would still be of about 50 % if their level of misallocation could be reduced to that observed in the USA.

To the best of our knowledge, there is no study that would attempt to relate greater churning/reallocation at the firm level and higher productivity growth at the urban level. However, there is a strong suspicion that larger cities should exhibit more churning. This is because, as already argued, larger cities are more innovative, experience more entry and exit, and have a greater fraction of their workforce in “new work.” At the same time, there is no indication that this greater amount of churning in larger cities is associated with higher productivity growth in those cities unlike what occurs at the country level.

We actually know little about productivity growth in cities. According to Lin (2011), the greater proportion of workers employed in new work in larger cities is not associated with faster productivity growth. In a rare study of the broader determinants of productivity growth in Italian cities, Cingano and Schivardi (2004) highlight the importance of both specialization and employment size. But given that specialization and employment size are negatively correlated, their positive effects arguably cancel out. Hence, more churning does not appear to lead to faster productivity growth in cities.

To confirm this conclusion, note that workers are somewhat mobile across cities. Then more churning associated with faster productivity growth in larger cities should imply a divergence in population growth rates. There is no evidence of such divergence. This lack of result regarding the link between churning and productivity should not be taken as negative evidence against the reallocation literature. As argued in the next section, it is possible that reallocation does not take place within cities but also across cities.

Turning to the second claim about misallocation, Combes et al. (2011) show that the distribution of firm productivity is unambiguously more dispersed in larger cities in France. In the framework of Hsieh and Klenow (2009), that would be interpreted as greater misallocation in larger cities. This seems hard to believe. The evidence about static agglomeration effects discussed above is instead best interpreted as agglomeration economies leading to a better allocation of resources (in a broad sense) in larger cities. When performing a productivity decomposition, Combes et al. (2011) find a similar covariance between establishment size and productivity in large and small cities which suggest a similar level of efficiency in the allocation of factors to firms across cities of all sizes.

To sum up, the evidence about firm dynamics and cities presented in this section is puzzling. Larger cities seem to be more innovative, be more entrepreneurial, experience more churning and reallocation, and generally enjoy a greater “economic dynamism.” At the same time, they do not appear to enjoy most of the benefits associated with such dynamism since neither productivity nor population appears to increase faster in larger cities. Of course, these conclusions need to be taken cautiously given the paucity of study, including their complete absence for cities in developing countries.

33.4 City Functionality, Urban Systems, and Policies

The answer to the apparent puzzle raised above is that when thinking about economic growth, it is wrong to think of cities as self-contained units. Cities are best viewed as small open economies which interact a lot with other cities and rural areas. They are part of an “urban system.” This implies that innovation, churning, and reallocation are best studied across the entire system of cities.

Starting with innovation, recall that larger cities offer many advantages for both product and process innovation. More specifically, as highlighted by many, cities favor the circulation and cross-fertilization of ideas. This naturally leads to more product innovations, and this is consistent with the evidence of Feldman and Audretsch (1999) discussed above. For process innovation, Duranton and Puga (2001) underscore the greater availability of intermediate goods in large cities which allows firms to proceed through trial and error at a faster pace. Put differently, the greater ability of larger cities to innovate may just be another manifestation of agglomeration economies. The key difference with many static aspects of agglomeration economies such as thicker local labor markets is that, with dynamic effects, co-location is not needed all the time. More precisely, spillovers may matter to develop an innovation, but after this is done, co-location is no longer needed.

Quite the opposite, larger cities are more expensive places to produce. After the dynamic benefits from agglomeration have been exploited, it can make sense for firms to relocate. Often, the entire firm does not need to relocate since it is only the production of particular products that is concerned.

Patterns of establishment relocations in France are highly consistent with this type of product cycle. As shown by Duranton and Puga (2001), about 75 % of French establishments that relocate do so from a city with above-median diversity to a city with below-median diversity and above-median specialization in the same sector. In addition, as documented by Fujita and Ishii (1998), large Japanese multinationals in the electronic sector produce their newest products in “trial” plants near Tokyo and Osaka. Less recent products are produced in rural locations in Japan while even older generations of their products are manufactured in less advanced countries in Asia. Hence, as their products mature, firms still search for agglomeration economies but will put a greater weight on the benefits of specialization. Large cities act as nurseries for new goods and new products. Once mature, new goods and products are best produced in more specialized places.

Cities are also specialized by sector. However, this tendency, while still present in the data, has diminished over time as documented by Duranton and Puga (2005). The same authors also document a rise in the functional specialization of cities with the emergence of cities specialized into management-type functions, whereas others specialize more into production activities. This rise in functional specialization is rationalized by Duranton and Puga (2005) in a model where lower communication costs make it easier for firms to separate management from production. Since these activities benefit from very different types of agglomeration economies, such separation is beneficial, provided the cost of separating activities is low enough. In turn, this separation of activities reinforces the functional specialization of cities.

These multiple dimensions of specialization are part of well-functioning urban systems in more advanced countries. Adding to this, the notion of cities being specialized by functions and activities is not static. The process of continuous location and relocation of economic activity is a crucial aspect of the growth of those activities. To take a simple example, when George Eastman developed a new revolutionary technology in the photographic industry in Rochester, the latter relocated from New York to Rochester. Then, much later, as the technology developed by Eastman got itself superseded by the digital revolution, Rochester lost its status of capital of the photographic industry.

That different cities specialize into different functions and are able to change their specialization after negative shocks presupposes a fair amount of “mobility” across cities. The first important dimension of mobility regards goods and services. It would make little sense for cities to narrowly specialize in an activity if its output cannot be exported. Continuously changing patterns of specialization also require labor mobility. For instance, Kerr (2010) documents that after “breakthrough” innovations, more innovations tend to take place in the same location for the same technology. This growth in patenting, in turn, depends on the mobility of scientists and engineers. Interestingly, the adjustment appears faster for technologies that depend more heavily on immigrant inventors who are more mobile.

While the foregoing discussion describes well what happens within the urban system of more advanced economies, it is a far less resemblant depiction of the situation of cities in developing countries. For instance, most very large cities in developing countries are still major manufacturing centers, whereas manufacturing production is mostly absent from the largest cities of Europe and North America. This lack of urban differentiation may be at the root of the problem. Urban systems in developing countries may be much less efficient than in more advanced countries because cities are much less differentiated in terms of functions.

More specifically, this lack of differentiation in urban functionality may hamper the dynamism of cities in developing countries. The largest cities there are burdened by many ancillary activities such as basic manufacturing and call centers. These add to urban crowding without adding to agglomeration benefits. On the other hand, smaller cities in developing countries often lag far behind, and getting some of these ancillary activities would be crucial for their development.

This said, a lack of well-functioning urban systems – however important (and neglected in urban policy) – is not the only cause for the lower efficiency of cities in developing countries relative to their counterparts in advanced economies. Nonurban factors such as weak national institutions and poor technology certainly play a role. Urban factors which hinder the functional differentiation of cities also have a direct negative effect on the efficiency of cities. For instance, as we discuss below, high transportation costs limit the specialization of cities by reducing their ability to trade. At the same time, even if we abstract from these effects, high transportation costs also affect the price of goods purchased by local consumers and reduce market access for local producers.

In the rest of this section, we examine a number of urban factors that both reduce the efficiency of the urban system as well as the efficiency of cities directly. Cities in developing countries are often acting as a brake on growth, whereas they should be a key driver of economic development.

The first key difference between cities in developing and more advanced countries regards the functioning of their labor market. In most developing countries, there is a well-known duality in the labor market which usually comprises a large informal sector alongside the formal sector. Aside from its detrimental implications for workers in the informal sector, this duality hinders urban development in several ways. First, it has been accused of inducing too much migration toward the largest cities where most of the formal sector is located. Duality may also limit mobility across cities since jobs in the informal sector tend to be filled by word-of-mouth through social connections which are missing to newcomers. High barriers to “good” jobs in the formal sector may also hold back the incentives of workers to improve their skills locally and thus limit the scope of agglomeration benefits.

To mitigate the effects of labor market duality, three broad types of policies can be envisioned. The first is to improve the working of labor markets. While this objective is certainly laudable, a discussion of this class of policies would certainly go beyond the scope of this chapter.

The second type of policy is to foster local job creation through “place-based” policies. Such policies typically involve tax exemptions or subsidies associated

with job creation within well-defined (and often tightly circumscribed) areas. These tools are frequently used to try to reduce the unemployment rate of the residents of poor areas in more advanced economies. While the labor market failures in developed and developing countries differ and the scale at which such policies might be implemented in developing countries may be much broader than poor neighborhoods of “rich” cities, there may be useful lessons to learn from the recent North American and European literature evaluating those policies. Simply put, the general record of place-based policies is in doubt. Detailed evaluations of particular policies are usually negative (Glaeser and Gottlieb 2008).

The third class of policies attempts to foster job creations in a particular locality by helping firms in a given sector. These policies are usually referred to as “cluster” policies and follow from the work of Michael Porter (1990). They often entail the development of subsidized supportive institutions and infrastructure using public subsidies and various types of fiscal incentives. The review of the literature in Puga (2010) implies negative conclusions about the possible benefits of cluster policies.

The second key difference between cities in developing and more advanced countries regards the functioning of their land market. Like labor markets, land markets in developing cities are characterized by a duality between land used with appropriate property titles and leases and squatted land. Recent empirical research has focused on the effects of the lack of effective, formal property titles which could prevent residents of squatter settlements from using their house as collateral. Informal land markets may thus be a major barrier to enterprise development. The empirical evidence about the relaxation of credit constraints associated with “titling” policies is weak. Recent work points instead to increases in labor supply (Field 2007) and to the adoption of more middle-class values and attitudes (Di Tella et al. 2007). While this evidence about titling policies is relatively optimistic about the merits of such policies, it must be noted that the existing literature focuses nearly exclusively on residential land. The extent of land illegality for commercial land (from illegal street vendors to squatter manufacturing) is poorly measured, and the solutions are not well developed.

The third key difference between cities in developing and more advanced countries regards infrastructure, particularly the road infrastructure. Two strands of research need to be distinguished here. The first finds its roots in international trade and focuses on the estimation of the effect of “market potential” variables. The market potential of a city is usually computed as the sum of the income (or population) of other cities weighted by their inverse distance to the city under consideration. Assuming transportation costs and other trade frictions associated with distance, many models of international and interregional trade generate the prediction that a location’s income will be determined by its market access (Krugman 1991). The literature offers strong empirical support regarding the importance of market access for cities in developing countries (Henderson 2005).

The second strand of literature focuses more closely on the effects of infrastructure. Baum-Snow’s (2007) pioneering work finds that the construction of the interstate highway system was a major impetus behind the suburbanization of US cities. Duranton and Turner (2012) also find that more kilometers of interstate

highways in US metropolitan areas in the early 1980s led to faster population growth over the subsequent 20 years.

This type of approach is also being applied to developing countries. In a remarkable piece of work, Donaldson (2010) documents the effects of the construction of India's railroad network by its colonial power. He shows that railroads increased trade and reduced price differences across regions. Even more importantly railroads increased real incomes and welfare. To minimize identification problems, he compares the network that was built to other networks that were considered but never developed.

In line with some of the arguments advanced above about the importance of transportation infrastructure for the decentralization of manufacturing activity away from large metropolises, Baum-Snow et al. (2011) underscore the importance of railroads in the decentralization of manufacturing production in China.

Storeygard (2011) provides evidence about the importance of inter-city transportation costs for inland African cities. Using new roads data for Africa and satellite data ("lights at night") to estimate economic activity, he assesses the effect of higher transportation costs. To circumvent the endogeneity of transportation costs (roads may be built to access growing cities), he uses arguably exogenous variations in oil prices. He finds an elasticity of economic activity with respect to transportation costs of about -0.2 .

All these findings are suggestive of the profound and long-lasting effects of major transportation infrastructure. One needs to keep in mind nonetheless that major transportation networks are extremely costly investments.

The last key difference between cities in developing and more advanced countries regards the effects of the favoritism by governments of the largest cities. While the reasons for primate city favoritism are still debated (Henderson 2005), there is little doubt that such favoritism takes place in many different ways. As argued in Henderson (2005), primate city favoritism harms the favored primate city by making it bigger than it should be. It also harms smaller cities which are, in effect, heavily taxed. The gap that is created between the primate city and other cities may also have negative dynamic effects since for most educated workers there is nowhere to go except stay in this primate city. As a result this may reduce the circulation of knowledge across cities. Reducing primate city favoritism and providing smaller cities with better local public goods (including education and health) are certainly a big part of any solution.

33.5 Conclusions

For individual workers, cities in developing countries appear to bring significant benefits both in the short run and in the long run. However, when taking a broader look, the urban system of developing countries appears to involve far less functional differentiation across cities than in more advanced economies. Such differentiation with different cities playing different roles in the urban system is important for the process of growth and development to proceed smoothly.

Larger cities innovate and manage. Smaller cities often produce a narrow range of goods. Having larger cities do everything like they often in developing countries reduces their dynamism and holds back small cities which remain stagnant.

A variety of policies can be envisioned to solve this problem. The three more promising areas are general policies to improve the functioning of labor markets, ending primate city favoritism, and development of major infrastructure to connect cities.

Abstract

This chapter looks at the recent developments in economic geography theory and sets out to shed light on its contribution to the understanding of the dynamics of technological change. The replacement of the linear model with more sophisticated conceptualizations of the process of innovation has made it possible to account for persistent disparities in innovative performance across space and has motivated researchers to incorporate the role of space and places in the analysis of innovation processes. From the physical-metrical approach of geography as distance to the emphasis on specialization and diversification patterns (geography as economic place), institutional-relational factors, nonspatial proximities, and “integrated” frameworks, economic geography theory has substantially

R. Crescenzi

evolved in terms of its contribution to the understanding of technological dynamics with significant implications for the rationale, design, and implementation of innovation policies.

34.1 Introduction

In an increasingly globalized world of intensified competition with ever-shorter product life cycles, new technologies and innovation are key determinants of regional and national competitiveness. This is certainly good news for developing and emerging countries and regions: economic performance can be boosted by stronger indigenous innovative capabilities but also by better accessibility to external knowledge. New windows of opportunity are being opened by innovation and technological change for new actors to emerge in the international technological competition arena. However, a large body of empirical evidence suggests that these opportunities are far from “universal”: knowledge generation and absorption are highly localized, and diffusion follows very complex (and ever changing) patterns. In both developing and developed countries, a small number of “hot spots” are pushing the technological frontier forward, followed by a set of emerging second-tier “imitative systems” and a large number of territories that exhibit little innovative dynamism and only marginal benefits from technological opportunities. Innovation is certainly spreading both internationally – as suggested, for example, by the success of China and India – and “nationally” with new territories gaining momentum in the “new” member states of the EU but only in a very circumscribed set of new suitable “locations.” This is true in Europe and the United States where around 70 % of total patenting remains concentrated in the twenty most innovative regions (Crescenzi et al. 2007) but also in China and India where these concentration patterns are even more significant.

Rather than waning, such spatial innovation disparities are increasing in both developed and developing countries, shattering hopes that rapid progress in information and communication technologies (ICT) and the dismantling of barriers to the movement of labor and capital can automatically decouple innovative performance from previous localized patterns of technological accumulation and contextual socio-institutional and geographical conditions. Conversely, the spatial concentration of knowledge generation in a few leading “hot spots” boosts their attractiveness for inward investment in innovative activities, further reinforcing the localization of the key nodes of “global” knowledge networks generated by the mobility of both capital (e.g., by multinational firms and their internal connections) and skilled labor (e.g., diasporic communities), generating a cumulative self-reinforcing process.

Technological change and innovation – with their capability to generate new economic opportunities – are features of cities, clusters, and regions whose contribution toward national and global systems and networks is highly asymmetric. This, therefore, calls for appropriate frameworks of understanding able to capture the two-way nexus between geography and innovation. Coherently with this

perspective, this chapter aims to critically review the existing literature on territorial innovation dynamics in order to shed light on how progressively more sophisticated conceptualizations of the role of geography in innovation dynamics have been developed, and how they can address the complexity of the “real” world processes discussed above in a more effective manner.

When looking at how the literature has conceptualized the economic geography of innovation dynamics, it is possible to identify four major streams of literature:

- a. Being based on physical-metric space, the first stream of literature has analyzed the role of *physical distance* between innovative agents in shaping their innovative capabilities.
- b. The second stream, instead, has focused on geography as an “*economic place*,” looking at how local sectoral and functional specialization patterns shape the generation of innovation.
- c. The third set of contributions has concentrated on *institutional-relational places*, looking at the impact on innovation of the rules and patterns shaping the interactions between innovative agents in a given locality.
- d. The final set of academic works has developed the idea that economic and institutional-relational processes can be de-decoupled from geographical proximity giving rise to *alternative* (“economic” and/or “institutional-relational”) *nonspatial proximities*.

Following the foregoing categorization, this chapter starts off by reviewing the archetypical a-spatial approach: that is, the linear model of innovation. The linear sequencing from basic into applied research and innovative products or processes leaves no conceptual room for geographical dynamics. The subsequent section looks at the literature that abandons the view of knowledge as a public good in order to explore the role of physical geographical distance in making knowledge a local quasi-public good. The fourth section places innovation “in context” by discussing (a) the influence of economic places – local agglomeration and specialization patterns – on the innovation process, by looking at how economists and geographers have tried to identify the type of sectoral specialization that is most conducive to innovation; (b) the role of local institutions is analyzed in the fourth section by reviewing the literature on regional systems of innovation (RSI) where the focus is on institutional-relational places. The fifth section will review recent research based on the multidimensional conceptualizations of proximity that broaden the analytical focus to nonspatial proximities as determinants of local innovative performance as also integrated approaches that combine and cross-fertilize the insights of various streams of literature. The final section concludes with some directions for future research.

34.2 The Linear Model of Innovation: The A-Spatial Benchmark

The linear model of innovation has for a long time been the most influential theoretical framework for the understanding of the economic impact of science and technology. It postulates that all innovations result from basic science

(Godin 2006): conducted in the research laboratories of universities and government research institutions, basic science produces new knowledge that is passed on to the applied science laboratories of private companies, where it is prepared for the translation into commercial products. The linear or “assembly-line model” (Ruttan 2001) conceives the innovation process as a one-way path:

Basic science → *Applied science* → *Development* → *Commercialization and Diffusion*

This view also implies that basic science creates positive externalities in the form of public knowledge: underinvestment in basic research must be expected in the absence of government intervention. The allocation of public resources to basic science is expected to maximize externalities that allow for the universal diffusion of knowledge as a public good.

Empirically, the reasoning behind the linear model lies at the core of econometric studies examining the link between R&D and patents, in the first instance, followed by that between patents and economic growth. These analyses are based on knowledge production functions (KPF), which allow for an investigation of the causal relation between productivity growth, unobservable knowledge capital, and its observable input (R&D) as well as output (typically patents), and further factors. Based on firm-level data, these studies are mostly conducted by “mainstream economists.”

The linear model of innovation has been particularly influential in the post-World War II when it shaped the US science and technology policies (Ruttan 2001) and remains popular with policy-makers in the twenty-first century, as evidenced by targets in terms of R&D spending to GDP ratios set in the EU’s Lisbon Agenda or by the contemporary policy focus on centers of excellence that still survives in the innovation policies of several countries. Two major reasons explain the lasting influence of the linear model. Firstly, the model conveys an unequivocal normative message: policy-makers should invest in basic research to maximize innovative potential. Second, national statistical offices and international organizations have reified “basic science,” “applied science,” and “development” into standard categories for the collection of data on innovative efforts, hardening the model as a concrete reference for policy discussions and transformed the linear model into a “social fact” (Godin 2006).

The most fundamental critique to this approach aims at the core of the model, that is, its linear character. The latter has been criticized for failing to reflect the complexity of innovation processes and the heterogeneity of its dynamics. These critics consider the production of new technological knowledge an interactive process between multiple agents. Since this process is assumed to involve continuous feedback, the advocates of this view reject the linear model’s conceptualization of innovation processes as a one-way sequence of steps. The creation of new knowledge is a socially embedded, interactive process. It is shaped by the interactions between innovative agents that, in their turn, are fundamentally influenced by physical space (that can facilitate or hamper their contacts) and by the places in which they are embedded being part of local industrial specialization processes, technological trajectories, and institutional modes of innovation.

34.3 Physical “Distance” Between Innovative Agents and Knowledge Flows

Once the view of knowledge as a pure public good – at the basis of the linear model – is replaced by a more realistic appreciation of its actual scope, geography as physical distance immediately becomes a fundamental component for the understanding of innovation processes. Knowledge has only a few of a public good’s characteristics: it is non-rivalrous and only to a limited extent excludable. In this regard, the literature on the role of geographical distance in innovation processes shares some common ground with the a-spatial linear model which assumes that knowledge production gives rise to external economies in the form of public knowledge. However, while in the linear model, the location of innovative agents is irrelevant to their capability to benefit from these externalities, the geographical literature considers knowledge as a spatially bounded quasi-public good whose circulation is largely restricted within the functional borders of the area where it is generated.

When looking at the spatial diffusion of knowledge flows, a crucial distinction is made between codified and tacit knowledge (Leamer and Storper 2001). The former is assumed to be relatively cheap to transfer since it can be expressed in a set of codes or instructions and distributed via communication channels (such as the Internet) and accessed by anybody familiar with the respective symbol system (e.g., language). Conversely, tacit knowledge is more expensive to transfer over long distances because – due to its higher complexity and context dependency – it is not codifiable (Leamer and Storper 2001). The relatively high cost of transferring tacit knowledge across space renders this type of knowledge geographically “sticky,” making face-to-face (F2F) contact an economically efficient means for its transmission. Encompassing verbal, physical, non-intentional, and intentional as well as contextual elements, F2F contacts allow for the communication of complex, contextual messages and minimize free rider problems by promoting the development of trust (Storper and Venables 2004).

The importance of F2F contacts can be interpreted as a pivotal factor underlying the spatial clustering of innovative activities: The complexity and context dependency of knowledge flows associated with innovative activities make the latter dependent on F2F – “an intrinsically spatial communication technology” (Rodríguez-Pose and Crescenzi 2008 p. 379). The dependency on F2F contacts may thus induce innovative actors to locate close to each other, which in turn leads to the emergence of geographical clusters of highly innovative agents.

In line with this conceptualization, geographical distance plays a major role in innovation processes: geographical proximity is deemed to facilitate the transmission of imperfectly appropriable but spatially sticky knowledge (Malecki 2010). Empirically, a large body of research on localized knowledge spillover (LKS) examines the importance of geographical proximity for the dissemination of knowledge (for a review, see Döring and Schnellenbach 2006): shifting from firm-based KPFs to regions as units of observation, this stream of literature finds

empirical support for the relevance of geographically mediated knowledge spillovers and identifies evidence of geographically bounded spillovers measuring their spatial extent (Döring and Schnellbach 2006). A second stream of empirical literature has used patent citations to track the spatial diffusion of patented inventions, suggesting that patent citations display a high degree of spatial autocorrelation: inventors refer to previous patents originating in the same city more frequently than to a control group.

When it comes to the design of regional innovation policies, the consideration that geographical distance acts as a barrier for the diffusion of knowledge flows leads to the acknowledgment of geographical peripherality as a source of structural disadvantage. The emphasis on the spatial boundedness of knowledge flows may also be interpreted as warranting interventions aimed at minimizing the geographical distance between innovative actors in the public and private sector. Incubators and science parks are two examples of policy measures reflecting the idea that public policies can actively maximize spillovers promoting regional innovative output by providing infrastructure that allows for a spatial concentration of regional innovative activities.

However, “classic” studies on LKS are often based on indicators that capture the potential for spatially bound knowledge spillovers rather than actual flows/contacts between agents. The mechanisms underlying the transmission of knowledge spillovers remain underdeveloped, meaning that the concept of LKS is still largely a “black box” (Döring and Schnellbach 2006): while some authors suggest that market transactions rather than externalities may explain local knowledge flows, others point out that members of epistemic communities may be connected by ties that transcend geographical proximity. The insufficient understanding of how knowledge is actually transferred between individuals located in the same geographical area impedes the formulation of a clear normative message to policy-makers.

In response to these criticisms, recent empirical work has focused more closely on the role of individuals as knowledge carriers and in particular on the mobility of knowledge-carrying workers and researchers. In addition, the literature has explicitly acknowledged that innovative agents cannot rely exclusively on local knowledge assets. Highly innovative actors benefit from a combination of “local buzz” (Storper and Venables 2004) – that is, the innovation enhancing local environment based on frequent F2F contacts of individuals who are collocated in a confined, typically urban place – and “global pipelines,” that is, communication channels formed by a differentiated set of “global” actors (different streams of literature have looked at multinational firms, diasporic communities, universities, and “star” scientists) that increasingly tap into pools of external knowledge bearing the associated communication cost/effort (Malecki 2010).

Only the most recent developments in economic geography theory (reviewed in Sect. 34.5) will overcome this dichotomous (local vs. global) conceptualization of knowledge transmission mechanisms developing more sophisticated frameworks of understanding.

34.4 Innovative Agents “in Context”: Local Specialization Patterns and Institutions

34.4.1 Economic Places: Industrial Specialization

Geographical distance between innovative agents is an important predictor of knowledge exchange costs. The communication of economically valuable potentially not codifiable/codified knowledge across large distances is possible but at increasing costs. However, a number of other characteristics of the local environment generate incentives for knowledge exchange and shape the synergies for innovation generation. In this context, a vast amount of literature has dwelt on the role played by specialization patterns by contrasting the innovation performance of both highly specialized and diversified economic environments that often coexist in both developing and developed countries.

A high degree of specialization facilitates the exchange of specialized, industry-specific knowledge. Occurring between firms active in the same industry, these Marshall-Arrow-Romer (MAR) knowledge spillovers are deemed to spur innovation. MAR spillovers are a typical feature of “classic” industrial districts. Conversely, “Jacobian spillovers” are associated with a diversified economic fabric, which is often found in big cities: the most valuable sources of knowledge of benefit to a firm lie outside its own industry. This view suggests that a diverse industrial structure allows for cross-industry knowledge flows that induce recombinant innovation.

The empirical literature suggests that both Jacobian and MAR externalities play an important part in enhancing innovation. Possibly due to differences regarding methodology and level of aggregation, analyses come to mixed, often conflicting results (for extensive reviews, see Beaudry and Schiffauerova 2009 and De Groot et al. 2009). Although part of the literature suggests that only specialization can be conducive to innovation, it must be stressed that MAR and Jacobian spillovers are not mutually exclusive (Beaudry and Schiffauerova 2009). Indeed, large cities can be simultaneously specialized in one or more sectors and simultaneously display a diverse range of further industries.

Specialization and diversification patterns have been harmonically combined into “economic places” by two sub-streams of literature. The first stream has combined specialization patterns with a product life-cycle perspective (Duranton and Puga 2001). Moving from a static to a dynamic view of the role of specialization patterns in the creation of new technological knowledge, innovation processes at different stages of the product life cycle rely on different types of knowledge spillovers. Firms develop new products in diversified urban contexts – termed “nursery cities” – benefiting from access to a greater variety of knowledge sources so that they can test new combinations until they identify the ideal production technology. Once production technology is standardized, firms relocate to specialized places as the focus shifts from radical to incremental innovations, and the ability to exchange knowledge with other firms from the same industry becomes more beneficial than having access to knowledge from a wide range of sectors.

In the nursery-city approach, both types of specialization patterns should coexist in a balanced system of cities, as they play different roles at different product life-cycle stages (Duranton and Puga 2001).

The second view that goes beyond the classic MAR versus Jacobian dichotomy proposes a more sophisticated understanding of sectoral diversity. The “related-variety” approach (Boschma et al. 2009) concentrates on cognitive proximity between sectors. Drawing on the notion of absorptive capacity, in a related variety framework, knowledge will necessarily “spill over” between any pair of industries: the identification and absorption of new knowledge requires a preexisting complementary knowledge. Related-variety industries share complementary competences (Boschma et al. 2009). Intermediate levels of cognitive proximity between related industries facilitate intersectoral knowledge flows conducive to innovation. Accordingly, neither specialization nor diversity per se enhances innovation: the former may lead to a too narrow knowledge base, whereas the latter might involve a lack of complementary knowledge across sectors. Instead, the composition of sectors in a region should ideally display an intermediate level of cognitive proximity between the different industries.

34.4.2 Relational-Institutional Places

While the industrial specialisation literature unquestionably abandons the a-spatial perspective of the linear model, it heavily concentrates on economic processes, essentially disregarding the institutional-relational dimension of territorial innovation processes. The concept of related variety does, however, share common roots with (regional) systems of innovation – the key components of institutional-relational places – and both streams are influenced by ideas from evolutionary economics and economic geography.

The systems of innovation (SI) perspective considers knowledge production as a nonlinear, interactive, and socially embedded process (Edquist 1997). SI literature adopts a systemic perspective and considers the creation of new knowledge as the result of evolutionary processes in complex systems. Its emphasis on multiple feedbacks between innovative agents sharply contrasts with the linear model’s conceptualization of innovation as a one-way process. While in the linear model there are only three major types of innovative actors (corresponding to the categories of basic research, applied research, and product development), the SI approach allows for a great variety of participants in the innovative process. The organizations with which firms interact “to gain, develop and exchange various kinds of knowledge” (Edquist 1997 p. 1) include other enterprises but also government bodies, research institutes, universities, and banks (Edquist 1997). By embedding innovation in its social environment, this approach puts culture and institutions at the core of the analysis: habits, norms, and laws shape the relations between the innovative agents.

The literature has deployed the SI perspective in three major analytical perspectives: the sectoral, national, and regional levels. The sectoral systems of

innovation (Malerba 2006) highlight sector-specific patterns of knowledge production and suggest that the relative importance of different types of knowledge spillovers and learning varies across sectors. At the national level, different institutional settings and governance structures shape the synergies between innovative agents and their evolutionary trajectory. Combining the SI literature with concepts from economic geography that emphasize the local roots of innovation and learning, economic geographers and regional economists have extended the SI perspective to the regional level (Edquist 1997). The Regional Systems of Innovation (RSI) literature puts geography in the sense of institutional-relational places at the center of the analysis of spatial disparities in innovative performance. Iammarino (2005 p. 499) defines an RSI as “the localized network of actors and institutions in the public and private sectors whose activities and interactions generate, import, modify and diffuse new technologies within and outside the region.” From an RSI perspective, regionally specific modes of learning, technological trajectories, and knowledge bases constitute important reasons for regional disparities in innovative output.

The consideration of both “economic” and “institutional-relational” places has profound implications for innovation policies that depart from the “one-size-fits-all” approach supported by the “linear model.” The design of any innovation policy should reflect region-specific modes of knowledge production and industrial specialization patterns, making the in-depth understanding of the technological trajectory and existing knowledge base of each region the starting point for any innovation policy (Iammarino 2005; Asheim et al. 2011).

The RSI’s emphasis on interactive learning in “regionally embedded, institutionally supported, networks of actors” (Uyarra 2010 p. 125) implies that by simply increasing innovation inputs, policy-makers are unlikely to maximize a place’s innovative potential. The shift from individual actors to a systemic view calls for policy-makers to address the institutionally shaped relations between the components of the system. The rationale for public intervention comes from some kind of systemic failure, which calls for corrective measures aimed at improving the local institutional setup of a place. Cross-fertilizing the RSI perspective with the notion of related variety, Asheim et al. (2011) urge policy-makers to enhance innovation via “platform policies” facilitating knowledge flows between related sectors.

In comparison with the clear-cut normative message of the linear model, just how policy-makers should translate the RSI approach into practice is less straightforward. The approach has been criticized because it provides little guidance on instruments and measures appropriate for tackling systemic failures. The approach’s interpretative flexibility or “fuzziness” (Markusen 2003) renders its use more difficult for policy-makers. Equally, there are divergent views regarding the exact components and borders of an RSI. On the empirical side, a bias toward high-performing clusters has been also criticized (Uyarra 2010). A further weakness of empirical RSI studies stems from the lack of indicators appropriate to truly measure the performance of a system in terms of the quality of knowledge flows and interactive processes rather than in terms of absolute innovative output (Iammarino 2005).

34.5 Bringing Different Approaches Together: Nonspatial Proximities and “Integrated” Frameworks

As discussed in the previous sections, knowledge spillovers do not spread uniformly across space but exhibit strong distance-decay effects. While geographical proximity (*geography as physical distance*) facilitates the transmission of imperfectly appropriable but spatially sticky knowledge, the creation of new knowledge remains a socially embedded, interactive process. However, despite its potentially supportive role for the exchange of knowledge, geographical proximity constitutes “neither a necessary nor a sufficient condition” for learning processes (Boschma 2005 p. 62). Learning processes and communication are shaped by industrial specialization, technological trajectory, and institutional modes of innovation that are characteristic of specific *economic and/or relational places*. Consequently, the analysis of the geography of innovative processes calls for the joint analysis of the full set of physical, economic, and institutional conditions that make innovation possible. Economic geography theory has responded to this challenge in two ways. On the one hand, it has explicitly conceptualized the differential (and potentially independent) role of spatial and nonspatial conditions and, on the other, has fully explored the full set of their interactions.

In the first stream, Boschma (2005) has proposed a framework that introduces four nonspatial types of proximity, conceptually independent of physical distance: (i) cognitive proximity, referring to the degree to which agents share a common knowledge base; (ii) organizational proximity, defined as “the extent to which relations are shared in an organizational arrangement” (Boschma 2005, p. 65); (iii) social proximity, measuring social embeddedness based on friendship, experience, and kinship of relations between agents; and (iv) institutional proximity, which is based on agents sharing the same institutional rules and cultural habits. In this framework, cognitive proximity is considered as the only form of proximity that is a permanent prerequisite for interactive learning and innovation: without overlapping knowledge bases, learning is impossible – even if there is high geographical proximity between the agents. In this context, colocation and physical proximity may still play an important role on a temporary basis to establish contacts that are then maintained through the continuous presence of organizational, social, or institutional proximity. The positive effect of geographical proximity (*geography as distance* in our framework) might be more indirect and subtle than frequently assumed: it may help innovative actors to find the “optimal” balance between different a-spatial forms of proximity shaping “economic” and “institutional” places conducive to innovation.

Acknowledging that proximity can be defined independently of physical-metric considerations prepares the stage for an integrated view of the forces influencing regional innovation processes. The introduction of alternative proximities makes it possible to adopt a new perspective on the role of *geography as distance*. Nonspatial proximities provide the justification for knowledge flows in networks as described by Breschi and Lissoni (2005). Regions may thus use alternative proximities to overcome geographical distance and tap into remote knowledge

pools via global pipelines. Although this relativizes the significance of colocation, it is important to emphasize that Boschma's (2005) framework is nonetheless compatible with the concept of local buzz (Storper and Venables 2004): we may conceive local buzz as "cognitive, organizational, social and institutional proximity brought together in a reduced geographical environment" (Rodríguez-Pose and Crescenzi 2008 p. 383). From this point of view, alternative proximities influence both interregional and intra-regional knowledge flows. With respect, instead, to *economic places*, the notion of cognitive proximity is particularly fruitful for analyses of opportunities of learning across industries. As stressed in the related-variety perspective, cross-sectoral knowledge flows hinge upon the right level of cognitive proximity. As far as *institutional-relational places* are concerned, the idea that place-specific innovation systems display idiosyncratic modes of learning suggests that a lack of local institutional proximity may impede successful learning.

The second stream of literature focused more directly on the interaction between geography as economic places, institutional-relational places, and physical-metrical distance – while simultaneously acknowledging the importance of alternative, nonspatial proximities. Following an "integrated approach," any analysis of a region's innovative performance has to take five keystones into account: (i) the link between local innovative efforts and knowledge generation as typically emphasized by a-spatial approaches, (ii) the geographical diffusion of knowledge spillovers and the region's industrial specialization (representing geography as distance and geography as an economic place), (iii) the presence of networks based on alternative, nonspatial proximities, (iv) the genesis and structure of local and regional policies, and (v) the existence and efficiency of regional innovation systems, with the last two keystones reflecting geography as institutional-relational places (Crescenzi and Rodríguez-Pose 2011). The interaction of these five pillars shapes the creation of new knowledge in a region. In accordance with recent changes in economic geography theory, the importance of a-spatial networks and mobile capital with respect to global knowledge flows is underlined in this framework: the ability of local actors to establish external relations based on alternative proximities is assumed to determine the position of the region in global networks (e.g., where MNEs "pump" global knowledge into the local economy and "channel" the results of local innovative activities into global knowledge pipelines).

A number of subsequent empirical studies have built upon such integrated perspectives, aiming to shed light on the relevance of two or more of their elements. These contributions can be grouped according to their treatment of space/place on the basis of the categories developed in this chapter.

Table 34.1 provides an overview of the factors taken into account by recent contributions that in different ways contrast, compare, and/or interact with alternative conceptualizations of "geography and space." The columns of the table correspond to the four categories developed in this chapter: geographical distance (covered by studies that examine distance-based aspects such as LKS and agglomeration economies), "economic places" (regional sectoral specialization patterns), "institutional-relational places" (regional systems of innovation and other local socio-institutional conditions), and "alternative nonspatial proximities."

Table 34.1 Classification of recent developments in economic geography theory and their contribution to the understanding of territorial innovation dynamics

Authors (year)	Physical Distance		Economic places		Institutional-relational places		Alternative nonspatial proximities			
	Localized flows	Knowledge	Specialization	Regional innovation	Institutional	Cognitive	Organizational	Social		
<i>Conceptualization</i>										
Boschma (2005)	X				X	X	X	X	X	X
Crescenzi and Rodriguez-Pose (2011)	X		X	X						X
<i>Empirical testing</i>										
Autant-Bernard and LeSage (2011)					X					
Crescenzi et al. (2007)	X		X	X						
Maggioni et al. (2007)	X						X			X
Ponds et al. (2010)	X									X
D'Este et al. (2012)	X							X		
Breschi and Lenzi (2012)	X				X					X
Marrouc et al. (2013)	X						X	X	X	X

The first two rows of the table highlight the conceptual basis of the proposed classification in relation to the two conceptual papers reviewed above: Boschma (2005) for the conceptualization of nonspatial proximities and Crescenzi and Rodriguez-Pose (2011) for the “integrated framework” and the interaction between various geographical innovation dimensions. The second section of the table refers to “representative” empirical works that explicitly test the differential role of the various geographical aspects. The key “benchmark” and point of departure of all these papers is “geographical distance” whose impact on innovative performance is compared and contrasted with other relevant dimensions/factors. Autant-Bernard and LeSage (2011) look at “geographical distance” and “economic places” (in a sectoral perspective) by examining the impact of Marshallian and Jacobian spillovers both within and between regions by means of a knowledge production function approach. Their results shed light on the differential spatial extent of different typologies of knowledge flows suggesting that Jacobian externalities tend to decay more rapidly with geographical distance. In their comparison of the territorial dynamics of innovation in the USA and in Europe, Crescenzi et al. (2007) assess the influence of physical-metric, economic, and institutional-relational dimensions of geography. They use a modified KPF framework to account for intra-regional and interregional knowledge spillovers, sectoral specialization, and regional innovation systems conditions. Their study finds that the geographical processes governing knowledge production differ between Europe and the USA. While institutional-relational factors (in the form of social filters) are fundamental in both continents, the role of spatial distance differs substantially. In the USA, innovation is generated in relatively self-contained and more specialized geographical areas, while European regions rely heavily on the capacity to assimilate interregional knowledge spillovers. The importance of a-spatial networks and proximities is also acknowledged, in particular as far as the USA is concerned, although this perspective is not directly tested in the paper.

The influence of nonspatial proximities is directly examined by Maggioni et al. (2007) who compare the role of geographical distance against the influence of social proximity between research staff by looking at co-patenting data and EU-funded research collaborations by means of KPF and gravity models. They find that spatial proximity is of greater relevance to knowledge production than social proximity. Additional empirical work examining the relation between geographical distance and nonspatial proximities comes from the literature on university-industry collaboration. Again in a KPF framework, Ponds et al. (2010) examine the relative importance of geographical and social proximity (proxied by co-publication patterns), for the impact of academic research on regional innovation: social proximity makes it possible for knowledge spillovers to diffuse over large distances, suggesting that geographical proximity is of limited relevance for spillovers resulting from research collaboration. Opting for a different methodology, D’Este et al. (2012) employ a case-control approach for the examination of the role of geographical and organizational proximity in the formation of university-industry partnerships. They suggest that British companies in spatially dense clusters of technology-intensive industries establish connections with universities

largely independently of the university's location, whereas firms outside dense clusters seem to place more weight on geographical proximity when establishing their links with universities.

The work by Breschi and Lenzi (2012) points in a similar direction. They look at the internal and external network structures of US cities by linking the interactions of innovative agents at the microlevel with innovative output at the city level. They include social network indicators in a KPF in order to compare the innovation impact of the internal city-level coinvention network with the embeddedness of local inventors in global coinvention networks after controlling for the role of specialization patterns. The empirical results suggest that external linkages are only likely to improve regional innovative performance if they are combined with an appropriate intra-regional network structure that facilitates knowledge diffusion.

In a comprehensive attempt to disentangle the role of different forms of proximity, Marrocu et al. (2013) use an augmented KPF to investigate the relevance of the five a-spatial proximities proposed by Boschma (2005) and interregional spillovers. Coinventorship serves as a proxy for social proximity, while a similarity index based on the sectoral distribution of patenting activity in each pair of regions defines cognitive proximity. Organizational proximity is measured by the affiliation of applicants and inventors to the same organization, whereas country dummies are used to account for institutional proximity. The authors thus succeed in linking a-spatial networks based on alternative proximities at the individual level with innovative performance at the regional level. Their results suggest that cognitive proximity is always relevant, while geographical proximity is not the most important type of proximity for innovation processes, while the role of social and organizational proximity appears to be marginal.

This highly dynamic but still embryonic stream of literature, which explicitly aims at disentangling the innovative impact of various spatial and nonspatial factors, has not yet reached a consensus on the relative importance of different forms of proximity. The heterogeneity of the results is likely to stem from both methodological and operational differences. The estimation of knowledge production functions "augmented" in order to account for the impact of various proximities, although now customary in this literature, remains problematic due to the strong collinearity among the various proximities (whose impact the foregoing functions set out to isolate and compare) and the potential simultaneity between innovative performance and the evolution of nonspatial proximity relations. In addition, the use of patent data to measure both "proximities" and performance might generate additional measurement problems. Thus, in order to further advance our understanding of the transmission mechanisms underlying the geography of innovation, the KPF approach should be supplemented by other techniques able to directly model the formation of links and networks and their spatiality before assessing their impact on "aggregate" performance.

34.6 Conclusions

The conceptualization of geography in innovation literature has changed substantially since the heydays of the linear model. Persistent disparities in innovative

performance across space have motivated researchers to develop progressively a more sophisticated analysis of the role of space and places in innovation processes. From the physical-metrical approach of *geography as distance* to the emphasis on specialization and diversification patterns (*geography as economic place*) and *institutional-relational factors*, economic geography theory has substantially evolved in terms of its contribution to the understanding of technological dynamics.

While the abandonment of the linear model has always been at the very center of the geographical analysis of innovation processes, the most recent developments in the discipline have questioned the excessive emphasis on spatially localized processes that have long dominated the geographical approach. Geographical proximity has progressively lost its role as the single most important type of proximity to influence innovation processes. Cognitive proximity has emerged as a permanent requirement for interactive learning while social, organizational, and institutional proximity may act as temporary substitutes for geographical proximity. Geographical proximity remains to strengthen nonspatial proximities and helps innovative actors to find the right balance of nonspatial forms of proximity. The analysis of the systematic interactions among these different dimensions calls for progressively more “integrated frameworks” in order to understand territorial innovation dynamics.

These shifts in economic geography theory have important implications for innovation policies. The conceptualization of innovation as an interactive process occurring within complex innovation systems requires that policy-makers tackle linkages between actors rather merely making investments in basic research. Innovation policy starts from a profound understanding of a region’s idiosyncratic institutional setup, technological trajectory, and knowledge base. However, the identification of the potential barriers to innovative performance cannot be limited to the local dimension: understanding the region as the intersection of global and local knowledge flows implies that cooperation and networking should also be encouraged with remote partners in other regions and countries. At the same time, results indicating that academic spillovers can be mediated over longer distances via nonspatial proximities suggest that policy measures aimed at stimulating knowledge flows should not merely concentrate on the local level but rather adopt a national or even international perspective (Ponds et al. 2010). In addition, the acknowledgement of the crucial role of people as carriers of knowledge also implies that the generation and attraction of highly skilled individuals should be part of regional innovation policy (Tripl and Maier 2011; Marrocu et al. 2011).

Influential reports by the World Bank (World Bank 2009), the European Commission (Barca 2009), the OECD (2009), and the Corporación Andina de Fomento (2010) in different ways reflect recent theoretical changes in economic geography. While the World Development Report 2009 has the important merit of fully incorporating geography as distance and economic places into the formulation of development policies, the policy conclusions formulated by the OECD, the Barca Report, and the Corporación Andina de Fomento fully endorse an integrated territorial approach to innovation which takes full account of the role played by institutional-relational factors and nonspatial proximities.

The development of the economic geography theory of innovation has contributed toward a progressive shift in the policy paradigm from a purely “science and

technology” approach to the emphasis on agglomeration and spatial proximity that has characterized innovation policies targeting cluster development and firm incubators. However, the most recent evolution in the territorial theory of innovation opens the way to more balanced integrated policies that systematically account for the multifaceted influence of geography on innovation processes.

If the effectiveness of innovation policies can substantially benefit from the evolution of economic geography theory, a number of relevant aspects remain to be further explored both conceptually and empirically. From the conceptual point of view, further research is needed on the linkages between the microlevel of the individual innovative actors, the meso-level of their territorial interactions, and the diffusion channels of “macro” global flows of skills and knowledge. A sound theory for this complex set of processes is a necessary condition to open the “black box” of knowledge generation and diffusion. If the (increasing) importance of nonspatial proximities is now fully acknowledged, further work is needed on the reasons and the mechanisms that govern the development and the evolution of such proximities. In the same way as location theory aims to explain the collocation decisions on economic agents in physical space, it is necessary to explore the fundamental mechanisms that drive the development of nonspatial proximities between innovative agents in the cognitive space.

Conversely, the empirical analyses of the geography of innovation need to substantially broaden their scope both in terms of methodologies and use of available data in order to cope with increasing theoretical sophistication and new policy challenges (in both developed and emerging countries). If regional “aggregate” knowledge production functions have greatly contributed to the development of this field of research, it is crucial to reinforce microlevel analyses that can clearly target relevant actors and their behavior. Substantial progress is needed for a more detailed identification of the role of spatial and nonspatial networks in this context. In addition, the reliance on patent data has also led to the under-examination of non-patented forms of innovation including process and organizational innovation. The integrated use of different data sources (including firm-level innovation surveys such as the Community Innovation Survey) is certainly an important development in this direction, but the emergence of new and more sophisticated research questions calls for the collection of more sophisticated micro-data on the innovation and relational behavior of firms, individuals, and institutions.

Acknowledgments The author would like to thank Alexander Jaax for his excellent research assistance. Financial support by ESPON 2013-KIT Project is gratefully acknowledged. The author is also grateful to Andrés Rodríguez-Pose and Manfred Fisher for comments on earlier drafts of this chapter. Abstract

This chapter is concerned with the process by which geographical economics influences policy. It considers a number of barriers that limit this influence focusing specifically on the availability of data, the limitations of spatial analysis, and the role of the evaluation of government policy. It considers why these problems present such significant barriers and proposes some solutions. In terms of the availability of data, the chapter explains why problems concerning the correct unit of analysis and measurement error may be particularly acute for spatial data (especially at smaller spatial scales). Resulting concerns about the representativeness of data and the mismatch between functional and administrative units may further hamper interaction with policy makers. For spatial analysis, the major problem concerns the extent to which empirical work identifies the causal factors driving spatial economic phenomena. It is suggested that greater focus on evaluating the impact of policies may provide one solution to this general identification problem.

35.1 Introduction

In most countries, economic prosperity is very unevenly distributed across space. Regions, cities, and neighborhoods seem to be very unequal. This is true if we look at average earnings, employment, education, and almost any other socioeconomic outcome. Regional policy, urban policy, and even neighborhood policy are all largely based on concerns about these kinds of disparities, and tackling these persistent disparities is a key policy objective in many countries. Providing a rigorous understanding of the nature, extent, causes, and consequences of these disparities has been a key motivation behind the development of geographical economics (broadly defined).

This chapter focuses on the policy response to these disparities and specifically on the interaction between academic research and spatial economic policy. In the limited space available, it is clearly not possible to summarize all the available research that has relevance to policy makers concerned with spatial economic policy. Instead, this chapter considers the process by which research informs policy, focusing specifically on the role of empirical analysis. In doing so, the chapter considers criticisms of existing empirical work, provides an introduction to means of evaluating the impact of spatial policies, discusses the major barriers to interaction, and makes some suggestions on how these might be addressed in future research. The last two of these issues have received some consideration by Markusen (2003) and Martin and Sunley (2011) from the perspective of economic geography “proper.” In contrast, this chapter is specifically concerned with geographical economics (i.e., the research field that has evolved at the interface between economics and geography and which this chapter treats as synonymous with spatial economics). However, it is clear that many of the issues apply more generally in terms of the impact of research on policy making.

The chapter focuses specifically on the role of *empirical* analysis and policy evaluation in informing policy. The strong theoretical bias of the new economic geography (Krugman 1991) means that many of the issues concerning the application of theory to policy have received fairly detailed consideration in the literature (see, e.g., Baldwin et al. 2003; Combes et al. 2005). Duranton (2011) provides a diagrammatic framework which carefully outlines many of the central issues. This literature reaches two broad conclusions. First, from a positive perspective (i.e., what will be the impact of a specific policy), the theoretical literature is better placed to provide general guiding principles rather than detailed answers. Second, our theoretical understanding of what policy should do (i.e., normative analysis) is far less developed and, as usual, depends crucially on assumptions about the relevant objective function. In short, from an academic perspective, while theoretical analysis is not always sufficiently well developed to be useful in guiding policy, the problems are at least well understood.

From a policy makers’ perspective, these theoretical issues are arguably second order. Instead, the fundamental concern is whether or not stylized formal modeling can ever provide “real-world” insights. Of course, these concerns are not unique to

policy audiences nor to spatial policy. However, assuming some policy makers do not hold such reservations on the validity of formal modeling (or, at least, are willing to set them aside), the central issue from a policy perspective becomes the provision of empirical evidence about the applicability of the underlying theory. This issue and the barriers faced in providing such evidence in the specific context of policy formation have received far less attention in the literature. It is for this reason that this chapter focuses on the role of the empirical analysis of spatial data in policy making.

Of course, questions concerning the empirical analysis of spatial data go beyond the role this might play in assessing the validity of formal modeling. Indeed, for most policy makers, this would be a distinctly second-order concern. Instead, experience suggests that policy makers look to empirical analysis to do (at least) three things: describe the problem, assess the underlying causes, and evaluate the alternative policy responses. In fact, these three roles are not so far removed from how many geographical economists would prefer to structure empirical research.

In an ideal world, theoretical modeling would deliver predictions about the underlying causes of spatial disparities. Appropriate data would then be used to describe these disparities and to test the validity of predictions from the theory. Assuming that the data support the predictions from the theoretical model, one could then use the model to think through the impact of alternative policy responses that have not yet been implemented. More recently, it has also been recognized that this logic can be reversed, with theory providing predictions about the impact of policy and empirical evaluation of policy that has been implemented then used to test the underlying theory. That is, assessing the causal impact of existing policies may be useful in increasing our theoretical understanding of how the spatial economy works, what causes spatial disparities, and what, if anything, policy might do to address these disparities. In addition, there is considerable interest in establishing the causal impact of existing policy independent of what it can tell us about theory.

Geographical economics faces a number of barriers in addressing each of these questions. Data availability can hamper the provision of basic descriptive statistics, as well as further empirical analysis. Spatial research (by academics) often fails to pay enough attention to the central question of identifying the causal mechanisms at work. Finally, and related, much policy evaluation (by governments and consultants) fails to identify the causal impact of policies, often despite claims to the contrary. On all three dimensions, and particularly with respect to policy evaluation, this chapter will argue that the empirical literature analyzing spatial data often falls somewhat short of the standards set by other fields of economics. This partly reflects the inherent difficulty of spatial analysis but also stems from a failure by some researchers to adopt methodological developments that might improve analysis. The empirical literature is only beginning to address this shortcoming.

The rest of this chapter is structured as follows. The next section focuses on the availability of suitable data, the starting point for better empirical analysis. The two subsequent sections deal with questions of causality and the policy evaluation of spatial policies, while a final section briefly concludes.

35.2 Empirical Analysis: Data

Problems of data availability depend on the policy context, but the most common problem tends to arise from the lack of available data at the appropriate spatial scale. Even at large spatial scales, these problems can be acute. For example, in the UK, even basic statistics to describe spatial disparities across cities are not easily available (DCLG 2006). In other countries, while data for larger spatial units is readily available (e.g., for US metropolitan areas), more detailed data (e.g., on firm location) may not be available or may be subject to quite restrictive access arrangements. From a policy perspective, the lack of spatial data that can be used to generate statistics to describe the problem at hand represents a major barrier to the use of geographical economics in policy making. This barrier is arguably greater for geographical economics than for some other disciplines similarly concerned with spatial disparities but which rely less on formal modeling and quantitative empirical analysis.

Even when data is available, however, there remains the fundamental problem that for most issues in geographical economics, the correct unit of analysis is difficult to define. For example, researchers in the field of international economics can often use nation-state boundaries to define the appropriate unit of analysis because these boundaries generate significant barriers to factor mobility (and differences in factor availability underpin many theories of international trade). For the spatial researcher, in contrast, city or regional boundaries are often no more than administrative creations. For some problems, where administrative units form the appropriate unit of observation, such data might be sufficient. This may partially explain, for example, why local tax competition and public good provision have been so extensively studied in the empirical literature. For other outcomes, such as economic growth, administrative units may provide a very poor substitute for properly defined functional economic areas (see Cheshire and Magrini (2009) for further discussion).

Problems concerning the definition of a suitable unit of analysis and the availability of data for these units often become more serious at smaller spatial scales. For example, the appropriate definition of a “neighborhood” is a major concern for researchers interested in identifying the importance of neighborhood effects (i.e., whether neighborhood composition affects individual outcomes over and above any effect of individual characteristics). As was the case for larger spatial units, these definitional problems may represent a more serious disadvantage for geographical economics than for disciplines that adopt qualitative approaches to consider the existence of neighborhood or peer effects. An ethnographic study, for example, can easily accommodate self-defined notions of neighborhoods. In contrast, (spatial) econometric analysis requires neighborhoods to be formally defined so that data can be collected that characterizes the structure of the neighborhood. Nor is this definitional problem the only, or even the most significant, barrier to econometric analysis in this area (and many related ones concerned with feedback between units of analysis in the outcome of interest). We return to this issue below.

Even when data is available for something approximating the correct unit of analysis for the question at hand, there may be considerable measurement error present. Of course, measurement error is usually present in nonspatial data, but the problem is more pronounced for spatial data because all of the standard problems occur (e.g., is employment correctly defined, measured, and recorded), but there is an additional spatial “allocation” problem. This spatial allocation problem arises because the construction of spatial data for any specific unit of analysis requires dots on a map to be allocated to units in a box (see Duranton and Overman (2005) for further discussion). Inaccuracies can occur both in terms of the geographical location of the “dot” (e.g., the spatial coordinates of zip codes) and the boundaries of the box. Uncertainty over the correct definition of the unit of analysis, as discussed above, exacerbates these difficulties.

These measurement problems become more profound as the spatial resolution of the data increases because any absolute measurement error translates in to greater relative error at smaller scales. Even if points are accurately allocated to geographical units, researchers using sampled data face an additional problem at small scales: For a given sampling frame, smaller spatial scales reduce the average sample size in any given geographical unit. As discussed in Duranton and Overman (2005), these problems can sometimes be avoided by working in continuous space. Whether this is a solution depends, however, on the problem at hand. When the issue is one of individual behavior (e.g., whether individual labor market outcomes are affected by employment accessibility), it may make sense to work in continuous space using geo-coded individual data. In contrast, when the interest is in broad spatial patterns (e.g., what causes differences in city growth), analysis in continuous space, based on individual geo-coded data, may not be helpful.

Regardless of whether or not switching to continuous space may help with analysis, it often will not solve the problems that poor data create in terms of generating descriptive statistics for spatial units of observation. Experience suggests that a lack of suitable data and the resulting inadequacy of *descriptive* statistics represent a significant barrier in using geographical economics to inform spatial policy making. As argued in Overman (2010), the increased use of geographical information systems (GIS) is slowly helping to solve many of these problems of data availability. GIS are helping reduce measurement error as well as making more data available by facilitating the reconciliation of data for different non-nested spatial units. The increased availability of geo-referenced data also allows researchers increasingly to avoid the need for arbitrary discretizations of data (because they allow the researcher to construct data for appropriate spatial units). Finally, new types of data are helping increase our understanding of spatial economic phenomena.

Interestingly, however, even if data availability becomes less of an issue in terms of analysis, a lack of descriptive statistics for specific administrative units may continue to cause a problem in terms of the interaction with policy makers. A major part of the problem stems from the fact that while these administrative units may be arbitrary from an analytical perspective, they are hugely important from a policy makers’ perspective. Policy makers want to know how these administrative units

are performing partly as an input into decision making but also because their performance is often assessed by comparison to other similar units. As a result, even when such data might not be a particularly useful guide for relative performance (if, say, a labor market boundary spreads beyond the administrative boundary), it will still be of great interest to policy makers.

The problem is further compounded when it comes to the empirical analysis of the underlying causes of spatial disparities. Specifically, in the absence of descriptive statistics based on representative data for particular places, many policy makers think that no progress is possible. This problem appears to arise because many policy makers struggle with the idea that sampled data can be informative about spatial processes unless the data is representative (which they equate with the production of “accurate” descriptive statistics for specific places).

Of course, this problem of representativeness is not unique to spatial settings, but experience suggests that it seems to be particularly important in terms of policy makers’ concerns about empirical analysis in this area. One possible underlying source of the problem may arise from the belief that each location is somehow unique either in terms of its characteristics or its responsiveness to policy initiatives (or both). However, as is increasingly recognized in applied microeconomics, such heterogeneity (including in the response to changes) may require care to be taken in interpreting statistical estimates but does not invalidate regression analysis of the problem at hand (see, e.g., the discussion of local average treatment effects in Angrist and Pischke (2009)). Given that these insights are often poorly understood by many researchers, it is no surprise that they have not had much influence to date on policy makers. It is not so clear why the criticism seems to have such bite in terms of the empirical analysis of spatial data. It would be interesting to know, for example, whether the problem is particularly acute because of the tendency of other disciplines’ strong emphasis on the uniqueness of location as an argument against quantitative approaches to spatial problems. Regardless of the underlying reason, the lack of large samples for administrative spatial units remains a barrier to informing policy making at all spatial scales even though it need not be.

35.3 Empirical Analysis: Causality

As discussed above, even when appropriate spatial data is available, the second broad set of problems concerns the type of empirical analysis that has been traditionally undertaken using such data. These problems are discussed in detail in Gibbons and Overman (2012) who argue that the biggest problem stems from the fact that traditional spatial econometric and statistical analysis has not paid sufficient consideration to the crucial issue of identification. This has profound implications for our ability to understand the causes of spatial disparities and for empirical analysis to influence the development of policy. To understand why, one needs to consider the way in which the empirical analysis of observed data might allow us to understand causality.

In many fields of economics, empirical research is increasingly concerned with questions about causality (Angrist and Pischke 2009). That is, questions of the type “if we change x what do we expect to happen to y .” This is particularly the case in fields focused on individual (microeconomic) rather than aggregate (macroeconomic) behavior. Although geographical economics is clearly concerned with both levels of analysis, if it is to be useful in policy making, then these types of questions must take center stage. After all, policy usually seeks to change some x in order, hopefully, to achieve some desired change in outcome y . Even when policy can directly influence the outcome of interest, we still need to understand how economic agents adjust to any change so that we can establish what will happen after this adjustment has taken place.

The fundamental challenge to answering these questions for (most) economic data is that the determinants (x) are not randomly assigned. This is certainly the case for many policy interventions, when x (e.g., investment in the transport network) will often be specifically set to (partially) reflect differences in the outcome of interest y (e.g., the level of GDP). As a result, in real-world data, we jointly observe x and y , so we lack the counterfactual. That is, what would have happened if x had been set at some different level? This is a problem because it is the comparison of actual outcomes to this counterfactual that identifies the causal impact of determinant x on outcome y . Fortunately, applied economics has come a long way in its efforts to find credible and creative ways to answer such questions by constructing counterfactuals from observational data. Unfortunately, however, such methods have not been widely applied in much applied analysis of spatial data, particularly in analysis undertaken using the standard spatial econometrics toolbox.

Instead, much applied spatial econometrics research assumes that we know the way in which spatial interactions occur, writes down the corresponding spatial econometric model, and estimates the parameters by nonlinear methods such as (quasi-)maximum likelihood. Questions of identification (i.e., does an estimated correlation imply that some determinant x causes outcome y ?) have generally been addressed by asking which spatial processes best fit the data. While this sounds straightforward, Gibbons and Overman (2012) explain that it is very hard to distinguish between alternative specifications that have very different implications for which causal relationships are at work. This fundamental identification problem, and the lack of attention given to it, significantly reduces the usefulness of this kind of spatial econometric analysis for policy making.

In practice, analytical capacity constraints limit the extent to which many government departments can engage with quantitative (econometric) analysis. Given this more general problem, it is perhaps no surprise that spatial econometric model specifications and estimation are sufficiently complex that research in this tradition has often proved very hard to communicate to policy makers. Coupled with concerns about the underlying secondary data, this can often lead policy makers to prioritize research which focuses on carefully describing the nature of spatial disparities rather than properly identifying the underlying causes. As discussed above, this tendency is reinforced by political interest in outcomes for specific administrative units. Again, it would be interesting to understand why this

tendency to conflate description with analysis is so pronounced in the area of spatial disparities and policy making.

If data availability and the type of analysis undertaken with available data represent significant barriers to informed policy making, a further barrier arises because, even when these problems are recognized, they can be very hard to address. The fundamental reason for this is that for many spatial economic phenomena of interest, suitable identification strategies can be hard to develop.

Researchers are making progress in this area, but, as argued in Gibbons and Overman (2012), progress is likely to remain slow unless issues of identification are given far more precedence in spatial empirical analysis. They suggest that these issues need to be put at center stage and discuss strategies for dealing with identification in spatial settings. One possibility is to use explicit sources of randomization that occur as a result of institutional rules and processes. For example, the random allocation of dorm-mates has been used by Sacerdote (2001) and others to study peer effects in college grades. Randomization often does not solve all identification problems, but it does reduce problems arising from the self-selection of individuals into groups. However, when it comes to areas of substantive policy interest, there are several barriers to randomization, especially in terms of exposure to policy interventions.

The major one is arguably political. While many academics are comfortable with randomization (e.g., because they are willing to start with the assumption that a policy will have no effect), this is a far harder proposition for policy makers. For example, if a policy maker starts with the assumption that policy will be beneficial, then randomization generates ethical concerns that those most in need might not be treated. These ethical, and other practical, issues have been extensively discussed by many of the so-called randomistas who advocate the use of random trials in the development context (see, e.g., Banerjee and Duflo 2009). While they are clearly making some mileage in specific circumstances, the general arguments are not yet won, even in circumstances in which randomization would be exceptionally helpful.

In addition to this central problem, large-scale field experiments such as the Moving to Opportunity program are rare and costly (and still suffer from very difficult to avoid design flaws). On the other hand, small-scale experiments suffer from concerns about external validity (i.e., the extent to which the results would generalize to other contexts). Such concerns about external validity, although not expressed in this way, may have particular bite for policy makers in the area of spatial policy who, as discussed above, often think of every place as being somehow unique. For all these reasons, it is hard to imagine policy makers agreeing to experiments to answer many spatial questions (even if such experiments could be designed), and it is therefore unlikely that randomization will represent a way forward for many areas of interest.

In the absence of suitably randomized data, appropriate instrumental variable strategies may represent an alternative way of circumventing the reverse causality problems that bedevil much spatial analysis (particularly in areas important to policy making). That said, it is often hard to think of suitable instrumental variables

in situations where we are interested in “area effects” that arise because of feedback to the outcome of interest from the outcomes of other economic agents located nearby. As has been understood for some time and formalized by Manski (1993), econometric analysis of such “endogenous social effects” faces severe identification challenges. This can make it very difficult to assess whether such effects are occurring or whether the appearance of interaction arises because of underlying similarities between nearby units of observation. It is interesting to note that empirical analysis looking at neighborhood effects (e.g., the impact of neighborhood on schooling) tends to find little evidence of strong effects when it carefully addresses these identification issues. This is in direct contrast to more qualitative approaches. As argued by Cheshire et al. (2008), this may partly explain why geographical economics has had relatively little influence on policy aimed at neighborhood “mixing” and other initiatives to “mitigate” neighborhood effects. It may be that the best we can do in these circumstances is to make policy makers realize the difficulties inherent in distinguishing these alternatives and point out that in research to date, the more careful the identification strategy, the less evidence there is of interaction through endogenous social effects.

In other spatial settings, however, where interest is not limited to endogenous social effects, it is increasingly possible to develop effective instrumental variable strategies as a result of policy designs, institutional rules, and natural environmental features (or even better, changes in these factors). Overman (2010) and Gibbons and Overman (2012) provide many concrete examples. One significant problem remains; however, these strategies can be very hard to explain to policy makers who do not fully understand the need for careful identification strategies (at least for those with little or no economics training).

One possible way to interest policy makers in these issues is through the use of identification strategies based on the details of existing policy interventions. Policy makers often need to evaluate the impact of policy. In addition, specific policy features may also help with the identification of causal factors at work in spatial processes. It would appear, then, that there may be two linked arguments for focusing greater efforts on credible policy evaluation. First, one would hope that effective policy evaluation should be a key input into policy development. Second, such policy evaluations may provide useful identification strategies to increase our understanding of the way the spatial economy works. Because of the possibilities this presents, it is worth considering these issues in some detail, and it is to this that we now turn.

35.4 Policy Evaluation

Policy specific outputs (e.g., the number of workers trained or firms assisted) are increasingly well monitored by governments. In contrast, many formal (i.e., government sponsored) evaluations of policies that seek to look at outcomes do not use credible identification strategies to assess the causal impact of policy interventions. As for spatial empirical analysis more generally, it could be argued that this

problem appears to be particularly acute for spatially targeted policies. Once again, these problems partly stem from the difficulty in coming up with identification strategies in spatial settings. That is, in assessing, what would have happened to the unit of analysis (the area, firm, worker, etc.) in the absence of the policy intervention? As emphasized by the literature on program treatment effects (see, e.g., DiNardo and Lee 2010), solving this problem requires the construction of a valid counterfactual that can then be compared to observed outcomes. In this section, we argue that, despite the difficulties, such an approach can be applied to many spatial policies and that the resulting evaluation can be informative about both the effect of policy and the spatial economic processes at work. Some concrete examples, mostly drawn from the USA and UK, will be used to help clarify the issues.

Let us start with the example of Enterprise Zones (also known as Empowerment Zones in the USA and referred to below as EZs). These spatially targeted policies aim to improve economic outcomes (e.g., employment and number of businesses) in deprived areas. To identify their causal effect, we need to figure out what would have happened in these areas in the absence of intervention. One possible identification strategy is to compare these areas to other similar areas that were not targeted by the policy. Actually, for many government-funded reports, even this simple strategy would substantially improve the quality of evaluations. From an academic perspective, however, such simple comparisons remain problematic because they require very strong identifying assumptions. Specifically, unless we have an exhaustive list of area characteristics that might influence local economic outcomes, we might worry that some unobserved characteristic of areas drives both the decision to target the area *and* outcomes in that area. In this case, we might wrongly attribute any change in outcomes to the policy when, in fact, it is driven by unobservable area characteristics. Much of the recent improvement in the evaluation of program treatment effects has come from novel ways of addressing this problem combined with a refined understanding of how to interpret the resulting estimates.

One possibility is to compare outcomes for those areas that receive funding to those areas that applied for, but did not receive, funding. This strategy has been used by Busso et al. (2010) in their recent evaluation of the US Empowerment Zone policy. Such a strategy can be highly effective in removing the influence of many unobservables that might bias estimates of policy impact, especially if restrictions to funding limit the number of areas treated so that selection among the applicants is less likely to be driven by these unobservable characteristics. More recently, the UK government announced that 29 sites will compete to host 10 new Enterprise Zones. As for US Empowerment Zones, with these new Enterprise Zones, the 19 sites that lose in the competition may provide a reasonable control group for the 10 that win. Comparing outcomes for the two groups will then tell us whether those that won the competition actually do better, and we may be willing to attribute this to the impact of the policy. Analysis could also compare those that entered the competition to areas that appear to be similar but that did not enter the competition (to see whether those that entered the competition somehow differ from those that do not). For these kind of strategies to achieve identification of the causal effect of the policy requires that, conditional on observable characteristics of areas, treatment is not correlated

with any unobservable characteristic that directly influences the outcome of interest.

The timing of policy interventions may provide another possible source of identification. For example, EZs given money early on should start improving before those given money later. If they do not, that raises questions about whether treatment caused any improvement (or decline) or instead whether this was caused by some other factor (such as changes in the macroeconomy). These strategies have received recent application in the literature including the work by Busso et al. (2010) on US Empowerment Zones. For this strategy, identification of the causal effect of the policy requires that, conditional on observable characteristics of areas, *timing* of treatment is not correlated with any unobservable characteristic that directly influences the outcome of interest.

Even in situations where the researcher cannot be sure that decisions to fund (or the timing of funding) are uncorrelated with all unobservable characteristics that directly influence the outcome of interest, we may believe that this condition holds for *marginal* decisions. Imagine, for example, that the government makes its funding decisions on the basis of a ranking of projects from best to worst. Such detailed assessment of projects often occurs after a rougher process has ruled out the weakest projects (so the sample of projects subject to the more detailed ranking may be those that make it through this first screening process). If a researcher has access to the ranking of projects, then this would allow the comparison of outcomes for otherwise similar areas that were just “above the bar” (and so got treated) to outcomes for areas just “below the bar” (who did not get treated). Sometimes, the criteria for treatment will be based on some observable characteristic of areas rather than some ranking based on the quality of bids submitted to the program under consideration. Then areas that just satisfy the criteria and so get treated can be compared to areas that just fail to satisfy the criteria and so do not get treated. Some policies, such as the UK’s Local Enterprise Growth Initiative may use a combination of cutoff criteria and competition to decide who gets treated (from among those that are eligible).

Applications of such regression discontinuity designs to spatial economic policies include Baum-Snow and Marion (2009) and Dachis et al. (2011). As discussed further in Lee and Lemieux (2010), these discontinuity designs can be used to identify the causal effect of policy, providing that applicants do not have full control over the characteristics that determine treatment. Notice that this is a weaker requirement than having no control (so that treatment need not be completely random across all areas) but comes at some cost in terms of the extent to which estimated effects generalize to areas that are further away from the policy cutoff. This is sometimes characterized as involving a trade-off between internal and external validity (i.e., the researcher gets good estimates of the causal effect for areas around the threshold, but it is not clear whether these would generalize to areas away from the threshold). This distinction provides one example of how the recent program treatment literature has clarified our understanding of how to interpret estimated parameters as well as how to estimate them in the first place.

So far there is nothing specifically spatial about these identification strategies (other than the fact that the policy intervention occurs in specific places) which have been more widely used in other applied microeconomic literatures (particularly in development, education, and labor). However, the fact that the policy intervention occurs in specific places and that these places have a geographical location provides a further source of discontinuity which may be useful in achieving identification. Specifically, we can use “spatial differencing” to compare treated areas to *nearby* non-treated areas. If unobservable characteristics vary smoothly over space, then such a comparison may help control for unobservable characteristics that affect both treatment and outcomes. As with regular (nonspatial) discontinuity designs, the validity and interpretation of the resulting parameter estimates depend crucially on how the borders of treated areas are determined and what happens to the unobservable characteristics of areas at those borders. If unobservable characteristics vary continuously at the border, then spatial differencing may give us the causal effect of the policy even if policy assignment is nonrandom (providing that policy makers do not have perfect control over the location of the boundary that determines the policy area). Even if unobservable characteristics do not vary continuously at the border, spatial differencing may still help if it eliminates larger spatial trends, making it easier to find suitable instruments for the spatially differenced variables (see Duranton et al. (2011) for further details and an application to the impact of local tax rates on employment).

A further complication arises when using spatial differencing if treatment effects spill over geographical boundaries to impact non-treated areas. This spillover might be positive (often referred to as a multiplier effect) or negative (often referred to as displacement). Regardless of the sign of the effect, if the interest is in the overall aggregate impact of the policy for an area that extends beyond the boundary of the treated zone (as it might be, e.g., for Enterprise Zones) such spillovers significantly complicate interpretation of estimated coefficients. Specifically, in the presence of positive spillovers, estimates of the effect of policy are biased downward and vice versa for negative spillovers. These issues are discussed further in Neumark and Kolko (2010), but the literature is only just beginning to grapple with the resulting complications.

Official evaluations of government policies (i.e., those paid for and sponsored by government) usually make little, if any, use of these program features to help identify the causal impact of policy. For a geographical economist, this significantly complicates the interaction with policy makers, because reports that are less careful about causality are often willing to make much broader claims about the impact of a policy (and how that impact was achieved). As a result, policy makers face a difficult trade-off when trying to decide how to evaluate policies. Wide-ranging “evaluations” that are less careful about causality *appear* to provide more information as an input in to the policy-making process. Taken at face value, such evaluations allow policy makers to both assess value for money and make changes to policy, while appearing to take into account evidence about the impact of the policy. In contrast, empirical research in the program treatment effects tradition often makes fairly narrow claims about whether the policy has a causal impact (and

then, sometimes, only for a particular part of the population depending on the methods used).

Of course, there are a number of arguments in favor of an approach which focuses on a narrower range of issues concerning the causal effects of policy. First, and most important, a policy evaluation that focuses on causal effects should substantially improve our understanding of whether policies such as Enterprise Zones have *any* net impact (including possibly whether or not they generate or mainly displace economic activity). This would help future governments when they decide whether to maintain or reintroduce such a scheme. In addition to this core reason, it is also interesting to note that in many circumstances, government could get this type of policy analysis at little cost because this kind of evaluation has the potential to be published in top academic journals (cf. a number of the references provided above). Such “open evaluation” will not work for all policies (because the degree of academic interest will usually depend on the extent to which the policy “design” allows causal effects to be identified), but it could work for a good proportion of them. In short, when appropriate, policy evaluation of this kind does not need to be big, expensive, and centralized. Instead, it can be outsourced by using open evaluation in the academic (and wider nongovernmental) community. A major barrier to such an approach to evaluation is, once again, the availability of data. But now the issue concerns the availability of information on the government policy to be evaluated. A first step in moving toward a more open evaluation model would require good information to be recorded at all stages of the policy-making process – for example, whether selection of projects is competitive, how decisions are made, what is the location and timing of intended and actual expenditure, and what types of expenditure (buildings, capital grants, training?) are funded. Information on bids needs to be available whether successful or not. Nearly all of this information will be available and processed when appraising the bids before a decision is made. The only additional costs involved arise from doing this in a consistent, well-documented manner and in somehow making this data available. Recording all of this detail would involve a small amount of expenditure but does take time at a point when officials are usually under pressure to make decisions and start spending money.

Unfortunately, it is arguable that costs are not the major barrier in terms of data availability. Using policy design to assess causal effects ideally requires government to have detailed information about the decision-making process. How were bids solicited and assessed? How were the winning bids selected? How were funding levels decided? At least in the context with which I am most familiar (the UK), it is remarkable how little of this information is systematically recorded even for internal purposes. I would assume that this problem applies much more widely beyond the UK. Assuming all this information (on the policy process and outcomes) is available, there is one remaining major barrier. Specifically, effective policy evaluation needs the government to make all this information available to researchers. For all kinds of reasons, governments remain reluctant to do this.

Of course, a genuine reason for resistance to transparency is that some of the information may be confidential (more so when it relates to individuals or firms

than areas). Fortunately, government departments and statistical agencies do appear to be increasingly willing to find mechanisms for circumventing this specific problem. In the UK, for example, they do this by making data “publicly” available to use in a secure data environment with controlled access and detailed disclosure rules (e.g., the ESRC-funded Secure Data Service). Again, there will be some cost to maintaining this data and providing access to it. The final barrier to more careful policy evaluation is that government needs to be patient. To perform the kind of analysis discussed in this section requires data on the policy and for a range of outcome variables, for example, firm performance, employment, and unemployment, for an appropriate number of geographical areas. That outcome data is usually only available with a time lag of several years which complicates the interaction between evaluation and policy formulation (because policy makers are often working on shorter time scales). But once the data becomes available, if the policy design is such as to interest academics, researchers will then spend many (unpaid) hours figuring out whether the policy in question had any causal impact on outcomes. In short, with a little patience and transparency, open evaluation has the scope to significantly increase our understanding of the causal impact of government urban policy at very little (direct) financial cost. In addition, such evaluation can also increase our understanding of how the spatial economy functions. For example, evaluation of place-specific policies can tell us the extent to which other “amenities” are likely to get capitalized into land values. Policy evaluation of transport projects can tell us whether or not market access (through the transport network) affects productivity. Looking at the impact of training policies can help increase our understanding of local labor markets. The geographical economic literature is only just beginning to explore these issues, but experience from other fields suggest that we might learn a lot more from such an approach.

35.5 Conclusions

To some extent, this chapter has been concerned with the “process” by which geographical economics influences policies. It has considered a number of barriers that limit this influence. The chapter has been structured around the three sets of constraints facing academic researchers – specifically in terms of the availability of data, the limitations of spatial analysis, and the role of the evaluation of government policy. But along the way, the chapter has also highlighted a number of constraints facing policy makers. Policy makers are accountable for the performance of particular places. This means that they need to be interested in data for administrative units even if they understand that these might not adequately capture how spatial disparities are developing and what, if any, impact policy is having. A lack of analytical capacity often exacerbates the problems caused by any disconnect between the data used for analysis and that used to assess the performance of different administrative units. In terms of the analysis, policy makers often perceive ethical or political problems with decision-making processes, such as randomization or competitive bidding, which many researchers advocate as “ideal” for

evaluation purposes. More careful evaluation calls for up-front costs in terms of systematic data collection but only delivers longer-term results once outcome data becomes available and analysis has been undertaken. Political imperatives, for example, an incentive to show short-term results, can easily override the desire of officials to take a longer-term view of the impact of the policies for which they are responsible.

Some of these issues stem from fundamental conflicts of interest between researchers and policy makers. Others are more easily addressed. Collecting data for more “sensible” spatial units – such as metropolitan areas – can better align the spatial scales used by policy makers and analysts. Using institutional features of policies to help improve the understanding of the causes of spatial disparities increases the relevance of academic research to the policy-making community. Secure data services allow governments to share data in a way that maintains some control over exactly how that data is used. In turn, open data allows for open evaluation where the academic community can provide longer-term assessments of the impact of policy even if policy makers’ attention remains focused on the short term.

Of course, addressing all of these barriers is only a necessary, but not sufficient, step in ensuring that insights from geographical economics help inform spatial policy. Belief- or principle-based policy making still trumps evidenced-based policy making in many situations. But addressing these problems also makes for good geographical economics regardless of any influence on policy. Fortunately, for academic researchers, even if we fail to change the world, improving our understanding of how the world works is hopefully reward enough for our efforts.

Abstract

This chapter focuses on the ways in which travel behavior and demand are analyzed within the framework of regional science. Unlike numerous recent surveys that cover the more technical and abstract aspects of mathematically modeling travel behavior and demand, the attention here is more on the practical aspect of applying travel behavior and demand analysis to subjects such as regional development, infrastructure investment, and congestion analysis. Thus, while the main methods of modeling travel behavior and demand are outlined and critiqued, there is also considerable references to such things as demand elasticities and their estimation that are at the core of applied regional analysis. These types of parameter provide a direct link between a soft policy shift or a harder infrastructure investment, travel behavior, and ultimately the implications of this for regions. There is also discussion of the uses made of the forecasts that are the de facto rationale for studying travel behavior and travel demand, and the ways that neutral forecasting can be manipulated in decision-making.

36.1 Introduction

Whatever we do takes up time; it takes time to watch a movie, to appreciate a good meal, or to see a favored soccer team lose. Time is important; why else do fast-food restaurants flourish? We like to save time to allow us to do more things over our limited life spans and in particular because there is considerable uncertainty about its duration. In a more prosaic context, we often try to save time to increase our economic productivity, or perhaps our employers do, because, after all as the old proverb says, “time is money.”

Time-saving is important in influencing travel behavior and on travel demand, as in most other activities, sometimes more so and sometimes less. The relationship is, as in all other similar matters, a complicated one because from a behavioral perspective, time is never consumed in isolation. Just as going to the opera involves consuming time, it also means spending money. Traveling thus costs money in several ways, be it a fare, fuel, or shoe leather, and involves some form of final consumption, and not just at the end of a journey, although this is often emphasized. In this sense, the demand for travel is also derived from what is to be “consumed” at the end of a trip, be it a work or leisure final activity; in economic terms time is a joint product.

Travel, therefore, entails considering the consumption not just of time but also of money and other things as well as enjoying a number of benefits at the end of the trip, in some cases, reading, sightseeing, listening to the radio, or enjoying having your Lamborghini admired on the trip. It is not surprising therefore that in practice, transportation analysts are often very bad at predicting travel behavior, particularly when there are major changes in underlying parameters over time or when some of the costs and benefits are not easily quantified.

36.2 The Behavior of Individuals

The focus here is exclusively on the travel behaviors of individuals; it does not consider the movement of goods or information electronically, other than those in cases when these may impact on personal movement. The overlap can, however, be rather more extensive than is often reflected in policy-making and academic analysis. In most cases, individuals accompany goods when they move, trucks would be immobile without truck drivers, and the personal involved have their own individual traits. In many cases, goods movements use the same infrastructure as individuals or the same piece of mobile plant, for example, passengers on the top deck of an aircraft and freight in the belly hold. The electronic transportation of information is important when it substitutes for a personal movement, for example, in the context of teleworking, or when it facilitates personal travel, as with airline computer booking systems or with automobile route guidance systems. We also say relatively little about where origins and destinations of trips are located, but there are clear links between where people choose to live and work and transportation facilities that in turn feed back on their travel behavior.

Additionally, handbooks have many purposes and many potential readerships ranging from those concerned with the highly theoretical and abstract to those wanting a quick guide to finding a practical, rough-and-ready solution to an immediate real-world problem. (Volumes dealing with the latter are often, with a degree of derision, described as manuals, but their approach is no different to “handbooks” providing recipes for developing abstract theorems.) Here we seek to function in the middle ground, by both discussing many of the widely used practical approaches to analyzing travel behavior and travel demand and making use of our knowledge of the subject, but also to offer some guidance as to the direction research at a more theoretical level is moving. While there will be some discussion of model derivation, in the spirit of handbooks, the emphasis is on setting down what we have and is currently being used, rather than plowing through all of the intellectual and mechanical background in detail.

36.3 Modeling Travel Behavior and Demand

Travel behavior is like any other activity, possibly excluding religion and politics, in that rational economic forces largely drive it. People base their decisions on the benefits they will enjoy from it, either directly or at the end of the trip, constrained by the generalized costs of the movement in terms of time and money, relative to available resources and the opportunity costs of using them in some other activity. Put this way, the study of travel behavior may seem rather trite; it is basically a constrained maximization problem. The devil, as is often the case, lies in the detail.

At the outset, it is important to distinguish between travel behavior and travel demand. The latter is a particular influence on the former. Travel behavior is what people actually do, the way that they behave, the trips they make, and the forms of transportation that they use. It is basically what the collection of transportation data on person and goods movements reflects and what those who invest in transportation or manage transportation assets try to forecast. Travel demand is one part of this and reflects what people’s travel behavior would be with various forms of transportation facilities available. It makes no allowance for the roads or transit facilities that exist, other than to extrapolate in some cases their current use to forecast future travel behavior. Thus, while travel behavior is dependent on travel demand, it is not only the demand for travel that influences final travel behavior outcomes but also the supply of transportation facilities.

Travel behavior can also be very variable in its nature, and virtually all analysis has to be taken as contextual and in particular is related to the physical facilities available and the flexibility the traveler enjoys. The timing of trips is far more important for commutes, for example, than for daily leisure activities, although over a longer period, the constraints of having set periods for vacations can be very restrictive in terms of vacation travel. Equally, travel at peak times of the day, the “rush hour,” or at common vacation times, such as Christmas, can put pressures on the existing transportation infrastructure, with those able trying to avoid the worst

excesses of congestion. But the very transport demands of people also affect the de facto supply of capacity available for their individual use. The classic example is that economies of agglomeration that, by concentrating employment, tend to push up the demand for urban transport infrastructure use in the morning and evening rush hours, leading to congestion and the increasing of the prices of these trips. This “club-good” problem, akin to golfers preferring to tee off in the early morning, puts pressure on the transport system leading to high levels of peak period congestion, a phenomenon that has attracted a lot of attention among urban and transportation scientists (Lindsey and Verhoef, 2008).

The information traditionally used for analyzing travel behavior and demand has been of the revealed preference form, and the tools of analysis have been Gaussian in orientation. Essentially this has involved the extrapolation of previous travel demand behavior into the future based on statistical analysis of prior relationships between travel and physical, economic, and sociological influences. The relationships are assumed to be constant over time. The stochastic nature of the underlying historical relationship allows confidence intervals to be drawn around the projections.

The traditional modeling approach to handling this information to, for example, forecast the implications on travel behavior of a policy shift in road investment was originally limited in part by the need for computational convenience. The models were developed mainly in the 1960s at a time when large-scale transportation and land-use plans were in vogue with an emphasis on providing road access along major commuter corridors, and this influenced the types of forecasts being sought. But these plans required considerable details of traffic effects over large interconnected networks, which in turn necessitate complex manipulating of very large databases.

The methodology involved breaking down travel demand analysis into a number of sub-questions, the “four-stage model.” In the urban context, this involves, what is essentially recursive modeling of the aggregate travel in an area, disaggregating this into trips between areas with the city, disaggregating these trip distributions according to the modes used, and finally assigning traffic to individual routes. In simple mathematical terms, the stages can be expressed as

$$T_i = f(X_i); T_j = f(X_j) \quad (36.1)$$

$$T_{ij} = f(T_i, T_j, C_{ij}) \quad (36.2)$$

$$T_{ijm} = f(T_{ij}, C_{ijm}, C_{ijm'}) \quad (36.3)$$

$$T_{ijmp} = f(T_{ijmp}, C_{ijmp}, C_{ijmp'}) \quad (36.4)$$

where T_i is the number of trips originating in i , T_j is the number of trips destined for j , T_{ij} is trips between i and j , X_i and X_j are the socioeconomic features of i and j , T_{ijm} is the trips between i and j by mode m , T_{ijmp} is the trips between i and j by mode m

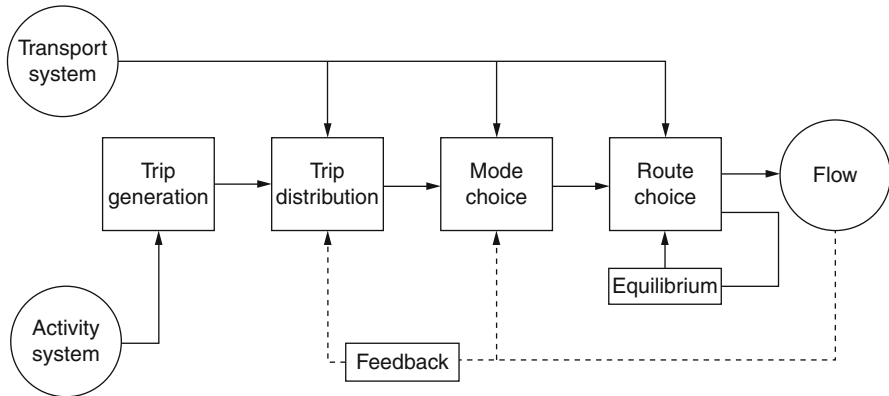

Fig. 36.1 The four-stage model sequence

along route p , C_{ij} is the generalized cost of travel between zones i and j , C_{ijm} is the generalized cost of travel between zones i and j by mode m , C_{ijmp} is the generalized cost of travel between zones i and j by mode m using route p , and the prime notation refers to alternative modes (m') or routes (p'). The four stages and their links with inputs, standard feedbacks, and outcomes are seen in Fig. 36.1.

This highly aggregated approach that looks at travel behavior in terms of zonal flows, however, has limited behavioral content. It also suffers from a number of technical weaknesses both in terms of the overall model and of individual sub-models, for example, it is recursive by nature, and although feedback loops are possible to reflect the impacts of traffic assignment on aggregate travel, this tends to be a mechanical rather than a behavioral process. It is also difficult to assess the overall statistical fit of the model; a series of relative small errors in individual components could be compounded over the sequence.

Despite these limitations, these four-stage models are still widely used for land-use transportation planning exercises, in part because they are relatively easy to understand and software is abundant, but intellectually they have been superseded by approaches more embedded in economic and social sciences and in particular by discrete choice and activity-based models.

Broadly, disaggregate models are characterized by two main features. First, they explicitly recognize that travel decisions emerge out of individuals' optimizing behavior and, if the final goods consumed as a result of travel are normal, then at a very minimum the demand for travel ought to be related positively to disposable incomes and negatively to the prices of transportation services. Secondly, most have their origins in the "attribute theory of demand." This approach to human behavior assumes that people desire to maximize a utility function that has, as its arguments, commodity attributes rather than the quantities of the actual goods consumed. In other words, if we represent the amounts of attributes by the vector z , the amounts of commodities (in this case travel alternatives) by the vector x , posit a utility function, $U(z)$, and a production of attribute function, $G(x)$, which reflects

the attributes of different travel alternatives, and assume that potential travelers are constrained by income, y , and the price of travel, p , then we can reduce the problem to solving

$$\begin{aligned} & \max U(z) \\ & \text{subject to } z = G(x) \\ & \quad x \geq 0 \\ & \quad px \leq y \end{aligned} \tag{36.5}$$

Because the unit of analysis is the household or individual, the decision to make a particular trip or use a specific mode requires some form of a discrete model specifications. Depending on the nature of the case, these are normally derivatives of logit or probit models; for estimation purposes, this can generally be expressed in log-odd terms as $\ln\left(\frac{P_i}{1-P_i}\right) = v(x_i)$, where P_i is the probability of, say, trip i being made by automobile given the attributes, x , of car travel and alternative modes. The framework can be extended, for example, to situations when there are multiple concurrent choices (multinomial logit model) or when choices are sequential (nested logit models). Theoretically, these types of model have a firm base in economic science and on the idea of random utility developed by McFadden (1974). The models have the practical advantage of requiring relative small data sets for estimation, and there is generic econometric software available to handle discrete choice situations. What they do not do is provide a mechanism for looking at large-scale shifts in travel demand across a large area or for integrating travel behavior with wider changes in activity patterns.

While the sequential and disaggregate approaches to transportation demand analysis concentrate on developing sophisticated mathematical simulations of travel behavior, recently there has been a growth of interest in “behavioral realism” and an emphasis on “understanding the phenomenon.” Sometimes called the activity-based approach because it has sought to embrace a richer, holistic framework in which travel behavior is analyzed as a daily or multiday pattern of behavior related to lifestyles and participation in various activities.

The idea is that the demand for travel is derived from the activity patterns of individuals and households. The basic idea has much to do with the concept of time geography dating back to Hägerstrand (1969) in which an individual’s choice of a specific activity pattern is viewed as being the solution to an allocation problem involving limited resources of time and space. In this sense, simply focusing on actual behavior is not that useful, but rather there is a need to put more emphasis on the constraints that limit people’s behavior, and these are often more difficult to define and measure.

These approaches to modeling have also been tied in with the greater use of stated preference techniques that question people about their probable travel reactions to say a change in gasoline prices or the introduction of a new public transportation service, rather than consider the revealed preferences of people to similar changes in the past. Stated preference methods themselves can be applied to

most forms of behavioral analysis, including narrower trip-based work, and has been more strictly defined by Kroes and Sheldon's (1988) as "a family of techniques which use individual respondents' statements about their preferences in a set of travel options to estimate utility functions," and is often claimed to be helpful when:

- There is insufficient variation in revealed preference data to examine all variables of interest.
- There is a high level of correlation between the explanatory variables in a revealed preference model making statistical estimation of parameters difficult.
- A radically new technology or policy takes the analysis outside of the realms where current revealed behavior is relevant.
- Variables are not easily expressed in standard units (e.g., when the interest is in the effects on demand of less-turbulent travel by air).

The aim of activity-based modeling, a specific form of interactive modeling, is to develop models that get closer to the essential decision process underlying travel behavior, and it is for this reason that stated preference techniques have generally been favored in this type of work. Rather than simply incorporate variables such as household status in mathematical models because the statistical "explanation" of the model appears to be improved, activity modeling seeks to explain why status affects travel behavior. Theoretically, travel is seen as one of a whole range of complementary and competitive activities operating in a sequence of events in time and space. It is seen to represent the method by which people trade time to move location in order to enjoy successive activities. Generally, time and space constraints are thought to limit the choices of activities open to individuals. The technique is still far from fully developed, but it began to be applied in a relatively limited number of small-scale forecasting studies from the late 1970s.

The emphasis of activity-based models is upon the household (or individual) as the decision-making unit. It focuses on the revealed pattern of behavior represented by travel and activities, both in home and nonhome over a defined period of time. It thus generally makes use of revealed preferences but can combine this with stated preferences analyses for forecasting the impacts of changes in activity options.

According to Heggie (1978), ideally, an activity-based model should exhibit six main properties:

- It should involve the entire household and allow for interaction between its members.
- It should make existing constraints on household behavior quite explicit.
- It should start from the household's existing pattern of behavior.
- It should work by confronting the household with realistic changes in its travel environment and allowing it to respond realistically.
- It should allow for the influence of long-term adaptation.
- It should be able to tell the investigator something fundamental that he did not know before.

In general, the approach is typified by a fairly small sample and careful survey techniques, often involving such things as "board games" – such as the

“household activities travel simulator” (HATS) developed by the Oxford University Transportation Studies Unit (Jones, 1978) – or other visual aids, frequently computer based these days, to permit households to appreciate the full implications of changes in transportation policy for their own behavior. In a sense, it represents an attempt to conduct laboratory experiments by eliciting responses in the context of known information and constraints.

The early HATS approach was to confront a household with a map of the local area together with a 24-h “strip representation of colored pieces” showing how current activities of the household are spread over space and throughout the day. Changes to the transportation system were then postulated and the effects on the household’s activities throughout the day were simulated by adjustments to the strip representation. In this way, changes in the transportation system could be seen to influence the 24-h life pattern of the household, and apparently unsuspected changes in “remote” trip-making behavior can be traced back to the primary change. It makes clear the constraints and linkages that may affect activity and transportation choices. More recent studies have adopted rather more sophisticated experimentation procedures, often involving computers, which provide for greater flexibility and easier interaction with those being “interviewed” – for a survey, see McNally and Rindt (2008). Examples of programs of this genre include ALBATROS (A Learning-Based Transportation Oriented Simulation System), the first computational process model of the complete activity scheduling process that could be fully estimated from data, and TRANSIMS, an attempt to replace the entire traditional travel paradigm, has an activity-based front end linked to a population synthesizer, and integrated with a micro-simulation of modeled travel behavior. Computer-based models include STARCHILD and AMOS with mathematical programming models such as HAPP. The development of geographical information and global positional systems has allowed for better data availability and real-time surveillance of travel and associated behavior.

While this aspect of the approach has been refined, important technical issues remain regarding using the information gathered from stated preference type experiments for forecasting. There is still, for example, much to be learned about why some households give strategically biased responses; in particular there are difficulties in handling habit, inertia, and hysteresis in an experimental framework. At a more technical level, John Bates (1988) points to our lack of knowledge about the error structures associated with stated preference data and the particular problems of pooling data across individuals.

In contrast to the more traditional revealed preference schools, advocates of this approach, however, point to both the specific recognition that travel is a derived demand and the fact that transportation policies have qualitative, as well as quantitative, effects on people’s lives. In the longer term, when operational models are more fully developed, the framework may offer the much-sought-after basis for integrating land-use and transportation planning assessment. In the short term, the approach has offered useful insights and a method for cross-checking the validity of conventional statistical analysis of behavioral data.

36.4 The Elasticity of Travel Demand

In many situations, the focal point for travel demand analysis is very specific, relating to a particular issue or policy question such as the impact of a fare rise on transit ridership or the implications for travelers of a new emissions charge. While larger models are often used to assess the general effects of these types of change, the estimation of the appropriate demand elasticity provides guidance to the specific effects on a target variable. There are an entire range of possible elasticities that may be considered (Oum et al., 2008), but all have the common feature of measuring the proportional change in a behavior relating to a target transportation variable (bus trips, fuel use, car pooling, or whatever) of a proportional change in the instrumental variable (a new tax, a new vehicle design regulation, the reduction of a speed limit, or whatever).

The estimation of basic elasticities is conceptually fairly straightforward (at its simplest it is $\varepsilon_A = \{\delta Q/Q\}/\{\delta P/P\}$ where Q is the “quantity” of travel measured in some way and P is the “price”) and spelled out in introductory microeconomics texts. For example, if we take a travel demand function, say, for bus travel, of the log-linear form $\ln Q_M = \alpha + \beta_1 \ln P_M + \beta_2 \ln Y + \beta_3 \ln P_N$, where, Q_M is the quantity of bus services demanded, P_M is the fare for bus travel M , Y is the income, and P_N is the price of an alternative, say, car travel, then N , the fare elasticity is parameter β_1 with the income elasticity of demand, reflecting the sensitivity of the quantity demanded to income changes being β_2 and the cross-elasticity of demand regarding the cost of car travel being β_3 . Here we focus on some of the more transportation specific nuances and also offer some discussion of the empirical values that have been derived.

Generalizations about the size of elasticities are difficult, especially across all modes of transportation, but in many cases it seems clear that price changes within certain limits have relatively little effect on the quantity of travel or transportation services demanded. Further, while demand elasticities often exhibit a degree of stability over time, they do not remain constant in part because of shifts in the demand function due to such things as rising incomes or changes in consumer tastes. Studies of urban public transportation in the 1970s, for example, covering a variety of countries indicate relatively low price elasticities with a direct fare elasticity of around -0.3 being considered normal, but emerged as somewhat higher in the 1980s. The effect of price change on private car travel must be divided between the effect on vehicle ownership and that specifically on vehicle use. Most early United Kingdom studies of car ownership, for example, indicated an elasticity of about -0.3 with respect to vehicle price and -0.1 with respect to gasoline price, but empirical work suggests a rather higher sensitivity in the United States: -0.88 purchase price and -0.82 fuel price elasticities. The generally low fuel price elasticity for car use in the short term is attributable to changing patterns of household expenditure between vehicle ownership and use and people’s perception of motoring costs. Bendtsen (1980) brought early findings together in an international comparison that found the petrol price elasticity of demand for car use to be -0.08 in Australia for the period from 1955 to 1976, -0.07 in Britain for

Table 36.1 Price elasticities of demand for passenger transportation expressed in absolute values

Mode	Range surveyed		Number of studies
	Market demand elasticities	Mode choice elasticities	
Air			
Vacation	0.40–4.60	0.38	8
Non-vacation	0.08–4.18	0.18	6
Mixed ⁺	0.44–4.51	0.26–5.26	14
Rail: intercity			
Leisure	1.40	1.20	2
Business	0.70	0.57	2
Mixed ⁺	0.11–1.54	0.86–1.14	8

All day ⁺	0.01–0.96	n.a.	15

Source: Oum et al. (2008)

1973/1974, -0.08 in Denmark for 1973/1974 and -0.12 for 1979/1980, and -0.05 in the United States for the period from 1968 to 1975. Oum et al. (1992) found a slightly greater degree of sensitivity when looking at seven studies covering the United Kingdom, the United States, and Australia; they yielded car usage elasticities in the range -0.09 to -0.52 .

Table 36.1 provides a survey of some estimates of automobile and public transportation elasticities. The market demand elasticities reflect the impacts on total mileage of a price change, while the mode choice elasticities refer to the probabilities of using a mode as its price varies. We immediately note that the former combines mode shift and distances per trip and thus tend to be greater than mode choice elasticities. Further, we see a wide range of elasticities emerging dependent on the nature of the trip, the mode used, and the time of day the travel takes place. In particular, when the timing and need for trips is very rigid, such as journeys to work during peak periods, the elasticities tend to be quite low. Leisure travel, where there is often more flexibility, is more sensitive to travel costs.

There is, in addition to the data in the table, an abundance of evidence that the fare elasticity for certain types of public transport trips is much higher than others. Business travel demand in particular seems to be relatively more insensitive to changes in transportation price than other forms of trip. The pioneering work of Kraft and Domenich (1970) found that public transportation work trips exhibited a fare elasticity of -0.17 in Boston compared with -0.32 for shopping trips. A similar pattern is found for business and nonbusiness air travel with the latter being generally higher. This is a pattern also seen, as one might expect, in terms of the type of fare being paid. Straszheim (1978) found some time ago that, "First class fares can be raised and will increase revenue. . . . The {price elasticity of} demand for standard economy service is about unity, and highest for peak period travel The demand for discount and promotional fares is highly price elastic...." This conforms to the intuition that vacation travelers have more flexibility in their actions (destinations, times of flights), whereas business trips often have to be taken at short notice. The lower sensitivity associated with first-/business class fares also reflects the service requirements of users who often seek room to work on planes and lounges. The estimates of the elasticities are also sensitive to the length of service with shorter routes generally exhibiting higher fare elasticities, in part because other modes of transportation become viable options.

Users of different forms of transportation, or different services of the same mode, are often confronted with a variety of payment options; their perceptions of the price of a journey may differ from the actual monies expended. Motorists generally perceive very little of the true overall price of these trips because they base decisions on a limited concept of short-term marginal cost – for example, they only buy fuel periodically and do not take this into account when deciding whether to make a particular trip – whereas users of public transportation have to buy tickets before traveling making them more aware of the costs of their behavior. Nevertheless, because of the range of season tickets that permit bulk buying of journeys over a specific route, and travel card facilities that permit bulk buying of journeys over a specified network, the distinction is not a firm one.
