Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These 11 volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors, many of the strategies and tools as well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the "organism approach" has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly, those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the "nitrosome," a unique nitrogen-fixing organelle. The study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become "dog-eared" and worn as students seek basic information for the hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, that is, from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator, these volumes should generate excitement.

Happy hunting!

Ralph S. Wolfe
Department of Microbiology
University of Illinois at Urbana-Champaign

Preface

During most of the twentieth century, microbiologists studied pure cultures under defined laboratory conditions in order to uncover the causative agents of disease and subsequently as ideal model systems to discover the fundamental principles of genetics and biochemistry. Microbiology as a discipline onto itself, e.g., microbial ecology, diversity, and evolution-based taxonomy, has only recently been the subject of general interest, partly because of the realization that microorganisms play a key role in the environment. The development and application of powerful culture-independent molecular techniques and bioinformatics tools has made this development possible. The fourth edition of *the Handbook of the Prokaryotes* has been updated and expanded in order to reflect this new era of microbiology.

The first five volumes of the fourth edition contain 34 updated and 43 entirely new chapters. Most of the new chapters are in the two new sections: Prokaryotic Communities and Bacteria in Human Health and Disease. A collection of microorganisms occupying the same physical habitat is called a "community," and several examples of bacterial communities are presented in the Prokaryotic Communities section, organized by Edward F. DeLong. Over the last decade, important advances in molecular biology and bioinformatics have led to the development of innovative culture-independent approaches for describing microbial communities. These new strategies, based on the analysis of DNA directly extracted from environmental samples, circumvent the steps of isolation and culturing of microorganisms, which are known for their selectivity leading to a nonrepresentative view of prokaryotic diversity. Describing bacterial communities is the first step in understanding the complex, interacting microbial systems in the natural world.

The section on Bacteria in Human Health and Disease, organized by Stephen Lory, contains chapters on most of the important bacterial diseases, each written by an expert in the field. In addition, there are separate general chapters on identification of pathogens by classical and non-culturing molecular techniques and virulence mechanisms, such as adhesion and bacterial toxins. In recognition of the recent important research on beneficial bacteria in human health, the section also includes chapters on gut microbiota, prebiotics, and probiotics. Together with the updated and expanded chapter on Bacterial Pharmaceutical Products, this section is a valuable resource to graduate students, teachers, and researchers interested in medical microbiology.

Volumes 6–11, organized by Erko Stackebrandt and Fabiano Thompson, contain 265 chapters in total on each of the ca. 300 known prokaryotic families, in some cases even higher taxa. Each chapter presents both the historical and current taxonomy of these taxa, mostly above the genus level; molecular analyses (e.g., DDH, MLSA, riboprinting, and MALDI-TOF); genomic and phenetic properties of the taxa covered; genome analyses including nonchromosomal genetic elements; phenotypic analyses; methods for the enrichment, isolation, and maintenance of members of the family; ecological studies; clinical relevance; and applications.

As in the third edition, the volumes in the fourth edition are available both as hard copies and as eReferences. The advantages of the online version include no restriction of color illustrations, the possibility of updating chapters continuously and, most importantly, libraries can place their subscribed copies on their servers, making it available to their community in offices and laboratories. The editors thank all the chapter authors and the editorial staff of Springer, especially Hanna Hensler-Fritton, Isabel Ullmann, Daniel Quiñones, Alejandra Kudo, and Audrey Wong, for making this contribution possible.

About the Editors

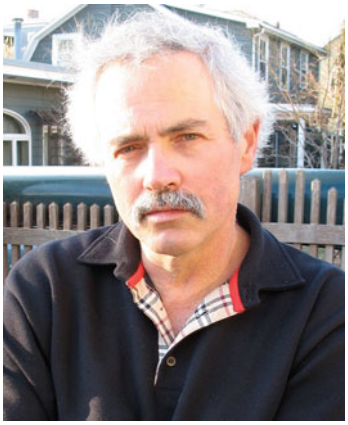
Eugene Rosenberg (Editor-in-Chief)
Department of Molecular Microbiology and Biotechnology
Tel Aviv University
Tel Aviv
Israel

Eugene Rosenberg holds a Ph.D. in biochemistry from Columbia University (1961) where he described the chemical structures of the capsules of *Hemophilus influenzae*, types B, E, and F. His postdoctoral research was performed in organic chemistry under the guidance of Lord Todd in Cambridge University. He was an assistant and associate professor of microbiology at the University of California at Los Angeles from 1962 to 1970, where he worked on the biochemistry of *Myxococcus xanthus*. Since 1970, he has been in the Department of Molecular Microbiology and Biotechnology, Tel Aviv University, as an associate professor (1970–1974), full professor (1975–2005), and professor emeritus (2006–present). He has held the Gol Chair in Applied and Environmental Microbiology since 1989. He is a member of the American Academy of Microbiology and European Academy of Microbiology. He has been awarded a Guggenheim Fellowship, a Fogarty International Scholar of the NIH, the Pan Lab Prize of the Society of Industrial Microbiology, the Proctor & Gamble Prize of the ASM, the Sakov Prize, the Landau Prize, and the Israel Prize for a "Beautiful Israel."

His research has focused on myxobacteriology; hydrocarbon microbiology; surface-active polymers from *Acinetobacter*; bioremediation; coral microbiology; and the role of symbiotic microorganisms in the adaptation, development, behavior, and evolution of animals and plants. He is the author of about 250 research papers and reviews, 9 books, and 16 patents.

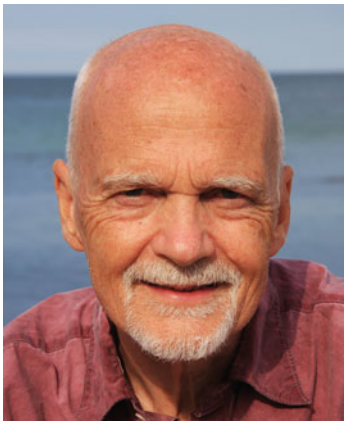
Edward F. DeLong
Department of Biological Engineering
Massachusetts Institute of Technology
Cambridge, MA
USA
and
Center for Microbial Oceanography: Research and Education
University of Hawaii, Manoa
Honolulu, HI
USA

Edward DeLong received his bachelor of science in bacteriology at the University of California, Davis, and his Ph.D. in marine biology at Scripps Institute of Oceanography at the University of California, San Diego. He was a professor at the University of California, Santa Barbara, in the Department of Ecology for 7 years, before moving to the Monterey Bay Aquarium Research Institute where he was a senior scientist and chair of the science department, also for 7 years. He has worked for the past 10 years as a professor at the Massachusetts Institute of Technology in the Department of Biological Engineering, and the Department of Civil and Environmental Engineering, and in August 2014 joined the University of Hawaii as a professor of oceanography. DeLong's scientific interests focus primarily on central questions in marine microbial genomics, biogeochemistry, ecology, and evolution. A large part of DeLong's efforts have been devoted to the study of microbes and microbial processes in the ocean, combining laboratory and field-based approaches. Development and application of genomic, biochemical, and metabolic approaches to study and exploit microbial communities and processes is his other area of interest. DeLong is a fellow in the American Academy of Arts and Science, the U.S. National Academy of Science, and the American Association for the Advancement of Science.



Stephen Lory
Department of Microbiology and Immunobiology
Harvard Medical School
Boston, MA
USA

Stephen Lory received his Ph.D. degree in microbiology from the University of California in Los Angeles in 1980. The topic of his doctoral thesis was the structure-activity relationships of bacterial exotoxins. He carried out his postdoctoral research on the basic mechanism of protein secretion by Gram-negative bacteria in the Bacterial Physiology Unit at Harvard Medical School. In 1984, he was appointed assistant professor in the Department of Microbiology at the University of Washington in Seattle, becoming full professor in 1995. While at the University of Washington, he developed an active research program in host-pathogen interactions including the role of bacterial adhesion to mammalian cells in virulence and regulation of gene expression by bacterial pathogens. In 2000, he returned to Harvard Medical School where he is currently a professor of microbiology and immunobiology. He is a regular reviewer of research projects on various scientific panels of governmental and private funding agencies and served for four years on the Scientific Council of Institute Pasteur in Paris. His current research interests include evolution of bacterial virulence, studies on post-translational regulation of gene expression in *Pseudomonas*, and the development of novel antibiotics targeting multi-drug-resistant opportunistic pathogens.



Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures
Braunschweig
Germany

Erko Stackebrandt holds a Ph.D. in microbiology from the Ludwig-Maximilians University Munich (1974). During his postdoctoral research, he worked at the German Culture Collection in Munich (1972–1977), 1978 with Carl Woese at the University of Illinois, Urbana Champaign, and from 1979 to 1983 he was a member of Karl Schleifer's research group at the Technical University, Munich. He habilitated in 1983 and was appointed head of the Departments of Microbiology at the University of Kiel (1984–1990), at the University of Queensland, Brisbane, Australia (1990–1993), and at the Technical University Braunschweig, where he also was the director of the DSMZ-German Collection of Microorganisms and Cell Cultures GmbH (1993–2009). He is involved in systematics, and molecular phylogeny and ecology of Archaea and Bacteria for more than 40 years. He has been involved in many research projects funded by the German Science Foundation, German Ministry for Science and Technology, and the European Union, working on pure cultures and microbial communities. His projects include work in soil and peat, Mediterranean coastal waters, North Sea and Baltic Sea, Antarctic Lakes, Australian soil and artesian wells, formation of stromatolites, as well as on giant ants, holothurians, rumen of cows, and the digestive tract of koalas. He has been involved in the description and taxonomic revision of more than 650 bacteria taxa of various ranks. He received a Heisenberg stipend (1982–1983) and his work has been awarded by the Academy of Science at Göttingen, Bergey's Trust (Bergey's Award and Bergey's Medal), the Technical University Munich, the Australian Society for Microbiology, and the American Society for Microbiology. He held teaching positions in Kunming, China; Budapest, Hungary; and Florence, Italy. He has published more than 600 papers in refereed journals and has written more than 80 book chapters. He is the editor of two Springer journals and served as an associate editor of several international journals and books as well as on national and international scientific and review panels of the German Research Council, European Science Foundation, European Space Agency, and the Organisation for Economic Co-Operation and Development.

Fabiano Thompson
Laboratory of Microbiology
Institute of Biology
Center for Health Sciences
Federal University of Rio de Janeiro (UFRJ)
Ilha do Fundão
Rio de Janeiro
Brazil

Fabiano Thompson became a professor of the Production Engineer Program (COPPE-UFRJ) in 2014 and the director of research at the Institute of Biology, Federal University of Rio de Janeiro (UFRJ), in 2012. He was an oceanographer at the Federal University of Rio Grande (Brazil) in 1997. He received his Ph.D. in biochemistry from Ghent University (Belgium) in 2003, with emphasis on marine microbial taxonomy and biodiversity. Thompson was an associate researcher in the BCCM/LMG Bacteria Collection (Ghent University) in 2004; professor of genetics in 2006 at the Institute of Biology, UFRJ; and professor of marine biology in 2011 at the same university. He has been a representative of UFRJ in the National Institute of Metrology (INMETRO) since 2009. Thompson is the president of the subcommittee on the Systematics of Vibrionaceae–IUMS and an associate editor of *BMC Genomics* and *Microbial Ecology*. The Thompson Lab in Rio currently performs research on marine microbiology in the Blue Amazon, the realm in the southwestern Atlantic that encompasses a variety of systems, including deep sea, Cabo Frio upwelling area, Amazonia river-plume continuum, mesophotic reefs, Abrolhos coral reef bank, and Oceanic Islands (Fernando de Noronha, Saint Peter and Saint Paul, and Trindade).

1 Harmonized Phylogenetic Trees for *The Prokaryotes*

Raul Munoz[1] · *Pablo Yarza*[1,2] · *Ramon Rosselló-Móra*[1]
[1]Marine Microbiology Group, Institut Mediterrani d'Estudis Avançats (CSIC-UIB), Esporles, Mallorca, Spain
[2]Ribocon GmbH, Bremen, Germany

Abstract
The taxonomic outline of the current edition of *The Prokaryotes* is accompanied with the phylogenetic reconstruction of each respective taxon. In order to harmonize the reconstruction procedures and layout of over 350 trees, reconstructions have been produced using the LTP database (The All-Species Living Tree Project). This database is a compilation of 16S rRNA gene sequences representing the type strains of species with validly published names. The LTP team has applied a unified methodology and criteria for the harmonized reconstructions. In all cases, corresponding authors' instructions served to fine-tune the phylogenetic analysis and select the final tree topology.

Introduction

Volumes 06–11 of *The Prokaryotes, 4th Edition* (PK4), compile the taxonomy of Archaea and Bacteria up to year 2013. Taxonomic classification is based on objective criteria spanning phylogeny, genomic coherence, and a phenotypic property that guarantees the identification of the taxon (Tindall et al. 2010; Wayne et al. 1987). The advent of the sequencing technologies revealed the nucleotide sequence of highly conserved molecules such as ribosomal RNAs, enabling the reconstruction of phylogenies that reflect genealogic relationships of microorganisms (Woese 1987; Ludwig and Schleifer 1994). These phylogenies allowed as well the recognition of wrongly classified taxa (i.e., para and polyphyletic groups) promoting many reclassifications and also new classifications. Therefore, following primarily genealogical criteria, a major improvement of the Bergey's taxonomic outline was achieved at the beginning of the twenty first century (Garrity 2001). For practical reasons related to its informative content and availability, the 16S rRNA gene has been regarded as a priority in the classification of prokaryotes (Stackebrandt et al. 2002; Ludwig et al. 2011). Consequently, during the last decade of the twentieth century, the yearly rates in publishing descriptions of new species increased about sixfold (Tamames and Rosselló-Móra 2012), being the current rate between 600 and 700 new species per year.

Based upon the high rate of annual species descriptions, the exponential growth of environmental and non-type species 16S rDNA sequence entries in public repositories, the lack of a coordinated curation of type strain 16S rRNA gene sequences, and the lack of curated sequence-associated information, our group initiated "The All-Species Living Tree Project" or "LTP" (Yarza et al. 2008) to provide a reference tool for taxonomic purposes. The LTP project produces a highly curated 16S rRNA gene sequence database, alignment, and phylogenetic reconstruction for all type strains of Archaea and Bacteria with validly published names. All these resources are regularly updated and publicly available at the project's Web site (http://www.arb-silva.de/projects/living-tree/). The sequence selection process is based on stringent criteria to retain only high quality and of almost full-length sequences, both important prerequisites to achieve a reliable phylogenetic inference. Missing sequences from type strains without a good-quality SSU entry in former LTP releases (called "orphan" species) have recently been resolved by some international public microbial resource centers (mBRC) in a project called SOS, Sequencing Orphan Species (Yarza et al. 2013): the catalogue of the hitherto validly named species for which a type strain is available in at least one mBRC is now completed. All sequences included in LTP are automatically aligned, and manually optimized, according to the ARB-SILVA standards (Ludwig et al. 2004; Quast et al. 2013), which takes into account the 16S rRNA's secondary structure. In addition,

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_415,

curated sequence-associated metadata is associated to all LTP entries, including updated nomenclature and taxonomic classification according to LPSN (Euzéby 1997; Parte 2014; Yilmaz et al. 2014).

The PK4 editorial board has used the LTP as a basic framework to harmonize the phylogenetic reconstructions and tree layouts of almost all taxa included in the present edition. The reconstruction of the phylogenetic trees was based on general standard procedures and in accordance with the particular author's instructions when possible. Authors were initially supplied with several preliminary trees. A dialogue between the authors and tree-editor was then initiated to fix three parameters: sequence dataset, phylogenetic filter, and treeing algorithm (see below for details). The comparison of multiple topologies allowed understanding the topology stability and the selection of the best tree based on current sequence availability. In some cases multifurcations were manually drawn to indicate branching orders that could not be resolved. All figures provided by the tree-editors were finally validated by the respective authors of each chapter (~320 chapters). For practical reasons, the PK4 team decided that trees requiring the inclusion of sequences of uncultured organisms, candidatus taxa, or the use of highly specialized phylogenetic methodologies would not be object of harmonization (12 chapters).

Software Tools

The ARB software version 5.5 (Ludwig et al. 2004) was used for database management, alignment edition, and tree reconstructions. Implemented in the software package, the SINA alignment program was used for multiple sequence alignments (Pruesse et al. 2012). In addition, phylogenetic reconstructions were performed using two algorithms: neighbor-joining with the Jukes-Cantor model (Saitou and Nei 1987) and RAxML (version 7.0.3) with the GTRGAMMA correction (Stamatakis 2006) also implemented in ARB. For the final figure production, the program Xfig 3.2.5 was used.

Datasets

Sequences used corresponded to the LTP release 111. The dataset was complemented with the classified taxa up to December 2013 not included in the release and additional taxa requested by the authors. For maximum likelihood reconstructions, few representatives from closest families were selected as outgroups. On the other hand, for neighbor-joining reconstructions, 758 reference sequences of representative taxa were selected by means of quality criteria (almost complete length and low ambiguity rates) and taxonomic coverage (i.e., balanced representation of all orders included in the LTP); these sequences were included in the analyses to stabilize the topologies calculated by neighbor-joining. The reference sequences can be found in the latest LTP release (LTPs115) with the field "NJ_support_pk4_ltp." Most taxa analyzed would comprise some of these supporting sequences; hence, we refer to them as "nearly 750 supporting sequences."

Phylogenetic Filters

The use of sequence conservation profiles as phylogenetic filters is highly recommended to recognize branch attraction effects resulting from plesiomorphic sites (Tindall et al. 2010). These are designed to remove alignment columns according to positional variability. In addition, filters reduce the noise produced by sequencing errors, ambiguities, homopolymers, and low-confidence areas of the alignment with dubious positional orthology. A "termini" filter was used in all cases to remove sequence overhangs beyond the gene ends. This filter removes occasional plasmid vector fragments or gene stretches that had not been properly trimmed. In addition, several filters that improved stabilization and resolution of the branching orders were used. To better resolve deeper branches, a 40 % maximum frequency conservational filter was used to remove all hypervariable positions. Alternatively, depending on each specific sequences set divergence (indicated in their respective reconstruction), 10 %, 20 %, or 30 % conservational filters were applied. Occasionally, only termini and Domain positional filters were applied to be less restrictive and allow variable positions to solve short branches.

Figure Conventions

All sequences in the trees display species name and, in brackets, the corresponding accession number. The type strain representing a type species of a genus is tagged as "type sp." and highlighted with black color (*Fig. 1.1*). In order to focus the attention into the main chapter's taxa, neighboring groups are often presented as folded clades. All sequences in PK4 trees correspond to type strains unless the opposite is indicated.

Acknowledgments

The team acknowledges the economic support of Springer for partially funding RM's work and specially acknowledges Prof. Erko Stackebrandt for his vision in working with standardized trees. In addition, this effort has been possible by the contribution of funds to RRM from the Spanish

2 The Family *Acidimicrobiaceae*

Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The order *Acidimicrobiales*, phylum Actinobacteria, is a phylogenetically well defined lineage that embraces 5 genera. While the family *Acidimicrobiaceae* harbors 5 genera, the family *Iamiaceae* is monogeneric. However, there is phylogenetic evidence that the genus *Ilumatobacter*, *Acidimicrobiaceae*, is more closely related to the genus *Iamia* than to other members of the family. While *Acidimicrobium*, *Ferrimicrobium, Ferrithrix and Aciditerrimonas* are obligate acidophilic, oxidize ferrous iron or reduce ferric iron and contain meso-diaminopimelic acid in their peptidoglycan, *Ilumatobacter* grows under neutral or slightly alkaline conditions, is and organotrophic and contains LL-diaminopimelic acid in its peptidoglycan. The iron oxidizing members are involved in uncontrolled pollution by heavy metals but are also used under controlled conditions for biomining.

Taxonomy, Historical and Current

The ranks subclass, order and family, *Acidimicrobidae*, *Acidimicrobiales* and *Acidimicrobiaceae*, respectively, were described by Stackebrandt et al. (1997) as ranks within the class *Actinobacteria*. The family has been emended by Zhi et al. (2009), by changing the set of 16S rRNA gene sequence signatures from 291 to 309 (U-A), 294–303 (C-G), 1118–1155 (C-G), 1311–1326 (A-U) and 1410–1490 (A-U), described in 1997 to 242–284 (U–G), 291–309 (U–A), 316–337 (C–G), 819 (U), 952–1229 (C–G) and 1115–1185 (U–G). The former set of signatures (Stackebrandt et al. 1997) were used for the affiliation of *Ferrimicrobium* and *Ferrithrix* to the family (Johnson et al. 2009).

The subclass was informally elevated to the rank of the class *Acidimicrobiia* (Garrity et al. 2005; Ludwig et al. 2012) and contains two families. The family *Acidimicrobiaceae* is composed of five monospecific genera, namely *Acidimicrobium* (Clark and Norris 1996), *Ferrimicrobium and Ferrithrix* (Johnson et al. 2009), *Aciditerrimonas* (Itoh et al. 2011) and *Ilumatobacter* (Matsumoto et al. 2009).

The family *Iamiaceae* comprises the monospecific genus *Iamia* and will be dealt with in a separate chapter (see chapter on ❯ *Lamiaceae*, Order, this volume). While the iron-oxiding taxa *Ferrimicrobium acidiphilum* $T23^T$ and *Ferrithrix thermotolerans* $Y005^T$ share 94.2 % 16S rRNA gene sequence similarity, *Acidimicrobium ferrooxidans* ICP^T is more distantly related (91–93 %). Even less close is *Ilumatobacter fluminis* $YM22^T$(<90 %), which clusters with *Iamia majanohamensis* in ❯ *Fig. 2.1*, though they are placed in separate families. The deep branching point of *I. fluminis* together with some markedly different features (❯ *Table 2.1*) cast doubt whether this organism should be retained in the family. The (tentative) decision to place this taxon into *Acidimicrobiaceae*, originally made solely upon its more closely relatedness to the iron-oxidizing taxa than to other members of the Actinobacteria (Ludwig et al. 2012), was adopted by Jean Euzeby (http://www.bacterio.cict.fr/).

The topology of the *Acidimicrobiaceae* lineage is not settled. As shown in a comparative study on 30 actinobacterial sequences (Rudi et al. 2006) only the tree based upon alignment-independent bilinear mathematical modeling showed a tight clustering of *Acidimicrobium* and *Rubrobacter* as a distinct subgroup of the Actinobacteria. A distinct lineage within Actinobacteria was also encountered in a phylogenetic analysis of ribosomal proteins (Lu and Zhang 2012). Maximum-parsimony and maximum-likelihood analysis of 16S rRNA gene sequences, on the other hand, showed a branching of *Acidimicrobium* and *Rubrobacter* outside the actinobacteria proper with low branch confidence (Rudi et al. 2006). This situation has also been encountered in a principal component analysis plot (Garrity and Holt 2001) in which *Acidimicrobium* was an outlier of the Actinobacteria, branching between Firmicutes and Actinobacteria. In the neighbor joining analysis of the LTP tree, the family appears as a sister clade of the family *Coriobacteriaceae*, distantly related *Rubrobacterales*. In the description of *Ilumatobacter* (Matsumoto et al. 2009) the family branches at the root of the order *Actinomycetales*.

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_198,

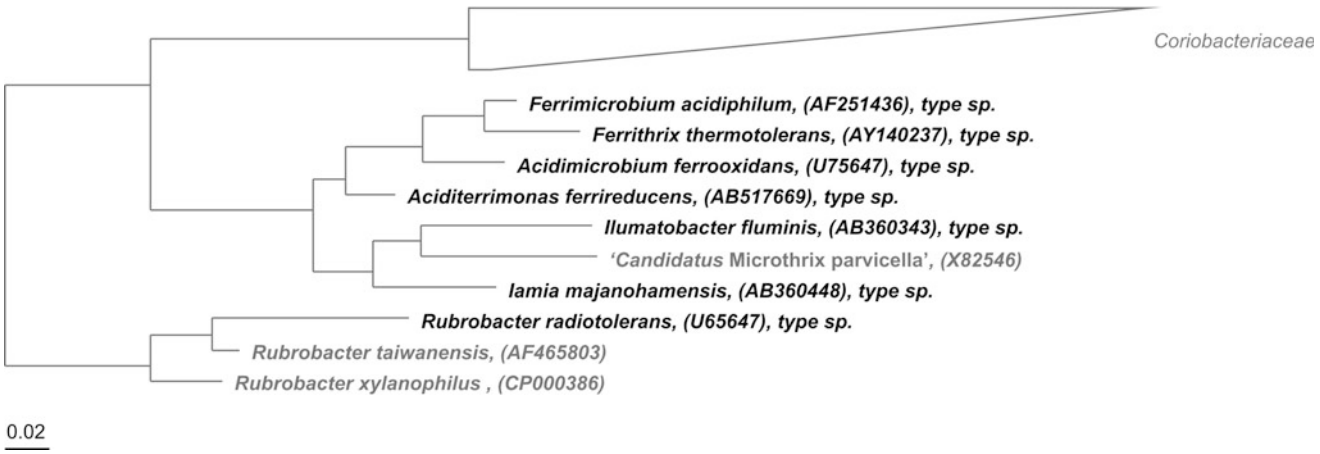

Fig. 2.1
Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the order *Acidimicrobiales* and some neighboring taxa present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences. List of type strains used for dendrogram construction: *Acidimicrobium ferrooxidans* strain ICP^T, *Aciditerrimonas ferrireducens* JCM 15389^T, *Ferrimicrobium acidiphilum* T23^T, *Ferrithrix thermotolerans* Y005^T, *Iamia majanohamensis* F12^T, *Ilumatobacter fluminis* YM22-133^T; no strain has been indicated for "*Candidatus* Microthrix parvicella." The bar indicates 1 % sequence divergence

The presence of additional members of *Acidimicrobiaceae*, one of them, even outnumbering A. ferrooxidans in nickel extraction from a mineral concentrate at 49 °C (Cleaver et al. 2007), has been mentioned before in several studies (Bond et al. 2000; Johnson et al. 2003; Cleaver et al. 2007). Norris et al. (2011) introduced the (as yet invalid) name "Acidithiomicrobium" for ferrous-iron organisms from geothermal habitats which were shown to grow autotrophically with sulfur as an energy source – a feature not expressed by any other member of the family (Clark and Norris 1996; Johnson et al. 2009). Two enrichment cultures, one from the island of Milos (strain P1), the other from a pyrite enrichment culture established with samples from several sources (Davis-Belmar and Norris 2009; Cleaver et al. 2007) (strain P2, also named strain sp. 2 by Cleaver et al. 2007), together with a uncultured organisms from acid volcanic soil (Mount Hood, USA), branches adjacent to *A. ferrooxidans* (see below).

As shown by Rheims et al. (1996) and later by Montalvo et al. (2005) on the basis of 16S rRNA gene sequences the nearest member of the family is "*Candidatus* Microthrix parvicella." This organisms is an uncultivated Gram-positive filamentous bacterium with filament of often <200 μm in length. It commonly occurs in low loaded domestic treatment plants where it is the most important cause of bulking sludge and frequently responsible for scum formation (Blackall et al. 1996; Rossetti et al. 2005).

Molecular Analyses

Due to the interest of bioleaching organisms, many strains of *Acidimicrobiaceae* have been enriched and identified by molecular means and several clone libraries have been generated which shows the abundance of these organisms in geothermal soil, acidic waters, sulfidic main waste and other mine environments as well as acidic biofilms (see Habitat). The most extensive compilation, based on 16S rRNA gene sequence comparison has been shown by Norris et al. (2011). While most clone libraries used extracted DNA for gene amplification, Militon et al. (2010) worked with reversely transcribed 16S rRNA.

Several probes for FISH and DNA dot blots were designed by Cleaver et al. (2007) to determine members of the *Acidimicrobium* group in bioreactor enrichment cultures: *Acidimicrobium* group (Am:654 CGATCYTCTACCGGACTC*)*, *A. ferrooxidans* (Amf:995 CTCTGCGGCTTTTCCCTC CATG) and "*Acidimicrobium*" species 2 (Am2:131 GTTGTCCCG-AACTATGGGG TAGG) (Bond and Banfield 2001) designed a FISH 16S rRNA gene probe to detect *Acidimicrobium ferrooxidans* and relatives from Iron Mountain, Ca (GTACCGGCCCAGATCGCTG). This probe was also used by Macalady et al. (2007) to identify the presence of these organisms in acidic, cave wall biofilms from the Frasassi cave system, Italy. Yet another 16S rRNA gene probe was designed by González-Toril et al. (2003) (CCT CCG AAT TAA CTC CGG) for the identification of *Acidimicrobium ferrooxidans* and *Ferrimicrobium* spp. in the Tinto river, Spain. The same environment was also probed by an oligonucleotide prokaryotic acidophile microarray (Garrido et al. 2008).

Among other Yellowstone isolates, the uniqueness of strain Y0018, closely related to *A. ferrooxidans* by 16S rRNA gene sequencing, was determined by Amplified ribosomal DNA restriction enzyme analysis (Johnson et al. 2003). ARDRA was also used to relate *Ferrimicrobium*-like organisms, originating from lithotrophic arsenite-oxidizing enrichment cultures (Sultana et al. 2012). Restriction fragment length polymorphism (RFLP) was used by Bond et al. (2000) to pre-screed the identity of isolated from a thick, subaerial, predominantly lithotrophic biofilm at an extreme acid Mine drainage site and by Norris et al. (2011) for a pre-analysis of organisms from two enrichment sources cultures of different origin and by Xin et al. (2008) to

Table 2.1

Properties of members of the family *Acidimicrobiaceae*. *Acidimicrobium* (Clark and Norris 1996), *Ferrimicrobium* and *Ferrithrix* (Johnson et al. 2009), *Aciditerrimonas* (Itoh et al. 2011), and *Ilumatobacter* (Matsumoto et al. 2009)

Property	*Acidimicrobium*	*Ferrimicrobium*	Ferrithrix	Aciditerrimonas	Ilumatobacter
Morphology	Rods with variable length, filaments are noticeable in strain TH3	Rods, short chains during exponential phase	Long entangled filaments, flocs; sometimes single rods	Short rod	Rods

[a]Data from Normand (1996, 2006)
[b]Data from Kurahashi et al. (2009)

determine the presence of members of actinobacteria in marine sponges. The terminal restriction fragment length polymorphism (T-RFLP) method was used to determine the appearance of *Acidimicrobium* like organisms spp. in a granular sludge bed-anaerobic filter bioreactor which was dominated by *Methanosaeta*-like Archaea and beta- and gammaproteobacteria (Collins et al. 2005), by Wakeman et al. (2008) to study the dynamics in simulated-heap leaching of a polymetallic sulfide ore, by Jenkins et al. (2009) to determine that acidification of grassland results in the accumulation of acidophilic actinobacteria, including *Acidimicrobium*, *Streptomyces* and *Actinospica*, and by Zammit et al. (2012) in a recent proteomic study on the effect of chlorine ions on acidiphilic model organism. Single Strand Conformational Polymorphism Analysis (SSCP) analysis in addition to ARDRA and BOX analysis, as well as analysis of the V4-V5 region of the 16S rRNA gene by DNA pyrosequencing was applied by Köberl et al. (2011) to determine the shift in microbial populations due to long-term farming of desert soil. Among others, several extremophilic bacterial groups, e.g., members of *Acidimicrobium*, *Rubellimicrobium* and *Deinococcus-Thermus*, disappeared from desert soil after agricultural use.

Acidimicrobium ferrooxidans DSM 10331^T is the only strain of the family for which a complete genome (CP001631) is available (Clum et al. 2009). The circular chromosome with a DNA G+C content of 68.3 % mol% is 2,158,157 bp long, contains 2,092 predicted genes, 2,038 of which were protein coding genes, 54 RNAs and two rRNA operons. 76 % of the genes were assigned a putative function. Genes involved in amino acid transport and metabolism (174) exceeds those defined for carbohydrate transport and metabolism (87).

Phenotypic Analyses

The phenotypic diversity of the family is broad, due to the inclusion of *Ilumatobacter fluminis*. It contains autotrophic strains when grown on ferrous iron and heterotrophic organisms grown on yeast extract and/or organic compounds. Autotrophic and heterotrophic growth is shown by *A. ferrooxidans*. The family embraces acidiphilic and slightly alkaliphilic, as well as moderately thermophilic and mesophilic organisms. The iron-oxidizing members of the family oxidize iron (Fe^{2+}) under aerobic conditions or reduce Fe^{3+} under anaerobic conditions as shown by Bridge and Johnson (1998) and Johnson et al. (2009). With this capacity some of its members are involved in the geomicrobiological cycling of iron and CO_2 in acidiphilic ore-containing environments, as

exemplified in acidic environments (González-Toril et al. 2003) or in ore bioleaching (see sections Habitat and Application). Elementous sulfur is not oxidized by any validly named member of the family, though the hitherto invalidly named taxon "*Acidithiomicrobium*" oxidizes pyrite during autotrophic growth and growth well autotrophically on sulfur (Davis-Belmar and Norris 2009; Norris et al. 2011).

Acidimicrobium Clark and Norris 1996, Validation List N° 59

a.ci.di.mi.cro'bi.um ML.n. *acidum* acid, L. masc. adj. acidus; gr. adj. *micros* small; gr. masc. n. *bios* life; ML neuter n *Acidimicrobium*, referring to a bacterium from acidic environments.

The only species *A. ferrooxidans* was described for two strains, strain TH3 originally isolated from a test copper leaching dump (Brierley 1978) and strain ICP^T, isolated from a pyrite enrichment established with a sample from a geothermal site, Island. Strain TH3 was reisolated by Norris and Barr (1985) and the phylogenetic position of this facultatively thermophilic and Gram indeterminate strain determined to be a member of the Actinobacteria (Lane et al. 1992). The two strains show the same electrophoretic whole cell protein pattern, the same DNA G+C content, autotrophic growth on ferrous iron, heterotrophic growth on yeast extract, during which the cells are motile. The two strains differ from each other in the filamentous growth of strain TH3 on ferrous iron and yeast extract. Cells are gram-positive rods, 0.35–0.4 × 1–1.5 μm, which may be filamentous with variable length. Other properties are listed in *Table 2.1*.

The species is able to fix CO_2 at normal atmospheric concentration. It contains a CO_2 uptake system which is induced when CO_2 is limiting. A ribulose bisphosphate carboxylase/oxygenase (RuBisCO) is active during CO_2 fixation (Norris et al. 2011). As discussed by Clark and Norris (1996) the release of unidentified fixed carbon from strain ICP supports the mixotrophic growth of the Firmicutes *Sulfobacillus* species in mixed cultures. Gene sequence analysis indicates the presence of the large subunit of RuBisCO forms I and II (cbbL-1 and cbbL2). While cbbL-1 is present in *A. ferrooxidans* strains DSM 10331^T and strain P2, the cbbl-2 gene is only present in strain P2 (note, that strain P2 is a representative of the unnamed iron and sulfur-oxidizing "*Acidithiomicrobium*" taxon). The gcbbL-1 gene has probably been acquired from the proteobacterium *Acidithiobacillus ferrooxidans* or its ancestor, while the cbbL-2 gene of strain P2 is more similar to that of *Acidiphilium cryptum* and its relatives.

The type strain DSM 10331^T growth in the presence of iron (4.4 g/L) and zinc (3.3 g/L), but not in the presence of nickel and copper (1.5 and 0.6 g/L respectively). Another isolate of the species from a copper sulfide heap, however (Watkin et al. 2009), grows up to 40 g/L nickel and 45 g/L copper.

A proteomic study included *A. ferrooxidans* DSM 10331^T to investigate the effect of 6 g L^{-1} NaCl in brackish water bioleaching (Zammit et al. 2012). The highest number of 2.6 × 10^9 cells were found at 0 g L^{-1} NaCl while 2.0 × 10^9 cells L^{-1} were present at 20 g L^{-1} NaCl. Ferrous iron oxidation, however, was the same. Among others, upregulated proteins were those involved in membrane biosynthesis, α-subunit of the ATP synthase, amino acid biosynthesis genes, an oxidative stress protein peroxidase and the large chain of RuBisCO. Among the downregulated genes were AMP-dependent synthase and ligase (breakdown of complex fatty acids), a cell shape determining protein (actine-like filament forming).

Ferrimicrobium Johnson et al. 2009, 1087^{VL}

Fer.ri.mi.cro'bi.um. L. neut. n. *ferrum* iron; N.L. neut. n. *microbium* microbe; N.L. neut. n.

Ferrimicrobium iron microbe.

The type strain T23^T of *Ferrimicrobium acidiphilum* was among a group of five organisms originally obtained from acid mine drainage from pyrite and cobalt mines in Wales and Idaho (Bacelar-Nicolau and Johnson 1999). 16S rRNA gene sequence analysis indicated that these mesophilic heterotrophic acidophiles form a distinct cluster, related to the moderately thermophilic *Acidimicrobium ferrooxidans*. As they appeared to represent more than a single species, only strain T23^T was further characterized and described. In order to catalyze the oxidative dissolution of pyrite this heterotrophic iron-oxidizing bacterium required a source of organic carbon, provided in the study of Bacelar-Nicolau and Johnson (1999) in form of yeast extract. The authors also mention that the requirement for organic carbon is minimal and might, in nature, be satisfied by the organic carbon originating from autotrophic acidophiles, as well as from other sources.

The mode of action involves the oxidation of pyrite by producing ferric iron which oxidizes pyrite in an abiotic reaction, in which ferric iron is reduced back to ferrous iron (Bacelar-Nicolau and Johnson 1999). In mixed cultures with e.g. *Thiobacillus oxidans*, the reduced sulfur compound is oxidized to SO_4^{2-}. The authors mention the unpublished hydrophobicity of strain T23^T which makes it likely to attach to pyrite similar to the feature reported for *T. ferrooxidans*.

On solid ferrous iron and tryptone soya broth strain overlay plates displays gelatinous colonies (1–3 mm) with ferric iron deposits in the centre (fried-egg morphology). It grows poorly on solid ferrous iron medium and on solid ferrous iron, tryptone soya broth and potassium tetrathionate (Johnson et al. 2009). Under anaerobic conditions the type strain was able to reduce ferric iron, using glycerol as an electron donor. Tolerant to 200 mM of both ferrous and ferric iron, 150 mM copper, and less than 50 mM zinc. Neither cbbL-1 nor cbbL-2 forms of the RuBisCO genes were amplified.

Cells are gram-negative, rod-shaped (1–3 μm long) and motile. In liquid iron-containing medium the broth becomes turbid and orange colored. Growth in ferrous sulfate and 0.01 % yeast extract is supported by 5–15 mM glycerol, citric acid and glutamic acid, but not by glucose, fructose, ribose, glucosamine, glucuronic acid and ethanol. Acetic acid was highly toxic. Other properties are indicated in *Table 2.1*.

Ferrithrix Johnson et al. 2009, 1088[VL]

Fer.ri.thr'ix. L. neut. n. *ferrum* iron; Gr. fem. n. *thrix* hair, thread; N.L. fem. n. *Ferrithrix* iron thread.

The type strain Y005[T] of the only species, *Ferrithrix thermotolerans*, has been isolated from a geothermal site in the Beryl Spring/Gibbon river area of Yellowstone National Park, Wyoming, USA (Johnson et al. 2003). It shares with *Ferrimicrobium acidiphilum* several properties, such as obligate acidophily, phylogenetic similarity, absence of RuBisCO genes, lack of elemental sulfur oxidation, dissimilatory oxidation of ferrous iron, pyrite oxidation in yeast extract containing medium, reduction of ferric iron under anaerobic conditions using glycerol as electron donor, and heavy metal tolerance (<100 mM).

On ferrous iron, ferrous iron/tetrathionate and inorganic iron solid overly media colonies are small (1–2 mm), rhizoidal and iron-encrusted. In ferrous iron containing liquid medium growth occurs as flocs, approx. 1–3 mm in diameter. Flocs consist of long entangled filaments, 0.5 × 3–4 μm. cells are non-motile. Growth in ferrous sulfate and 0.01 % yeast extract is supported by 5–15 mM glycerol and ethanol, but by glucose, fructose, ribose, glucosamine, glucuronic acid, citric acid glutamic acid and ethanol. Acetic acid was highly toxic. Other properties are indicated in ● *Table 2.1*.

Aciditerrimonas Itoh et al. 2011, 1284[VL]

A.ci.di.ter.ri.mo'nas. L. neut. n. *acidum* an acid; L. n. terra soil; L. fem. n. *monas* a unit, monad; N.L. fem. n. *Aciditerrimonas* acidic soil monad.

The type strain IC-180T, isolated from a sulfataric field at Ohwaku-dani in Hakone, Japan, is facultatively anaerobic and autotrophic, reducing ferric iron with H_2/CO_2 (4:1 v/v) under anaerobic conditions, but not under an $N_2/CO2$ (4:1 v/v) atmosphere. Does not oxidize ferrous iron. Heterotrophic growth occurs using yeast extract, glucose, lactose, mannose and xylose as carbon and energy sources. Yeast extract cannot be replaced by arabinose, fructose, galactose, ribose, sucrose, starch, acetate, butyrate, formate, fumarate lactate, malate, propionate or succinate. Cells are short rods, 0.5–0.6 × 0.8–1.1 μm, motile with peritrichous flagella. In addition to properties listed in ● *Table 2.1*, grows at 35–58 °C and pH 2.0–4.5; the phospholipid composition includes phosphatidyl-*N*-methylethanolamine and an unknown ninhydrin-positive phosphoglycolipid.

The 16S rRNA signature pattern is the same as that of the family *Acidimicrobiaceae* as indicated by Zhi et al. (2009), except for 952: 1229 (U–A).

Ilumatobacter Matsumoto et al. 2009, 204[NL]

I.lu.ma.to.bac'ter Gr. n. *iluma* -atos sediment deposited in water; N. L. masc. n. *bacter*, a rod, a bacterium; N. L. masc. n. *Ilumatobacter* a rod isolated from sediment.

The type strain of the monospecif genus, *I. fluminis* YM22-133[T], was isolated from sediment of the mouth of the Kuira river on the island Iriomote, Okinawa prefecture, Japan at the depth of 1 m. Colonies on Marine Agar were colorless and small (<1 mm). Aerobic, rod shaped 0.4–0.5 × 1.3–1.6 μm. As determined by the API ZYM (bio-Merieux) test panel, the following enzymes, among others, were active: alkaline phosphatase, esterase, (C4), esterase lipase (C8), leucin arylamidase, valin arylamidase, cystine arylamidase, acid phosphatase, α-glucosidase, and β-glucosidase. α-galactosidase, β-glucuroninidase, α-mannosidase and α-fucosidase were absent. Other properties are indicated in ● *Table 2.1*.

Isolation, Enrichment and Maintenance Procedures

The isolation protocols of ferrous iron-oxidizing actinobacteria differ widely. As indicated by Johnson et al. (2003) the main problem is the poor growth of these organisms on solid media and the separation from other strains exhibiting a similar metabolism. In the description of the type strain ICP[T] (Clark and Norris 1996) a Percoll gradient (Pertoft et al. 1978) was used to separate the larger *Sulfobacillus*-like organisms from the smaller *Acidimicrobium* cells. As the separation was not complete, the latter organisms was obtained in pure culture on solid medium after 35 serial autotrophic cultures under air. Another successful method includes the use of the overlay plating technique (Johnson and McGinness 1991; Johnson 1995). This method, leading to the isolation of a strain of the genus *Acidimicrobium* (Johnson et al. 2003) and the type strains of *Ferrimicrobium acidiphilum* (T23[T]), and *Ferrithrix thermotolerans* (Y005[T]) (Johnson et al. 2009), includes the use of overlaid solid media containing either ferrous sulfate (Feo) or ferrous sulfate plus potassium tetrathionate (FeSo); both media (pH ∼ 2.5), containing a small amount (0.025 %, w/v) of tryptone soya broth (TSB). *Aciditerrimonas ferrireducens* was isolated on *Sulfolobus* medium (Brock et al. 1972), supplemented with 1.0 g yeast extract (L^{-1}) at pH 2.2. and 55 °C. This medium was also used for maintenance, omitting $FeCl_3 \times 6H_2O$ (alternatively DSMZ medium 1189 (DSMZ 2001)).

Isolation of single colonies of "*Acidithiomicrobium*" was done on Phytagel plates (Sigma) supplemented with ferrous iron ($FeSO_4$. $7H_2O$, 13.9 g L^{-1}) and tetrathionate ($K_2S_4O_6$ 0.1 5 g L^{-1}) (Clark and Norris 1996), incubated at 47 °C. "*Acidithiomicrobium*" strain P2 were grown in shaken flasks with elemental sulfur as substrate (5 g L^{-1}) in a medium (Norris et al. 1996) initially at pH 3. This medium contained, per liter, $MgSO_4 \times 7$ H_2O, 0.5 g; $(NH_4)_2SO_4$, 0.4 g; K_2HPO4, 0.2 g; and KCl, 0.l g. With 50 mM ferrous iron as the substrate the pH was initially adjusted with H_2SO_4 to 1.7. Cultures growing autotrophically on ferrous iron, sulphur or pyrite were gassed with 5 % (v/v) CO_2, in air. All cultures were grown at 48 °C.

The establishment of enrichment cultures has been described by Johnson et al. (2003) and includes basically

a ferrous sulfate, yeast extract medium, pH 2.0 incubated, with intermittent shaking, at 45 °C. After 6 days (iron/yeast extract enrichments) or 35 days (pyrite enrichments), samples from these cultures were again streak inoculated onto Feo and FeSo solid media.

Isolates were purified by repeated single-colony isolation on Feo or FeSo solid media and maintained in ferrous iron/yeast extract liquid media or 10 mM ferrous sulfate/0.025 % Tryptic Soy Broth (pH 1.5), depending on the strain. Routine maintenance is recommended on DSM medium 709 consisting of $MgSO_4 \times 7\ H_2O$ 0.5 g, $(NH_4)_2SO_4$ 0.4 g, K_2HPO_4 0.2 g, KCl 0.1 g, distilled water 1,000 ml, pH adjusted to 2.0 with H_2SO_4. *Ferrimicrobium acidiphilum* and *Ferrithrix thermotolerans* are grown routinely in liquid media containing 10 mM ferrous sulfate and 0.02 % (w/v) yeast extract at pH 2.0. at 30 °C and 45 °C, respectively.

Ilumatobacter fluminis was obtained on medium "R" after cultivation at 25 °C for 30 days. Medium "R" is a mineral salt medium supplemented with antibiotics and Eagle's minimal essential medium. Enrichment was on Difco Marine Broth which can also be used for routine maintenance.

While *A. ferrooxidans*, *Aciditerrimonas ferrireducens* and *Ilumatobacter fluminis* are shipped as freeze dried cultures by the DSMZ, *F. acidiphilum* and *F. thermotolerans* are shipped as active cultures.

Habitat

Excluding *Ilumatobacter fluminis*, the range of habitat for the cultured acidiphilic autotrophic and heterophilic members of the family is rather narrow. The oldest representative, strain TH3, had been isolated from a Copper leach dump, Kennecott Chino Mine, New Mexico. Other strains originate from iron and pyrite mines or spent ore heaps (Bacelar-Nicolau and Johnson 1999; Cleaver et al. 2007; Readett et al. 2003; Yin et al. 2008; Davis-Belmar and Norris 2009), mine drainage water (Hallberg et al. 2006; Johnson et al. 2009), forested wetland impacted by reject coal (Brofft et al. 2002) and in geothermal sites in Yellowstone National Park (Johnson et al. 2009), Iceland (Clark and Norris 1996) or Milos, Greece (Norris et al. 2011).

The range of acidic habitats was verified and geographical sites expanded by non-culture studies. A large number of clones with BLAST similarity values above 95 %, even as high as 99 %, were found to be related to all acidophilic members of the family, with DNA retrieved from river water (González-Toril et al. 2003; Urbieta et al. 2012; Garrido et al. 2008; Garcia-Moyano et al. 2012; Souza-Egipsy et al. unpublished, EU370264), acid mine effluent (González-Toril et al. 2011), sulfidic mine waste dumps (Breuker et al. 2009), volcanic deposits (Fujimura et al. unpublished) and various hot springs (e.g., Korf et al. unpublished). Clone sequences of family members have also been found in acidic saline drain (Zammit et al. 2012), and in the soil environment, such as aliphatic hydrocarbon-contaminated soil (Militon et al. 2010), grassland (Jenkins et al. 2009), arsenic-contaminated soil (Sultana et al. 2012), desert soil (Köberl et al. 2011). They were also found in association with sponges (Montalvo et al. 2005; Xin et al. 2008) and in the biofilm on walls of sulfide mines (Bond et al. 2000; Bond and Banfield 2001) and cave environments (Macalady et al. 2007).

Not all sequences are highly related to the type strains of the three acidiphilic species, giving the impression of the occurrence novel species, even genera. Norris et al. (2011) and Itoh et al. (2011) compiled the phylogenetic position of many of the sequences of cultured strains and of clone sequences. Some of them cluster between *Ilumatobacter fluminis* and *Iamia majanohamensis* on the one side and members of *Acidimicrobium*, *Ferrimicrobium* and *Ferrithrix* on the other side, giving the impression that iron and heavy metal oxidation and reduction might be a widespread metabolic feature of members of the *Acidimicrobiales*. A few additional strains of *Ilumatobacter* have mainly been detected in the marine environment (e.g., AB286031, Kasai, unpublished).

Ecology and Application

Ferrous iron oxidizing organisms are widely present in appropriate environments in nature where they are involved in the oxidation of pyrite and other sulfidic minerals. As this also happens uncontrolled in ore waste and in active and shut-down mines and the environment, mainly streams and rivers, the environment is confronted with a serious pollution problem in terms of heavy loads of metals such as copper, nickel, cobalt, zinc and iron. Rowe and Johnson (2008) summarizes the main points of the microbial involvement in the iron cycle. Mainly bacteria are involved in biomining which is the controlled solubilization of sulfidic ores by acidophilic organisms, such as *Sulfobacillus* spp., *Thiobacillus* spp., *Leptospirillum* spp. and many other chemolithotrophic and heterotrophic acidiphilic strains that are either enriched by, or inoculated for, commercial bioleaching operations (Wakeman et al. 2008). The role of members of the family *Acidimicrobiaceae* to optimize such processes is acknowledged, though they are not considered to be the main players in iron and sulfur cycles. The ability of certain strains of *Acidimicrobium ferrooxidans* and other members of the family (as well as other moderately thermophilic iron-oxidizing bacteria) to reduce ferric to ferrous iron acid under oxygen limitation gives them an advantage to exploit environments, i.e., using reduced sulfur compounds as electron donors, when the oxygen content is lowered, such in thermal environments as seen in heap leaching, mineral waste dumps, tank reactor biomining and in geothermal sites (Bridge and Johnson 1998). Because it this potential, *A. ferrooxidans* is frequently used in experiments attempting to optimize conditions for commercial biomining (Bridge and Johnson 1998; Bacelar-Nicolau and Johnson 1999; Rowe and Johnson 2008; Wakeman et al. 2008; Watkin et al. 2009).

Abstract
Family *Acidothermaceae*, within the order *Actinomycetales*, contains thermophilic bacteria isolated from thermal springs and placed in genus *Acidothermus*. Genus *Acidothermus* was found and isolated from Yellowstone National Park, Wyoming, USA, in the course of a search for thermostable cellulases (Mohagheghi et al. Int J Syst Bacteriol 36:435–443, 1986). *Acidothermus cellulolyticus* is presently the sole species, in the sole genus of the family *Acidothermaceae*. A 16S rRNA-based phylogenetic study has found *Acidothermus* to be most closely related to *Frankia*; however, other genes have yielded different topologies. The genome of *A. cellulolyticus* strain 11B has been sequenced recently. Several genes for plant biomass degradation have been characterized; the thermostable properties of *A. cellulolyticus* enzymes for both cellulose and hemicellulose degradation have value for biotechnological applications.

The family *Acidothermaceae* was initially described as phylogenetically close to *Frankia* (*Frankiaceae*), *Cryptosporangium* (*Cryptosporangiaceae*), *Geodermatophilaceae*, (*Geodermatophilaceae*), *Nakamurella* (*Nakamurellaceae*), and *Sporichthya* (*Sporichthyaceae*) and grouped into suborder *Frankineae*. However, this suborder is now an order, *Frankiales*, and now considered to contain six families: besides the *Frankiaceae* the *Acidothermaceae*, the *Cryptosporangiaceae*, the *Geodermatophilaceae*, the *Nakamurellaceae*, and the *Sporichthyaceae* (Normand P et al. 2012).

Introduction

Thermal springs constitute highly unusual ecological islands, surrounded by mesophilic biotopes where forests and grasslands thrive, producing enormous amounts of cellulosic and lignin materials. Thermal springs are associated with fissures or faults in the earth's crust resulting from volcanic activity, as in the case of the Kamchatka Peninsula (Russia), or ancient caldera, as in the case of Yellowstone National Park (Wyo, USA). The resulting vertical circulation of water brings cold surface water in contact with hot deep layers with resulting geysers, pools, and more ephemeral thermal features. Microbial inhabitants of thermal features such as *A. cellulolyticus* have been the source of enzymes with thermostable properties that are useful in biotechnological applications.

Acidothermus strains were first isolated because they are capable of carrying out rapid degradation of cellulose, at relatively high growth temperatures (55 °C optimum, Mohagheghi et al. 1986). Cellulose is the most abundant form of carbon on earth, constituting the major fraction of plant structural matter that contributes to soil organic matter formation over centuries. Most animals cannot catabolize cellulose, except those that harbor cellulolytic bacteria in their caecum, rumen, or intestine.

The *Acidothermus* genome contains a gene cassette coding for highly efficient, thermostable enzymatic cellulose degradation (Tucker et al. 1989) that is now being employed in biotechnological applications. Cellulase enzymes from a few microorganisms are used industrially in paper and textile industries to modify fibers and improve textures and applications are increasingly possible during bioconversion of plant feedstock biomass to ethanol. However, to date, with the exception of the *A. cellulolyticus* E1 enzyme, the commercial cellulases are not thermostable.

The analysis of the complete genome of *A. cellulolyticus* 11B revealed the presence of genes predicted to encode xylanase (2), xylan esterase (3), and xylosidase (1) (Barabote et al. 2009), enzymes that degrade the hemicellulosic fraction of plant cell walls. Subsequent biochemical characterization has confirmed

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_199,

the thermostability and activity of one endoxylanase over a broad pH range (Barabote et al. 2010).

Recently, a cellulase from *A. cellulolyticus* has been incorporated into crop plants by genetic transformation and expressed to enhance digestibility during pretreatment of cellulosic biomass for biofuel production (Brunecky et al. 2011; Chou et al. 2011). The thermal adaptation of the enzyme prevents digestive activity until the feedstock is heated.

Taxonomy, Historical, and Current

Aci.do.ther.ma.ce'ae. masc. n. *Acidothermus* type genus of the family; suff. -aceae ending to denote a family; N.L. fem. pl. n. Acidothermaceae the *Acidothermus* family. This description is an emended version of the one given in the *Bergey's Manual*, 2nd edition (Normand et al. 2012).

The family *Acidothermaceae* was created by Rainey, Ward-Rainey, and Stackebrandt (in (Stackebrandt et al. 1997)) and emended by Zhi et al. (2009) to accommodate the single genus *Acidothermus* and the single species *Acidothermus cellulolyticus* (Mohagheghi et al. 1986). As its name implies, it grows in hot acidic springs (pH 4–6, 45–65 °C). Phylogenetic analyses based on the 16S rRNA gene have shown that *Acidothermus cellulolyticus* has as closest neighbors members of the genus *Frankia* (Normand et al. 1996).

Type genus: *Acidothermus* Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442^{VP}.

Genus I. *Acidothermus* Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442^{VP}.

A.ci.do.ther'mus. L. adj. *acidus* sour, acidic; Gr. adj. *thermos* hot; N.L. masc. n. *Acidothermus* acidic and hot (loving).

Slender rods and filaments, 0.4 × 5–20 μm, with rounded ends (Fig. 3.1a–d). Cell morphology in liquid culture depends on carbon source. When glucose or cellobiose is provided as sole carbon source, the organism grows as slender filaments, whereas on cellulose or xylan, the cells grow as short rods (Fig. 3.1a–d). No endospores are formed. No flagella have been reported, and no motility has been observed, although the genome of *Acidothermus cellulolyticus* contains the complete coding sequences for a flagellar apparatus (Barabote et al. 2009); expression of a *flaF* homolog has been detected in liquid culture in mid-log phase (M. Lee, Y.Y. Guo, R.D. Barabote, A.M. Berry unpublished). Gram-stain variable but generally Gram-stain negative. Thin sections show no outer cell membranes. The main constituents of purified cell walls are DAP, glucosamine, muramic acid, serine, and alanine. On LPBM mineral salts agar (Mohagheghi et al. 1986), colonies are creamy white, smooth, circular, entire, and 1–3 mm in diameter. In liquid culture, moderate turbidity is observed and cells may tend to flocculate and sediment out after 3 days. Obligate aerobes, prototrophic, grow on several carbon sources including D-glucose, cellobiose, and cellulose. Thermophilic with type species optimal temperature of 55 °C (range 37–70 °C) and acidophilic with optimal pH of 5.5 (pH range 3–7). Isolated from 45 °C to 65 °C acidic water and mud samples in Yellowstone National Park in the course of a screening program to obtain thermostable cellulases, but it has also been detected in soils by PCR (Talia et al. 2012) as well as a colonizer of plant tissues (Rezaei et al. 2011). Cells may be stored in 20 % (v/v) glycerol in LPBM medium at −80 °C and thawed on ice.

DNA G + C content (mol%): 66.9 (determined by complete genome sequencing).

Type species: *Acidothermus cellulolyticus* strain 11B Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442^{VP}.

1. *Acidothermus cellulolyticus* Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442^{VP}

cell.u.lo.ly'ti.cus. N.L. n. *cellulosum* cellulose; N.L. masc. adj. *lyticus* (from Gr. masc. adj. lutikos) able to loosen, able to dissolve; N.L. masc. adj. *cellulolyticus* cellulose-dissolving.

Morphology is as described for the genus. Grows on D-glucose, cellobiose, cellulose, xylan, D-galactose, maltose, sucrose, raffinose, D-mannose, D-mannitol, or D-sorbitol as sole carbon and energy sources. *A. cellulolyticus* 11B is auxotrophic and requires the addition of either yeast extract or Casamino acids to low-phosphate basal salts medium (LPBM) supplemented with a carbon source for growth. This organism could grow very well when all 20 proteinogenic amino acids were added to LPBM-cellobiose medium. Sequential elimination of each of the 20 amino acids revealed that the organism is unable to grow in the absence of either one of eight amino acids: arginine, aspartic acid, glutamic acid, histidine, lysine, proline, tryptophan, and tyrosine. The *A. cellulolyticus* 11B genome encodes all enzymes for the synthesis of arginine, glutamic acid, and proline from ornithine. When a pool of five of the eight amino acids (aspartic acid, histidine, lysine, tryptophan, tyrosine) were supplemented with ornithine, growth was restored (Fig. 3.2). This suggests that *A. cellulolyticus 11B* may be deficient in the biosynthesis of ornithine, an intermediate in arginine biosynthesis and the urea cycle.

No growth is observed on nutrient broth, acetate, lactate, citrate, or pectin. Citrate and acetate are inhibitory at 0.01 M. Resistant to penicillin G at 100 μg/ml; sensitive to vancomycin and lysozyme. Catalase-positive (Mohagheghi et al. 1986). Does not contain polyamines (Hamana et al. 1991). Actively digests cellulose and hemicellulose. Contains several genes for cellulose degradation (McCarter et al. 2002) and for hemicellulose degradation (Barabote et al. 2009). Contains a gene for *shc* (squalene-hopene cyclase) that may be involved in the ability to grow at high temperatures (Alloisio et al. 2005).

Source: isolated from 55 °C to 65 °C acidic water and mud samples in Yellowstone National Park in the course of a screening program to obtain thermostable cellulases (Mohagheghi et al. 1986).

DNA G + C content (mol%): 66.91 (determined by complete genome sequencing).

Type strain: ATCC 43068, 11B.

Sequence accession nos: AJ007290 (16S rRNA gene sequence of ATCC 43068 T); CP000481 (complete genome sequence of strain 11BT).

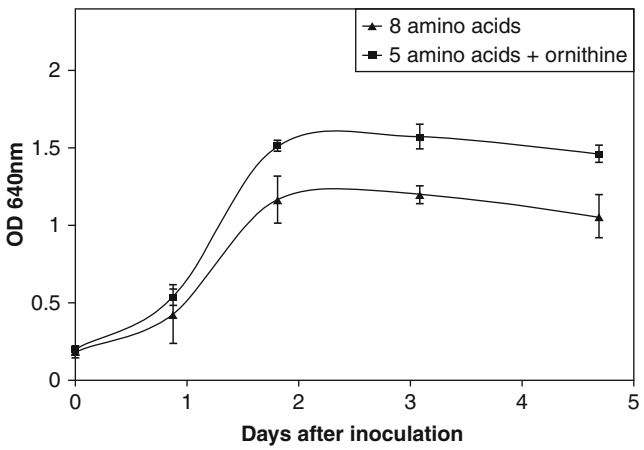

Fig. 3.2
Growth of *A. cellulolyticus* 11B in liquid culture, LPBM supplemented with eight amino acids (arginine, aspartic acid, glutamic acid, histidine, lysine, proline, tryptophan, and tyrosine) or with five amino acids (aspartic acid, histidine, lysine, tryptophan, tyrosine) plus ornithine (R.D. Barabote, S. Paliwal, A.M. Berry, unpublished)

Phylogenetic Structure of the Family and Its Genera

See *Fig. 3.3*

Analyses of 16S rRNA sequence have resulted in positioning genus *Acidothermus* in the Actinobacteria close to *Frankia* (Rainey and Stackebrandt 1993), despite a complete lack of common phenotypic features and their contrasted ecological biotopes. This proximity was confirmed by analysis of *recA* (Marechal et al. 2000) and *glnA* (Clawson et al. 2004), but the number of taxa sampled was in both studies limited. A more recent multi-locus genome-wide approach has not confirmed this proximity, positioning *Acidothermus* away from *Frankia* in a rake-like position with *Thermobispora bispora*, *Streptosporangium roseum*, *Thermomonospora curvata*, *Thermobifida fusca*, and *Nocardiopsis dassonvillei* (Wu et al. 2009).

These differences illustrate the difficulty of using a single marker to reconstruct the phylogeny of the genome as a whole. Each gene must thus be considered as having evolved independently from the others and to have moved from one microbe to the other. If *Nocardiopsis* is

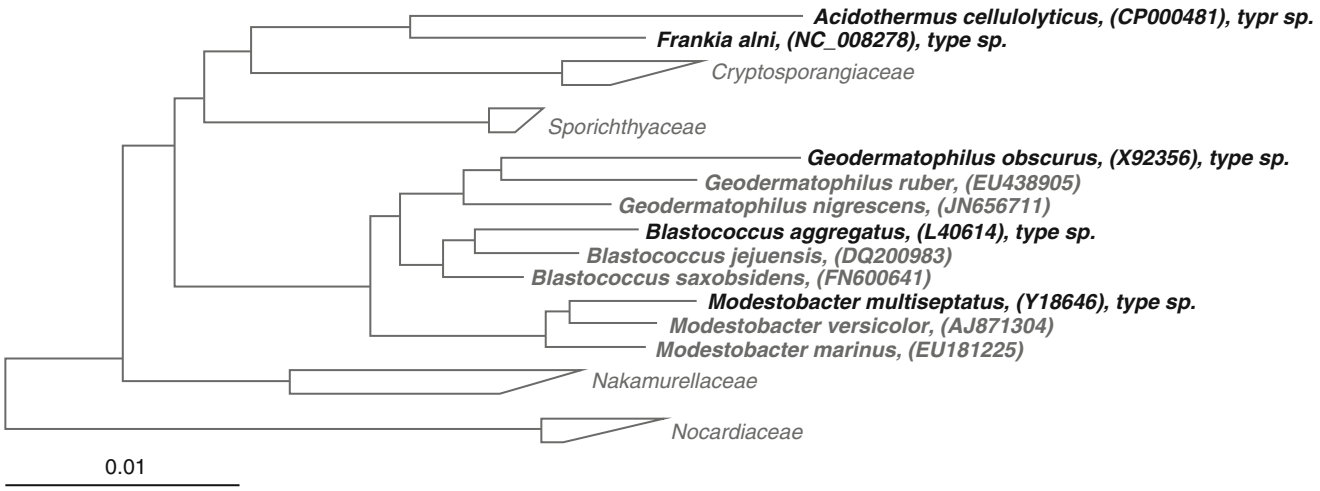

Fig. 3.3

Phylogenetic reconstruction of the family *Acidothermaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database ((Yarza et al. 2010); http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Table 3.1

Characteristics of the *Acidothermus* genome compared with representative phylogenetic neighbors

Characteristic	*Ac*	*Fa*	*Go*
Genome size (nt)	2 443 540	7 497 934	5 322 497
G + C% of genome	66.9	72.8	74.0
G + C% of rRNA	60.8	58.3	59.4
# of genes	2,321	6,718	5,334
# of tRNA	46	46	48
# of rRNA operons	1	2	3
Protein coding density %	88.50	86.02	85.66
Genome accession number	CP000481	CT573213	CP001867

a skin pathogen and *Streptosporangium* is a soil inhabitant, it must be underlined that three of the neighbors mentioned (*Thermobispora*, *Thermomonospora*, *Thermobifida*) are thermophiles, which may have resulted in a high exchange rate to facilitate adaptation of an ancestral soil microbe to thermal springs life.

Dating the transition is not easy. It has been proposed that genes accumulate mutations at a constant rate, and by using some evolutionary events that have left fossil traces, it has been proposed that a 1 % difference in the 16S rRNA genes corresponded to 50 MY (Ochman et al. 1999). Since the distance between *Acidothermus* and *Frankia* spp. ranges from 4.6 % to 5.1 %, the emergence of *Acidothermus* from the *Frankia* clade would have occurred 230–250 MY ago at a time when higher land plants were becoming established over continents (Simon et al. 1993) but before the emergence of major actinorhizal lineages (Normand et al. 1996).

Molecular Analysis

The genome sequence of *Acidothermus*, a single chromosome with no separate plasmids, was published in 2009 (Barabote et al. 2009) and found to have features contrasted to those of its closest 16S-relatives, *Frankia* and *Geodermatophilus* (*Table 3.1*). The most striking feature is genome size, 2.44 Mb, less than half of that of its phylogenetic neighbors, a feature that is in all likelihood related to the habitat, thermal

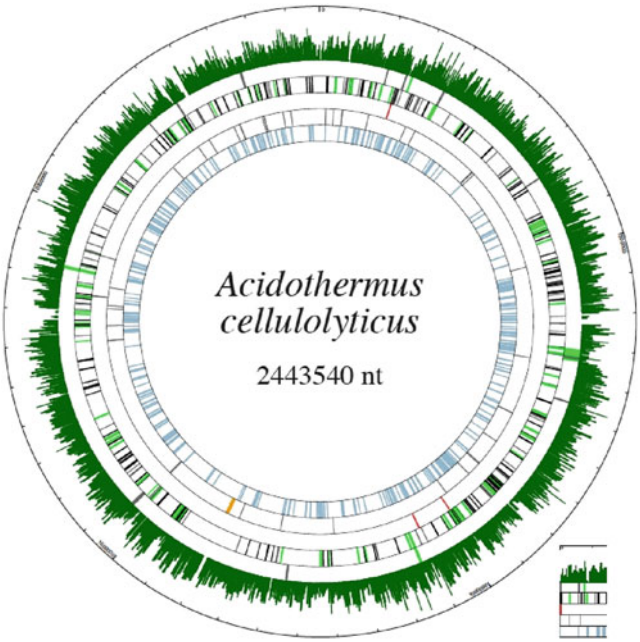

Fig. 3.4
***Acidothermus* circular map. 1-GC (range 55–80 %). 2-*Acidothermus* cellulase genes (*green*) and other glucanase genes (*gray*). 3-*Acidothermus* specific genes (unknown in *gray*; conserved in *black*; others in *green*). 4-Transposases (*gray*) and phage (*red*). 5-rRNA (*yellow*), and tRNA gen (*gray*). 6- *Acidothermus* Lgt genes (absent in *Frankia*, present in other actinobacteria, threshold 30 %)**

springs where high temperature likely imposes streamlining selection, and thus a reduced genome size (Sabath et al. 2013). The genome GC% is 66.9 %, markedly lower than those of its neighbors, while the GC% of the ribosomal genes is higher, illustrating that selection for adaptation to a thermophilic lifestyle is more targeted to rRNA than to DNA (Hurst and Merchant 2001).

Other potential genomic adaptations to a high temperature lifestyle such as revealed by principal component analysis (PCA) of global as well as synonymous codon usage, or ratios of IVYWREL amino acids in the *A. cellulolyticus* proteome and cytosolic subproteome, were investigated; however, no adaptational trend could be discerned (Barabote et al. 2009). These findings suggest that *A. cellulolyticus* may have only recently moved from a soil biotope to a hot spring lifestyle and is not yet fully optimized for it.

Several genomic islands with a lower G + C% and deviant dinucleotide signature were identified (Barabote et al. 2009); these carried no recognizable orthologs in close relatives but had their highest similarity to proteins from low G + C Gram-positives *Bacteroides, Nitrosococcus*, and *Thermoanaerobacter*. Furthermore, there were 21 secreted biomass-degrading enzymes whose genes are spread around the genome (◉ *Fig. 3.4*).

Fig. 3.5
Thermal features in the Norris Geyser Basin area, Yellowstone National Park, Wyoming, USA (Photo: A.M. Berry)

Phages: No phage has been described for *Acidothermus*; however, no specific work has been done for that purpose. A search in the genome for "phage" as keyword revealed only two occurrences; however, these genes are not conserved and are not close to one another.

Phenotypic Analysis

A. cellulolyticus utilizes plant biomass as carbon source, likely primarily cellulose and hemicellulose. This organism is not a hyperthermophile, but rather an intermediate thermophile, likely dwelling in acid thermal pools, streams, or other thermal features, which are surrounded by vegetation. In Yellowstone National Park, thermal features of the temperature range amenable to *A. cellulolyticus* typically occur in meadows or small riparian areas (◉ *Fig. 3.5*).

Plant cell walls are structurally highly complex. Even though cellulose and hemicellulose are primary components, pectins are also abundant in the matrix of primary cell walls. Lignin permeates plant secondary cell walls, e.g., in xylem (woody tissue). The genome of *A. cellulolyticus* does not contain homologs for pectin or lignin polymer degradation. Hence the plant biomass available as carbon source in the thermal features must be subject to additional mechanisms of processing. A comprehensive ecological study of *A. cellulolyticus* remains to be performed; however, it is reasonable to expect that both biotic community interactions and abiotic (thermal) factors may be involved in a coordinated process of biomass degradation. Pectin, for example, can be efficiently leached from plant cell walls simply by heating at low pH. Several fungal taxa degrade lignin effectively. Growth of *A. cellulolyticus* in liquid culture or on solid plant biomass substrate was strongly inhibited by a range of plant phenolic compounds, including monomers typical of lignin

formation or breakdown (Joh et al. 2011). Once the pectin (or lignin) is removed in the aqueous environment of a thermal pool, *A. cellulolyticus* would be capable of degrading the remaining hemicellulose and cellulose.

The endoglucanases are a class of enzymes used to recycle cellulose and generate glucose which can in turn generate fuels such as ethanol. One endoglucanase from *A. cellulolyticus* has thus been cloned into the fungus *Trichoderma reesei* to obtain hyper-expression (Zou et al. 2012). A codon-optimized synthetic gene encoding this thermostable enzyme was also transformed into rice (*Oryza sativa* L. ssp. *japonica*) under the control of the rice seed storage protein Gt1 promoter, with the enzymes produced in the seeds having an optimum pH of 5.0 and optimum temperature of 80 °C, which is similar to the enzymes produced by the native bacterium host, thus demonstrating that transgenic rice seeds could be used as a bioreactor for production of enzymes for cellulosic biomass conversion (Zhang et al. 2012). It is also a way to enhance cellulose digestion in the cow's rumen (Chou et al. 2011) or provide a pretreatment of plant feedstocks to facilitate subsequent bioconversion for biofuels (Brunecky et al. 2011).

Other thermostable determinants in the genome are interesting from an industrial point of view, such as the highly thermostable xylanases and related enzymes that can degrade hemicelluloses (Barabote et al. 2010), an alditol oxidase that can catabolize an array of polyols (Winter et al. 2012), or an aminopeptidase engineered into a transaminopeptidase by site-directed mutagenesis of catalytic Ser(491) into Cys to cause the formation of peptide bonds to yield linear homo-oligopeptides, hetero-dipeptides, and cyclic dipeptides (Usuki et al. 2011).

Conclusion

Acidothermus appears alone in its clade, with no close neighbor. It has been isolated from an acidic thermal spring but has also been detected directly from mesophilic soil and aquatic communities through 16S rRNA targeted studies (Talia et al. 2012). Its origin could be a recent evolutionary transition from a mesophilic soil ancestor and illustrates the speed at which bacteria can adapt to extreme conditions, presumably by taking up genes from bacteria already inhabiting the biotope.

Hyperthermophiles in some thermal springs have been well studied, especially in the emblematic Yellowstone National Park; however, aquatic ecosystems harboring organisms of moderate thermal adaptation are still waiting for an exhaustive study and may reveal the presence of *Acidothermus* relatives with varied metabolic or ecological properties. The expected massive arrival of metagenomic data, in particular from moderately acidic thermal features (streams, seeps, etc.) may contain genomes from *Acidothermus* relatives.

The study of the genomes of *Acidothermus* and relatives will likely continue to yield interesting thermostable enzymes for the conversion of plant biomass into fuel material. It may also help understand how genomes adapt to a range of extreme conditions.

4 The Family *Actinomycetaceae*

Atteyet-Alla Fetouh Yassin
Institute of Medical Microbiology, Bonn University, Bonn, Germany

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_171,

Abstract

Actinomycetaceae, the only family classified in the order *Actinomycetales* of the phylum Actinobacteria, embraces the genera *Actinomyces*, *Actinobaculum*, *Arcanobacterium*, *Mobiluncus*, *Trueperella*, and *Varibaculum*. Of these genera, the genus *Actinomyces* has been indicated to be quite diverse, and in a phylogenetic tree based upon 16S rRNA, it showed polyphyletic branching into a number of different clusters and individual lineges. Therefore, it is evident that the generic limits within the family are still uncertain, and although the genera *Actinobaculum*, *Arcanobacterium*, *Mobiluncus*, *Trueperella*, and *Varibaculum* have been studied in considerable detail, their relationship to the lesser known hypothetical genera is still unresolved. Members of the family are defined by a wide range of morphological and chemotaxonomic properties, such as polar lipids, fatty acids, amino acids of peptidoglycan, and whole-cell sugars which are used for the delineation of genera and species. Although many of the species of *Actinomycetaceae* have been extensively studied, using standard biochemical tests, the applicability of such tests have remained limited because the results are often irreproducible. The family harbors many important species which can be found in a wide range of habitats including human, animal, and environmental. Many of these species have been proven to be the casual agents of many human and animal infections.

Family *Actinomycetaceae* Buchanan 1918, 403 (emend. Stackebrandt, Rainey, and Ward-Rainey 1997, 484), emend. Zhi, Li, and Stackebrandt 2009, 594^{VP}.

Ac. ti. no. my. ce. ta' ce. ae. N. L. masc. n. *Actinomyces*, the type genus of the family; -*aceae*, ending to denote the family; N. L. fem. pl. n. *Actinomycetaceae*, the *Actinomyces* family.

Taxonomy, Historical and Current

The family *Actinomycetaceae* was created by Buchanan in 1918 and was originally used to accommodate many diverse organisms such as members of the genera *Actinobacillus*, *Leptotrichia*, *Actinomyces*, and *Nocardia*. After several revisions, membership of the family was restricted to bacterial species that appeared to be linked taxonomically by the following phenotypic characteristics, ability to produce Gram-positive, branching, and, later on, fragmenting filaments without aerial hyphae and spores; comparatively exacting nutritional requirements; facultatively anaerobic (capnophilic) to anaerobic growth; and fermentative carbohydrate metabolism (Slack 1974; Slack and Gerencser 1975). Taking into account these common features, the family *Actinomycetaceae* was thought to include the genera *Actinomyces*, "*Arachnia*," *Bifidobacterium*, "*Bacterionema*," and *Rothia* (Slack 1974). However, the validity of this family concept was increasingly questioned after modern and more relevant taxonomic techniques such as chemotaxonomic, numerical phenetic, and molecular genetic procedures had been applied to the respective organisms.

In the initial hierarchical classification of the class *Actinobacteria* using 16S rRNA gene sequence phylogenetic clustering and taxon-specific 16S rRNA signature nucleotides (Stackebrandt et al. 1997) and subsequent update of this classification by Zhi et al (2009), the family *Actinomycetaceae* Buchanan 1918 with the type genus *Actinomyces* Harz 1877 has been accommodated in the suborder *Actinomycineae* (Stackebrandt et al. 1997), emend. Zhi et al. 2009, order *Actinomycetales* Buchanan 1918 (Skerman et al. 1980), emend. Stackebrandt et al. 1997, emend. Zhi et al. 2009. This order has been included in the class *Actinobacteria* by Stackebrandt et al. (1997) and Zhi et al. (2009).

Additionally, in the current edition of *Bergey's Manual of Systematic Bacteriology*, a taxonomic modification of taxa with higher ranks has been proposed (Ludwig et al. 2012). Thus, with the elevation of the suborders of Zhi et al. (2009) to orders, the family *Actinomycetaceae* was classified as the only member of the order *Actinomycetales* of the phylum Actinobacteria. The family appears as an independent clade somewhat related to the family *Jonesiaceae* of the order *Micrococcales*. Though the current edition of *Bergey's Manual of Systematic Bacteriology* appeared in print later after the dissection of the genus *Arcanobacterium* to the genera *Arcanobacterium* and *Trueperella* (Yassin et al. 2011), the family comprises now the diffuse type genus *Actinomyces* and the five genera *Actinobaculum*, *Arcanobacterium*, *Mobiluncus*, *Trueperella*, and *Varibaculum*.

Molecular Analyses

Phylogenetic analysis using 16S rRNA sequence provided valuable insight into the classification and evolution of *Actinomycetaceae* (Fig. 4.1a). One major finding is that the family forms a monophyletic group within the Actinobacteria. Further, all tree construction methods agree that the family is divided into well-separated clades including the genera *Actinobaculum*, *Actinomyces*, *Arcanobacterium*, *Mobiluncus*, *Trueperella*, and *Varibaculum*. The monophyly of the genera *Mobiluncus* and *Trueperella* are strongly supported (bootstrap values = 96–100 %). On the other hand, the monophyly of the genus *Actinobaculum* is moderately supported (bootstrap value 73 %), whereas the monophyly of the genus *Arcanobacterium* is poorly supported (bootstrap value 63 %). The monophyly of the genus *Actinomyces* is not supported (bootstrap value 32 %). Interestingly, the monospecific genus *Varibaculum* is highly nested within the genus *Actinomyces* as sister to the species *Actinomyces neuii* (bootstrap value 98 %). The association of *Varibaculum* and *A. neuii* was recognized by Hall et al. (2003a). Strong support (bootstrap values = 96 %) for sister-clade relationship is found between the genus *Arcanobacterium* and the genus *Trueperella*. Noteworthy, all tree construction methods consistently indicated that the genus *Actinomyces* is polyphyletic, result which was foreshadowed by Pascual Ramos et al. (1997a).

Currently, the family *Actinomycetaceae* is delineated from other members of the phylum Actinobacteria solely on the basis of its branching position in 16S rRNA gene trees. With the exception of the genus *Actinomyces*, all genera of the family are primarily distinguished on the basis of genus-specific 16S rRNA signature nucleotides (Table 4.1). However, these signature nucleotides are based on published 16S rRNA sequences of type strains, and they change when new sequences are added to the databases.

Overview of Genomic Features of *Actinomycetaceae*

Genomic features of limited numbers of *Actinomycetaceae* have been described by various authors (Gorlas et al. 2012; Roux et al. 2012; Yasawong et al. 2010). Some features of the completed genomes are summarized in Table 4.2. The sequenced genomes varied in size from 1.71 Mb (*Actinomyces coleocanis*) to 2.39 Mb (*Mobiluncus mulieris*) with G+C contents varying from 49.6 % (*Actinomyces coleocanis*), 53.1 % (*Arcanobacterium haemolyticum*), and 55.6 % (*Mobiluncus curtisii*) to 68.73 % (*Actinomyces urogenitalis*) and possess a large number of tRNA molecules ranging from 46 (*A. coleocanis*) to 50 (*Arcanobacterium haemolyticum*). The genomes had similar global partition of protein functions, as measured by the distribution of COG families. COG analysis revealed that members of the *Actinomycetaceae* had significantly higher abundance of the proteins responsible for carbohydrate transport and metabolism (6.77–14.25 % of total gene count), translation (6.08–10.87 %), transcription (6.36–9.08 %), amino acid transport and metabolism (5.49–8.56 %), energy production and conservation (5.21–6.29 %), and inorganic ion transport and metabolism (4.04–6.72 %), but lower abundances of the proteins responsible for defense mechanisms (2.01–3.16 %), lipid transport and metabolism (1.85–2.93 %), and secondary metabolite biosynthesis (0.68–1.09 %). This profile indicates that the principal source for energy production and biosynthesis of cellular

components in this group of bacteria originates from the fermentation of polysaccharides or dietary fiber, which results in the production of short-chain fatty acids that are then used as energy sources. This probably explains their specific ecological success as commensals of the mucous membranes of the gastrointestinal tract, vagina, and dental plaque of humans and animals.

Furthermore, a number of conserved signature indels (CSIs) and whole proteins or conserved signature proteins (CSPs) that are specific for species have been identified in the genome of sequenced species of *Actinomycetaceae* (Gao and Gupta 2012). The latter authors reported that the enzyme deoxy-D-xylulose 5-phosphate reductoisomerase (DXR), which is a part of the nonmevalonate pathway of isoprenoid biosynthesis, contains a 12-amino acid (aa) insert in a highly conserved region that is uniquely present in all available sequences of the genera *Actinomyces*, *Arcanobacterium*, and *Mobiluncus*. Another CSI consisting of a 6-aa insert that is specific for all sequenced *Actinomycetaceae* species is present in the integral membrane protein. The high degrees of conservation and specificity of these signatures for species of this family indicate that they provide good and reliable molecular markers for this family. Isoleucine tRNA synthetase (IleRS), which is essential for protein synthesis, also contains a 3-aa insert in a conserved region that is specifically present in all available sequences of the genera *Actinomyces* and *Mobiluncus* but which is lacking in *Arcanobacterium haemolyticum* as well as all other actinobacteria

Genome Properties of the Genus *Actinomyces*

Of the currently recognized 41 *Actinomyces* species, two type strains that belong to *A. coleocanis* DSM 15436^T and *A. urogenitalis* DSM 15434^T in addition to *A. odontolyticus* ATCC 17982 and a number of clinical isolates belonging to different *Actinomyces* species are at various stages of sequence completion (Table 4.2). The genomes size of *Actinomyces* species range from 1.7 to 3.04 Mb and possess a large number of tRNA molecules (from 46 to 51). Genomic G+C content ranging from 49.6 % to 68.73 %. The overall composition of COG supracategory was similar throughout the genus.

The genome of the type strain of *A. urogenitalis* DSM 15434^T (BCM-HGSC). (GOLD ID Gi02602) is 2, 614,023 bp long, contains 2,453 genes, including one copy for the 16S rRNA gene, and the mol% G+C of DNA is 68.73 %. Of the 2,453 gene predicted, 2,403 were protein-coding genes and 50 RNA genes were identified (Table 4.2). The majority of the protein-coding genes (68.2 %) were assigned with a putative function while the remaining ones were annotated as hypothetical proteins. The highest number of genes associated with general COG functional categories is found for carbohydrate transport and metabolism (263) followed by amino acid transport and metabolism (158) and transcription (145).

The genome of *A. coleocanis* DSM 15436^T (BCM-HGSC). (GOLD ID Gi02601) consists of 1,719,346 base pairs with

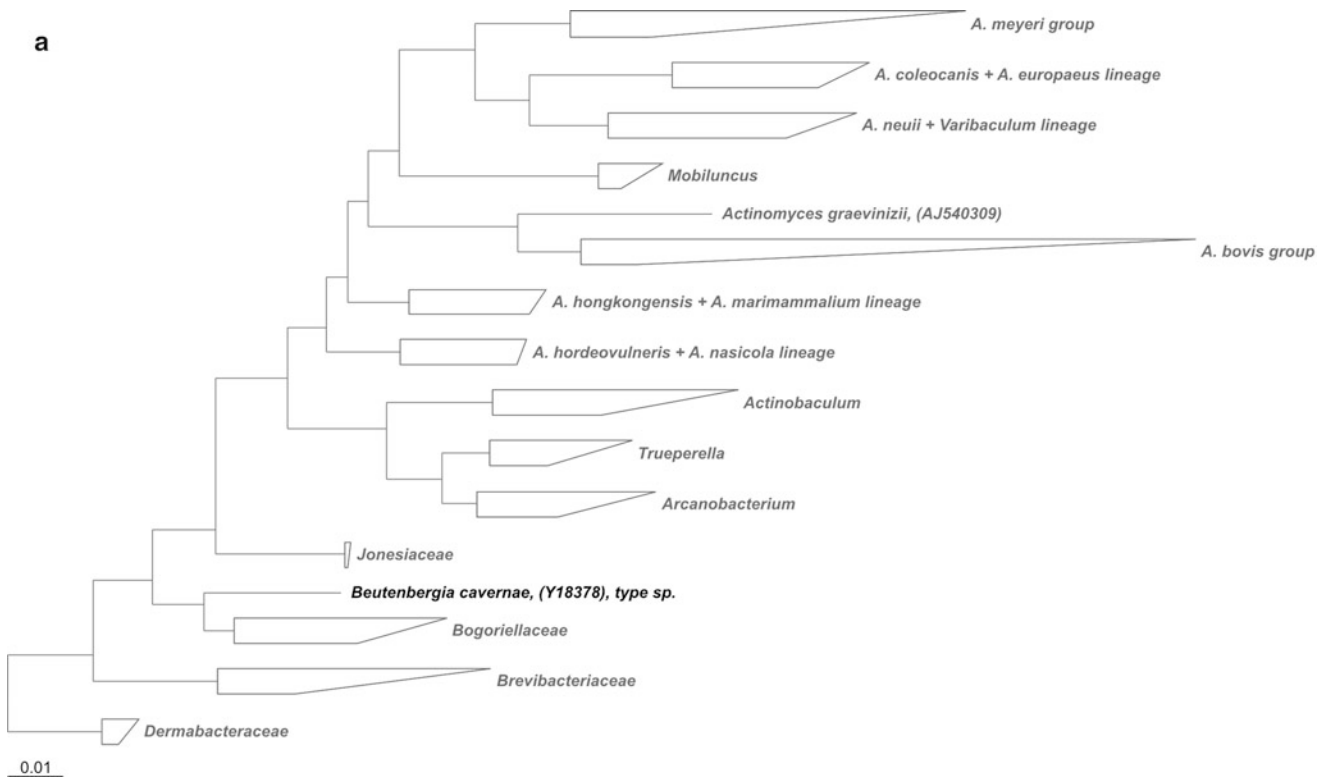

Fig. 4.1 (Continued)

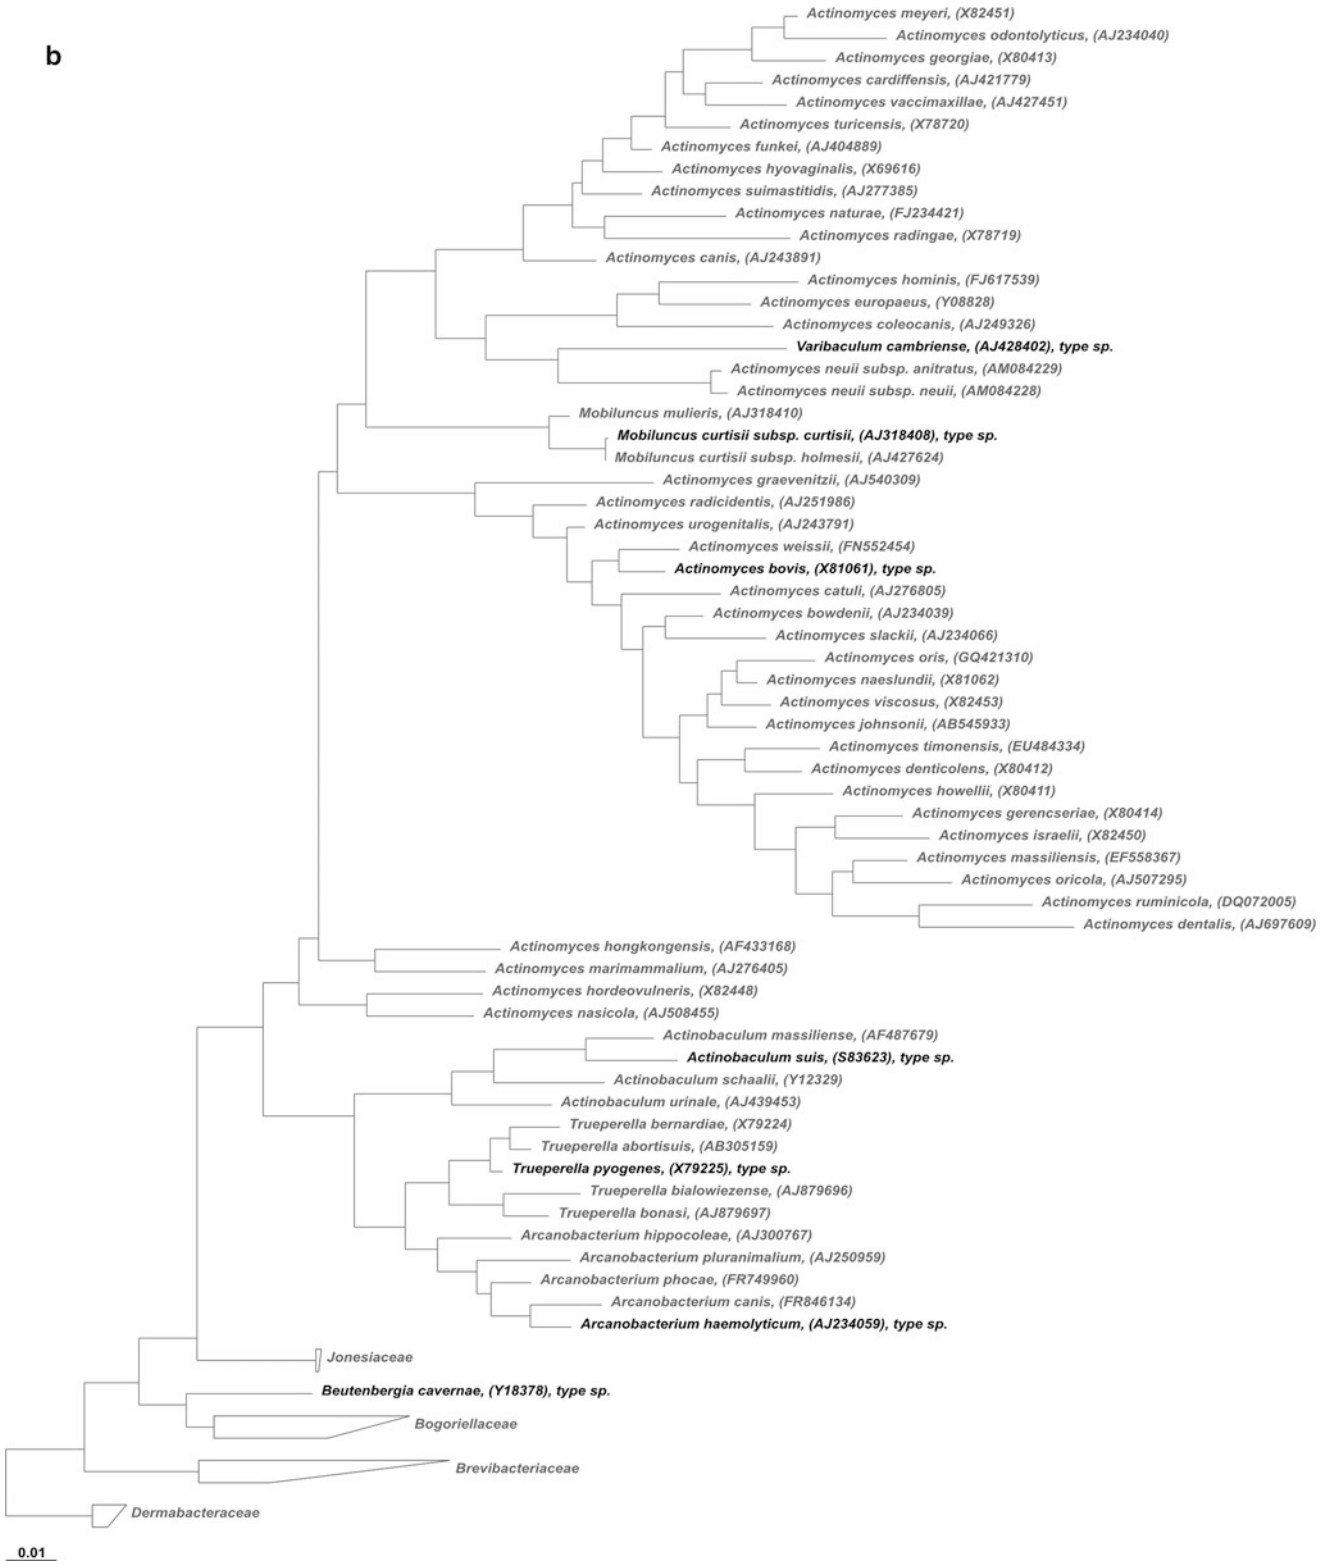

Fig. 4.1

Phylogenetic reconstruction of the family *Actinomycetaceae*, (a) folded tree and (b) unfolded tree, based on 16S rRNA and created using the maximum-likelihood algorithm RAxML (Stamatakis 2006). The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Table 4.2
General genome features of some members of the family *Actinomycetaceae*

Organism	Genome size (Mb)	% G+C content	No. of protein-coding genes	No. of RNA genes	No. of rRNA genes	No. of 16S rRNA	No. of tRNA genes	No. of pseudogenes	Reference
Actinomyces coleocanis DSM 15436^T	1.71	49.6	1,546	52	4	1	48	–	BCM-HGSC
Actinomyces naselundii MG1	3.04	68.47	2,489	63	9	3	51	–	J. Craig Venter Institute
Actinomyces oris K20	2.87	67.8	2,939	53	3	1	50	–	Osaka University
Actinomyces odontolyticus ATCC 17982	2.39	65.45	2,159	60	10	3	48	–	Washington University, St. Louis
Actinomyces urogenitalis DSM 15434^T	2.61	68.73	2,403	50	4	1	46	–	BCM-HGSC
Arcanobacterium haemolyticum DSM 20595^T	1.98	53.1	1,821	64	12	4	50	90	Yasawong et al. (2010)
Mobiluncus curtisii subsp. *curtisii* ATCC 35241^T	2.13	55.66	1,894	52	3	1	46	–	Baylor College
Mobiluncus curtisii subsp. *holmesii* ATCC 35242	2.08	55.62	1,829	52	3	1	46	–	Baylor College
Mobiluncus mulieris ATCC 35243^T	2.39	55.14	2,300	48	3	1	45	–	Baylor College

49.6 % G+C content. Of the 1,598 genes predicted, 1,546 were protein-coding genes and 52 rRNA genes (*Table 4.2*). The majority of the protein-coding genes (68.9 %) were assigned a putative function, while the remaining ones were annotated as hypothetical proteins. The most represented classes of genes were those involved in carbohydrate transport and metabolism, followed by transcription (119 and 86, respectively) and amino acid transport and metabolism (80).

The genome of *Actinomyces odontolyticus* ATCC 17982^T (Washington University). (GOLD ID: Gi01705) consists of 2,393,758 bases with 65.45 % G+C content. Of the 2,219 genes predicted, 2,159 were protein-coding genes and 60 rRNA genes (*Table 4.2*). The majority of the protein-coding genes (66.7 %) were assigned a putative function, while the remaining ones were annotated as hypothetical proteins. The highest number of genes associated with general COG functional categories is found for carbohydrate transport and metabolism, followed by amino acid transport and metabolism (174 and 135, respectively) and transcription (113). Interesting from the perspective of pathogenicity, one gene annotated to COG category cell motility predicted to code for Flp pilus assembly protein TadC (COG2064). Pili are protein structures that extend from the surface of bacterial cells to allow the bacteria to adhere to their environment (Gerlach and Hensel 2007). Other *Actinomyces* species, for which whole-genome sequences currently available and its genome contains genes annotated to COG category cell motility are *A. naeslundii* MG1 and *A. oris* K20 (each containing three genes). One of these genes (COG3063) encodes for Tfp pilus assembly protein PiLF which enable bacteria to attach to host cells and other substrates (Burrows 2005; Skerker and Berg 2001).

Genome Properties of the Genus *Arcanobacterium*

The complete genome sequence of two species branching within the 16S rRNA gene tree of *Arcanobacterium* has been released. The genome of the type strain of *Arcanobacterium haemolyticum* DSM 20595^T (Yasawong et al. 2010). (GOLD ID Gco1291) is 1,986,154 bp long and contains 1,885 genes, including four copies for the 16S rRNA gene, and the mol% G+C of DNA is 53.1 %. The latter value falls into the range of 50–57 mol% determined for species of the genus *Arcanobacterium*. Of the 1,885 gene predicted, 1,821 were protein-coding genes and 64 RNAs; 90 pseudogenes were also identified (*Table 4.2*). The majority of the protein-coding genes (68.5 %) were assigned with a putative function while the remaining ones were annotated as hypothetical proteins. The highest number of genes associated with general COG functional categories is found for translation, ribosomal structure, and biogenesis (136), followed by carbohydrate transport and metabolism (125) and replication, recombination, and repair (119). In accord

with the genus description, a gene (GenBank:YP 003696699) specifying homologs of CAMP (Christie, Atkins, Munch-Petersen) factor family protein, which are typically found in pathogenic staphylococci, was also identified. CAMP factors have been shown to bind to immunoglobulins of the G and M classes and have long been known as pathogenic determinants. Interestingly, two genes, one encoding hemolysin A (GenBank: YP 003697287) and the other encoding phospholipase D (GenBank:YP 003697432), were also identified. Hemolysin A and phospholipase D are virulence factors involved in *A. haemolyticum* infections and both with cytotoxic effects.

Genome Properties of the Genus *Mobiluncus*

The complete genome sequence of two species branching within the 16S rRNA gene tree of *Mobiluncus* has been released. The genome of the type strain of *Mobiluncus curtisii* subsp. *curtisii* ATCC 35241^T (Baylor College of Medicine). (GOLD ID Gi03779) is 2,136,873 bp long and contains 1,946 genes, including one copy for the 16S rRNA gene, and the mol% G+C of DNA is 55.66 %. The latter value falls over the range of 49–54 mol% determined for species of the genus *Mobiluncus* (Hoyles et al. 2004). Of the 1,946 genes predicted, 1,894 were protein-coding genes and 52 RNAs were identified. The majority of the protein-coding genes (69.8 %) were assigned with a putative function while the remaining ones were annotated as hypothetical proteins. The highest number of genes associated with general COG functional categories is found for translation, ribosomal structure, and biogenesis (135), followed by amino acid transport and metabolism (116), followed by replication, recombination, and repair (105) and carbohydrate transport and metabolism (99). In accord with the genus description is the presence of genes (43) related to cell motility.

Phenotypic Analyses

The family encompasses non-spore-forming, nonmotile, ordinarily facultatively anaerobic bacteria that belong to the order *Actinomycetales* and contain Gram-positive, non-acid-fast, predominantly diphtheroid cells that tend to form branched filaments in tissue or in some stages of cultural development. The metabolism of these chemoheterotrophic bacteria is fermentative.

Examination of the chemical markers across the family *Actinomycetaceae* has not been thoroughly investigated enough to draw any firm conclusions regarding the delimitation and description of the family. Currently, extensive study has been performed to examine the chemical constituents of individual species assigned to genera of *Actinomycetaceae*. Table 4.3 (A. F. Yassin unpublished) provides a general overview of the distribution of particular chemical markers within the family.

The mode of cross-linkage and the amino acid composition of the tetrapeptide bridge of the peptidoglycan layer vary between members of the *Actinomycetaceae*. Generally, the type abbreviated A5 (Schleifer and Seidl 1985) is the only peptidoglycan type found, so far examined, in the genera *Actinomyces*, *Actinobaculum*, *Arcanobacterium*, and *Trueperella* (Table 4.3). Two subtypes have been identified: the one abbreviated A5α with L-lysine or L-alanine as the diamino acid in position 3 of the tetrapeptide subunit (L-Lys-L-Lys-D-Glu or L-Lys-L-Ala-L-Lys-D-Glu) was

Table 4.3
Chemotaxonomic characteristics of the genera of the family *Actinomycetaceae*

Organisms	Peptidoglycan type	Peptidoglycan	Cell-wall sugars	Acyl type	Menaquinones	Phospholipids	Fatty acids	Mol % G+C
Actinomyces bovis	A5α	L-Lys-L-Lys-D-Asp	Glucose + mannose + rhamnose + 6-deoxytalose	Acetly	MK-8 + MK- 9[a] + MK-10	DPG, PG, PC, PI, PIM	S, U	63.8
Arcanobacterium	A5α	L-Lys-L-Lys-D-Glu	Rhamnose + glucose	Acetyl	MK-8(H_4) + MK-9(H_4)[a]	DPG, PG, PI	S, U, I, A	50–52
Trueperella	A5α	L-Lys-L-Lys-D-Glu or L-Lys-L-Ala-L-Lys-D-Glu	Rhamnose + glucose	Acetyl	MK-9(H_4) + MK-10(H_4)[a]	DPG, PG, PI, PGL	S, U, I, A	56–58
Actinobaculum	A5α	L-Lys-L-Lys-D-Glu or L-Lys-L-Ala-L-Lys-D-Glu	Glucose + rhamnose + 6-deoxytalose	Acetyl	Abscent	DPG, PG, AbGL	S, U	55–57
Varibaculum	ND	Not determined	Galactose	Acetyl	MK-8(H4) + MK-9(H4)[a]	DPG, PG, PC, PI, PIM	S, U, I, A	51–55
Mobiluncus curtisii subsp. *holmesii*	ND	Not determined	Galactose + rhamnose	Acetyl	MK-8 + MK-9[a]	DPG, PG, PGL	S, U, I, A	49–52

[a]Major component; *DPG* diphosphatidylglycerol, *PG* phosphatidylglycerol, *PC* phosphatidylcholine, *PI* phosphatidylinositol, *PIM* phosphatidylinositol mannosides, *PGL* phosphoglycolipid, *AbGL* choline-containig phosphoglycolipid. *S* straight-chain, saturated, *U* monounsaturated, *A anteiso*-methyl-branched, *I iso*-methyl-branched. Mol% G+C, guanine phus cytosine content of the DNA

found in the peptidoglycan of the genera *Actinobaculum*, *Arcanobacterium*, *Trueperella*, and some *Actinomyces* species. The second subtype abbreviated A5β with L-ornithine as the diamino acid in position 3 of the tetrapeptide subunit (L-Orn-L-Lys-D-Glu) is restricted to some species of the genus *Actinomyces* (Table 4.6).

The principal respiratory quinones distributed in the genera of the family *Actinomycetaceae*, except the genus *Actinobaculum*, are menaquinones with eight, nine, and ten isoprene units with varying degree of saturation (Table 4.3). Though the menaquinones of the majority of *Actinomyces* species have not yet been analyzed, two distinct patterns have been identified in the genus. The first pattern is characterized by fully unsaturated menaquinones MK-8 and MK-9 with the latter component being the major one. This pattern has also been found in the genus *Mobiluncus*. The second pattern consisted of MK-8(H_4) and MK-9(H_4) with the latter compound as the major component. This pattern was also present in the genus *Arcanobacterium*. The genus *Trueperella*, thus far, exhibits MK-10(H_4) as major menaquinone in addition to minor amount of MK-9(H_4). Species of the genus *Actinobaculum* differ from other genera of the *Actinomycetaceae* by their conspicuous lack of respiratory quinones.

A variety of phospholipid classes have been identified in members of the family *Actinomycetaceae*. For instance, diphosphatidylglycerol or cardiolipin (DPG) was found almost entirely in all members of the family. Generally, phosphatidylglycerol (PG), phosphatidylcholine (PC), phosphatidylinositol (PI), and phosphatidylinositol mannosides (PIMs) are variably distributed. The occurrence of phosphoglycolipids (PGL) is limited to the genus *Trueperella* (Yassin et al. 2011) and *Actinomyces naturae* (Rao et al. 2012). Noteworthy is the absence of phosphatidylethanolamine (PE) and monomethylphosphatidylethanolamines (PMME) and dimethylphosphatidylethanolamines (PDME). Of interest, members of the genus *Actinobaculum* are characterized by the presence of a choline-containing phosphoglycolipid resembling the compound isolated from *Mycoplasma fermentans*. However, the exact chemical structure and function of this compound remains obscure.

The cellular fatty acid profiles of the genera of *Actinomycetaceae* are very similar to each other and contain saturated normal and monounsaturated fatty acids from 12 to 20 carbon atoms. Striking, however, is the presence of one or two types of major fatty acids, which account for 60–90 % of the fatty acid mass. In particular, the dominant fatty acids are 18:1ω9c (accounting for 50–60 % of total fatty acids) and 16:0 (accounting for 12–18 % of total fatty acids). Traces of diunsaturated fatty acid 18:2 ω6,9c, *iso*-branched, and *anteiso*-branched fatty acids vary.

The following sugars were found as common constituents of the whole-cell hydrolysates of members of the family *Actinomycetaceae*: fucose, galactose, glucose, mannose, rhamnose, and 6-deoxytalose. However, differences in the cell wall sugar composition were observed in whole-cell hydrolysates of the different genera. Thus, the predominating cell wall sugar liberated from the whole-cell hydrolysate of *Varibaculum* is galactose, while galactose and rhamnose are the characteristic sugars released from the whole-cell hydrolysates of member of the genus *Mobiluncus*. The cell wall sugars of members of the genera *Arcanobacterium* and *Trueperella* are virtually identical, containing rhamnose and glucose. Species of the genus *Actinobaculum* are characterized by the presence of glucose, rhamnose, and 6-deoxytalose (except for *Actinobaculum suis* which do not contain 6-deoxytalose). In contrast, marked differences in the composition of cell wall sugars were observed between *Actinomyces* species. For instance, the cell wall sugars of *Actinomyces bovis* consists of glucose, mannose, rhamnose, and 6-deoxytalose, whereas the cell wall sugars of *A. meyeri* consists of galactose, glucose, mannose, fucose, and rhamnose and the cell wall sugars of *A. georgiae* consists of only galactose.

Thus, also the chemotaxonomic patterns that emerge strongly suggest that the genus *Actinomyces* is heterogenous and that some *Actinomyces* species should be excluded from the genus, even constituting the nuclei of new genera. In addition, certain variations concerning the peptidoglycan structure and cell wall sugars have been observed between *Actinobaculum suis* and the remaining members of the genus *Actinobaculum*. Apart from the genera *Actinomyces* and *Actinobaculum*, the distribution of a combined set of chemical markers have been considered typical for delineating the genera *Arcanobacterium*, *Trueperella*, *Mobiluncus*, and *Varibaculum*.

Isolation, Enrichment, and Maintenance Procedures

Most species of the genera of the *Actinomycetaceae* have been isolated from human and veterinary clinical materials. They are generally considered to be opportunistic pathogens, which seldom recovered as single isolates but found in association with other bacteria. The ability to isolate and distinguish these bacteria and to determine their sensitivity to antibiotics, could greatly assist treatment of diseases in which they are involved. The successful isolation of members of the *Actinomycetaceae* from clinical materials and environment depend on several factors such as oxygen requirements, incubation temperature, pH and provision of suitable medium. Members of the family vary considerably with respect to their oxygen requiremnets. Some are considered strict anaerobe growing well in the obsence of oxygen, while others are considered facultative anaerobe grown in an atmosphere containing 5%CO_2. The nutritional requirements of species within the family have been very little studied, and therefore, it is difficult to make generalization of the nutritional requirements. However, it is recommended that a combination of different media be used to maximize recovery rates from clinical materials.

Sampling Techniques

The specimens of choice for the isolation and enumeration of strains belonging to the genera *Actinobaculum*, *Actinomyces*, *Arcanobacterium*, *Mobiluncus*, *Trueperella*, and *Varibaculum* include deep-needle aspirates, draining sinus, body fluids, and

biopsy specimens. Inappropriate specimens for isolation of *Actinomyces* species include swabs, sputum, and urine. During sampling, precautions must be taken to avoid contamination with normal flora from skin or other body sources that may be introduced into the sample. An effective means of collecting material for microbiological examination is the use of fine-needle aspiration (Hong et al. 1993; Vera-Alvarez et al. 1993). Although some species are facultative anaerobes, samples obtained from sites of infection should be treated as anaerobic and exposure to atmospheric oxygen should be avoided to optimize recovery rates.

Transport Media

The most important parameter in the successful isolation of species of the genera *Actinobaculum*, *Actinomyces*, *Arcanobacterium*, *Mobiluncus*, *Trueperella*, and *Varibaculum* is minimizing the time between specimen collection and the incubation of the inoculated media. Therefore, prompt transport of clinical specimens to the microbiology laboratory is necessary for optimal isolation. In addition, techniques for collection and transport of clinical specimens should maintain anaerobiosis to enable satisfactory recovery of these anaerobic bacteria. The transport medium should also preserve the organisms at the same level and in the same properties they had at the sampling. To fulfil these requirements the transport medium should have low nutrients contents, no inhibitory factors, low oxidation–reduction potential, and physiological pH. Adequate transport media are commercially available, e.g., Port-A-Cul (Becton–Dickinson) and Portagerm (bioMérieux) which should be used according to the manufacturer's instructions. Apart from the commercially available media, a considerable variety of transport and culture materials have been designed for use in the clinical laboratory. Möller (1966) described a transport medium (VMG) which he found superior for demonstrating streptococci and anaerobic nonsporulating bacteria in endodontic sample. In contrast to non-nutrient transport medium such as Stuart medium, VMG contains ingredients which support growth and a bacteriostatic agent.

Formula of VMG II Medium (Möller 1966)

Part a	
Agar	0.1 g
Aq. dest.	900 mL

Dissolve the agar in distilled water by boiling.

Part b	
Salt stock solution II	
Phenylmercuric acetate	0.03 g
$CaCl_2 \cdot 6H_2O$	2.4 g
KC1	4.2 g

Part b	
NaCl	10.0 g
$MgSO_4 \cdot 7H_2O$	1.0 g
Sodium glycerophosphate	100.0 g
Distilled water	1,000 mL

Dissolve phenylmercuric acetate in about 800 mL of distilled water by gentle heating. Then add the other salts. Make up to volume with distilled water. Store at room temperature.

Part c	
Bacto-gelatin	10.0 g
Tryptose	0.5 g
Thiotone	0.5 g
Cysteine hydrochloride	0.5 g
Thioglycolic acid	0.5 mL
Bacteriological charcoal (Oxoid)	10.0 g
Stock salt solution II	100 mL

Dissolve the ingredients of part (c) in part (a) after cooling the latter to approximately 50 °C. Add part (b) and adjust pH to 7.5 with 1 M sodium hydroxide. Dispense in screw cap vials or small test tubes and autoclave at 121 °C for 20 min. Store at room temperature.

SBL Medium

This medium was designed by Gästrin et al. (1968) and recommended as a suitable transport medium in different types of bacteriological examinations.

Formula of SBL Medium (Gästrin et al. 1968)

Bacto agar	8–10 g
Thioglycolic acid	0.5 mL
Sodium glycerophosphate	10.0 g
$CaCl_2$ (1 % in H_2O)	10.0 mL
Cysteine hydrochloride	0.025 g
Methylene blue (0.1 % in H_2O)	2.0 mL
Distilled water	950 mL
pH	7.2

Reduced Transport Fluid (RTF) Medium

This medium was designed by Syed and Loesche (1972) for the transport and storage of oral specimens. This medium should best maintain the viability of microorganisms present within a clinical specimen at refrigeration temperature.

Formula of RTF Medium (Syed and Loesche 1972)

Mineral Salt Solution No. 1	
K_2HPO_4	0.6 %
Mineral Salt Solution No. 2	
NaCl	1.2 %
$(NH_4)_2SO_4$	1.2 %
KH_2PO_4	0.6 %
$MgSO_4$	0.25 %
Complete RTF Medium	
Stock solution no.1	75.0 mL
Stock solution no. 2	75.0 mL
0.1 M EDTA	10.0 mL
8 % Na_2CO_3	8.0 mL
1 % dithiothreitol (freshly prepared)	20.0 mL
0.1 % Resazurin (optional)	1.0 mL
Distilled water	814 mL

This medium was filter-sterilized by using a membrane filter (0.22 µm pore size) and dispensed into screw cap tubes. The pH of this medium was 8 ± 0.2 without adjustment, and it decreased to 7 after 48 h incubation in anaerobic atmosphere (85 % N_2, 10 % H_2, and 5 % CO_2).

General-Purpose Culture Media

For the recovery of *Actinomycetaceae*, several general-purpose media have been recommended and are usually satisfactory for primary isolation and subsequent cultivation from clinical specimens and from natural habitats. It is recommended to use several types of media supplemented with sheep, horse, or human blood. These media include fluid thioglycollate broth (THIO), possibly supplemented with 0.1–0.2 % sterile rabbit serum; peptone-yeast extract-glucose broth or agar (PYG, PYGA); Brain Heart Infusion broth or agar (BHIB, BHIA); Trypticase soy broth or agar (TSB, TSA); heart infusion agar or TSA or Columbia agar supplemented with 5 % defibrinated rabbit, sheep, or horse blood; Chocolate agar; Schaedler broth or agar (Slack and Gerencser 1975; Schaal and Pulverer 1981); Fastidious Anaerobe Agar (FAA) supplemented with 5 % horse blood; plate count agar (PCA); and CC-medium (Heinrich and Korth 1967). Generally, enhanced growth occurs under anaerobic conditions. Some strains may also grow well in an atmosphere containing 5 % CO_2 and others may grow poorly in ambient air. The optimum growth temperatures range between 35 °C and 37 °C. Colonies may appear after 3–7 days of incubation.

Methods for Reducing Oxygen Tension

In addition to appropriate media, successful isolation of members of the genera *Actinobaculum*, *Actinomyces*, *Arcanobacterium*, *Mobiluncus*, *Trueperella*, and *Varibaculum* requires an atmosphere of reduced oxygen and increased carbon dioxide concentrations (microaerophilic environment). Numerous methods, which do not necessitate the use of conventional anaerobic equipment, have been devised to provide this appropriate atmosphere. These include the use of candle jar, the use of the anaerobic jar technique such as the commercially available GasPak BBL Microbiology Systems, and the use of a method that apply the Fortner principle (Fortner 1928) of oxygen consumption by microorganisms in culture. The latter method is a simple biological technique for reducing oxygen tension, based on the Fortner principle which utilizes the ability of a rapidly growing facultative anaerobe to reduce the oxygen tension in a closed system, thus making possible the growth of oxygen-sensitive organisms. In this method the agar medium poured into a glass Petri dish and one-third of the plate was streaked with *Serratia marcescens*, and the left part of the plate was inoculated with the clinical material or with a pure culture of an anaerobic organism such as *Actinomyces* species. The plate was then covered with a sterile glass top and sealed with plasticine and incubated at 37 °C for at least 4 days.

Isolation of *Actinomyces* Species

Since most of the clinical specimens used for isolation are either from the mouth or from the female genital tract, the profuse commensal flora present make the isolation and recognition of *Actinomyces* spp. laborious. Therefore, sampling techniques that avoid contamination of the samples with normal microbiota and culturing media which appear to optimize the recovery of *Actinomyces* are recommended.

Processing of Samples

Plaque samples or pus were resuspended by being shaken in small screw-capped vials containing 1.0–2.0 mL of a reduced transport medium (RTF) (Syed and Loesche 1972) or Fastidious Anaerobe Broth (FAB) (LAB071) and sterile glass beads (diameter: 1–4 mm). The samples were vortexed for 15 s to disperse bacterial aggregates and to facilitate the extraction of bacteria from infected dentin tissue. Serial tenfold dilutions were made in MI broth (Boue et al. 1987) containing, per liter, biotrypcase, 10 g; neopeptone, 5 g; yeast extract, 1 g; NaCl, 5 g; sodium thioglycollate, 0.5 g; and 3-(*N*-Morpholino) propanesulfonic acid (MOPS), 2.5 g. The pH was adjusted to 7.0 and 100 µl aliquots of appropriate dilutions were spread onto a range of culture media.

In the same manner intrauterine contraceptive device (IUCD) was soaked in 15 mL of Brewer's modified thioglycollate broth (BD, 11716) or Brain Heart Infusion (BHI) broth (CM225, Oxoid) or FAB for 30 min. The broth was vortexed for 15 s and diluted. 100 µl aliquot was inoculated on to each of the following pre-reduced culture media: Columbia agar (CM0331, Oxoid)

supplemented with 5 % defibrinated horse blood, Columbia agar supplemented with 5 % defibrinated horse blood and gentamicin (14 mg/L), Mupirocin–metronidazole blood agar (MMBA, see below for composition), and Schaedler K-V agar with 5 % sheep blood (221556, BD). Columbia blood agar and MacConkey agar (CM7, Oxoid) were similarly inoculated and incubated in air plus 5 % CO_2 for 24–48 h. Similarly endocervical swabs collected from women with pelvic inflammatory disease (PID) are processed.

Media for Isolation and Subsequent Cultivation of *Actinomyces*

The isolation and enumeration of oral *Actinomyces* from dental plaque has previously been possible only when they represented a major component of the plaque flora. They have been isolated under relatively nonselective conditions, on infusion medium alone (Pine and Watson 1959), or on infusion medium supplemented with blood or serum (Sykes and Skinner 1973). However, from the large number of media available, it can be concluded that there is no standard medium for the detection of *Actinomyces*. In addition to the general-purpose media enriched with blood or serum, other media without blood such as CC-medium (Heinrich and Korth 1967) and Tarozzi's liver broth have been used for the isolation and cultivation of *Actinomyces* from the mouth and actinomycotic lesions.

Formula of CC-Medium (Heinrich and Korth 1967)

Sol. I Mineral and trace element solution	
$MgSO_4 \cdot 7H_2O$	20.0 g
$CaCl_2 \cdot 2H_2O$	2.0 g
$FeSO_4 \cdot 7H_2O$	0.4 g
$MnSO_4 \cdot 2H_2O$	15.0 mg
$Na_2MoO_4 \cdot 2H_2O$	15.0 mg
ZnSO4	4.0 mg
$CuSO_4 \cdot 5H_2O$	0.4 mg
$CoCl_2 \cdot 4H_2O$	0.4 mg
Boric acid	20.0 mg
Potassium iodide	10.0 mg

Dissolve in 1 L of distilled water and acidify with 10 mL of 10 % HCl.

Sol. II Vitamin Solution	
Thiamine HCl	20.0 mg
Pyridoxine HCl	20.0 mg
Biotin	1.0 mg
Folic acid	5.0 mg
Vitamin B_{12} (1 mg/100 mL)	1.0 mL
p-Aminobenzoic acid	20.0 mg

Sol. II Vitamin Solution	
myo-Inositol	20.0 mg
Nicotinamide	10.0 mg
Nicotinic acid	10.0 mg
Ca-Pantothenate	20.0 mg

Dissolve in 100 mL of distilled water.

Sol. III Amino Acid + Vitamin Solution	
Casein hydrolysate	12.0 g
Yeast extract	12.0 g
L-Cysteine HCl	500.0 mg
L-Asparagine	30.0 mg
DL-Tryptophan	20.0 mg
Sol. II (vitamin solution)	12.0 mL

Final CC-Medium

Dissolve 4.0 g of KH_2PO_4 in 250 mL of distilled water and adjust to pH 7.3 with NaOH. Add 10 mL of Sol. I, 500 mg of potato starch dissolved in 70 mL of boiling distilled water, about 20 g of agar (depending on quality), and distilled water to give a final volume of 900 mL. Sterilize by autoclaving at 121 °C for 15 min. After cooling to about 50 °C, add Sol. III under aseptic conditions. Adjust the final pH to 7.3. Pour the medium into glass Petri dishes.

Formula of Tarozzi's Liver Broth

Fresh beef liver	300.0 g
Bacto peptone	12.0 g
NaCl	3.0 g
K_2HPO_4	2.0 g
Distilled water	1,000 mL
pH	7.8

Firstly skin the liver and then boil in 1 L of distilled water for ca. 1 h. Cut the boiled liver into pieces measuring approximately 2 × 1 × 1 cm and distribute into test tubes (1 piece per tube). Dissolve the medium ingredient in the water used for boiling the liver and dispend 8 mL of the medium to each tube. Sterilize by autoclaving at 121 °C for 15 min. Inoculate when cool and then aseptically seal with a layer of sterile paraffin wax or with liquid Vaseline. Colonies growing on the surface of the liver slices appear cottony and white. This medium is also recommended for the short-term preservation of *Actinomyces* in the laboratory.

Partially Selective Culture Media

The isolation and enumeration of *Actinomyces* from dental plaque and actinomycotic lesions may be influenced by the presence of other microorganisms, particularly the acidogenic oral streptococci and other Gram-negative bacteria. The influence of

sodium fluoride on the growth and viability of streptococci was demonstrated by Bibby and van Kesteren (1940). They found that sodium fluoride at concentration >100 p.m. in medium exerted a bactericidal effect on streptococci. The observation that sodium fluoride at a concentration ≥250 μg/mL inhibits the growth of all commensal oral streptococci whereas all oral *Actinomycetaceae*, except for *Propionibacterium proprionicum*, grew without any or with only minimal inhibition (Beighton and Colman 1976) and that colistin has bactericidal activity against most Gram-negative bacteria without affecting the growth of Gram-positive bacteria (Garrod and O'Grady 1971) enabled the formulation of several media for selective isolation of *Actinomyces* species from clinical samples. Therefore, the strategy of choice was the use of selective media that simultaneously enable the proliferation of *Actinomyces* but inhibit the growth of oral streptococci and other interfering bacteria.

Several chemical agents, in varying concentrations, have been shown to suppress the growth of oral streptococci and a variety of Gram-positive and Gram-negative interfering bacteria but allow substantial proliferation of *Actinomyces* species. In particular, cadmium compounds, tellurite compounds, and flavine dyes have been used alone or in combinations. The ability of these substances to increase significantly the antimicrobial effect of many antibiotics has led to heightened interest in the formulation of selective media for improved recovery of *Actinomyces* species from dental plaque and actinomycotic lesions. However, these media are only partially selective as they may be inhibitory to some strains of *Actinomyces*.

CNAC-20 Medium (Ellen and Balcerzak-Raczkowski, 1975)

CNAC-20 is a partially selective medium based on Columbia CNA agar base supplemented with cadmium sulfate for detecting colonies of *Actinomyces viscosus* and *Actinomyces naeslundii* in dental plaque samples. The addition of the antimicrobial agents, colistin, and nalidixic acid renders the medium selective for Gram-positive microorganisms, especially streptococci and staphylococci, while they inhibit the growth of *Enterobacteriaceae* and *Pseudomonas*. Cadmium sulfate is added in a concentration sufficient to inhibit substantially full growth of many strains of dental plaque streptococci but insufficient to inhibit the growth of *A. viscosus* and *A. naeslundii* (Ellen and Balcerzak-Raczkowski 1975). Strains of *A. viscosus*, *A. naeslundii*, and *A. israelii* grew on CNAC-20 in characteristic round, white, smooth, and opaque colonies.

Formula of CNAC-20	
Columbia CNA agar base (BBL)	42.5 g
$3CdSO_4.8H_20$	20.0 mg
Distilled water	1,000 mL

Suspend 42.5 g of Columbia CNA agar base (BBL Cat. No. 212104) in 1 L distilled water. Sterilize by autoclaving at 121 °C for 12 min. Cool to 45–50 °C and add aseptically 50.0 mL sterile defibrinated sheep blood. Alternatively the medium could be prepared from the ingredients as follows:

Ingredient per 1 L distilled water	
Peptone from casein	12.0 g
Peptone from meat	5.0 g
Yeast extract	5.0 g
Beef extract	3.0 g
Corn starch	1.0 g
Sodium chloride	5.0 g
Agar	15.0 g
Colistin	10.0 mg
Nalidixic acid	10.0 mg
$3CdSO_4{\cdot}8H_2O$	20.0 mg
Final pH	7.3 ± 0.2 at 25 °C

Sterilize in autoclave at 121 °C for 15 min. Cool to 50 °C and add aseptically 50.0 mL sterile defibrinated sheep blood.

Plates containing the CNAC-20 medium are incubated at 35 °C in 90 % air and 10 % CO2 to stimulate the growth of the microaerophilic species *A. viscosus* and *A. naeslundii* while impairing the growth of anaerobic A*ctinomyces* species and other Gram-positive bacteria, which prefer anaerobic conditions for primary isolation.

BYS Medium (Beighton and Colman 1976)

This medium was employed by Beighton and Colman (1976) for the isolation of *Actinomyces* from dental plaque. The inclusion of sodium fluoride (NaF) and colistin sulfate as selective agents enabled an increase in proportion of *Actinomyces* species recovered from dental plaque in the presence of small count of other oral flora. The medium composed of two parts, a basal culture medium (BYS medium) and enrichment medium (FS medium) for supplementation of the BYS medium.

Formula of BYS medium	
Brain Heart Infusion	37.0 g
Yeast extract	5.0 g
Polyvinylpyrrolidone	10.0 g
Cysteine HCl	1.0 g
Agar	15.0 g
Distilled water	1,000 mL

After sterilization at 121 °C for 15 min, the medium was cooled to 50 °C and 50.0 mL of sterile horse serum was added.

Formula of FS medium	
NaF solution	25.0 mg/mL
Colistin sulfate solution	1.0 mg/mL

The solutions are sterilized separately by autoclaving at 121 °C for 15 min.

The complete medium was prepared by aseptically adding 10.0 mL of a NaF solution plus 5.0 mL of colistin sulfate solution to 1,000 mL of sterile BYS medium.

Modification of FS Medium (Boue et al. 1987)

The selectivity of the medium designed by Beighton and Colman (1976) for the recovery of *Actinomyces* from dental plaque was further improved by the following modification of the FS medium as proposed by Boue et al. (1987):

Formula of modified FS medium	
NaF	100 μg/mL
Cadmium sulfate	20 μg/mL
Polymyxin	20 μg/mL
Oxolinic acid	30 μg/mL
Nystatin	30 μg/mL

Cadmium Sulfate Fluoride Acridine Trypticase (CFAT) Agar (Zylber and Jordan 1982)

CFAT medium was developed by Zylber and Jordan (1982) for the detection and selective isolation of *Actinomyces naeslundii* and *Actinomyces viscosus* from dental plaque. The medium contains neutral acriflavin and potassium tellurite in combination with the selective agents cadmium and fluoride to eliminate most of the competing plaque flora. Colonies of *Actinomyces* spp. appear cream to slightly greenish in color, entire edged, convex or raised, and opaque on this medium.

Formula per Liter of CFAT	
Tryptic soy broth	30.0 g
Glucose	5.0 g
Agar	15.0 g
Cadmium sulfate	13.0 mg
Sodium fluoride	80.0 mg
Neutral acriflavin	1.20 mg
Potassium tellurite	2.50 mg
Basic fuchsin	0.25 mg
Defibrinated sheep blood	50.0 mL
Distilled water	1000.0 mL
Final pH	7.0 ± 0.2

GMC Medium (Kornman and Loesche 1978)

GMC is a gelatin-based medium containing metronidazole (10 μg/mL) and cadmium sulfate (20 μg/mL) for selective isolation of *Actinomyces* species from dental plaque samples. Metronidazole was chosen as the primary selective agent which is relatively ineffective in vitro against most microaerophilic *Actinomyces* species but inhibits the growth of many anaerobic species in vitro. The combination of metronidazole and cadmium sulfate effectively suppressed anaerobes and facultative Gram-positive cocci while allowing good recovery of the microaerophilic *A. viscosus* and *A. naeslundii* strains. The addition of gelatin to the GMC medium allows differentiation of catalase-positive, gelatinase-positive organisms, e.g., propionibacteria, which might otherwise be confused with *A. viscosus*.

Formula of GMC	
Agar	15.0 g
Trypticase (BBL)	10.0 g
Gelatin	30.0 g
Sodium acetate	1.0 g
Sodium formate	1.0 g
Sodium lactate (60 %)	5.0 mL
Sodium succinate	1.0 g
Yeast extract (Difco)	1.0 g
Sodium chloride	2.0 g
Glucose	1.0 g
D-Mannitol	1.0 g
Potassium nitrate	0.5 g
$3CdSO_4 \cdot 8H_2O$	20.0 mg
Distilled water	874 mL
Final pH	7.2 ± 0.1

After sterilization at 121 °C for 15 min, the medium was cooled to 50 °C and added aseptically with the filter-sterilized solution containing the following ingredients:

Menadione (0.05 % stock solution)[a]	2.0 mL in the refrigerator
Dithiothreitol	0.1 g
Sucrose	0.5 g
Cysteine hydrochloride	0.5 g
Sodium phosphate dibasic	1.0 g
Sodium carbonate (anhydrous)	0.5 g
Distilled water	50 mL

[a]Prepared in 50 % ethanol in distilled water; filter-sterilized and stored in an amber glass bottle in the refrigerator.

Finally, add 1.0 mL of filter-sterilized metronidazole solution (0.5 g in 50.0 mL distilled water).

Columbia Agar Base Supplemented with Metronidazole (Traynor et al. 1981)

Traynor et al. (1981) described CBA containing 2.5 mg/L of metronidazole for the isolation of *Actinomyces* spp. from cervical specimens of women using IUCDs. Although the isolation rate of *Actinomyces* species was significantly increased, it should be noted that a time-consuming serial dilution technique of a kind not commonly used for routine specimens was used to remove competing flora from the primary inoculum prepared by soaking the specimens in thioglycollate broth.

Formula of CBA-metronidazole	
Columbia agar base (Oxoid CM0331)	39.0 g
Metronidazole	2.5 mg
Distilled water	1,000 mL
pH	7.3 ± 0.2 at 25 °C

Dissolve 39.0 g of Columbia agar in 1 L of distilled water. Boil to dissolve the medium completely. Sterilize by autoclaving at 121 °C for 15 min. Cool to 50 °C and add 5 % sterile defibrinated horse blood. Add the corresponding amount of filter-sterilized metronidazole.

Mupirocin–Metronidazole Blood Agar (MMBA) (Lewis et al. 1995)
A selective culture medium contains two antibiotics, mupirocin (pseudomonic acid) and metronidazole, which are inhibitory for most overgrowing competing microorganisms found in dental plaque, cervical specimens from women using IUDs, and other medical specimens (Lewis et al. 1995). Mupirocin inhibits the growth of staphylococci, streptococci, *Haemophilus*, *Neisseria*, *Enterococcus*, *Escherichia coli*, and other enterobacteria, while metronidazole at a concentration of 2.5–5.0 mg/L inhibits most of the obligate anaerobes found in clinical material with only the genera *Actinomyces*, *Bifidobacterium*, and *Propionibacterium* being regularly resistant.

Formula of MMBA medium	
Columbia agar base (Oxoid CM0331)	39.0 g
Mupirocin	128.0 mg
Metronidazole	2.5 mg
Distilled water	1,000 mL
pH	7.3 ± 0.2 at 25 °C

Dissolve 39.0 g of Columbia agar in 1 L of distilled water. Boil to dissolve the medium completely. Sterilize by autoclaving at 121 °C for 15 min. Cool to 50 °C and add 5 % sterile defibrinated horse blood. Add the corresponding amount of filter-sterilized mupirocin and metronidazole.

Media for Isolation of *Actinomyces* from Environmental Sources

For the isolation of *Actinomyces* species from oil-contaminated groundwater or oil-contaminated soils, the samples are serially diluted with distilled water, and 500 mL aliquots were spread on R2A plates or plate count agar (PCA, Difco Nr. 247940) or peptone/yeast extract/fructose (PYF) solidified with 15.0 g agar/L. According to Bowman et al. (2006), the R2A agar was supplemented with 1.0 mg/L resazurin (as a redox indicator) and 0.25 g/L-cysteine hydrochloride (as a reducing agent) and buffered at pH 5.0 with 20 mM acetate buffer prior to solidification with agar. All plates were incubated at 30 °C. Anaerobic plates were incubated in an anaerobic chamber supplied with gas comprised 90 % N_2, 5 % CO_2, and 5 % H_2.

Formula of supplemented R2A agar (Bowman et al. 2006)	
Yeast extract	0.5 g
Proteose peptone (Difco)	0.5 g
Casamino acids	0.5 g
Cysteine hydrochloride	0.25 g
Glucose	0.5 g
Soluble starch	0.5 g
Sodium pyruvate	0.3 g
K_2HPO_4	0.3 g
$MgSO_4 \cdot 7H_2O$	0.05 g
Resazurin	1.0 mg
Distilled water	1,000 mL
Agar	15.0 g
pH	5.0

Alternatively suspend 18.2 g of R2A agar (BD, Nr. 218263) in one liter of distilled water. Mix thoroughly and then add 1.0 mg/L resazurin and 0.25 g/L-cysteine hydrochloride. Sterilize by autoclaving at 121 °C for 15 min. Cool to 50 °C and adjust to pH 5.0 with 20 mM acetate buffer.

Formula of PYF medium (Engelmann and Weis 1985)	
Peptone	5.0 g
Tryptone	5.0 g
Yeast extract	10.0 g
Fructose	5.0 g
Na_2HPO_4	2.0 g
Tween 80	1.0 mL
Cysteine HCl	0.5 g
Distilled water	1,000 mL
Agar	15.0 g
Adjust pH to 7.0	

Isolation of *Arcanobacterium* Species

For primary isolation, complex media such as Columbia blood agar supplemented with 5 % horse, sheep, or human blood, BHI broth (or agar), or Trypticase soy broth (or agar) have been recommended and are usually satisfactory. *A. haemolyticum* and *A. hippocoleae* are more difficult to grow in liquid media. However, addition of serum may enhance growth of *A. haemolyticum* considerably. Thus, a suitable liquid medium for *A. haemolyticum* consists of BHI broth supplemented with 5 % horse serum (Collins and Cummins 1986). All of the other *Arcanobacterium* species apparently grow well on Columbia blood agar supplemented with 5 % horse or sheep blood and incubated under increased CO_2 tension (~5 %) at 36 ± 1 °C.

Recognition of *A. haemolyticum* in cultures from clinical specimens is often hampered by its delayed β-hemolysis and

the presence of additional pathogens (e.g., streptococci) or microbes from the indigenous flora of the affected mucous membranes. Thus, media for selective isolation or improved recognition of this organism were developed. A selective medium that greatly reduces the growth of commensal organisms and permitting easier recognition of *A. haemolyticum* was used by (Brenwald et al. 1990). This medium consisted of a blood agar base (Oxoid No 2) containing 5 % horse blood, 8 mg/L mupirocin, 4 mg/L aztreonam, and 1 mg/L amphotericin B. Mupirocin is highly active against commensal staphylococci and streptococci, whereas aztreonam and amphotericin B were used to inhibit the growth of Gram-negative bacteria and yeasts, respectively. Cummings et al. (1993) found that medium and atmosphere had measurable effects on the colonial and beta-hemolysis of *A. haemolyticum*. They tested Trypticase soy agar, Columbia agar, and heart infusion agar containing 5 % sheep blood, and cultures were incubated in ambient air, 6–8 % CO_2 for 24, 48, and 72 h of incubation times. They found that Trypticase soy agar was the superior medium and CO_2 was the superior atmosphere for beta-hemolysis. A minimum of 48 h was needed for expression of beta-hemolysis and pitting. Agar pitting was not significantly affected by variations in medium or atmosphere. Anaerobic incubation produces the smallest *A. haemolyticum* colonies and zones of hemolysis. Coman et al. (1996) used a medium containing 5 % sheep blood agar and 3.5 % NaCl for selective isolation of *A. haemolyticum* from pharyngeal swabs of children. Jurankova and Votava (2001) applied sheep blood agar with a streak of *Staphylococcus aureus* to recognize *A. haemolyticum* on the basis of the reverse CAMP (Christie, Atkins, and Munch-Petersen) phenomenon. The medium of Votava et al. (2000) containing Columbia blood agar base and 5 % washed sheep erythrocytes sensitized with equi factor (EF) of *Rhodococcus equi* is based upon the same principle.

Isolation of *Trueperella* Species

For isolation of *Trueperella* species from clinical specimens, it is recommended to use several types of media such as Columbia agar supplemented with 5 % sheep or horse blood, Chocolate agar, Brucella agar with 5 % sheep blood, *Brucella* lacked blood agar with kanamycin–vancomycin, and Phenylethyl alcohol agar with 5 % sheep blood. Growth is much enhanced by the addition of 1 % Tween 80 to nutrient agar or BHI agar. Good growth occurs under aerobic and strictly anaerobic conditions, but optimal growth is obtained in a 5–10 % CO_2-enriched atmosphere. The optimum temperature for growth is 37 °C and the temperature range of growth is from 20 °C to 40 °C.

The nutritional requirements of *Trueperella pyogenes* have been investigated by several authors (Reddy et al. 1977, 1980, 1982; Fraga and Reddy 1982). For these purposes they used semidefined (SDM) and chemically defined (CDM) media. They reported that the addition of hemin greatly increased the growth of *T. pyogenes* strains. All *T. pyogenes* strains showed an obligate requirement for CO_2/HCO_3^- for their growth. Peptides are required for growth even in the presence of a complete complement of 20 amino acids and $(NH_4)_2SO_4$. Inositol can replace the peptide requirement for growth. Furthermore, *T. pyogenes* strains require a fermentable carbohydrate for growth. All strains required riboflavin and nicotinic acid and most require adenine and uracil for optimal growth.

Isolation of *Actinobaculum* Species

Actinobaculum species are slow growing, obligate anaerobe requiring enriched culture media that contain blood or blood product for their isolation from clinical materials. Attempts to grow *A. suis* aerobically or under 10 % CO_2 were unsuccessful (Soltys 1961). The nutritional requirements and metabolic features of *A. suis* were studied by Wegienek and Reddy (1982). They employed a peptone–yeast extract–starch (PYS) medium which support optimal growth of *A. suis* and containing Trypticase, yeast extract, starch, minerals, cysteine, and sodium carbonate. The replacement of starch in PYS medium with maltose resulted in decreased growth, while the deletion of starch or maltose from the medium resulted in no growth of the organism, indicating that a fermentable carbohydrate is required for growth of *A. suis*. Deletion of Na_2CO_3 from PYS led to approximately 20 % decrease in growth. This suggests that *A. suis* fixes CO_2 released during the metabolism of starch or maltose and uses it for biosynthetic purposes such as production of acetate. The deletion of only yeast extract from PYS resulted in about 75 % decrease in growth but growth inhibited by the simultaneous deletion of yeast extract and Trypticase. Supplementation of a defined mixture of purine and pyrimidine bases, vitamins, and amino acids to PYS minus yeast extract effectively replaces yeast extract. Vitamins are essential for growth of *A. suis*. A mixture of pyridoxal, riboflavin, and nicotinic acid stimulates growth comparable to that obtained in the medium with the full complement of all 10 vitamins. Purine and pyrimidine bases are required for optimal growth. The deletion of Trypticase resulted in negligible growth even in the presence of amino acids, suggesting a peptide(s) in Trypticase is a requirement for the growth of *A. suis*.

The nutritional requirements of *Actinobaculum* species associated with human diseases, *A. massiliense*, *A. schaalii*, and *A. urinale*, are not known in detail. Media commonly used for cultivation include 5 % Columbia sheep blood agar, 5 % and 10 % horse blood agar, Chocolate agar, *Brucella* blood agar with hemin and vitamin K1 (BD), nutrient agar, and semisolid agar containing pepsin blood and thioglycollate. Generally, they require 3 days to produce good growth in an anaerobic atmosphere at 35 °C but grow poorly in air with 5 % CO_2 and not at all in ambient air. The selective use of anaerobic blood cultures, e.g., Bactec Lytic Anaerobic/F bottle, is useful for isolation of *Actinobaculum* from the blood of infected patients. Unlike *A. suis*, enhanced growth of *A. massiliense*, *A. schaalii*, and *A. urinale* is obtained in BHI broth supplemented with 1 % Tween 80 (Yassin unpublished).

Isolation of *Varibaculum* Species

Varibaculum cambriense requires enriched culture media such as Columbia agar or Fastidious Anaerobe Agar (LabM, Bury, United Kingdom) supplemented with 5 % horse blood or Chocolate agar for cultivation. Good growth was obtained under anaerobic conditions or in an atmosphere containing 5% CO_2 after 3–7 days incubation at 37 °C.

Isolation of *Mobiluncus* Species

Mobiluncus species are strict anaerobes and are extremely fastidious, requiring fresh moist media and extended anaerobic incubation for multiplication. The fastidious nature of these organisms has greatly impeded their recovery form vaginal fluid by conventional culture techniques (Spiegel et al. 1983b; Hjelm et al. 1984; Holst et al. 1984a). Because of the difficulty in isolating these organisms by culture, most researchers attempting to define the prevalence of this organism have used direct techniques such as Gram stain, wet smear, direct staining with monoclonal antibodies, or DNA probes. However these procedures may also detect other motile bacteria unrelated to the curved rods. Therefore, it was important to find a means of isolating *Mobiluncus* spp. selectively in primary culture, a difficult task because the anaerobic flora of the vagina is profuse (10^{12} bacteria/g of secretion). Approaches to this objective have concentrated on attempts to inhibit the growth of other more rapidly growing bacteria present in vaginal specimens by using antibiotics and other agents in solid media (Durieux and Dublanchet 1981; Holst et al. 1984a; Thomason et al. 1984a), alkaline pretreatment (Påhlson and Forsum 1985; Påhlson et al. 1986), and cold enrichment (Smith and Moore 1988) to improve the rate of recovery.

Nonselective Solid and Liquid Culture Media

Several commercial nonselective solid media were reported for recovery of *Mobiluncus* from clinical specimens. However, these media vary in their ability to support growth of fresh clinical isolates (Smith and Moore 1988). These include Columbia agar, Brain Heart Infusion agar, brucella agar, Chocolate agar, DST agar, peptone–yeast extract–glucose agar, Schaedler agar, and Trypticase soy agar (Vetere et al. 1987; Smith and Moore 1988; Spiegel 1992). An addition of 4–15 % horse, human, sheep, or rabbit blood enhances growth. A supplementation of culture media with one of the potential growth factors arginine-free base, sodium hippurate, sodium formate, sodium fumarate, bovine serum, and campylobacter growth supplement-FBP, however, did not result in any significant improvement of growth (Vetere et al. 1987; Thomason et al. 1984a; Taylor-Robinson and Taylor-Robinson 2002). From the 12 liquid culture media evaluated by Taylor-Robinson and Taylor-Robinson (2002), only Columbia blood broth (CBB) and peptone–starch–dextrose (PSD) supplemented with 10 % horse serum supported the growth of some strains of *Mobiluncus curtisii* and *Mobiluncus Mulieris* to 10^9 organisms/mL within 48 h, and viable bacteria persisted longer in some media (e.g., CBB) than in others. Such maintenance of viable organisms in liquid medium is particularly important in the production of soluble metabolic products, such as the cytotoxin.

Selective Culture Media

Due to the mixed nature of infections from which *Mobiluncus* species are usually isolated, it was necessary to develop selective growth media that enhance the growth of *Mobiluncus* and in the meantime suppress the growth of competing flora such as *Gardnerella vaginalis*, *Mycoplasma hominis*, *Prevotella* spp., and *Atopobium vaginae* involved in bacterial vaginosis (Holst et al. 1984a; Thomason et al. 1984a; Smith and Moore 1988; Spiegel 1989). For these purposes several media containing effective antimicrobial agents such as colistin plus nalidixic acid (Durieux and Dublanchet 1980, 1981), polymyxin plus metronidazole or tinidazole (Sturm 1989), and colistin plus nalidixic acid, tinidazole, and Nile blue A (Spiegel 1986) have been designed. For instance, Smith and Moore (1988) described two selective media, Rlk and SA, combined with cold enrichment at 4 to °C to aid the isolation of *Mobiluncus* species from vaginal specimens. The Rlk medium is based on Columbia CNA agar supplemented with 2 % peptone, 0.6 % yeast extract, and 5 % laked rabbit or sheep blood. Tinidazole (48 mg/L) and nalidixic acid (20 mg/L) were added to the medium after autoclaving. The SA medium is also based on Columbia CNA agar supplemented with 2 % rabbit serum, 1.6 % laked rabbit or sheep blood, nalidixic acid, and tinidazole. After pouring the Rlk and SA media, the plates are left to dry in room for 1–2 days and then pre-reduced for 1–7 days before use. A further selective medium referred to as Mobi agar was designed by Spiegel (1989) as follows:

Formula of Mobi Agar Spiegel (1989)	
Columbia broth (Difco)	35.0 g
Cysteine HCl	0.4 g
Soluble starch (Difco)	10.0 g
Resazurin solution (11 mg/44 mL)	4.0 mL
Colistin methane sulfonate	10 μg/mL
Nalidixic acid	15 μg/mL
Deionized water	950.0 mL
Bacto agar (Difco)	15.0 g

The components are boiled with frequent agitation to dissolve solid components. After autoclaving, the medium cooled to 45–50 °C. Add 20.0 mL rabbit serum, 0.6 μg/mL tinidazole, and 1.2 mL of Nile blue A solution (0.5 g/10 mL). The plates were reduced over night prior to inoculation in an atmosphere consisting of 80 % nitrogen, 10 % hydrogen, and 10 % carbon dioxide.

Maintenance and Preservation Procedures

Short-Term Maintenance

Satisfactory maintenance of the viability and physiological characteristics of strains belonging to the genera of the *Actinomycetaceae* involves serial transfer of the organisms to fresh medium. The majority of species grow well on Columbia agar supplemented with 5 % sheep blood and incubation under anaerobic conditions or under increased CO_2 tension (~5 %) at 35 °C. Furthermore, tryptose agar supplemented with 5 % sheep blood was used to maintain cultures of *Trueperella pyogenes* with subcultivation at 3-week intervals (Roberts 1968; Reddy et al. 1982). In addition, Fortner plates containing CC-medium without carbohydrates but supplemented with 0.2 % (v/v) rabbit or fetal bovine serum were used for the maintenance of *Actinomyces* species. In the latter case, care should be taken as contamination may be caused by the *Serratia* strain simultaneously grown on the plate especially when the agar surface is too wet upon inoculation. Nevertheless, the frequency of transfer varies with the organism, and repeated subculturing or leaving the culture in the incubator beyond the time at which subculturing should be made results in loss of viability. For example, culture of *Actinobaculum urinale* loses its viability when incubated for longer than 10 days at 35 °C in an atmosphere containing 5 % CO_2 on Columbia blood agar, while cultures of *Actinobaculum massiliense* and *Actinobaculum schaalii* lose their viability under the same conditions after 14–21 days. In contrast, the cells of *Actinobaculum suis* continue to proliferate after 40 days of incubation. Notably, it is advisable not to store living cultures of *Actinomycetaceae* strains in the refrigerators at 4 °C as the cells of many species lose viability.

Liquid media such as BHI broth or BHI broth supplemented with 1 % Tween 80 dispended in test tubes have been used successfully for maintaining *Actinomycetaceae* strains alive. After inoculation the tubes are incubated under anaerobic conditions either using the GasPack jars or they may be sealed using sterile liquid paraffin. The layer of paraffin prevents dehydration of the medium and ensures anaerobic conditions. For members of the genera *Arcanobacterium* and *Trueperella*, the tubes may be incubated under anaerobic conditions or under increased CO_2 tension (~5 %). An advantage of the use of liquid culture is the reduction of subculture frequency.

Long-Term Maintenance

The most efficient and reliable method for storing stock cultures of *Actinomycetaceae* strains is by freeze drying in a suitable stabilizer such as fetal calf serum or skim milk. A thick suspension of the strain scraped from agar was suspended in fetal calf serum or 10 % skim milk. This suspension is dispended into small glass vials and rapidly frozen at low temperature (−70 °C). Once frozen the vials are placed in the drying chamber of a freeze dryer and lyophilized by standard techniques. Lyophilized cultures should be rehydrated in 0.8 % NaCl and streaked directly on Columbia agar with 5 % sheep blood plates for routine use.

Alternatively, cryopreservation at low temperature (−70 °C) using cryoprotectant such as dimethylsulfoxide (DSMO) or glycerol has been used by some authors. Rao et al. (2012) used peptone/yeast extract/glucose (PYG) containing 15 % glycerol and 5 % dimethylsulfoxide as a cryoprotectant medium for storing environmental isolates of *Actinomyces* species. The suspension was then dispended into small vials and stored at −80 °C to reduce the metabolic activity of the strains. Microbank cryogenic beads (Prolab Diagnostics) has been used successfully by Hoyles et al. (2004) for maintaining stock cultures of *Mobiluncus* species stored at −70 °C according to the manufacturer's instructions.

Ecology

Members of the family *Actinomycetaceae* are found in a wide range of habitats varying from human and animal to environmental sources. They form a significant component of the indigenous microflora of humans and animals (Beighton and Miller 1977; Dent and Marsh 1981) and their distribution is very similar in these habitats. Therefore, they may be expected to be recovered from any body fluid or tissue contaminated, colonized, or infected by these endogenous bacteria. In addition, one member of the family has been recently detected and isolated from oil-contaminated sites (Bowman et al. 2006; Duarte et al. 2001; Rao et al. 2012).

Distribution of Members of the Genus *Actinomyces*

Distribution of *Actinomyces* in Human

Actinomyces species are frequently found as commensal members of the normal microflora of human mucous membranes of the oropharynx, gastrointestinal tract, and female genital tract. Naeslund (1925) was the first to show by cultural means that anaerobic species of actinomycetes existed in tonsils. *Actinomyces* are predominant members of the human oral commensal microbiota and are among the initial colonizers of oral surfaces. They contribute to the development of oral biofilm at early stages and may constitute up to 27% of the pioneer bacteria (Socransky et al. 1977; Theilade et al. 1982; Nyvad and Kilian 1987; Gibbons 1989; Li et al. 2004). They have evolved unique mechanisms that favor colonization and persistence in this microenvironment (Yeung 1999). Several species have been isolated from the human oral cavity. These include *A. georgiae*; *A. gerencseriae*; *A. israelii*; *A. meyeri*; *A. naeslundii* genospecies I, II, and III; *A. odontolyticus*; and *A. viscosus* (Tanner et al 1994). *A. odontolyticus*, *A. naeslundii*, and *A. viscosus* are the primary species in infants' mouths (Sarkonen et al. 2000) as well as in early dental plaque formation (Liljemark et al. 1993;

Mishra et al. 2010; Nyvad and Kilian 1987). *Actinomyces georgiae*, *Actinomyces gerencseriae*, and *Actinomyces meyeri* have been isolated from gingival crevices of periodontally healthy individuals (Cato et al. 1984; Johnson et al. 1990). Other *Actinomyces* species of oral origin include *A. radicidentis* isolated from infected root canals (Collins et al. 2000) and *A. graevenitzii* isolated from respiratory tract secretions (Pascual Ramos et al. 1997b) and infants' saliva (Sarkonen et al. 2000). In addition, the use of highly discriminatory genotypic methods facilitated the resolution of subspecies variations most pronounced in *A. naeslundii* and *Actinomyces viscosus* (Johnson et al. 1990; Bowden et al. 1999; Henssge et al. 2009). It is now recognized that *Actinomyces oris*, previously known as *A. naeslundii* genospecies II, is considered to be the most abundant *Actinomyces* species in the human oral cavity (Ton-That et al. 2011). Thus, the number and variety of periodontal species recognized seems to be continually increasing and undergoing taxonomic revision.

The occurrence of *Actinomyces* species as normal inhabitants of the intestinal tract has not been clearly documented. Although Naeslund (1931) failed to identify *Actinomyces* in any fecal samples from asymptomatic individuals, he suggested that they appear in the gut by transit from the oral mucosa. Indirect evidence for the view that these organisms may form a small but significant component of the intestinal flora can be derived from cases of abdominal actinomycosis thought to be induced endogenously after abdominal surgeries, appendicitis, bowel perforations, or neoplasm. The colonization is almost exclusively by *Actinomyces israelii*, and the most common sites of infections are the transverse colon and the cecum with the appendix predominating (Ferrari et al. 2000; Garner et al. 2007).

There are controversies as to whether *Actinomyces* are normal members of the vaginal flora. Curtis and Pine (1981) demonstrated *A. israelii* in the genital tract of virtually healthy women. In an extensive study performed on 1,108 samples from the cervix, vagina, and perineum of 15 women (5 IUD users, 5 using oral contraceptives, and 5 without contraception), *A. israelii* in varying frequencies was identified in all women (Persson and Holmberg 1984a). As a mean, *A. israelii* was recovered in 24 % of the perineal samples, 13 % of the vaginal, and 6 % of the cervical samples. From this study Persson and Holemberg concluded that *A. israelii* is a part of the indigenous genital flora of healthy women. In contrast to Persson and Holemberg, Dybdahl et al. (1991) regarded *Actinomyces* colonization of the female genital tract as a rare event in women who are not users of intrauterine devices (IUCDs). The frequent isolation of *Actinomyces* from the genital tract of women using intrauterine devices (IUDs) has been reported (Evans 1993; Fiorino 1996; Westhoff 2007). It is estimated that the prevalence of *A. israelii* in IUD users worldwide may range between 1.6 % and 11.6 % (Valicenti et al. 1982; Nayar et al. 1985; Cleghorn and Wilkinson 1989; Dybdahl et al. 1991). These findings were based on either the observations of *Actinomyces* species in the cervical smears of generally asymptomatic women with IUDs (Valicenti et al. 1982) or on cases of IUD-associated pelvic actinomycosis in women using the device (Fiorino 1996). However, it is noteworthy to mention that the specificity and sensitivity for identifying the organisms depends on the detection methods. It is suggested that the prevalence of *Actinomyces*-positive cervical smears range from 0 % to 31 % with an average of 7 % (Gupta 1982; Fiorino 1996). Because the Papanicolaou test (Pap test) lacks specificity and sensitivity, other diagnostic approaches have attempted to produce more consistent results and to clarify whether *Actinomyces* is a normal inhabitant of the female genital tract in the absence of IUD (Pine et al. 1981; Persson and Holmberg 1984b, 1985). Generally immunofluorescent staining of smears is most sensitive and specific. Although culture is the gold standard for identifying the organism, it is not routinely useful due to special handling and the time required; in addition, results of cultures are often not concordant with cytology or stained tissue. Therefore, culturing and immunofluorescent staining are often used as complementary methods. The most common *Actinomyces* species associated with pelvic colonization is *A. israelii*. However, apart from *A. israelii* and *Propionibacterium propionicum*, other *Actinomyces* species such as *A. gerencseriae*, *A. naeslundii*, *A. viscosus*, *A. odontolyticus*, *A. meyeri*, and *A. cardiffensis* were recovered from specimens of the female genital tract (Slack and Gerencser 1975; Schaal and Pulverer 1984; Schaal and Lee 1992; Hall et al. 2002).

Besides the well-known *Actinomyces* species mentioned above, a plethora of new *Actinomyces* species such as *A. dentalis* (Hall et al. 2005), *A. europaeus* (Funke et al. 1997a), *A. funkei* (Lawson et al. 2001b), *A. hominis* (Funke et al. 2010), *A. massiliense* (Renvoise et al. 2009), *A. neuii* (Funke et al. 1994), *A. timonensis* (Renvoise et al. 2010), *A. turicensis* (Wüst et al. 1995), and A. urogenitalis (Nikolaitchouk et al. 2000) have been identified from human sources, and there are indications that much new diversity still remains to be discovered. Although knowledge about their exact ecological function is still rudimentary, they are found to participate in many infections, such as actinomycosis, human bite wounds and abscesses at different body sites, eye infections, and oral, genital, and urinary tract infections (Sabbe et al. 1999; Schaal and Lee 1992).

Distribution of *Actinomyces* in Animals

Little efforts have been directed to study the establishment of different *Actinomyces* species as part of the indigenous microflora of healthy domestic and wild animals. However, they occur commonly on the buccal and nasopharyngeal mucous membranes of several animal species and thus assumed to represent part of the indigenous microflora of host animals. *A. bovis* has also been isolated from cattle, sheep, pigs, dogs, horses, and other mammals. *Actinomyces viscosus* has been isolated from gingival plaques of hamsters and from cervical plaque of rats (Howell 1963; Jordan et al. 1972). *A. denticolens*, *A. howellii*, and *A. slackii* were recovered from the dental plaque of dairy cattle (Dent and Williams 1984a, b, 1986). Similarly, *A. viscosus* and *A. naeslundii* were found among the major bacteria that contribute to the initial dental plaque formation of neonatal monkeys (Kilian and Rölla 1976; Beighton 1985). Love et al. (1990)

studied the anaerobic bacterial flora of the oral cavity of healthy feline and found that *A. viscosus*, *A. hordeovulneris*, and *A. denticoIens* comprised 12 % of the facultative anaerobic flora. *A. hyovaginalis* was found among the nasal and tonsillar flora of piglets before and after weaning (Baele et al. 2001).

Some other *Actinomyces* spp. recovered from animal sources such as *A. canis*, *A. bowdenii*, *A. catuli*, *A. coleocanis*, *A. bowdenii*, *A. suimastitidis*, *A. marimammalium*, *A. vaccimaxillae*, and *A. weissii* have been reported, to date, only in the original descriptions of these species. It is still disputed whether these organisms have a natural habitat outside the animal.

Distribution of *Actinomyces* in Nature

Actinomyces spp. have been demonstrated in nature outside of an animal or human host (Duarte et al. 2001; Rao et al. 2012). Molecular community profiling via soil DNA-based PCR-denaturing gradient gel electrophoresis (PCR-DGGE) and analysis of the sequences of three prominent bands of the profiles generated with the highly polluted soil samples suggested that the underlying organisms were related to *Actinomyces* sp., *Arthrobacter* sp., and a bacterium of uncertain affiliation (Duarte et al. 2001). Later, *Actinomyces naturae* was isolated from contaminated groundwater collected from a well at an area where petrochemical wastes were deposited (Rao et al. 2012).

Distribution of Member of the Genus *Arcanobacterium*

A. haemolyticum is generally thought of as an obligate human pathogen, being only isolated in association with clinical symptoms. Isolation of the bacterium from the nasopharynx of asymptomatic persons is rare. A number of studies have shown that carriage in the throats of healthy individuals was generally less than 0.2 % of the sampled populations (Banck and Nyman 1986; Wat et al. 1991; Mackenzie et al. 1995). Although 16S rRNA metagenomic sequencing of human skin microbiota has revealed that actinobacteria represent 51.8 % of the skin bacteria (Grice et al. 2009), *Arcanobacterium* spp. have not yet been identified. Carriage still may occur in other parts of the body, as no studies have examined whether *A. haemolyticum* is present on the skin or other mucosa, thus acting as either part of the normal flora or being a reservoir for disease. An interesting finding is that *A. haemolyticum* could be identified as one of the major secondary colonizers of leprosy skin ulcers (Sturm et al. 1996) and may contribute to the inflammatory reaction of these lesions. *A. haemolyticum* is currently thought to be spread via aerosolized droplets from infected persons (Banck and Nyman 1986; Gaston and Zurowski 1996), but direct contact may also spread the bacteria.

Although human beings are considered to be the main reservoir of *A. haemolyticum*, reports of sporadic isolations from animals, including horses (Hassan et al. 2009), sheep (Roberts 1969), cattle (Richardson and Smith 1968), and a pet rabbit (Tyrrell et al. 2002), have been published. In addition *A. haemolyticum* has been isolated from a female European badger, a wildlife host, for which the potential for direct human contact is minimal (Wragg et al. 2011). The likely role of *A. haemolyticum* in this single case is uncertain, and further study is necessary to determine how widespread this potentially zoonotic organism is among badgers.

The natural habitat of *A. phocae* is unknown. The bacterium was isolated from nasal, fecal, and vaginal swabs taken from healthy harbor seals in California and was often isolated from infected bite wounds, including those from conspecifics, as well as superficial wounds, suggesting that *A. phocae* is part of the normal oral or skin flora of marine mammals (Johnson et al. 2003). *A. canis* has been isolated from otitis externa of a 7-year-old female English bulldog (Hijazin et al. 2012b).

Distribution of Member of the Genus *Trueperella*

Trueperella species occur as commensals of the mucous membranes of many domestic animals such as dairy and beef cattle, sheep, swine, and goats. *Trueperella pyogenes* was isolated from up to 100 % of the udders, urogenital, upper respiratory, and gastrointestinal tracts of healthy animals (Timoney et al. 1988; Carter and Chengappa 1991; Quinn et al. 1994; Jost et al. 2002a; Billington et al. 2002a). *T. pyogenes* is one of the common tonsillar and nasal flora of piglets (Baele et al. 2001). The organism is part of the bacterial flora of the scrotal skin and the preputial cavity of rams (Gouletsou et al. 2004). In addition, this organism was isolated from semen of beef breed bulls (Sprecher et al. 1999) without a significant relationship between the cultural results and possible sperm abnormalities.

Distribution of Member of the Genus *Actinobaculum*

Actinobaculum is a well-recognized commensal flora of the mucosal surfaces and skin of animals and humans. *A. suis* is a common inhabitant of the preputial sac in the scrotum of boars (Jones and Dagnall 1984). It is occasionally isolated from the vagina of healthy sows (Jones 1984). Carr and Walton (1990) isolated *A. suis* from footwear of handlers working with boars. It may also be isolated from voided urine and pen floors of farrowing and nursery rooms.

A. schaalii, *A. massiliense*, and *A. urinale* are natural components of the human genitourinary tract. They have been recovered from human blood and urine (Lawson et al. 1997; Greub and Raoult 2002; Hall et al. 2003a). Although *A. massiliense* has been reported to cause skin infection (Waghorn 2004), it is not known whether the organism contributes to resident commensal skin flora or represents exogenous acquisition.

Distribution of Member of the Genus *Varibaculum*

Although its natural habitat remains unknown, *V. cambriense* is occasionally considered to be skin commensal organism

(Chu et al. 2009) and one of the vaginal anaerobic microflora (Verhelst et al. 2005). It has been isolated from intrauterine devices and human vagina and abscess specimens. In a study of the vaginal microflora, Verhelst et al. (2005) found that *Varibaculum cambriense* represent 2.2 % and 13.6 %, respectively, of cultured organisms in grade II and grade III specimens.

Distribution of Member of the Genus *Mobiluncus*

The normal ecological niche for *Mobiluncus* species is not known. However, they are most often found in vaginas with a disturbed ecology, primarily of women with BV, but rarely found in healthy women. Thus, they have been isolated from the vaginas of women with BV in up to 85 % of cases (Holst et al. 1987). The organisms have also been recovered in high rates from the rectal specimens of women with clinically evident BV, but in lower rates from the rectal specimens of women without vaginal infections, children, and men (Hallén et al. 1987, 1988; Holst et al. 1987). The difference in isolation rates between women with BV, on the one hand, and healthy women, on the other, might be due to the occurrence of the microorganisms in higher numbers in the rectums of women who develop this condition compared with those in the rectums of healthy subjects (Holst 1990). The observations of the simultaneous occurrence of *Mobiluncus* in the vaginas and rectum of women with BV led to the suggestion that rectal colonization may predispose to vaginal colonization (Holst et al. 1987).

Mobiluncus has been isolated from the vagina and cervical canal of pregnant women (Krohn et al. 1989; Kaneko et al. 1992). However, the rates of colonization of the organism differ according to the groups of women. Thus, Krohn et al. (1989) detected *Mobiluncus* morphotypes by Gram stain in 3 % of 471 pregnant women without clinical signs of BV compared with 28 % of 122 pregnant women with BV. On screening of *Mobiluncus* species in female lower genital tract, Kaneko et al. (1992) detected the organisms from the vagina in 2/280 cases (0.7 %) in healthy pregnant women and from the cervical canal in 3/278 cases (1.1 %).

Mobiluncus species were only infrequently recovered from genital samples from males (Holst 1990). They have been isolated from the seminal fluid, urethras, and/or coronal sulci of male consorts of women with bacterial vaginosis, but were never recovered from the male consorts of healthy women (Holst et al. 1984b; Holst 1990; Magnanelli et al. 1990).

Pathogenicity, Clinical Relevance

Members of the family *Actinomycetaceae* are generally considered to be of relatively low virulence and are especially prevalent in infections associated with predisposing or underlying conditions such as trauma, surgery, malignancy, immunodeficiency, and presence of foreign bodies. They are seldom recovered as single isolates but are often mixed with other anaerobic or aerobic bacteria.

Genus *Actinomyces*

The most frequent illness of humans and cattle that is caused by anaerobic species of the genus *Actinomyces* is called actinomycosis. The term "actinomycosis" was introduced by Bollinger (1877) to describe case of cervicofacial disease in cattle "lumpy jaw" followed by Israel (1878) in his accurate description of cervicofacial and thoracic cases of the disease and in humans. As currently defined, actinomycosis is a subacute-to-chronic, granulomatous inflammatory disease characterized by suppuration, abscess formation, and draining sinus tracts, which erupt to the skin or mucosal surfaces and drain pus that may contain sulfur granules (Slack and Gerencser 1975; Pulverer and Schaal 1984).

Histologic Findings

The visualization of actinomycotic granules in exudates or in histopathologic tissue sections is strongly supportive of the diagnosis. Multiple sections of a biopsy specimen from affected tissue should be used for histologic diagnosis. Sections of biopsy material typically reveal acute or chronic inflammatory granulation tissue with infiltration by neutrophils, foamy macrophages, and lymphocytes surrounding dense fibrosis (Slack and Gerencser 1975). Sulfur granules may comprise no more than 1 % of total tissue in a given lesion and hence are easily missed by routine tissue staining. Visualization is facilitated by special stains such as Grocott–Gomori methenamine silver, *p*-aminosalicylic acid, and McCallen–Goodpasture and Brown–Brenn Gram stain. The sulfur granules are approximately 0.1–1 mm in diameter and may be seen with the naked eye as yellowish particles, and because of their yellowish appearance, they are commonly referred to as "sulfur granules" even though there is no clear evidence that they contain sulfur at all (*Fig. 4.2*). The sulfur granules are nearly pathognomonic, but their absence does not exclude the diagnosis of actinomycosis. Similar granules may also be found in infections with other organism such as *Nocardia brasiliensis*, *Streptomyces somaliensis*, or *Actinomadura madurae*. Microscopically, the granules manifest a cauliflower-like shape at low magnification (*Fig. 4.2*), and at higher magnification a clump of filamentous actinomycete microcolonies surrounded by polymorphonuclear neutrophils can be observed (*Fig. 4.3*). Brown–Brenn Gram stain renders these microcolonies visible as Gram-positive, intertwined branching filaments, with radially arranged, peripheral hyphae. Coexisting with them are the companion bacteria, which are Gram-positive and Gram-negative cocci and rods.

Etiology

Actinomycosis generally is a polymicrobial infection that involves *Actinomyces* associated with different bacteria, so-called concomitant bacteria (Brown 1973; Schaal and Lee 1992). It has been suggested that *Actinomyces* species are pathogenic only

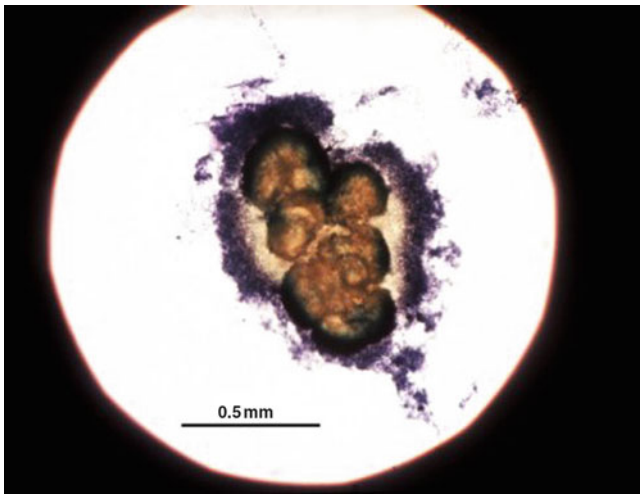

Fig. 4.2

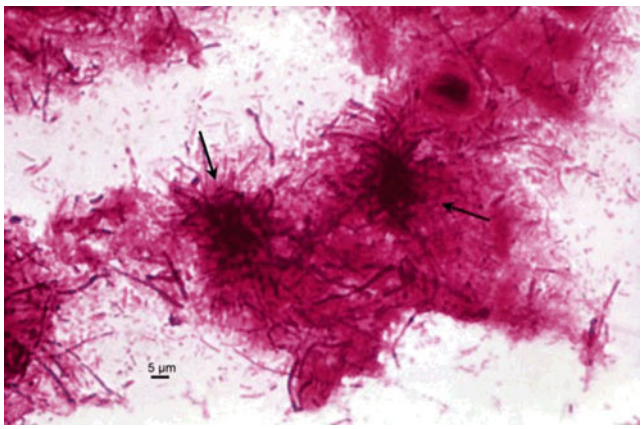

Fig. 4.3
Gram-stained smear of a crushed actinomycotic sulfur granule. Note the host of various Gram-positive and Gram-negative bacterial forms in addition to the nests → of Gram-positive, interwoven and branching filaments which represent the causative *Actinomyces* species.

with the synergistic action of concomitant bacteria. *A. israelii* and *A. gerencseriae* are by far the most common cause of infection, while *A. meyeri*, *A. naeslundii*, *A. odontolyticus*, *A. oris*, and *A. viscosus* are less common causes (Pulverer et al. 2003). In addition to these well-known actinomycotic species, some coryneform anaerobic bacteria capable of causing actinomycosis have also recently been assigned to the genus *Actinomyces*. Among these, *A. graevinitzii* an early colonizer of the oral cavity (Sarkonen et al. 2000) has been reported in a case of multiple pulmonary abscesses (Nagaoka et al. 2012) and in a case of pneumonia (Fujita et al. 2012). Another species of non-oral origin, *A. turicensis* was reported in a case of abdominal actinomycosis with clinical feature of multiloculated cystic mass in the left iliac fossa (Ong et al. 2012), in a case of hepatic abscess in a patient with previous dental manipulation (Riegert-Johnson et al. 2002), and in a case of soft tissue abscess of the breast (Attar et al. 2007) and to be associated with genital, skin-related, and urinary tract infections (Sabbe et al. 1999). Conversely, *A. funkei*, *A. radingae*, and *A. europaeus* have been isolated from soft tissue infections, usually in mixed anaerobic/aerobic infections, but have not been reported to be associated with cases of actinomycosis. Another species of related anaerobic Gram-positive, filamentous bacteria, *Propionibacterium propionicum* (formerly *Arachnia propionica* and *Actinomyces propionicus*) is a less common cause of actinomycotic infections (Wunderink et al. 2011).

The type and number of concomitant bacteria present in actinomycotic lesions varied according to the site of infection. The most commonly recovered concomitant bacteria include Gram-negative facultative anaerobe, e.g., *Aggregatibacter actinomycetemcomitans, Eikenella corrodens, Capnocytophaga, Enterobacteriaceae*; Gram-negative anaerobe, e.g. *Bacteroides* species, *Fusobacterium* species; as well as Gram-positive aerobe cocci such as *Staphylococcus* species and *Streptococcus* species. (Holm 1950; Fiorino 1996; Garner et al. 2007; Ghafghaichi et al. 2010; Ochiai et al. 1993; Simpson et al. 1996). The frequency of recovery of the different species found in an actinomycotic lesion varies from case to case, but an average of two to four and sometimes up to ten of these concomitant species are usually found in association with the causative actinomycete. Thus, in abdominal cases coliforms and Gram-negative bacilli, e.g., *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp., and *Bacteroides* spp. are predominated. Several observations reported the high frequency of *Peptostreptococcus* and *Bacteroides fragilis* associated with *Actinomyces israelii* in pelvic actinomycosis (Henderson 1973; Lomax et al. 1976; Valicenti et al. 1982). The bacteria that are involved in periodontitis comprises Gram-negative strict anaerobic rods such as *Porphyromonas gingivalis*, *Prevotella intermedia*, *Fusobacterium nucleatum*, *Bacteroides* spp., and *Selenomonas* spp. (van Winkelhoff et al. 2002) as well as some anaerobic Gram-positive microorganisms such as *Peptostreptococcus micros* and *Eubacterium* species (Nonnenmacher et al. 2001). Their contribution to the pathogenesis in actinomycosis is unclear. It is possible that these concomitant bacteria may serve as copathogens, enhancing the progress of the disease by creating an anaerobic milieu in which *Actinomyces* thrives. This may be due to the reduction of oxygen tension in tissues and through anaerobiosis-induced inhibition of phagocytes Ochiai et al. (1993).

Clinical Manifestations

Infections are usually associated with the breakdown of normally physical barriers, such as disruption of mucosal membranes in the mouth and gastrointestinal tract. Infection spreads contiguously, ignoring tissue planes. Four clinical forms of actinomycosis, i.e., cervicofacial, thoracic, abdominopelvic, and cerebral, account for the majority of infections in humans (Slack and Gerencser 1975).

Cervicofacial Actinomycosis

Cervicofacial actinomycosis is the most common manifestation, comprising 50–70 % of reported cases. The face and neck are the most common sites of infection. The disease is characterized by soft tissue swelling of the perimandibular area, but it may spread into the orbita, sinuses, ear, or neck (Olson et al. 1989; Gazzano et al. 2010). The majority of cases have been observed in patients with poor oral hygiene and/or a history of invasive dental procedures or trauma. The most involved etiologic agents belonged to at least nine different species, among which *A. israelii* and *A. gerencseriae* predominated (Pulverer et al. 2003). The highest incidence was found in female patients aged 11–40 years and in male patients aged 21–50 years. Cervicofacial actinomycosis may extend to the underlying mandible or facial bones, leading to the development of periostitis or osteomyelitis.

Thoracic Actinomycosis

Thoracic actinomycosis accounts for 15–20 % of cases. Thoracic actinomycosis may involve the lungs, pleura, mediastinum, or chest wall. Aspiration of oropharyngeal secretions containing actinomycetes is the usual mechanism of infection. Occasionally, thoracic actinomycosis may result from the introduction of organisms via esophageal perforation, by direct spread from an actinomycotic process of the neck or abdomen, or via hematogenous spread from a distant lesion (Rose et al. 1982; Apothéloz and Regamey 1996). Poor oral hygiene and associated dental disease may increase the risk (Russo 2005). Misdiagnosis of the disease as tuberculosis, lung abscess, or bronchial carcinoma is common (Russo 1995). Untreated cases can spread to involve the pleura, pericardium, and chest wall, ultimately leading to the formation of sinuses that discharge sulfur granules.

Abdominal and Pelvic Actinomycosis

Abdominal actinomycosis accounts for approximately 10–20 % of reported cases (Postal et al. 2001). The disease has been recognized as one of the most misdiagnosed disease. It presents as an indolent chronic suppurative process with atypical symptoms that are often misinterpreted as malignant disease. Patients who have undergone appendectomy or have had a missed perforated appendicitis or women with a history of intrauterine contraceptive device use are at an increased risk (Garner et al. 2007). The ileocecal region is the most commonly affected abdominal site with the appendix predominating (Ohmagari et al. 1988; Thanos et al. 2004). Hepatic involvement is often associated with multiple small abscesses (Sharma et al. 2002; Lai et al. 2004). Other reported sites include the colon (Cowgill and Quan 1979; Heer et al. 1986), stomach (Van Olmen et al. 1984; Fernández-Aceñero et al. 2004), gallbladder (Freland et al. 1987), pancreas (Somsouk et al. 2008), small bowel (Belak et al. 2001), anorectal region (Smith 1992; Coremans et al. 2005), pelvis, and abdominal wall (Lau et al. 1986; Gupta et al. 1990). Involvement of retroperitoneal organs may result from hematogenous dissemination or direct extension (Berchtenbreiter et al. 1999; Olson et al. 1993).

Pelvic actinomycosis is associated with long-term use of an intrauterine contraceptive device (Henderson 1973; Fiorino 1996; Lely and van Es 2005). The incidence of actinomycotic infection increases with duration of IUCD use and the mean duration of coil usage in women with actinomycosis is 8 years (Fiorino 1996). Symptoms and signs of genital actinomycosis are nonspecific, and in the majority of cases, women may complain of abdominal pain, weight loss, vaginal discharge, and fever (Duguid 1983). The reason for the association with IUCD usage is unclear. Insertion of the device may traumatize the cervical and uterine mucosa, inducing mild inflammatory changes in the endometrium with necrosis that creates an anaerobic environment that favors growth of *A. israelii* and other anaerobics (Valicenti et al. 1982). When pelvic actinomycosis occurs, it usually causes endometritis, salpingo-oophoritis, or tubo-ovarian abscess, and a mass in the adnexa might be palpable, suggesting a pelvic malignancy (Hinnie et al. 1995; Perlow et al. 1991; Hwang et al. 2009). Ultimately, extension to the abdominal wall or deep pelvic structures can occur. Even involvement of the urinary bladder presenting with frequency, dysuria, hematuria, or a suprapubic mass and sulfur granules in the urine has been observed (Wajszczuk et al. 1984; Zakut et al. 1987).

Cerebral Actinomycosis

Actinomycosis of the central nervous system (CNS) is rare and is usually secondary to hematogenous spread from primary infection in the lung, abdomen, or pelvis. However, extension from foci of infection in the ears and cervicofacial regions may proceed along connective tissue planes or through foramina at the base of the skull, causing focal infection of the CNS or diffuse basilar meningitis. The disease may present as a brain abscess, meningitis or meningoencephalitis, a subdural empyema (Louie et al. 1979; Soto-Hermández et al. 1999), an actinomycoma, and a spinal and cranial epidural abscess (Albright et al. 1974; Brunon et al. 1980; Schwartz and Christoff 1960; Smego 1987; Wickbom and Davidson 1967; Yung et al. 2000). Actinomycotic cerebral abscesses are usually singular but may be multiple, unilocular or multilocular, and encapsulated or, less frequently, unencapsulated (Bolton and Ashenhurst 1964). The clinical features are indistinguishable from those of pyogenic infections of intracranial and spinal structures.

Cutaneous Actinomycosis

Cutaneous localizations of actinomycosis generally occur by contiguity of underlying foci of tooth or lung, by direct inoculation, or by spread through the bloodstream during a septicemic phase of the infection. In the latter case, there are often multiple lesions. Primary cutaneous actinomycosis of the extremities is uncommon and usually has an association with trauma and bites (Gupta et al. 2012; Reiner et al. 1987; Sardana et al. 2001). Skin, subcutaneous tissues, muscle, and bone (with periostitis or acute or chronic osteomyelitis) are involved alone or in various combinations (Blinkhorn et al. 1988; Rippey and Hendry 1988; Kargi et al. 2003; Mah et al. 2005).

Lacrimal Canaliculitis and Other Eye Infections

Infection of the eye with *Actinomyces* species has been recognized for many years. The most common site of infection involving the eye is the lacrimal system. Canaliculitis is more common in women. It is usually unilateral and more frequently involves the lower canaliculus. Epiphora, caused by obstruction, may be the only initial symptom, followed by localized swelling. The classic clinical features of *Actinomyces* canaliculitis are mild to severe swelling of the canaliculus, mucopurulent discharge from the punctum, inflamation of the medial canthus, epiphora, and a red pounting punctum (Fulmer et al. 1999; MacNab, 1994). Actinomycosis less frequently results in conjunctivitis, lacrimal sac involvement, keratitis, and endophthalmitis (Briscoe et al. 2004; Caretti et al. 2011; Hussain et al. 1993; Pine et al. 1960a; Roussel et al. 1991). Various microorganisms have been implicated as causal pathogens. Besides the most commonly identified species, *A. israelii*, *A. gerencseriae*, *A. naeslundii*, *A. viscosus*, and *A. odontolyticus*, another related organism, *Propionibacterium propionicum*, has also been frequently isolated (Seal et al. 1981). The incidence of isolation of the latter organism from lacrimal concretions was as frequent as was *A. israelii* (Hussain et al. 1993; Schütt-Gerowitt et al. 1999). These anaerobic bacteria may likely gain entry to the canaliculi indirectly from the saliva via the fingers or directly via the nasal passage and nasolacrimal duct (Pine et al. 1960a; Hussain et al. 1993). In addition to these common pathogens, *A. neuii* has been reported to be associated with acute postoperative endophthalmitis (Garelick et al. 2002).

Complications Associated with Actinomycosis

Systemic dissemination and potentially life-threatening complication can occur if *Actinomyces* infections are unrecognized and/or inadequately treated (Shay 2002). Hematogenous seeding from an oral source is a dominant cause of bacterial endocarditis (Cohen et al. 2007; Huang et al. 1998), pericarditis (Jánoskuti et al. 2004; Llenas-García et al. 2012), liver abscess (Lall et al. 2010; Riegert-Johnson et al. 2002; Sharma et al. 2002; Uehara et al. 2010), and renal abscess (May et al. 2008).

The most important neurologic complications associated with CNS infection include brain abscesses (Adeyemi et al. 2008; Navas et al. 1994) followed by meningitis or meningoencephalitis. Furthermore, cranial epidural and subdural empyemas (Louie et al. 1979; Soto-Hermández et al. 1999) and spinal epidural abscesses (Yung et al. 2000) have been reported. Severe neurologic deficits can result if there is delay in diagnosis or treatment of CNS actinomycosis (Alday et al. 1989).

The most common complications associated with pulmonary actinomycosis include lung abscesses (Nagaoka et al. 2012; Takiguchi et al. 2003), pleural empyemas (Vallet et al. 2004), and necrotizing pneumonia (Costiniuk et al. 2011). Invasion of the chest, soft tissues, and bony structure wall leading to the formation of draining sinus tracts with purulent discharge may occur. Osteomyelitis due to *Actinomyces* infection can involve the bones of the mandible (Bala et al. 2011; Smith et al. 2011), sternum (Panilla et al. 2006), ribs and vertebrae (Honda et al. 2008), and the skull base (Nomura et al. 2011).

Besides its serious nature of organ involvement, other complications include hip prosthesis infection (Wu et al. 2011b; Wüst et al. 2000), septic arthritis (Lequerré et al. 2002), endodontic infection (Xia and Baumgartner 2003), and postoperative endophthalmitis (Scarano et al. 1999). Opportunistic actinomycotic infection has been reported in osteoradionecrosis (Curi et al. 2000) in patients having head and neck cancer.

Actinomyces in Oral Health and Disease

The significance of *Actinomyces* in oral health and disease has been documented (Beighton and Miller 1977; Dent and Marsh 1981; Bowden 1990). *Actinomyces* and *Streptococcus* species dominate among the early colonizing bacteria, both on the teeth and oral mucosal surfaces (Socransky and Manganiello 1971; Gibbons 1989; Hsu et al. 1994; Jenkinson and Lamont 2005). The result of coaggregation and adhesion between *Actinomyces* spp. and *Streptococcus* spp. is the formation of the initial layer of oral biofilm (Palmer et al. 2003). In this layer *Actinomyces* and *Streptococcus* species then offer adhesion sites for additional bacteria, through co-adhesion/coaggregation. *Actinomyces* spp. coaggregate through the type 2 fimbriae (Palmer et al. 2003), while *Streptococcus* spp. have several adhesins involved in coaggregation, including the Ag I/II family, Csh family, and Fap1-including family of adhesins (Elliott et al. 2003; Jakubovics et al. 2005). The coaggregation of different species is highly specific, and each species seems to have specific partners, such as *Streptococcus*/*Actinomyces*, *Veillonella*/*Streptococcus* and *Actinomyces*, and *Prevotella*/*Actinomyces* species (Hughes et al. 1988; Kolenbrander 1988; Nesbitt et al. 1993). Thus, the mature oral biofilm is a multispecies community, with more than 700 different species and phylotypes, the majority belong to the phyla Deferribacteres, Spirochaetes, Fusobacteria, Actinobacteria, Firmicutes, Bacteroidetes, and Proteobacteria (Dewhirst et al. 2010; Jenkinson and Lamont 2005; Paster et al. 2001).

Though *Actinomyces* species are part of the normal, resident microbiota of distinct surfaces of the mouth, they contribute to different plaque-involved diseases, e.g., dental caries and periodontal diseases (Syed et al. 1975; Ellen et al. 1985; Bowden 1990; Moore and Moore 1994). The disease results only when there is a shift in the homeostatic balance of the resident microflora due to a change in local environmental conditions (such as pH) which favor the growth of pathogens (Jenkinson and Lamont 2005; Marsh 1994; Marsh and Nyvad 2008). Under such circumstances, it is suggested that acidogenic (acid producing) and aciduric (acid resistant) bacteria other than mutans streptococci (MS), including "low-pH" non-MS and *Veillonella* spp. as well as *Actinomyces naeslundii*, *A. viscosus*, *A. odontolyticus*, and *A. israelii*, are responsible for the initiation of caries (Nyvad and Kilian 1990; van Houte et al. 1994, 1996; Brailsford et al. 1998; Becker and Paster 2002; Becker et al. 2002; Tanner et al. 2002; Aas et al. 2008). Thus, the bacterial

communities associated with root caries are highly diverse and undergo succession during lesion formation, and therefore the caries disease is an outcome of the overall activity of the total plaque microflora and not a specific organism (Loesche 1976).

Dental caries is the localized destruction of the tissues of the tooth by bacterial action. In root caries, enamel or cementum is demineralized by microbial acids, predominantly lactic acid, produced by fermentation of dietary sugars. Evidences of the role of *Actinomyces* species in root surface carious lesion induction were initiated in the 1970s and received some impetus from caries studies on experimental animals where it was shown that strains of *Actinomyces* from humans could cause root surface caries (Socransky et al. 1970; Jordan et al. 1972). *Actinomyces* species possess several attributes that contributes to its success as a cariogenic organism. The expression of cell surface fimbriae is correlated with the ability of these bacteria to adhere to specific receptors on the tooth and mucosal surfaces of the oral cavity (Cisar 1986; Cisar et al. 1997b). Adherence of *Actinomyces* to teeth is mediated by type 1 fimbriae through interactions with salivary proline-rich proteins (PRPs) that coat the enamel surfaces (Cisar et al. 1988; Gibbons et al. 1988; Clark et al. 1989). In contrast, adherence to mucosal epithelial cells depends on the presence of type 2 fimbriae (Brennan et al. 1984, 1986; Sandberg et al. 1986, 1995; Cisar et al. 1995). In addition, *Actinomyces* spp. are known to produce sialidases (Costello et al. 1979; Moncla and Braham 1989), enzymes that enhance fimbriae-mediated adherence by unmasking the fimbrial receptors on mammalian cells (Cisar 1986).

Furthermore, oral *Actinomyces* produce fructosyltransferase (FTF) enzymes which convert sucrose into polymers of D-fructose, known as levans, and these polymers are thought to contribute to the development of dental caries by allowing plaque bacteria to utilize a greater proportion of dietary sucrose over a longer period of time, thus enhancing acid production (Bergeron et al. 2000). Fructans also are effective T-cell-independent antigens, can trigger inflammation, and are mitogenic for B cells (Couthino and Moller 1973; Desaymard and Ivanyl 1976). Thus, it is possible that an immune response to levans may contribute to the inflammation seen in periodontal diseases.

Actinomyces species also can metabolize a variety of sugars, resulting in the production of a number of weak acids, including lactic, succinic, and acetic acids that generate a low-pH environment and enrich for aciduric organism. When the plaque pH drops below about 5, the balance between enamel demineralization and remineralization shifts toward solubility and the caries process is initiated. In contrast, *Actinomyces* species demonstrates urease activity that allows these bacteria to hydrolyze urea to ammonia (Salako and Kleinberg 1989; Morou-Bermudez and Burne 1999). Ammonia production by ureases of oral bacteria in dental plaque causes a considerable increase in plaque pH, inhibiting the emergence of a cariogenic flora and the development of dental caries (Kleinberg 1967; Shu et al. 2007). However, urea metabolism is thought to have detrimental effects as well, enhancing the formation of tartar or calculus (Wong et al. 2002; Wong and Sissons 2007), inducing inflammation at the gingival margin, and enhancing inflammation in periodontal pockets (Burne and Chen 2000). Ureolysis has been found to protect *Actinomyces* against acid damage and allows the organism to use urea as a nitrogen source for growth (Morou-Bermudez and Burne 1999).

Susceptibility of Actinomyces to Antibiotics and Recommended Treatment

Currently there are no CSLS standards published for the reliable testing and reporting of antibiotic susceptibility results for *Actinomyces* species. The use of various enriched broths, undefined inocula, prolonged periods of incubation, and gradations of growth suppression, rather than total growth inhibition, makes it difficult, if not impossible, to compare published results (Blake 1964; Lerner 1974; Schaal and Pape 1980). Despite such extreme variations in assay technique, almost all investigators showed, however, that *Actinomyces* spp. are susceptible to a wide range of beta-lactam antibiotics (Smith et al. 2005; Tanaka-Bandoh et al. 1997). Thus, using the Etest methodology, it was found that all isolates of *A. israelii*, *A. gerencseriae*, *A. turicensis*, *A. funkei*, *A. graevenitzii*, and *A. europaeus* are susceptible to penicillins, cephalosporins, carbapenems, lincomycins, linezolid, macrolides, and tetracyclines (MIC$<$1 mg/L) (Smith et al. 2005). Using the broth microdilution method, poor or intermediate susceptibility to amikacin was observed for *A. israelii*, *A. viscosus*, *A. naeslundii*, and *A. gerencseriae* (Tanaka-Bandoh et al. 1997). In contrast all *Actinomyces* species are resistant to ciprofloxacin, ofloxacin, and metronidazole (Smith et al. 2005; Tanaka-Bandoh et al. 1997; Wade 1989).

Due to the polymicrobial nature of the infection with *Actinomyces*, successful treatment of actinomycosis depends not only on the type of disease and its localization, but also, often more importantly, on the composition of the concomitant flora. Treatment for actinomycosis requires long-term administration of parenteral and oral antibiotics. Optimal duration of antimicrobial therapy should be tailored depending on the severity of illness. However, a longer duration with antimicrobial agents is usually necessary since premature termination of antimicrobial therapy may cause a relapse of actinomycosis. Surgical intervention may be required in selective cases (Berardi 1979; Mabeza and Macfarlane 2003; Hayashi et al. 2010). Penicillin is the drug of choice. Conventional therapy for actinomycosis is high-dose intravenous penicillin at a dosage of 18–24 million units daily for 2–6 weeks, followed by oral penicillin or amoxicillin for a period of 6–12 months (Russo 2005). However, treatment failures and relapses have been documented. This can be attributed to the presence of β-lactamase-producing concomitant flora. Therefore, current treatment schemes include drugs effective against *Actinomyces* species and potential β-lactamase producers such as Staphylococcus aureus, Gram-negative anaerobes, and members of the *Enterobacteriaceae*. A possible scheme for the antibiotic treatment of cervicofacial actinomycosis may consist of amoxicillin plus clavulanic acid or possibly ampicillin plus sulbactam (Smith et al. 2005). The treatment of choice for

abdominal actinomycosis is a combination of amoxicillin and clavulanic acid with metronidazole (or clindamycin) for strict anaerobes plus tobramycin or gentamicin.

In pregnant patients, erythromycin is a safe alternative. In case of patients for whom penicillins allergy is a concern, infections may be treated with ceftriaxone (Skoutelis et al. 1994), doxycycline (Davanos et al. 2008), imipenem (Edelmann et al. 1987; Yew et al. 1994), minocycline (Martin 1985), or erythromycin.

For treatment of lacrimal canaliculitis, a local therapy with penicillin G (100,000 U) or erythromycin, imipenem, or gyrase inhibitor, e.g., norfloxacin or levofloxacin, should be initiated for 1–2 weeks. Caries and periodontitis can usually be treated successfully using the various local measures of conservative and operative dentistry, although administration of suitable antibiotics may facilitate therapy of periodontitis and especially of gingivitis. Recently Comelli et al. (2009) selected a lactic bacterium strain for the preparation of a composition intended for reducing dental plaque and for treating or preventing root caries and other diseases related to *Actinomyces naeslundii* in mammals.

Animal Infections Caused by *Actinomyces* Species

Actinomyces species, which are known to occur commonly on the buccal and nasopharyngeal mucous membranes of several animal species, can cause sporadic pyogranulomatous lesions (Quinn et al. 1994). *A. bovis* is the etiologic agent of actinomycosis, or lumpy jaw, in cattle, horses, goats, sheep, and wildlife species such as elk and pronghorn antelope (Allred and Bradley 1965; Hoefs and Bunch 2001; Vos 2007). The disease is an osteomyelitis that affects the mandible or maxilla. Gross lesions of mandibular osteomyelitis include distortion and proliferation of the jaw bones, damage to teeth, abundant scar tissue, and in some cases fistulas draining through the skin (Bunch et al. 1999). *A. bovis* has also been isolated from nodular abscesses in the lungs of cattle and from infrequent infections in sheep, pigs, dogs, and other mammals, including chronic fistulous withers and chronic poll evil in horses (Kimball and Frank 1945). Furthermore, *A. denticolens* has been reported in a case of mandibular and submandibular abscesses in horses (Albini et al. 2008; Beck et al. 2011).

Actinomyces hyovaginalis is an important cause of disseminated necrotic lung lesions in slaughtered pigs and is believed to be acquired via inhalation (Aalbebaek et al. 2003). Furthermore, it has been associated with rare cases of porcine abortion (Hogg et al. 2012) and lymphadenitis in goat (Schumacher et al. 2009) and is a potential cause of skin abscesses and other sites in small ruminants (Foster et al. 2012).

A. hordeovulneris was isolated from cases of chronic pyogranulomatous pleuritis, pericarditis, peritonitis, visceral abscesses, septic arthritis, and recurrent localized infections in dogs (Buchanan and Scott 1984; Pelle et al. 2000). Infection has been reported in association with penetration of *Hordeum* grass awns.

Actinomyces viscosus is the etiologic agent of canine and feline actinomycosis. Cutaneous actinomycosis is the most common manifestation and is often associated with subcutaneous abscess formation and pyothorax. Infections are usually secondary to perforating injuries caused by bite wounds or foreign bodies. In the most common forms of clinical disease in the dog, the cervicofacial, abdominal, and thoracic regions are involved (Davenport et al. 1975; Donahue and Brightman 1995; Georg et al. 1972). *A. viscosus* has also been isolated from skin pustules and nodules in horses (Specht et al. 1991).

Actinomycosis involving the central nervous system (CNS) is rare in animals. Several cases of *Actinomyces* causing CNS disease have been reported in animals: meningitis in an Arctic fox (Raju et al. 1986), encephalitis associated with hydrocephalus in a dog (Anvik and Lewis 1976), and pyogranulomatous meningoencephalitis in a dog (Couto et al. 2000). In all these cases, however, identification of the organisms could not be made. *A. viscosus* was isolated from the inflammatory tissues of a 3-year-old female domestic cat with paraplegia (Bestetti et al. 1977). *A. naeslundii* has been identified in a case of pyogranulomatous meningoencephalitis and osteomyelitis of the temporal bone in a goat (Hirai et al. 2007).

Furthermore, *Actinomyces* species have been rarely implicated in ocular infections in animals. Sherman et al. (2012) reported on a case of ulcerative keratitis in a dog attributed to *A. bowdenii*. *Actinomyces* sp. has been associated with a case of endophthalmitis in a dog (Barnes and Grahn 2007).

Potential Virulence Factors of *Actinomyces*

Actinomyces species are not virulent or have a low potential to produce diseases, and they require a break in the integrity of the mucous membranes and the presence of devitalized tissue to invade deeper body structures and cause illness. Establishment of infection may require the presence of other bacteria, which participate in the production of infection by elaborating a toxin or enzyme or by inhibiting host defenses. These companion bacteria act as copathogens enhancing the low invasiveness of *Actinomyces* species. After establishment of infection with *Actinomyces*, the host mounts an intense inflammatory response, i.e., suppurative and granulomatous, and fibrosis may develop subsequently. Infection typically spreads contiguously, frequently ignoring tissue planes and invading surrounding tissues or organs. Ultimately, the infection produces draining sinus tracts. Hematogenous dissemination (Apothéloz and Regamey 1996; Colmegna et al. 2003) to distant organs may occur in any stage of the infection, whereas lymphatic dissemination is unusual.

Although the exact mechanism by which *Actinomyces* species exert their pathogenicity has not been totally clarified, there is some evidence that can help explain infections caused by these microorganisms. Several *Actinomyces* species, including *A. naeslundii*, *A. oris*, and *A. viscosus*, have fimbriae which mediate adhesion of these bacteria to dental and mucosal

surfaces and interactions with streptococci as well as other members of the biofilm community (Cisar et al. 1997b; Rickard et al. 2003; Yeung 1999). *Actinomyces* species have two antigenically and functionally distinct types of fimbriae; type 1 fimbriae mediate adhesion of *Actinomyces* to the tooth surface through binding to salivary proline-rich proteins (PRPs) and to statherin (Clark et al. 1989; Gibbons et al. 1988; Wu et al. 2011a), whereas type 2 fimbriae are associated with a lactose-sensitive mechanism (a lectin-like activity) to recognize specific saccharide motifs present in both streptococcal coaggregation receptor polysaccharides (RPS) and host cell surface glycoconjugates (Cisar et al. 1995, 1997a; Mishra et al. 2010; Strömberg et al. 1992). Type 2 fimbrial lectins facilitate phagocytosis by recognizing the lactose-containing receptors on polymorphonuclear leukocytes (Sandberg et al. 1986).

The genetic components for type 1 and 2 fimbrial assembly of *Actinomyces* are arranged in two distinct gene clusters (Donkersloot et al. 1985; Mishra et al. 2007; Yeug and Cisar 1988; Yeung and Ragsdale 1997). Type 1 fimbria of *A. oris*, encoded by the gene cluster *fimQ-fimP-srtC1*, is made of the fimbrial shaft FimP and the tip fimbrillin FimQ, which is the adhesin interacting with PRPs (Wu et al. 2011a). On the other hand, type 2 fimbria, encoded by the gene locus *fimB-fimA-srtC2*, is made of the fimbrial shaft FimA and the tip fimbrillin FimB (Mishra et al. 2007). FimA is essential for coaggregation of *A. oris* with oral streptococci, adherence to red blood cells (RBCs), and biofilm development (Mishra et al. 2010). Assembly of type 1 fimbrial polymers requires sortase SrtC1 (Wu et al. 2011a), whereas type 2 fimbrial assembly involves sortase SrtC2 (Mishra et al. 2010). An *Actinomyces oris* mutant lacking *srtC2* fails to coaggregate with oral streptococci, adhere to RBCs, and form biofilms (Mishra et al. 2010).

In addition, the ability of *Actinomyces* species to produce exopolysaccharides (EPSs) contributes to their survival and the development of persistent infections in the human body. Exopolysaccharides are key components of the matrix in cariogenic oral biofilms and in biofilms formed on abiotic surfaces such as IUD and are recognized virulence factors involved in the pathogenesis of dental caries and pelvic actinomycosis in IUD users (Bowen and Koo 2011). Carrillo et al. (2010) showed that *A. israelii* was able to attach and grow in synthetic intrauterine media and to survive copper toxicity due to its ability to produce EPS and to form biofilms. Yamane et al. (2013) demonstrated the capacity of a strain of *A. oris* to produce EPSs in liquid culture as viscous materials and as meshwork structures around the cell on agar plates and its capability to induce persistent abscess lesions in mice. EPS produced by microorganisms are a complex mixture of biopolymers primarily consisting of polysaccharides, as well as proteins, nucleic acids, lipids, and humic substances. This matrix was considered essential for the existence of the biofilm lifestyle and full expression of virulence by bacterial pathogens (Costerton et al. 1999; Flemming and Wingender 2010). EPS immobilizes biofilm cells and keeps them in close proximity, thus allowing for intense interactions, including cell–cell communication and the formation of synergistic microconsortia (Flemming and Wingender 2010).

Serological Diagnosis of *Actinomyces* Infections

Because of difficulties in obtaining suitable clinical specimens and isolating *Actinomyces* species, there has always been a demand for diagnosing actinomycotic infections by means of serological techniques. Various serological techniques including fluorescent antibody (FA) staining, gel precipitation, enzyme immunoassay, and immunoelectrophoresis have been used for identifying and enumerating *Actinomyces* species. However, few studies have been carried in the past concerning the serological diagnosis of actinomycosis, and the results cannot be regarded as sufficiently satisfactory.

Fluorescent-conjugated antibody (FA) staining provided a rapid method for the identification of various *Actinomyces* species (Slack and Gerenscer 1970, 1976, Gerencser and Slack 1976). In addition, FA permits rapid diagnosis of actinomycosis by direct staining of clinical materials, even after fixation in formalin (Happonen and Viander 1982; Hothci and Schwarz 1972). In a comparative study of fluorescent antibody technique and conventional staining methods for the diagnosis of cervicofacial actinomycosis in formalin-fixed and paraffin-embedded biopsies using antiserum specific against *A. israelii*, a good correlation was found between conventional staining and FA staining in both suspected positive and negative controls (Happonen and Viander 1982).

Holmberg et al. (1975) developed a serological test based on crossed immunoelectrophoresis (CIE) for detecting precipitating antibodies against *A. israelii* and applied it for the detection of humoral antibodies in sera from nine patients with actinomycosis. They found that all sera of patients had antibodies against one or more *A. israelii* antigens in the preparations. In a subsequent study the diagnostic sensitivity of the CIE assay was evaluated by Persson and Holmberg (1984b). The sensitivity of the assay was 83 %, its specificity was 98 %, and its accuracy was 100 % for negative prediction and 45 % for positive prediction. However, the CIE assay could not be relied on for a presumptive diagnosis of actinomycosis as cross-reacting antibodies were detected in serum specimens from some patients, particularly with tuberculosis, nocardiosis, candidiasis, or aspergillosis (Holmberg 1981). Furthermore, although precipitation reactions against *A. israelii* antigens were found in uterine secretions from women with long-term use of IUD, the nature of the precipitating components could not be proved to be immunoglobulins (Persson and Holmberg 1985), and therefore, the method is inconclusive.

Furthermore, the relationship between antibody response to *Actinomyces* antigens and dental caries has been studied (Levine and Movafagh 1984; Levine et al. 1984, 2005). Human serum from many individuals has predominantly IgG precipitating antibodies to two antigens identified in dental plaque and various oral bacteria (Levine and Bush 1981). One antibody (A+) recognizes an antigen from *Actinomyces* spp. (Levine and

Movafagh 1982). The other antibody (S+) is specific for D-alanyl glycerol teichoic acids found in cell walls in many Gram-positive bacteria. The presence of an elevated IgG antibody response to *Actinomyces* antigen (A-Ab) enhances caries protection directly and in association with effective oral hygiene using fluorinated dentifrices (Levine et al. 1984, 2005). Conversely, a low A-Ab response is suggestive of greater caries experience.

Genus *Arcanobacterium*

Arcanobacterium haemolyticum is an opportunistic pathogen that occurs almost exclusively in symptomatic patients, with sporadic finding in healthy individuals. It is believed that humans are the only reservoir of this bacterium. Although *A. haemolyticum* has been most commonly associated with pharyngitis (Funke et al. 1997b), it has been implicated in a wide spectrum of diseases (Linder 1997; Skov et al. 1998; Vargas et al. 2006). These include endocarditis (Alos et al. 1995; Wong et al. 2011), skin and soft tissue infection (Dobinsky et al. 1999; van Loo et al. 2007), urinary tract infection (Ciraj et al. 2006), osteomyelitis (Biswas et al. 2003), peritonitis (Farmer et al. 2007), brain abscess (Vargas et al. 2006), pneumonia (Stacey and Bradlow 1999), pyothorax (Parija et al. 2005), bacteremia (Fernández-suárez et al. 2009), and septic arthritis (Goyal et al. 2005). Infections can be transmitted between humans or from humans to animals.

Human Infections Caused by *Arcanobacterium* Species

A. haemolyticum is almost exclusively a human pathogen, making it somewhat unique within the genus (Jost and Billington 2005). *A. haemolyticum* is a well-recognized cause of pharyngitis, skin, and soft tissue infections (Maclean et al. 1946; Miller et al. 1986). An estimated 0.5–2.5 % of all cases of pharyngitis are caused by *A. haemolyticum* (Mackenzie et al. 1995; Linder 1997). Infection occurs predominantly in adolescents and young adults with maximum incidence in the 15–18-year-old age group (Masckenzie et al. 1995). Clinically, *A. haemolyticum* pharyngitis resembles that caused by *Streptococcus pyogenes*, in that patients complain of sore throat and pharyngeal edema. In addition, about half of the patients complain of fever, swollen lymph glands, nonproductive cough, and purulent secretions from the tonsils. One unique feature of *A. haemolyticum* pharyngitis is that 33–67 % of patients display an erythematous, morbilliform, or scarlatinal rash along with other symptoms (Miller et al. 1986; Carlson et al. 1994c).

An individual with *A. haemolyticum* cutaneous infections displays chronic ulcerations and cellulitis. In addition, bacteremia secondary to skin and soft tissue infections has been reported and in reported cases the source of infection is most likely a skin wound. In some cases, the clinical presentation of soft tissue abscess caused by *A. haemolyticum* mimics a soft tissue tumor in patients without an underlying immunosuppressive condition (van Loo et al. 2007; Dobinsky et al. 1999).

Less commonly, *A. haemolyticum* causes systemic invasive disease and deep-seated infections such as meningitis (Minarik et al. 1997), endocarditis (Alos et al. 1995; Wong et al. 2011), septic arthritis (Goyal et al. 2005), pneumonia (Stacey and Bradlow 1999; Therriault et al. 2008), osteomyelitis (Biswas et al. 2003), and sinusitis (Volante et al. 2008). It has been isolated as a sole cause of infection in a number of cases (Vargas et al. 2006; van Loo et al. 2007; Therriault et al. 2008), but in others it has been isolated in combination with other pathogens (Dobinsky et al. 1999; Younus et al. 2002; Lundblom et al. 2010) such as *Bacteroides* spp., *Staphylococcus aureus*, Group G *Streptococcus*, *Pseudomonas aeruginosa*, *Escherichia coli*, *Mycoplasma pneumoniae*, and *Fusobacterium necrophorum*. Invasive disease caused by *A. haemolyticum* shows a special predilection for males and is often seen in two distinct subset of patients: a subset of otherwise healthy adolescents presenting with upper respiratory tract infections (pharyngitis, tonsillitis, sinusitis) and a subset of older, often immunocompromised patients presenting with skin and soft tissue infection (Skov et al. 1998; Tan et al. 2006; Therriault et al. 2008).

The other species are uncommonly isolated from human.

Animal Infections Caused by *Arcanobacterium* Species

A. haemolyticum has been known as an occasional cause of infections in domestic (Hassan et al. 2009; Tyrrell et al. 2002) and farm (Richardson and Smith 1968; Roberts 1969) animals for which human contact is a possible source of infection. The organism has been identified as one of the pathogens responsible for mandibular and maxillary abscesses in pet rabbits (Tyrrell et al. 2002). It has also recently been reported as a cause of necrotizing fasciitis and myositis in cattle (Bancroft-Hunt et al. 2010). *A. hippocoleae* is reported to be associated with vaginitis and placentitis in horse (Hoyles et al. 2002b; Bemis et al. 2008). *A. phocae* was recovered in mixed culture from various tissues and fluids of common seals (*Phoca vitulina*) and gray seals (*Halichoerus grypus*) (Pascual Ramos et al. 1997a). It is a common pathogen of wound infections that is occasionally associated with systemic infections in stranded marine mammals (Johnson et al. 2003). *A. pluranimalium* was recovered from the spleen of a dead harbor porpoise (*Phocoena phocoena*) and lung abscess in a fallow deer (*Dama dama*) (Lawson et al. 2001a) and was frequently isolated from abortion materials derived from ovine (Foster and Hunt 2011). *A. pluranimalium* is thought to be a cause of occasional opportunistic infections in sheep, particularly abortion, in England and Scotland (Duff et al. 2001).

Potential Virulence Factors of *Arcanobacterium*

A. haemolyticum expresses a number of virulence factors that are important for the organism to cause disease. *A. haemolyticum* expresses an unusual phospholipase D (PLD), which is responsible for efficient host cell adhesion by reorganizing lipid rafts (Lucas et al. 2010). PLDs are enzymes which cleave host membrane phospholipids, although the *A. haemolyticum* PLD has restricted substrate specificity, cleaving only sphingomyelin. The activities of PLD promote damage, either directly or via host inflammatory processes, to the epithelial lining, which provides an opportunity for bacterial dissemination from the site of primary infection (throat or skin) to distal sites to cause systemic disease. PLD present in all strains of *A. haemolyticum* and the loss of its production does not affect bacterial invasion (Lucas et al. 2010). This is in contrast to the most closely related PLD of *Corynebacterium pseudotuberculosis* (Cuevas and Songer 1993) that is absolutely required for virulence (McNamara et al. 1994). PLD expressed by intracellular bacteria is cytotoxic to host cells and caused host cell death via necrosis (Soucek and Souckova 1974).

In addition, *A. haemolyticum* secrete arcanolysin (ALN), a cholesterol-dependent cytolysin (CDC), which is most closely related to pyolysin (PLO) from *Trueperella pyogenes*. ALN, like PLD, was present in all strains of *A. haemolyticum*. It has variable hemolytic and cytotoxic activity against mammalian cells from different species with high activity against human, horse, and rabbit cells and lesser activity against cells derived from other species (Jost et al. 2011). This selectivity appears to function at the level of membrane binding and may contribute to the host range of *A. haemolyticum*.

Aside from PLD, *A. haemolyticum* also expresses neuraminidase activity (Mueller 1973) and has been shown to exhibit binding to several human plasma proteins, including fibrinogen and fibronectin (66).

Virulence factors of the other *Arcanobacterium* species have not been studied.

Antigenic Structure

A. haemolyticum induces an antibody response, as demonstrated in sera of patients with acute infection or from convalescents, in patients from whom the organism was cultured (Nyman et al. 1997; Votava et al. 2001). Votava et al. (2001) reported the detection of *A. haemolyticum* PLD-neutralizing antibodies in patients with acute tonsillitis. The antibodies react primarily with four distinct cell wall-associated proteins with estimated molecular masses of 80, 60, 50, and 30 kDa. Of the four proteins, the 80-kDa protein is the dominant antigen (Nyman et al. 1997).

Antigenic properties of PLDs produced in vitro have been used in the serodiagnosis of infections caused by bacteria that produce PLDs in vivo (Cuevas and Songer 1993; McNamara et al. 1995; Skalka et al. 1998; Votava et al. 2001). The sera obtained from spontaneous infection cases react with the homologous PLD of the bacterial species which had caused the infection. The antigenic properties of PLD from *A. haemolyticum* (PLD-A) and from *Corynebacterium pseudotuberculosis* (PLD-C) are similar but not identical (Cuevas and Songer 1993; McNamara et al. 1995). Skalka et al. (1998) used PLD neutralization to examine sera of humans with a spontaneous infection by *A. haemolyticum*. A positive result of neutralization was due to an inhibition of the hemolytic synergism with the equi factor (ef) from *Rhodococcus equi*. They found that the titers of sera neutralizing the homologous PLD were always significantly higher than those neutralizing the heterologous PLD. However, these tests are not yet available as a matter of routine.

Antigens of the other *Arcanobacterium* species have not been studied.

Susceptibility of Arcanobacterium to Antibiotics

A. haemolyticum is susceptible to most classes of antimicrobial drugs, including penicillins, cephalosporins, carbapenems, macrolides, fluoroquinolones, tetracyclines, clindamycin, and vancomycin (Carlson et al. 1994a, 1999; Arikan et al. 1997; Almuzara et al. 2002). General resistance has been reported against trimethoprim/sulfamethoxazole (Carlson et al. 1994a, 1999; Therriault et al. 2008). Although *A. haemolyticum* is susceptible (thus far, universally) to penicillin by in vitro MIC testing, treatment failures have been documented (Nyman et al. 1990; Osterlund 1995; Volante et al. 2008; Bomke et al. 2009). Clinical failures that have been reported were associated with penicillin tolerance (Carlson et al. 1999). Isolates resistant to ciprofloxacin (Vargas et al. 2006), vancomycin (French et al. 1992), macrolides, and quinolones (Carlson et al. 1999) have also been reported.

There are no established guidelines for the treatment of *A. haemolyticum* infections and it is recommended that treatment should be based on in vitro susceptibility profiles of individual strains and on the site of infection (Carlson et al. 1999). Skov et al. (1998) suggest that high doses of parenteral penicillin combined with an aminoglycoside would be preferable to beta-lactam antibiotics in cases of systemic *A. haemolyticum* infection. Theriault et al. (2008) recommend the use of intravenous penicillin or a cephalosporin as first-line pharmacologic management of deep-seated infections caused by this organism, whereas Van der Eerden et al. (2006) found that a macrolide antibiotic was the treatment of choice for a case of pharyngitis caused by *A. haemolyticum*.

Strains of *A. phocae* recovered from marine mammals were 100 % susceptible to amikacin, ampicillin, amoxicillin/clavulanate, cefazolin, ceftiofur, ceftizoxime, chloramphenicol, enrofloxacin, erythromycin, gentamicin, oxacillin, penicillin, rifampin, tetracycline, ticarcillin/clavulanate, and trimethoprim/sulfamethoxazole (Johnson et al. 2003). This suggests that beta-lactam antibiotics should be useful in treating *A. phocae* infections in marine mammals.

Detailed studies on the antibiotic susceptibility of the remaining *Arcanobacterium* species have not been reported.

Genus *Trueperella*

Trueperella are known as opportunistic pathogen of a number of economically important livestock such as domestic animals and pigs, causing a variety of purulent infections involving the skin, joints, and organs (Jost and Billington 2005). Infection is not confined to domestic animals but a number of various animal species including antelopes, bisons, camels, cats, chickens, deer, dogs, elephants, gazelles, horses, macaws, reindeers, turkeys, and wildebeests (Jost and Billington 2005). As a commensal, the source of infections is usually endogenous (Baumann et al. 2001; Dieleman et al. 1989; Lechtenberg et al. 1988; Jonsson et al. 1991; Jost and Billington 2005; Therriault et al. 2008; Volante et al. 2008). Infections can be transmitted from animal to animal, from animals to humans, or even between humans. However, members of different species vary considerably with regard to virulence, types of pathological lesions induced, and host specificity.

Human Infections Caused by *Trueperella* Species

Trueperella pyogenes has not been isolated as a part of the human normal flora (Jost and Billington 2005). It is an infrequent cause of infections in humans, and early reports are plagued by limited details on the microbiological tests performed, raising the possibility of misidentification (Gahrn-Hansen and Frederiksen 1992). Infections are mostly related to patients living in rural areas or had a history of contact with animals (Palmondon et al. 2007; Levy et al. 2009). Severe infections like endocarditis (Palmondon et al. 2007), pneumonia (Hermida et al. 2004), septicemia (Levy et al. 2009), septic arthritis (Lynch et al. 1998), and soft tissue (Kavitha et al. 2010) have been reported.

The role of *Trueperella bernardiae* in human infections has not been clearly established. The organism has been implicated in urinary tract infections (Lepargneur et al. 1998), septic arthritis (Adderson et al. 1998), osteitis (Bemer et al. 2009), and necrotizing fasciitis (Weitzel et al. 2011). The remaining *Trueperella* species appear to occur only in animals.

Animal Infections Caused by *Trueperella* Species

Trueperella pyogenes is an opportunistic pathogen of economically important livestock. As a commensal, the source of *Trueperella pyogenes* infections is often autogenous. Although *T. pyogenes* is capable of acting as a primary pathogen, infection often follows a physical or microbial trauma to the mucous membrane, allowing dissemination of the organism. *T. pyogenes* can cause a variety of suppurative infections involving the skin, joints, testes, and visceral organs. Economically significant disease includes mastitis (Quinn et al. 2002; Unnerstad et al. 2009), endometritis (Williams et al. 2005), liver abscesses (Doré et al. 2007), osteomyelitis (Firth et al. 1987; Bürgi et al. 2001; Martínez et al. 2007), pneumonia (Vogel et al. 2001; Fulton et al. 2009) peritonitis, and pleuritis in cattle, sheep, goats, and swine. *T. pyogenes* was also found to be etiologically involved in pneumonia in deer (Hattel et al. 2004; Tell et al. 2011) and in osteomyelitis in turkeys (Barbour et al. 1991; Brinton et al. 1993) and in chronic otitis externa in cats and canine cystitis (Billington et al. 2002a). It is noteworthy to mention that *T. pyogenes* induces orchitis in experimentally injected ovine (Gouletsou et al. 2004).

Of the remaining *Trueperella* species, *A. bernardiae* has as yet only been isolated from human sources, whereas *T. abortisuis* has been isolated from a sow's placenta after an abortion (Azuma et al. 2009). *T. bialowiezense* and *T. bonasi* were isolated from the prepuce of European bison (*Bison bonasus*) bulls suffering from balanoposthitis (Lehnen et al. 2006).

Potential Virulence Factors of *Trueperella*

A. pyogenes harbors a number of virulence factors that contribute to its pathogenic potential. These factors include pyolysin (PLO), two neuraminidases (NanH and NanP), a collagen-binding protein (CbpA), and fimbriae (Jost and Billington 2005; Pietrocola et al. 2007). Pyolysin (PLO) is a cholesterol-dependent cytotoxin produced by all *T. pyogenes* strains examined to date (Ding and Lämmler 1996; Billington et al. 1997; Jost et al. 1999; Silva et al. 2008) and is detected in culture supernatant as a 55-kDa protein. PLO is cytolytic for a number of cell types including PMNs and macrophages (Jost et al. 1999). It exerts its cytolytic effects through the formation of large pores in eukaryotic cell membranes (Billington et al. 2002a; Jost and Billington 2005). PLO also kills endometrial cells in vitro (Miller 2009) and the tissue damage associated with *T. pyogenes* infection in cows is an important mechanism compromising endometrial health and fertility (Sheldon et al. 2009).

T. pyogenes expresses two cell wall-bound neuraminidases, NanH and NanP. Neuraminidases (sialidases or *N*-acetylneuraminyl hydrolase) remove sialic acid from carbohydrates or glycoproteins. The NanH found in all *T. pyogenes* isolates (Jost et al. 2001), while the NanP is found only in 64.2 % of the examined strains (Jost et al. 2002b). The neuraminidases are important factors in promoting adhesion to host epithelial cells. In addition, the action of neuraminidase can decrease mucus viscosity (Gottschalk 1960), possibly enhancing bacterial colonization of the underlying tissues. Furthermore, neuraminidases impair the host immune response as desialylation increases the susceptibility of mucosal immunoglobulin A (IgA) to bacterial proteases (Frandsen 1994; Reinholdt et al. 1990).

T. pyogenes also expresses a collagen-binding protein, CbpA, which mediates adhesion and promotes colonization of *T. pyogenes* cells to collagen-rich tissues of the host. The mature CbpA protein is 1,124 amino acids long, has a molecular mass of 121.9 kDa, and contains the domain structure typical of microbial surface components recognizing adhesive matrix molecules (MSCRAMM) (Esmay et al. 2003; Pietrocola et al. 2007). CbpA displays 30.9 % identity and 50.4 % similarity to the collagen adhesin (Cna) of *Staphylococcus aureus*. CbpA is present in 48 % of *T. pyogenes* isolates. However, 100 % of turkey osteomyelitis

isolates carry *cbpA* gene, suggesting that CbpA may act as a virulence factor for *T. pyogenes* osteomyelitis (Esmay et al. 2003).

Furthermore, *T. pyogenes* expresses fimbriae, hairlike surface projections which are involved in adhesion to host cells. Four fimbrial biogenesis operons which are required for the expression of fimbriae in *T. pyogenes* are identified (Jost and Billington 2005). One of these operons consists of three genes, *fimB*, *fimA*, and *srtA*, which are similar in genetic organization to those from *Actinomyces naeslundii* type 2. *fimA* encodes a 45.7-kDa protein, FimA, responsible for fimbrial biogenesis, and shows 27 % identity and 41 % similarity to the *A. naeslundii* type 2 fimbrial subunit. fimA and fimB are both carried or neither present in approximately 94 % of examined *T. pyogenes* isolates. In contrast, *srtA* is found in all *T. pyogenes* isolates examined to date, including those lacking fimA and fimB, which suggests that in addition to fimbrial biogenesis, this enzyme may be required for the sorting of other cell surface molecules. Like other bacterial fimbriae, it is assumed that the fimbriae of *T. pyogenes* are involved in adhesion to the host, possibly by binding to fibronectin through FimB. The *T. pyogenes*-specific *fimA* gene is significantly associated with clinical endometritis in cows (Bicalho et al. 2012; Santos et al. 2011).

Antigenic Structure

PLO expressed by *T. pyogenes* is required for bacterial survival in the hosts and, like other thiol-activated cytolysins (TACYs), it is cytotoxic for phagocytic cells (Jost et al. 1999). In addition, PLO is also an important host-protective antigen, as formalin-inactivated, recombinant, His-tagged PLO (HIS-PLO) was shown to be efficacious in mice (Jost et al. 1999). However, the toxicity of PLO limits its usefulness as a vaccine without prior inactivation (Jost et al. 1999). Mutational analysis of the undecapeptide in PLO and other CDCs has identified residues which are critical for cytotoxic activity (Billington et al. 2002b; Korchev et al. 1998; Sekino-Suzuki et al. 1996). Knowledge of the residues critical for toxic activity allowed the design of genetic toxoids, i.e., recombinant toxins with mutations affecting activity, for use as immunoprophylactic agents. Three genetically toxoided, HIS-PLO.F_{497}, HIS-PLO.ΔP_{499}, and HIS-PLO.A_{522}, were found to be nontoxic, and vaccination of the mice with these toxoids protected mice from infection with *T. pyogenes* (Jost et al. 2003). The protective capacity of these vaccines appears to be in the stimulation of a humoral immune response, as passive immunization with anti-PLO goat serum could also prevent *T. pyogenes* infection in the mouse model system (Billington et al. 1997). These results suggest that PLO may be a promising vaccine candidate. However, unlike laboratory mice, healthy domestic animals are naturally colonized with *T. pyogenes* and often have antibodies to the organism and to PLO. Vaccination with whole cell and culture supernatant can increase antibody titers without giving any protection. However, it is uncertain how these neutralizing antibodies in these animals will translate to protection from *T. pyogenes infections*.

Antigens of the other *Trueperella* species have not been studied.

Susceptibility of *Trueperella* to Antibiotics

The antimicrobial susceptibility patterns of *T. pyogenes* vary depending on the host species and the anatomical site from which they were isolated (Cohen et al. 1996; Brooks and Jayarao 2008; Tell et al. 2011). Cohen et al. (1996) observed a difference between susceptible patterns of *T. pyogenes* isolated from bovine udder and bovine uterus to oxytetracycline and trimethoprim–sulfadiazine. They found that most of the isolates that originated from the uterus were resistant to oxytetracycline and trimethoprim–sulfadiazine, whereas udder isolates were sensitive to both drugs. Furthermore, Brooks and Jayarao (2008) found that bovine and porcine isolates of *T. pyogenes* behaved differently to certain antibacterial drugs where more isolates of porcine origin were resistant to oxytetracycline, erythromycin, tilmicosin, and lincomycin as compared to those isolated from cattle.

In a study of antimicrobial resistance in *T. pyogenes* isolated from the uteri of postpartum Holstein dairy cows, Santos et al. (2010) found that there was a broad and variable antimicrobial resistance profile among *T. pyogenes* organisms isolated from bovine uterine fluid. More than 50 % of the total isolates were resistant to amoxicillin, ampicillin, chloramphenicol, florfenicol, oxytetracycline, and penicillin. Malinowski et al. (2011) found that *T. pyogenes* strains isolated from the uteri of cows with metritis/endometritis were susceptible mostly to amoxicillin/clavulanic acid, ceftiofur, and norfloxacin and were resistant or slightly susceptible to oxytetracycline, ampicillin, cloxacillin, rifaximin, and cephapirin. Silva and Lobato (1998) found that in vitro *T. pyogenes* was most sensitive to ampicillin, enrofloxacin, cephalothin, lincomycin, neomycin, penicillin, novobiocin, gentamicin, chloramphenicol, and tetracycline. Sheldon et al. (2004a, b) reported the highest activity of cephalosporins (cefquinome, cephapirin, ceftiofur) and enrofloxacin against *T. pyogenes*.

Although susceptibility standards for human isolates are not available for *T. pyogenes*, Levy et al. (2009) reported the treatment of a case of human sepsis using a combination of ampicillin 6 g/day plus gentamicin 240 mg/day.

Genus *Actinobaculum*

Actinobaculum species are strongly associated with urinary tract infections (UTIs) in swine and human. The spectrum of UTIs primarily ranges from benign cystitis to severe pyelonephritis with urosepsis. *A. suis* is a common cause of cystitis and pyelonephritis in breeding sows in North and South America, Europe, Asia, and Australia. *A. suis* may be transmitted from boars to sows at the time of mating. The source of infections with the human isolates is thought to be endogenous.

Human Infections Caused by *Actinobaculum* Species

Actinobaculum species associated with human infections include *A. massiliense*, *A. schaalii*, and *A. urinale*. It has been reported that they are responsible for numerous urinary tract infections, mainly in elderly patients with underlying urological predispositions (Hall et al. 2003a; Greub and Raoult 2002; Fendukly and Osterman 2005; Reinhard et al. 2005; Bank et al. 2010; Nielsen et al. 2010). A recent study showed that 22 % of 252 urine samples from patients >60 years were positive for *A. schaalii* (Bank et al. 2010). Besides UTI, *A. schaalii* also cause septic complications such as urosepsis (Sturm et al. 2006), bacteremia (Hesstvedt et al. 2006; Gomez et al. 2011), abscess (Tschudin-Sutter et al. 2011), osteomyelitis (Haller et al. 2007), endocarditis (Hoenigl et al. 2010), and Fournier's gangrene (Bempt et al. 2011). It is estimated that *A. schaalii* is associated with an infection—primarily sepsis and abscesses—in 81.5 % of patients (Tschudin-sutter et al. 2011). *A. massiliense* has been reported to cause superficial skin infections (Waghorn 2004).

Animal Infections Caused by *Actinobaculum* Species

A. suis is a well-established veterinary pathogen causing UTI, cystitis, pyelonephritis, and metritis with abortions in sows (Yamini and Slocombe 1988; Walker and MacLachlan 1989; Taylor 2012). In contrast with cystitis caused by other bacteria, infection with *A. suis* resulted in a hematuria and urinary pH values above 8.0 (Liebhold et al. 1995). In acute and severe cases, affected animals die suddenly from acute renal failure.

Potential Virulence Factors of *Actinobaculum*

Larsen et al. (1986) demonstrated that some strains of *A. suis* are heavily fimbriated and adhere to epithelial cells of the porcine bladder where glycoconjugates are specific receptor sites for its attachment. *A. suis* produces the urease enzyme able to cause cleavage of urea into ammonia. The elevated pH, increased from a normal range of 6.0–7.5 to 8.0–9.0, enhances bacterial proliferation and causes an inflammatory reaction of the mucosal surface, inhibiting the growth of competitive microflora and promoting the precipitation of urinary salts and crystals, which in turn increases inflammatory changes in the bladder mucosa and provides a nest for bacterial growth and protection from antibiotics and host defense mechanisms.

Most interesting is the finding that the cell membranes of *Actinobaculum* species are characterized by the presence of choline-containing phosphoglycolipids. These are known as potent virulence factors that participate in the adhesion of pathogenic bacteria to eukaryotic target cells (Rottem 2002). Nevertheless, the exact chemical structure of the choline-containing phosphoglycolipids from *Actinobaculum* is not yet determined and its role in colonization and pathogenesis of *Actinobaculum* species is not examined.

The human pathogen, *A. urinale*, as yet known is the only one which produces the urease enzyme and which may be a functional factor in the pathogenicity of this bacterium.

Antigenic Structure

The 6-deoxyhexoses, rhamnose and 6-deoxytalose, are cell wall constituents of *Actinobaculum* species. Deoxyhexoses are substantial cell wall components of several human pathogens such as *Actinomyces bovis* (MacLennan 1961), *Mycobacterium avium* (MacLennan 1962), and *Aggregatibacter actinomycetemcomitans* (Amano et al. 1989). Because of their presentation on the cell surface, they represent antigenic determinants that contribute to serological specificity (Bishop et al. 1982). However, to date there is no data describing the structure/biological activity of these deoxy sugars and its involvement in the pathogenicity of the genus *Actinobaculum*.

Susceptibility of *Actinobaculum* to Antibiotics

In vitro susceptibility testing showed that all of the type strains of *Actinobaculum* species are susceptible to nearly all β-lactam antibiotics, tetracyclines, vancomycin, linezolid, and clindamycin but are completely resistant to metronidazole (MIC >256 mg/L). All species, except *A. suis* and *A. urinale* (MICs ≥256 mg/L), were highly susceptible to trimethoprim. Although it has been reported that clinical isolates of *Actinobaculum schaalii* are resistant to trimethoprim (Cattoir et al. 2010; Cattoir 2012), MIC determined for the type strain *A. schaalii* CCUG 27420^T indicates that it is susceptible against this antibiotic (MIC <0.002 mg/L). Of the antibiotics tested, fluoroquinolones exhibit variable reactivities. Whereas older fluoroquinolones (i.e., norfloxacin, ciprofloxacin) exhibit weaker antimicrobial effect (MIC 1.5–2 mg/L) against *Actinobaculum* species, newer compounds (i.e., levofloxacin, moxifloxacin) have greater activity (MIC 0.094–0.25 mg/L).

Treatment failure with amoxicillin was reported for patients with chronic UTI due to *A. massiliense* and *A. schaalii* (Greub and Raoult 2002; Reinhard et al. 2005).

Genus *Varibaculum*

Information on the clinical prevalence and pathogenic potential of *Varibaculum cambriense* is inadequate. The organism has been isolated from human abscesses such as brain abscess, postauricular abscess, ischiorectal abscess, submandibular abscess, breast abscesses, cheek abscess, intrauterine contraceptive devices or vaginal swabs, hidradenitis and a fistula, umbilical scar, sebaceous cysts, skin abscess, and hip joint abscess

(Hall et al. 2003c; Chu et al. 2009; A. F. Yassin, unpublished). It was also identified in cultures and tDNA-PCR among the species typically associated with bacterial vaginosis (Verhelst et al. 2005). The organism was always isolated as part of polymicrobial infections associated with other potentially pathogenic bacteria such as *Peptostreptococcus* sp., *Peptoniphilus* sp., *Porphyromonas* sp., *Prevotella* sp., *Propionibacterium* sp., and *Bifidobacterium* sp.

Genus *Mobiluncus*

Mobiluncus species have been associated with several types of infections in humans. They have been isolated, either alone or in concert with other anaerobes, from breast and umbilical abscesses (Glupezynski et al. 1984; Sturn and Sikkenk 1984; Weinbren et al. 1986; Edmiston et al. 1989), blood cultures (Glupezynski et al. 1984; Gomez-Garces et al. 1994; Sahuquillo-Arce et al. 2008), and the chorioamnionic membranes of a placenta at preterm delivery (Hillier et al. 1988). Multivariate analysis of vaginal flora has shown that *Mobiluncus* spp. occur in large numbers in bacterial vaginosis (BV) and may therefore serve as an indicator organism for this clinical syndrome (Spiegel 1995; Hillier et al. 1991). In a study of the prevalence of antibody to *Mobiluncus* among women with and without BV, Moi et al. (1991) found that women with BV had significantly higher titers of IgG antibody than those without BV. Titers of antibody to *M. mulieris* were significantly lower than those to *M. curtisii*. The seroprevalence of IgG antibody to *M. curtisii* was also demonstrated in 75% of a cohort of pregnant females by Schwebke et al. (1996). These results in addition to the ability of *M. curtisii* to escapes phagocytosis more easily as observed in luminol chemiluminescence, indicate that *M. curtisii* is more virulent than *M. mulieris*, and agree with reports of *M. curtisii* found in postoperative and extragenital infections (Moi et al. 1991).

Human Infections Caused by *Mobiluncus* Species

Bacterial Vaginosis (BV)

Bacterial vaginosis (BV) is a polymicrobial, superficial vaginal infection involving a reduction in the amount of hydrogen peroxide-producing lactobacilli and an overgrowth of anaerobic bacteria (Eschenbach 1989). Normally, lactobacilli such as *Lactobacillus crispatus*, *Lactobacillus jensenii*, and *Lactobacillus iners* (Hillier et al. 1993; Antonio et al. 1999; Vásquez et al. 2002; Vallor et al. 2001) constitute 95 % of the bacteria in the vagina. The predominance of lactobacilli helps maintain the ecological balance of the vaginal environment by maintaining a low pH and by preventing overgrowth of other microbes (Aroutcheva et al. 2001). In women with BV, the prevalence of lactobacilli is considerably reduced and the concentration of other bacteria increased by 10^2 to 10^4 (Eschenbach 1989). Microorganisms associated with BV include *Gardnerella vaginalis*, *Bacteroides* sp., *Mobiluncus* species, *Prevotella* species, *Fusobacterium nucleatum*, *Peptostreptococcus* sp., *Ureaplasma urealyticum*, *Mycoplasma hominis*, and a wide variety of other microbes (Krohn et al. 1989). Although most of these organisms are present in small numbers in the normal vagina, *Mobiluncus* is rarely found in the normal vagina and has been considered as a sensitive marker for the diagnosis of BV. *Mobiluncus* has been reported to be found in up to 50 % of women with BV (Spiegel et al. 1983b; Hallén et al. 1987; Thomason et al. 1984b; Hillier et al. 1991; Tohill et al. 2004). The association between *Mobiluncus* spp. and a positive amine odor after KOH preparation ("whiff test") has been reported (Hallén et al. 1987; Pereira et al. 2005; Nyirjesy et al. 2007). Despite an increasing understanding of the microbiology of BV, the etiologic agents remain unknown.

The most common BV symptoms that resulted from the shift in vaginal flora are a malodorous discharge and itching (Amsel et al. 1983). The discharge results in part from degradation of the normal vaginal mucin gel, which is efficiently performed by mucin-degrading enzymes produced by BV-associated bacteria (Olmsted et al. 2003). The odor, usually described as "fishy," is derived from volatilization of the amines produced by the metabolism of anaerobic bacteria. Chen et al. (1979) found methylamine, isobutylamine, putrescine, cadaverine, histamine, tyramine, and phenethylamine in the vaginal discharge of patients with symptoms of nonspecific BV. The profound increase in *Mobiluncus* concentrations is characterized by enhanced production of volatile amines (Cruden and Galask 1988).

Diagnosis of BV Currently the Amsel criteria and the Nugent score (NS) are the most commonly used methods for BV diagnosis. Clinical diagnosis of BV, according to Amsel's clinical criteria, is based on the presence of three of the following four criteria: an elevated (>4.5) vaginal pH, release of a fishy odor on addition of 10 % KOH to the vaginal fluid, an abnormal discharge that is thin and homogenous, and clue cells in the vaginal fluid (Amsel et al. 1983). An increase in pH rapidly releases amines such as trimethylamine (TMA), which are dissolved in the discharge as amino acids when the pH is low. TMA is responsible for the smell of fishy odor and can be detected in vaginal specimens using the sniff test/whiff test by adding one drop of 10–20 % KOH to the discharge. Clue cells are epithelial cells of the vagina whose borders are difficult to see in wet mount microscopic preparation because so many bacteria are found on the surface of the cells. It has been reported that the presence of *Mobiluncus* morphotypes with Gram stain may be associated with higher numbers of clue cells and positive "whiff" tests (Pereira et al. 2005).

Direct Gram stain of vaginal fluids has been used to diagnose BV (Spiegel et al. 1983a; Nugent et al. 1991). For the interpretation of Gram-stained smears, Nugent et al. (1991) proposed a scoring system that is based on the observation of three morphotypes to create a total score of zero to ten. These three morphotypes are large Gram-positive rods (*Lactobacillus*), small Gram-negative or Gram-variable rods (*Bacteroides* or *Gardnerella*), and curved Gram-negative to Gram-variable rods (*Mobiluncus* spp.). The total scores were computed by adding the weighted quantitation (0 to 4+) of the three morphotypes. A score of 0–3 is considered normal flora,

a score of 4–6 is classified as intermediate flora, and a score of 7–10 is consistent with BV. Today, the Nugent scoring is considered as the gold standard for laboratory diagnosis of BV and is employed in many research studies.

Molecular methods have been recently used for the detection and quantification of BV-associated bacteria to improve the diagnosis of BV (Fredricks et al. 2007; Menard et al. 2008, 2010; Obata-Yasuoka et al. 2002; Schwebke and Lawing 2001; Zariffard et al. 2002). Generally, good agreement and high sensitivity and specificity have been reported for PCR-based assay in comparison to standard methods. Schwebke and Lawing (2001) used PCR to characterize *Mobiluncus* spp. in women with BV and a control group of women without BV as determined by Nugent scoring. The authors detected *Mobiluncus* by PCR in 84.5 % of women with BV and in 38 % of women without infection. *M. curtisii* was rarely detected in the latter group, though it was found in 65.3 % of women with bacterial vaginosis. The sensitivity and specificity of Gram stain compared with PCR were 46.9 % and 100 %, respectively. In a multiplex PCR assay for diagnosing BV via quantifying *Mobiluncus mulieris*, *Mobiluncus curtisii*, *Bacteroides fragilis*, and *G. vaginalis* from vaginal swabs in pregnant and nonpregnant women, Obata-Yasuoka et al. (2002) reported 78.4 % and 95.6 % sensitivity and specificity, respectively, for multiplex PCR in comparison to the Nugent score. Fredricks et al. (2007) detected *Mobiluncus curtisii* by PCR in 55.6 % of subjects with BV with a specificity of 93 % and *Mobiluncus mulieris* in 22.2 % of subjects with BV with a specificity of 100 %. PCR assay performance for the *Mobiluncus* species did not improve when the Nugent criteria were used to define BV.

Furthermore, several studies have investigated the utility of quantitative PCR (qPCR) as a diagnostic tool for BV. Sha et al. (2005) demonstrated that qPCR for *Gardnerella vaginalis*, *Mycoplasma hominis*, and lactobacilli significantly correlates with the Nugent Gram stain method to diagnose BV. The authors found that women with BV diagnosed by Nugent score have significantly higher numbers of *G. vaginalis* and *M. hominis* and significantly lower numbers of lactobacillus organisms than women without BV. The sensitivity and specificity of the method were 83 % and 78 %, respectively, in comparison with Nugent score. The specificity and sensitivity of the method for *G. vaginalis* and *M. hominis* and decreasing levels of *Lactobacillus* spp. were significantly associated with BV with a sensitivity of 83 % and 87 % when compared to Nugent score. Furthermore, Menard et al. (2008) found that the molecular quantification of two microorganisms, *Atopobium vaginae* and *G. vaginalis*, had excellent sensitivity (96 %) and specificity (99 %) when compared with the Nugent Gram stain classification of BV. Although the study represents a major step toward a molecular diagnostic test for BV, the generalizability of the results to other populations needs to be established before widespread application of this method is advocated.

Complications Associated with Bacterial Vaginosis Bacterial vaginosis is an important public health problem that is characterized by abnormal changes in the vaginal flora (Koumans and Kendrick 2001). Numerous reports have hightend the association between bacterial vaginosis and serious medical complications in many gynecologic conditions, such as pelvic inflammatory disease (Faro et al. 1993), endometritis (Abner et al. 1998), amniotic fluid infection (Hillier et al. 1988), preterm labor and delivery (Eschenbach et al. 1988; Kurki et al. 1992; Meis et al. 1995), premature rupture of the fetal membranes (Krohn et al. 1993), miscarriage (Hay et al. 1994), and spontaneous abortion (McGregor et al. 1995). Pregnant women with BV are also at increased risk urinary tract infections (Sharami et al. 2007). Moreover, there is now evidence linking bacterial vaginosis to an increased susceptibility to acquisition of other sexually transmitted diseases (STDs), including HIV infection (Hillier 1998; Royce et al. 1999; Taha et al. 1999; Schmid et al. 2000; Sobel, 2000; Cu-Uvin et al. 2001). The enhanced susceptibility to STDs and HIV infection among women with bacterial vaginosis proposed to be related to decreased amounts of H_2O_2-producing lactobacilli in women with bacterial vaginosis (Eschenbach et al. 1989; Hillier and Holmes, 1998a, b). Most women with bacterial vaginosis have a relative decrease in lactobacilli concentration, and some have a complete absence of lactobacilli (Agnew and Hillier 1995; Hillier and Holmes 1998a). H_2O_2 is toxic to many microorganisms at concentrations that are readily achievable in the vaginal fluid and, thus, provides an intrinsic protective mechanism in the vaginal compartment (Eschenbach et al. 1989; Hillier and Holmes, 1998a; Klebanoff and Coombs 1991). The presence of BV also increases the risk of infection with herpes simplex virus type 2 (HSV-2) (Cherpes et al. 2005), acquisition or reactivation of human papillomavirus (HPV) (da Silva et al. 2004) as well as infection with gonorrhea and *Trichomonas vaginalis* and *Chlamydia trachomatis* (Wiesenfeld et al. 2003).

Extragenital *Mobiluncus* Infections

Although *Mobiluncus* species are seen with relative frequency in the genital tract, they are uncommonly isolated from nongenital sites, and reports on their involvement in extravaginal infections in humans are increasingly recognized (Glupezynski et al. 1984; Mayer et al. 1994; Sahuquillo-Arce et al. 2008; Sherlock et al. 2005; Sturm 1989; Weinbren et al. 1986). *Mobiluncus* have been isolated, either alone or in concert with other anaerobes, from several cases of breast and umbilical abscesses (Glupezynski et al. 1984; Sturn and Sikkenk 1984; Sturm 1989; Weinbren et al. 1986; Edmiston et al. 1989), from the chorioamnionic membranes of placenta at preterm delivery (Hillier et al. 1988), and have been found to be associated with septicemia (Glupezynski et al. 1984; Gomez-Garces et al. 1994; Mayer et al. 1994; Hill et al. 1998; Sahuquillo-Arce et al. 2008). *M. mulieris* has been reported as a copathogen with *Haemophilus aphrophilus* in a case of liver abscess (Sherlock et al. 2005). These infections outside of the reproductive tract could indicate that *Mobiluncus* is potentially pathogenic for human.

Potential Virulence Factors of *Mobiluncus*

Mobiluncus species possess several factors that contribute to the impairment of host defense component of the cervicovaginal mucus. *Mobiluncus*, *G. vaginalis*, and other BV-associated organisms produce a host of enzymes such as sialidase, prolidase (proline aminopeptidase), and mucinase (McGregor et al. 1994; Thomason et al. 1988). Sialidases and prolidases are potentially able to degrade several key mucosal protective factors, such as mucins, cytokines, immunoglobulins, antimicrobial molecules, and host cell receptors (Cauci et al. 1998, 2008). The combined action of different hydrolytic enzymes like sialidase and prolidase can dysregulate several crucial host antimicrobial/immune responses, creating a local immunosuppression. In addition, the observation that clue cells (the main hallmark of BV) are positively correlated to microbial enzymes suggests that sialidase and prolidase contribute to exfoliation and detachment of vaginal epithelial cells, which are major effectors of vaginal innate immune responses (Valore et al. 2002, 2006; Wira et al. 2005). Furthermore, *Mobiluncus* may contribute to the pathogenesis of BV infections by direct inhibition of neutrophil function. It is well known that *Mobiluncus* species produce succinic, acetic, and lactic acids as major metabolic by-products. In vitro studies demonstrated that increased succinic acid dramatically impairs neutrophil phagocytic killing, response to chemotactic stimuli, and generation of respiratory bursts required for bacterial killing (Rotstein et al. 1988).

Nevertheless, in a study of the adherence capability, biofilm-forming potential, and cytotoxic activity of *Gardnerella vaginalis* and other BV-associated anaerobes, Patterson et al. (2010) showed that *M. mulieris* and other BV-associated anaerobes were neither able to adhere to ME-180 vaginal epithelial cells nor to display cytotoxic activity under the conditions used. Only *G. vaginalis* and *Peptonophilus* sp. form a dense biofilm, but *M. mulieris* and none of the other BV-associated anaerobes formed biofilms. Together, these findings cast doubt on the role of *Mobiluncus* in the pathogenesis of BV. However, *Mobiluncus* is one important component of the complex bacterial community of BV, a polymicrobial infection in which no one species alone is capable of causing disease, but rather the synergistic effects of the consortium give rise to the pathophysiology (Dowd et al. 2008).

Susceptibility of *Mobiluncus* to Antibiotics and Recommended Treatment

The susceptibility of *Mobiluncus* species to antimicrobial agents have been investigated in several studies (Carlone et al. 1986; Spiegel 1987; Puapermpoonsiri et al. 1997; Gatti 1999; Bahar et al. 2005). All *Mobiluncus* strains were susceptible to amoxicillin, chloramphenicol, clindamycin, penicillin G, amoxicillin/clavulanic, piperacillin/tazobactam, cefotaxime, cefoxitin, cefotetan, erythromycin, imipenem, meropenem, rifampin, tobramycin, and vancomycin. All *M. curtisii* strains and some *M. mulieris* strains have been reported to be resistant to metronidazole. Some strains of *M. curtisii* subsp. *holmesii* were resistant to tetracycline (Gatti 1999). Interestingly, among Gram-positive bacteria, some strains of *M. curtisii* carried one or two of the tetracycline resistance genes, *tetQ* and *tetO*, which encode proteins that protect the bacterial ribosomes from tetracycline both in vivo and in vitro and are often associated with conjugative transposons (Leng et al. 1997).

Recommended treatments for BV in both pregnant and nonpregnant women include application of antimicrobial agents such as metronidazole and clindamycin (Joesoef et al. 1999; Koumans et al. 2002). Either systemic (usually oral) or intravaginal antibiotics can be used to treat BV (Mikamo et al. 1997; Paavonen et al. 2000; Sobel et al. 2001). Although metronidazole is usually effective in treating women with BV leading to resolution of symptoms, high recurrence rates of the disease have been reported (Bradshaw et al. 2006; Hay 1998). Clindamycin reduces the presence of vaginal *Mobiluncus* to a greater extent than metronidazole; this correlates with a higher BV cure rate (Nyirjesy et al. 2007).

Probiotics Treatment

Probiotics are defined as live microorganisms which, when administered in adequate amounts, confer a beneficial health effect on the host (Senok 2005). Probiotics have been a more recent approach for treatment of bacterial vaginosis. The dominance of lactobacilli in healthy vaginal microbiota and its depletion in BV has given rise to the concept of oral or vaginal instillation of probiotic *Lactobacillus* strains for the management of this condition. Available evidence indicates that certain strains of lactobacilli when administered to patients can colonize the vagina and reduce the risk of BV (Reid et al. 2001). Several studies have shown high cure rate of BV using a combination of metronidazole treatment along with administration of probiotics (Anukam et al. 2006; Martinez et al. 2009). The success of this approach has been attributed to the observation that metronidazole treatment decreases the numbers of pathogenic bacteria while leaving the population of lactobacilli unaffected, thereby allowing the lactobacilli to recolonize the vagina. Studies have been carried out to assess the efficacy of single strain or cocktail of probiotics administered orally or intravaginal in the treatment of BV (Falagas et al. 2007). In addition, the effect of probiotics in conjunction with antibiotic regimen has also been evaluated. Lactobacilli probiotics can be used over a long time without adverse effects, making them an attractive option to antibiotics, particularly in addressing the problem of high recurrence rates.

Application

The main attraction of using members of the family *Actinomycetaceae* centers around their mode of metabolism and the formation of fermentation products which could be of biotechnological importance.

Bioremediation

Actinomyces species are promising candidates for bioremediation of spilled oil. The detection of *Actinomyces* sp. among the bacteria found in soil samples taken from oil-polluted field along a concentration gradient of sulfurous oil and from unpolluted soil treated with dibenzothiophene (DBT)-containing petroleum suggests that they are likely to play a role in hydrocarbon degradation processes in soils (Duarte et al. 2001). Further, the successful isolation of three strains of *A. naturae* (Bowman et al. 2006; Rao et al. 2012) from chlorinated solvent-contaminated groundwater at Petro-Processors of Louisiana (USA) and their ability to grow in the presence of high concentrations of chlorinated (e.g., 1,2-dichloroethane, 1,1,2-trichloroethane, tetrachloroethane) and non-chlorinated solvents (e.g., toluene) has potentially important implications for cleanup at contaminated sites.

Genus I. *Actinomyces* Harz 1877, 133[AL], emend. Georg, Pine and Gerencser 1969, 292[VP].

Ac.ti.no.my'ces. Gr. fem. n. *aktis*, *aktinos*, ray; Gr. masc. n. *mykes*, fungus; M.L. masc. n. *Actinomyces*, ray fungus referring to the radial arrangement of filaments in *Actinomyces bovis* sulfur granules.

Taxonomy, Historical and Current

Cohn (1875) observed a filamentous branched organism in stained preparations of concrements taken from an infected lacrimal duct of a patient. He gave this organism the name "*Streptothrix foersteri*." Thereafter, Bollinger (1877) focused on an organism with branching mycelia in a pathological specimen obtained from the lesions within the jaw bones of cattle and he used the term "actinomycosis" to refer to the disease. In the same year, Harz (1877) named this organism, observed in a pathological specimen submitted to him from Bollinger, the "ray fungus" or *Actinomyces bovis* to refer to the raylike appearance of the organism in the granules that characterize the lesion. No pure culture was obtained. In the following year James Israel (1878), independently of Bollinger and Harz, characterized a similar "fungus" in a human clinical case and he gave an accurate description of the disease, but he, too, failed to cultivate the organism. Later Bujwid (1889) succeeded in isolating and culturing this human pathogen. The cultural characteristics and the anaerobic peculiarity of the human pathogen were described in considerable detail by Wolff and Israel (1891). The name "*Streptothrix israeli*" was applied by Kruse (1896) to the organism isolated by Wolff and Israel. However, the generic name "*Streptothrix*" was not valid as it had been preempted by Corda (1839) for a true fungus designated as "*Streptothrix fuca*." In 1898 Lachner-Sandoval completed a dissertation on the "ray fungi" and applied the name *Actinomyces israelii* Kruse to the isolates of Wolff and Israel. Lachner-Sandoval (1898) was the first to unite *Actinomyces* with the genera *Mycobacterium* and *Corynebacterium* (Lehmann and Neumann 1896) into a family Actinomycetes. This name has latter been altered to *Actinomycetaceae* by Buchanan (1918).

Breed and Conn (1919), who have revised the question of nomenclature very carefully, concluded that *Actinomyces* Harz (1877) is the only valid generic name. Winslow et al. (1920) approved the genus name *Actinomyces* and they designated *A. bovis* as the type species of the genus. This was supported by Lessel (1960) in his extensive review and *A. bovis* has been included in each edition of *Bergey's Manual*, including the eighth edition (Slack 1974). However, a type strain for *A. bovis* has not been proposed. For many years it was believed that *Actinomyces bovis* (Harz 1877), isolated from lumpy jaw of cattle, and *A. israelii* (Kruse 1896) Lachner-Sandoval (Breed et al. 1957), isolated from human actinomycosis, were one single species. However, studies by Erikson (1940, 1949), Thompson (1950), and Pine et al. (1960b) provided morphological and biochemical evidence that there are two agents of actinomycosis: *A. bovis*, usually associated with bovine infection, and *A. israelii*, the common cause of human infections. Division of the agents of actinomycosis into several species has received further support from cell wall analyses by Cummins and Harris (1958), serological studies by King and Meyer (1963), and electron microscopy studies by Overman and Pine (1963). Since type strains for *A. bovis* and *A. israelii* were not designated and because none of the strains on which the original descriptions of these organisms were based upon were extant, Slack and Gerencser (1976) defined strains ATCC 43683[T] and ATCC 12102[T] as the neotype strains of *A. bovis* and A. *israelii*, respectively.

Later, Thompson and Lovestedt (1951) described strains of *Actinomyces* which grew in ambient air on primary isolation. For this group, they proposed the name *Actinomyces naeslundii*. Howell et al. (1959) provided a more precise definition and delineated this group from other *Actinomyces* species. Subsequently, a Gram-positive, catalase-positive, filamentous organism isolated from subgingival plaque in hamsters was described by Howell (1963) and Howell and Jordan (1963). This organism was later named "*Odontomyces viscosus*" (Howell et al. 1965) and then renamed as *Actinomyces viscosus* by Georg et al. (1969) after the generic description of *Actinomyces* was broadened to include catalase-positive organisms.

Rapid progress in molecular biology methods have led to the recognition of several new *Actinomyces* species. Currently, the genus includes 41 species of Gram-positive, mainly facultatively anaerobic or microaerophilic rods with various degrees of branching. *Actinomyces gerencseriae* was named for strains previously classified as *A. israelii* serotype 2 (Johnson et al. 1990). The two species are also distinct in their 16S rRNA sequences (Stackebrandt and Charfreitag 1990). *A. naeslundii* was heterogeneous, as shown by DNA–DNA relatedness data (Johnson et al. 1990), immunological studies (Putnins and Bowden 1993), genomic DNA fingerprinting, and rRNA gene probes (Bowden et al. 1993). There were 3 genetically distinct groups that are sufficiently different to be designated as separate species. Genospecies 1 comprised *A. naeslundii* serotype 1 strains; genospecies 2 included strains previously classified as *A. naeslundii* serotypes 2 and 3, *A. naeslundii* serotype NV, and *A. viscosus* serotype 2 strains. Genospecies 3 comprised *A. naeslundii* serotype WVA 963 (previously serotype 4).

The identification of these genospecies had been problematic because neither 16S rRNA gene sequencing nor biochemical tests discriminate between these three genospecies. However, Henssge et al. (2009) demonstrated that the partial sequences of two housekeeping genes (*atp*A and *met*G) can separate the three *A. naeslundii* genospecies. They proposed the name *A. oris* for *A. naeslundii* genospecies II and the name *A. johnsonii* for *A. naeslundii* genospecies III (genospecies WVA 963). In this classification, *A. naeslundii* genospecies I remains as *A. naeslundii*.

The descriptive part of novel *Actinomyces* species proposals described recently, though useful for identification, appears somewhat monotonous. These have been mainly based on morphological and physiological grounds as well as on a 16S rRNA gene sequence-based phylogeny. Unfortunately, little attention has been paid to investigate the chemotaxonomic markers which are important for delineating taxa. After several revisions some former members of the genus *Actinomyces*, e.g., "*A. bernardiae*," "*A. pyogenes*," and "*A. suis*," have been moved to the closely related genera *Arcanobacterium*, *Actinobaculum*, and *Trueperella* (Lawson et al. 1997; Pascual Ramos et al. 1997a; Yassin et al. 2011). Therefore, the genus *Actinomyces*, in its state, appears as merely a collection of phylogenetic related species, and it is in need of a comprehensive chemotaxonomic study of its members in order to confirm their assignment to the genus.

Molecular Analyses

Similarity values of 16S rRNA gene sequence analyses for members of the genus *Actinomyces* range from 88 % to 99 %, indicating the presence of several phylogenetically defined clusters (*Fig. 4.1a, b*), which are separated by intra-cluster similarity values ranging from 88–90 % to 89–92 %. The idea that the genus *Actinomyces* may not represent a monophyletic taxon has been expressed before by Pascual Ramos et al. (1997b). Because of the lack of phenotypic and chemotaxonomic properties that support a taxonomic dissection of the genus, the genus serves as a phylogenetic dumping ground. Chemotaxonomic properties, demonstrated to correlate well with phylogenetic structure in other actinobacterial genera, are either not available or not exclusive in phylogenic clusters. Although tempting, a purely phylogeny-based dissection is not favored, as novel sequences may blur the present topology of the genus.

Phylogenetic analysis based on 16S rRNA gene sequences revealed that members of the genus *Actinomyces* resolved in two major phylogenetic clusters along with four separate lineages (*Fig. 4.1a, b*). The clusters were designated as cluster I (*Actinomyces bovis* group), comprising 21 species, and cluster II (*Actinomyces meyeri* group) which contains 12 species. Three of the four separate lineages are represented by two species each and are designated according to the species they include: *A. hordeovulneris–A. nasicola* lineage, *A. hongkongensis–A. marimammalium* lineage, and *A. coleocanis–A. europaeus* lineage. The fourth lineage consists of only one species, *A. neuii*, which cluster with the monospecific genus *Varibaculum* and designated *A. neuii–Varibaculum* lineage. These groupings were assigned under the consideration that all members of a particular group or lineage are monophyletic, showing the same topology regardless of the method used: neighbor-joining, maximum-parsimony, or maximum-likelihood, and on the presence of group or lineage-specific signature nucleotides. However, the level at which members of the two groups and the separate lineages are considered taxonomically coherent entities should be decided on the basis of the results of chemotaxonomic investigations.

Description of the Phylogenetic Groups and Lineages

Cluster I (*Actinomyces bovis* Group)

This cluster, including 21 species which share 87.1–98.1 % sequence similarity, can be considered authentic *Actinomyces* species as it contains the type species *A. bovis*. This species is closely related to *A. urogenitalis* (97.3 % similarity) as originally pointed out in the description of this species (Nikolaitchouk et al. 2000) and to *A. weissii* (97 % similarity). Likewise, the similarity values between *A. johnsonii*, *A. naeslundii*, *A. oris*, and *A. viscosus* vary between 96.3 and 98.1 %, indicating that these organisms may be strains of the same species (Stackebrandt and Goebel 1994). However, the results of a DNA–DNA hybridization study (Johnson et al. 1990) and sequence analysis of two housekeeping genes (*atp*A and *met*G) (Henssge et al. 2009) confirmed the identification of these organisms as separate species. The latter four species form a subcluster supported by a bootstrap value of 89 %. The group-specific signature nucleotides (*Table 4.1*) include 146–176 (U-G), 1118–1155 (U-A), 1122–1151 (G-C), and 1311–1326 (U-A).

The distinct phylogenetic position of *A. graevenitzii* sharing less than 93 % 16S rRNA gene sequence similarity with other species of the genus has been verified in several studies (Pascual Ramos et al. 1997b; Nikolaitchouk et al. 2000; Hoyles et al. 2001, 2002a). In all the dendrograms generated, *A. graevenitzii* constituted either the deepest branch or it branched off even deeper, giving the appearance of an isolated phylogenetic lineage within *Actinomyces*. Although *A. graevinitzii* shares with *Actinomyces bovis* group the entire signature nucleotide characteristic of this group, it possesses a set of distinctive signature nucleotides (*Table 4.1*) which is not found elsewhere in the genus. These include 145–177 (U-G), 446–488 (G-C), 450–483 (C-G), 668–738 (U-A), 669–737 (A-U), 835–851 (A-U), and 1308–1329 (U-A). The phylogenetic distinctness clearly indicates that *A. graevinitzii* might represent an individual distant lineage. Further evidence is required to resolve its evolutionary history and taxonomic placement.

Cluster II (*Actinomyces meyeri* Group)

This cluster comprises 12 *Actinomyces* species with an overall 16S rRNA gene sequence similarities ranged from 91.1 % to

97.2 % and a high bootstrap support (83 %). Within this cluster, *A. georgiae*, *A. meyeri*, and *A. odontolyticus* form a subcluster with 88 % bootstrap support (Fig. 4.1b). The three species have very similar host ranges as they all were isolated from human supra- and subgingival plaque. They showed sequence similarity values ranging from 96 % to 97.2 %. The separate species status of the three species has been confirmed by low DNA–DNA hybridization values (Johnson et al. 1990).

A. canis occupied an isolated position at the periphery of cluster II, showing a distant relationship to member of this cluster. The 16S rRNA gene sequence similarity values found between *A. canis* and members of this cluster ranged between 91.3 % and 95.3 %. Its separate phylogenetic placement in a basal position to cluster II organisms (Fig. 4.1b) is in accord with the original description of Hoyles et al. (2000). The most striking feature that distinguishes the 16S rRNA gene sequence of *A. canis* from other members of cluster II is a stretch of base pairs at positions 614–626 (A-U), 615–625 (C-G), and 616–624 (A-U).

A. naturae, isolated from oil-contaminated groundwater (Rao et al. 2012), clustered with the pathogenic species *A. radingae*. They are two remotely related species sharing 91.8 % similarity. Their association was supported by a moderate bootstrap value (76 %). *A. naturae* shared sequence similarities ranging from 91.3 % to 94.7 % whereas *A. radingae* showed 91.1–93.3 % with other members of cluster II. Additional pairs of phylogenetic neighbors are *A. suimastiditis* and *A. hyovaginalis* (96.7 % similarity) and *A. cardiffensis* and *A. turicensis*, (96.5 % similarity). The group-specific signature nucleotides (Table 4.1) include 146–176 (G-Y), 316–337 (U-G), 444–490 (C-G), 450–483 (C-G), 1118–1155 (C-G), 1122–1151 (A-U), and 1311–1326 (G-C).

Individual Lineages

These lineages could be regarded as candidate divisions.

A. coleocanis–A. europaeus Lineage

The two species share a remote relationship of 93.2 % sequence similarity. Although the association of the two species is supported by all tree methods and high bootstrap support (100 %), the branching point of this lineage is not settled, as seen by low bootstrap values and different affiliations of either one or both species in dendrograms previously published in species descriptions (Funke et al. 1997a; Collins et al. 2000; Hoyles et al. 2000, 2002a; Nikolaitchouk et al. 2000). The presence of unique 16S rRNA gene nucleotide signatures at positions 146–176 (U-A), 501–544 (U-A), 502–543 (A-U), and 929–1388 (A-U) highlights the separate phylogenetic position of this lineage.

A. neuii–Varibaculum Lineage

Unlike other *Actinomyces* species, *A. neuii* shares a common node in the phylogenetic tree with the genus *Varibaculum* to form a separate clade (Fig. 4.1a, b). This clade was strongly supported by a 98 % bootstrap score. This clade represents the deepest branching within the family *Actinomycetaceae*. The phylogenetic placement of this lineage sister to the *A. coleocanis–A. europaeus* lineage is poorly supported (61 % bootstrap value). The level of sequence similarity of *A. neuii* and *Varibaculum cambriense* is low (89.8 % sequence similarity), whereas the overall sequence similarity values of *A. neuii* with other *Actinomyces* species ranged from 85.6 % to 90.4 %.

A. hordeovulneris–A. nasicola Lineage

A. hordeovulneris and *A. nasicola* are remotely related species sharing a similarity value of 93.8 %. The phylogenetic placement of *A. hordeovulneris* sister to *A. nasicola* is poorly supported (65 % bootstrap value). The similarity values of *A. hordeovulneris* with other *Actinomyces* species range between 85.8 % and 92.5 % and that of *A. nasicola* with other member of the genus range between 87.5 % and 92.5 %. There are no group-specific signature nucleotides that would support the association of members of this lineage (Table 4.1). The inclusion of new sequences corresponding to new taxa will help to clarify the taxonomic placement and the phylogenetic relationships of the two species.

A. hongkongensis–A. marimammalium Lineage

Phylogenetic analysis indicated that *A. hongkongensis* has a close affinity with *A. marimammalium* and both species form a clade that is moderately supported by bootstrap analysis (79 %). The two species share 93.3 % 16S rRNA gene sequence similarity. In the neighbor-joining tree, this lineage seems to have diverged prior to the main radiation that gave rise to *Mobiluncus*, *A. coleocanis–A. europaeus* lineage, *A. neuii–Varibaculum* lineage, and cluster II of *Actinomyces*. The similarity values of *A. hongkongensis* and *A. marimammalium* with other *Actinomyces* species range between 86.6–91.6 % and 86.8–91.9 %, respectively. The set of signature nucleotides (Table 4.1) support recognition of the isolated lineage: 146–176 (G-U), 590–649 (G-U), and 1244–1293 (C-G).

Phenotypic Analyses

Morphology

Members of the genus *Actinomyces* demonstrate considerable variations in both cellular and colonial morphologies so that morphology becomes insignificant as basic taxonomic criterion in the genus. They may resemble nocardiae, bifidobacteria, corynebacteria, propionibacteria, and even streptococci.

Cellular Morphology

Generally *Actinomyces* cells are Gram-positive, non-acid-fast, non-spore-forming, and (with the exception of *A. naturae*) nonmotile. The cellular morphology may vary from species to species and strain to strain within one species. In *A. bovis* cells appear straight to slightly curved (diphtheroid-shaped) rods (Fig. 4.4); in some species such as *A. bowdenii, A. canis,*

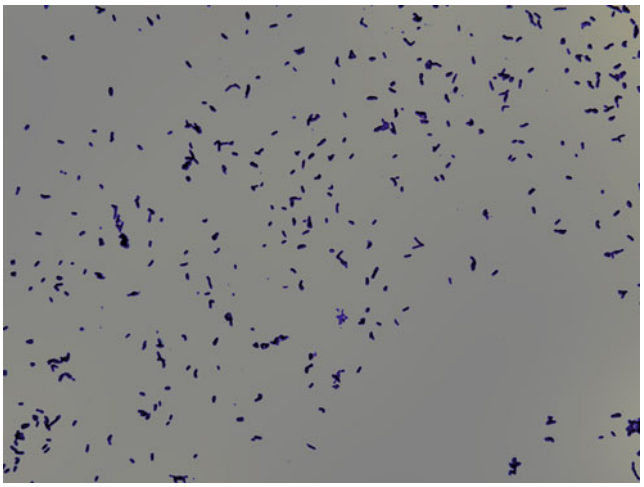

Fig. 4.4
Gram-stained smear from culture of *Actinomyces bovis* ATCC 13683^T on brain heart infusion agar supplemented with 1% Tween 80 showing diphtheroid froms.

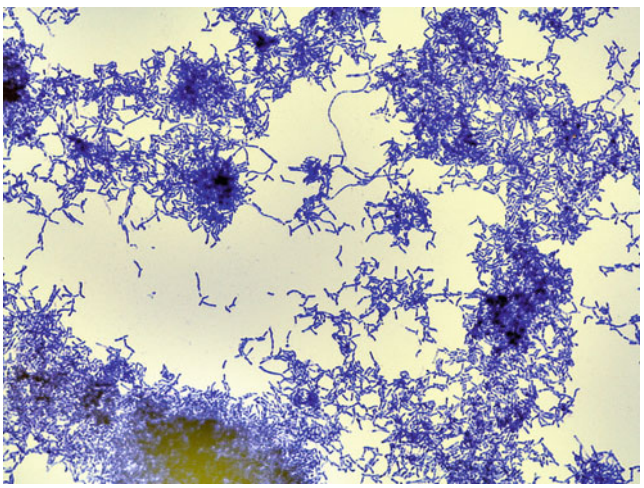

Fig. 4.5
Gram-stained smear from culture of *Actinomyces israelii* ATCC 10048 on CC agar showing branching filamentous forms which stained irregularly given a beaded appearance.

A. catuli, *A. coleocanis*, *A. funkei*, and *A. marimammalium*, curved rods may show branching, which in the case of *A. georgiae* and *A. graevenitzii* have swollen ends. *A. marimammalium*, sometimes with swollen ends in *A. georgiae* and *A. graevenitzii*. In few species, the rods develop into filamentous, beaded, branching forms, e.g., *A. cardiffensis* and *A. dentalis*. Yet other species, e.g., *A. howellii*, *A. radicidentis*, *A. radingae*, *A. nasicola*, *A. neuii*, and *A. vaccimaxillae*, may exhibit coccoid or coccobacillary forms. Moreover, some species are characterized by the production of nonseptate mycelia which are long and exceedingly branched, e.g., *A. israelii* (Fig. 4.5), *A. hordeovulneris*, and *A. viscosus*. Notably, the mycelia may have swollen termini as in *A. hordeovulneris*.

Gross Morphology

For most part, the gross morphology reflects the color, size, and shape of colonies. Variations in gross colonial morphology depend on the species and are affected by the nutrient content of the medium. Most of the *Actinomyces* species colonies appear white, grayish white, or creamy white. However, some species produce red to pinkish colonies. The red pigmentation of mature *Actinomyces odontolyticus* colonies is a well-known distinguishing characteristic of this species. Mature colonies of *A. cardiffensis* are creamy to pinkish, whereas colonies of *A. bowdenii*, *A. europaeus*, *A. funkei*, *A. hominis*, *A. marimammalium*, *A. nasicola*, and *A. radingae* are grayish in appearance. Colonies may be flat or convex, circular, entire edged or irregular, smooth or dry to viscous, shiny, and opaque. Only few species such as *A. europaeus*, *A. georgiae*, *A. howellii*, *A. meyeri*, *A. odontolyticus*, and *A. slackii* produce translucent colonies.

Several species produce pinpoint colonies, e.g., *A. dentalis*, *A. hongkongensis*, *A. marimammalium*, *A. massiliense*, *A. meyeri*, *A. nasicola*, *A. oricola*, and *A. timonensis*. Molar-toothed colonies are rough colonies common in *A. israelii*, *A. gerencseriae*, and *A. hordeovulneris*. Bread crumb-like colonies are prevalent in *A. israelii*, *A. gerencseriae*, *A. hordeovulneris*, *A. dentalis*, and *A. oricola*. Well developed molar-tooth and bread crumb-like colonies are very hard pitting the agar and adhere firmly to the medium. The molar-toothed colonies have tendency to shift to the buttery less adherent bread crumb-like type.

Biochemical Characteristics

Aside from the morphological variations, *Actinomyces* species vary also in the physiological aspects. They are chemoorganotrophs with complex nutritional requirements and a fermentative metabolism. Some species are catalase-positive; others are catalase-negative. Nitrate reduction is variable among species. They are constantly negative for the production of indole, H_2S, and acetoin as well as for blood hemolysis (exception *A. weissii*) and gelatin hydrolysis.

Members of the genus *Actinomyces* vary considerably with respect to their oxygen requirements (Tables 4.4 and 4.5). Strict anaerobic *Actinomyces* species show scant to no growth when incubated in air or in 5 % CO_2 and include *A. bovis*, *A. cardiffensis*, *A. georgiae*, *A. gerencseriae*, *A. hordeovulneris*, *A. hongkongensis*, *A. israelii*, *A. meyeri*, *A. nasicola*, *A. oricola*, *A. ruminicola*, and *A. vaccimaxillae*. Facultative anaerobic or rather capnophilic *Actinomyces* species (all others) showed significantly enhanced growth after 48 h incubation in the presence of 5 % CO_2. It is worth mentioning that some species of the latter group are also able to grow on the surface of suitable agar media after prolonged incubation in air without CO_2. These species could therefore be considered as aerotolerants, e.g., *A. bowdenii*, *A. canis*, *A. catuli*, *A. coleocanis*, *A. europaeus*, *A. funkei*, *A. graevenitzii*, *A. hyovaginalis*, *A. marimammalium*, *A. naturae*, *A. neuii*, *A. odontolyticus*, *A. naeslundii* sensu stricto, *A. oris*,

[a]Data compiled from Dent and Williams (1984b), Schaal (1986a), Schaal et al. (2006), An et al. (2006)
Symbols: + positive, present, – negative/absent, *w* weakly positive, *d* strain differences, *ND* available

A. johnsonii, *A. radicidentis*, *A. radingae*, *A. slackii*, *A. turicensis*, *A. urogenitalis*, *A. viscosus* sensu stricto, and *A. weissii*.

The temperature optimum for growth of *Actinomyces* species ranges from 30 °C to 37 °C. Certain members of the genus vary in their response to growth at higher temperatures. Thus, *A. naturae* reported to grow at temperature range of 20–43 °C (optimum 30–37 °C) (Rao et al. 2012). Optimum growth of *A. ruminicola* occurs at 46 °C (An et al. 2006), while strains of *A. viscosus* and *A. naeslundii* may also grow at 45 °C (Holmberg and Nord 1975). In contrast, *A. meyeri* does not grow at all at 45 °C (Cato et al. 1984). Growth of *Actinomyces* species occurred at pH range of 4.5–9.0 (optimum pH 6.5). The pH value of the growth medium continued to decrease to a limiting value of pH 5.0, and colonies harvested continued to grow at the same rate when subcultured to a medium of the same initial pH 7.2.

Apparently, variation in nutrient requirements in *Actinomyces* is minimal, since most species investigated grow well on complex agar media such as Brain Heart Infusion, meat extract, and yeast extract. The nutrient requirements have been investigated for relatively few species. The ability of a strain of *A. israelii* to grow in partially defined media supplemented with various nitrogen compounds has been investigated (Christie and Porteous 1962). They found that L-cysteine and L-tryptophan were essential for growth, whereas glutathione, ammonium sulfate, purine, or pyrimidine bases are not required. For the most part organic nitrogen sources such as casein hydrolysate and peptone are satisfactory sources of nitrogen for *Actinomyces* species.

Some species vary more in response to vitamins and growth factors than to basic elements of nutrition. *A. meyeri* is known to have an absolute requirement for vitamin K_1 for growth (Cato et al. 1984). Addition of 0.02 % Tween 80 to broth media also enhanced growth and carbohydrate fermentation of strains of *A. meyeri* (Cato et al. 1984), *A. georgiae*, *A. gerencseriae*, *A. naeslundii*, *A. odontolyticus*, *A. oris*, and *A. johnsonii* (Johnson et al. 1990). In this context, it is worth mentioning that the growth of almost all *Actinomyces* species is stimulated by the addition of Tween 80 (1 % v/v) to Brain Heart Infusion broth (A. F. Yassin unpublished). Likewise, the addition of serum to the medium enhances growth of *Actinomyces*. Buchanan et al. (1984) reported that the growth of *A. hordeovulneris* is considerably stimulated when the medium is supplemented with 10–20 % (v/v) fetal calf serum. In contrast, addition of 20 % bile inhibits the growth of *A. meyeri* (Cato et al. 1984).

Interestingly, tolerance to organic solvents has been reported for *A. naturae* (Rao et al. 2012). Fermentative growth of *A. naturae* was observed in the presence of near saturation concentrations of perchloroethylene (PCE) and toluene and at concentrations up to at least 24.4 mM and 11.2 mM in the presence of 1,2-dichloroethane (1,2-DCA) and 1,1,2-trichloroethane (1,1,2-TCA), respectively. The ability of *A. naturae* strains to grow in the presence of chlorinated and non-chlorinated solvents has potentially important implications for cleanup at the contaminated sites. Likewise, *A. naturae* grows at NaCl concentrations up to 3.0 % (w/v), while a concentration of 6.5 % NaCl inhibits the growth of *A. meyeri* (Cato et al. 1984).

Furthermore, carbohydrates are the preferred nutrient as they provide immediate carbon and energy sources. Members of the genus *Actinomyces* can utilize a diverse range of carbohydrates that support growth, but the different species may vary in their carbohydrates utilizing abilities (*Table 4.4* and *Table 4.5*). These variations do not correlate in any obvious manner with morphology or recorded pathogenicity and may have little taxonomic significance. In some instances variation in carbohydrates utilization capacity within strains of the same species has been reported (Dent and Williams 1984a, b; Johnson et al. 1990). Glucose is universally utilized by nearly all of the *Actinomyces* species with the exception of *A. hongkongensis* (Woo et al. 2003) and *A. nasicola* (Hall et al. 2003a). The end products of glucose fermentation were acetate, lactate, succinate, and formate.

Actinomyces species exhibit enzymatic activities for the degradation of diverse classes of substrates. The most common enzyme activities present in most species were α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, and leucine arylamidase, while the least common was β-glucuronidase demonstrated only by *A. catuli*. α-Mannosidase activities were demonstrated only by *A. hordeovulneris*, *A. neuii*, and *A. weissii*. None of the *Actinomyces* species are positive for the urease test. However, due to the inconclusiveness of the results, it is difficult to use the enzymatic activity test using the API ZYM test system to differentiate *Actinomyces* species.

Chemotaxonomic Properties

Present members of the genus *Actinomyces* appear to be heterogeneous with regard to their amino acid composition of the cell wall peptidoglycan, cell wall sugars, menaquinone composition, polar lipid profiles, and DNA mol% G+C content (*Table 4.6*). Thus, elucidation of the amino acids sequences of the peptidoglycans across the genus, although many species remain to be investigated, revealed the presence of the main type abbreviated A5 (Schleifer and Seidl 1985). In structural term, the main type A5 includes two subtypes. Peptidoglycan subtype A5α (L-Lys-L-Lys-D-Glu) was found in *A. europaeus* (Funke et al. 1997a). *A. radingae* also exhibits this subtype with L-lysine in position 3 of the tetrapeptide being partially replaced by L-ornithine (L-Lys [L-Orn]-L-Lys-D-Glu) (Wüst et al. 1995). Although *A. bovis* was shown to belong to peptidoglycan type A4, which is characterized by L-lysine in position 3 of the tetrapeptide subunit and a D-asparagine residue forming the interpeptide bridge (L-Lys-D-Asp; Schleifer and Kandler 1972), recent analysis of the peptidoglycan revealed that the peptidoglycan of *A. bovis* (L-Lys-L-Lys-D-Asp) corresponds to subtype A5α (A11.52; according to the nomenclature suggested by Schumann 2011). This is also true for *A. israelii* (www.peptidoglycan-types.info). Subtype A5β (L-Orn-L-Lys-D-Glu) is found in *A. georgiae* (www.peptidoglycan-types.info), *A. gerencseriae*

Table 4.6

Chemotaxonomic characteristics of selected members of the genus *Actinomyces*

Organisms	Chemotaxonomic characteristic					
	Peptidoglycan types	Acyl type	Cell wall sugars	Phospholipid	Menaquinones	Fatty acids
Actinomyces bovis	A5α (L-Lys-L-Lys-D-Asp)	Acetyl	Glucose + mannose + rhamnose + 6-deoxytalose	DPG, PG, PC, PI, PIM	MK-9[a]	C16:0, C16:1ω7c
						C18:1 ω9c, C18:2 ω6,9c
Actinomyces europaeus	A5α (L-Lys-L-Lys-D-Glu)	Acetyl	Galactose	DPG, PC, PI, PIM	MK-9(H4)[a]	C16:0, C18:0,
						C18:1 ω9c
Actinomyces naturae	A5β (L-Orn-L-Lys-D-Glu)		Mannose + rhamnose	DPG, PG, PGL, GL	MK-9(H4)[a]	C14:0, C16:0,
						C18:1 ω9c
Actinomyces turicensis	A5β (L-Orn-L-Lys-D-Glu)	Acetyl	Rhamnose + fucose + 6-deoxytalose	DPG, PC, PI, PIM	MK-9(H4)[a]	C16:0, C16:1ω7c
						C18:1 ω9c, C18:2 ω6,9c

Abbreviations: *DPG* diphosphatidylglycerol, *PG* phosphatidylglycerol, *PC* phosphatidylcholine, *PI* phosphatidylinositol, *PIM* phosphatidylinositol mannosides, *PGL* phosphoglicolipids, *GL* glycolipids, MK-n(Hx) represents a partially hydrogenated menaquinone with x hydrogen atoms on the side chain containing n isoprene units; S, straight-chain saturated, and *U* monounsaturated

[a]Major component

(www.peptidoglycan-types.info), *A. hyovaginalis* (Collins et al. 1993), *A. naturae* (Rao et al. 2012), and *A. turicensis* (Wüst et al. 1995).

Several cell wall sugars have been detected in *Actinomyces* species. The cell wall of *A. canis*, *A. coleocanis*, *A. europaeus*, *A. israelii*, *A. georgiae*, *A. gerencseriae*, *A. hordeovulneris*, *A. marimammalium*, and *A. neuii* contained only galactose (Buchanan and Scott 1984; A. F. Yassin, unpublished). Dent and Williams (1984) reported that the cell wall of *A. denticolens* contained rhamnose. A variety of cell wall sugars, including glucose, mannose, rhamnose, and 6-deoxytalose, have been detected in the cell wall of *A. bovis* (*Table 4.6*; A. F. Yassin, unpublished). Fucose, in addition to other sugars, is found distributed in the cell wall of *A. meyeri*, *A. turicensis*, and *A. hyovaginalis*. Thus, in term of cell wall sugars composition, members of the genus *Actinomyces* were diverse.

The principal respiratory quinones among *Actinomyces* species are menaquinones with eight, nine, and ten isoprene units. *Actinomyces bovis*, *A. urogenitalis*, and *A. weissii* were found to contain fully unsaturated menaquinones with eight (MK-8) and nine (MK-9) isoprene units, with MK-9 predominating. This data imply that these species are closely related and correlate well with their affiliation to the same phylogenetic cluster I as judged from phylogenetic analysis (*Fig. 4.1b*). Interestingly, the menaquinone pattern of *A. nasicola* deviates from that reported in the original species description by Hall et al. (2003b). Exact mass measurements of the constituent menaquinones extracted from *A. nasicola* using mass spectrometry revealed the presence of tetrahydrogenated menaquinones with eight [MK-8(H_4)] and nine [MK-9(H_4)] isoprene units, with the latter compound being the major component. This result convincingly supports the phylogenetic placement of *A. nasicola* outside the phylogenetic cluster I (*Fig. 4.1b*). Several species, including *A. europaeus*, *A. colecanis*, *A. naturae*, *A. oricola*, and *A. turicensis* contain MK-8(H_4) and MK-9(H_4) as major components.

Polar lipid types have been reported for sparingly few members of the genus *Actinomyces*. Investigation of the polar lipids profile in *A. bovis* revealed the presence of diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), phosphatidylcholine (PC), phosphatidylinositol (PI), phosphatidylinositol mannoside (PIM), and several unidentified phospholipids (*Table 4.6*; A. F. Yassin, unpublished). It is not surprising to find this pattern, though with variations in the amounts of the different phospholipids, in *A. weissii* (Hijazin et al. 2012a) as both species are members of the same phylogenetic cluster (*Fig. 4.1b*). In contrast, the polar lipids of *A. naturae* were reported to include DPG, PG, phosphoglycolipids (PGL), glycolipids (GL), and an unidentified phospholipid (PL) Rao et al. (2012). From these preliminary data, it seems that there are no universal phospholipids patterns of *Actinomyces* species.

The cellular fatty acids of members of the genus *Actinomyces* consisted of straight-chain saturated and monounsaturated types with $C_{16:0}$, $C_{16:1}$ ω7c, $C_{18:0}$ and $C_{18:1}$ ω9c as the predominating ones. In addition, diunsaturated fatty acid of $C_{18:2}$ ω6,9c was detected in *A. bovis*, *A. cardiffensis*, and *A. weissii*. *A. nasicola* contains an unusual cellular fatty acids profile consisting of a complex mixture of straight-chain saturated, monounsaturated, iso- and anteiso-branched-chain fatty acids (Hall et al. 2003b). *A. massiliense* contains traces of iso-$C_{17:0}$, anteiso-$C_{17:0}$, and anteiso-$C_{17:1}$.

Thus, the genus *Actinomyces* encompasses a chemotaxonomic highly variable group of bacteria and deserves division into separate taxonomic entities. These new entities should be defined using morphological, chemotaxonomic, and molecular data.

Taxonomic Comment

The taxonomy of the genus *Actinomyces*, as currently treated, is largely based on morphology. However, advances in chemical, numerical, and molecular systematic methods have contributed greatly to the circumspection of *Actinomyces*. Therefore, the taxonomic positions of *Actinomyces* species have undergone incisive changes over the past several years and today remain in a state of flux as false names are corrected, existing strains are sorted out into newly recognized genera (e.g., *Actinobaculum* and *Trueperella*), and new species are identified. Nevertheless, the genus *Actinomyces* remains a poorly defined genus.

A wide range of morphological, chemical, and molecular variations are present within members of the genus *Actinomyces*, causing major problems for genus delineation and identification. The morphology of *Actinomyces* species is diverse and varied in some species with the growth stages of the culture. Besides the mycelial state of some species, they can exhibit coryneform morphology with diphtheroidal arrangements (Y, V, T forms) or even coccoid or coccobacillary forms. Considerable variation was recognized also with respect to motility and flagellation. Although all *Actinomyces* species are nonmotile, flagellation and motility was observed in *A. naturae* (Rao et al. 2012). Therefore, retaining *A. naturae* in the genus is not justifiable.

Molecular phylogeny indicates that the genus *Actinomyces* as presently circumscribed is polyphyletic. The phylogeny based on 16S rRNA gene sequences recovers two major clusters and four distinct evolutionary lineages with high bootstrap support. These results strongly support the fact that the genus *Actinomyces* should be dissected into a number of distinct genera. However, this proposal needs to be evaluated critically based on the phenotypic variations among species.

Apart from the phylogenetic evidence, chemotaxonomic data unambiguously indicate that the generic boundaries of *Actinomyces* need further resolution. Although the genus *Actinomyces* has never been subjected to a broad and exhaustive chemotaxonomic study, a wide range of chemical variations or chemosyndromic variations between species have been documented, making the generic chemotaxonomic distinctions challenging. Several chemotypes have been identified in some taxa, e.g., *A. bovis*, *A. europaeus*, *A. naturae*, and *A. turicensis* (Table 4.6). The chemotaxonomic features of *A. bovis* are shared by its phylogenetic closely related species *A. urogenitalis* (97 % sequence similarity) and *A. weissii* (96.9 % sequence similarity). These findings have important implications for the generic delimitation of *Actinomyces*.

In view of the conspicuous chemotaxonomic and phylogenetic variations within the genus *Actinomyces*, it is obvious that the generic boundaries of the genus are in need of further evaluation. Therefore, for correct evaluation of the taxa that are assigned to the genus *Actinomyces*, a proper definition of the genus *Actinomyces* sensu stricto is required. In light of the currently available data on *A. bovis*, the type species of the genus, the following definition of the genus *Actinomyces* sensu stricto is proposed.

Definition of the Genus *Actinomyces* Sensu Stricto

The definition of the genus *Actinomyces* proposed herein, is focused on the close relationship amongst *A. bovis*, *A. urogenitalis* and *A. weissii*. It is supported by 16S rRNA gene sequences and chemotyonomic analyses and provide sound basis for future taxonomic restructuring. Among the criteria for restrictive membership in the genus *Actinomyces* are: Cells are straight or slightly curved rods (with or without swollen ends) which may occur singly or in pairs with diphtheroidal arrangements (Y, V, T forms and palisades). Cells are Gram-reaction-positive, non-acid-fast, non-spore-forming, and nonmotile. Strains grow at 37 °C under anaerobic conditions or in a 5% CO_2 atmosphere. The peptidoglycan is of the type A5α, variation L-Lys–L-Lys–D-Asp. The muramic acid residue of the peptidoglycan is *N*-acetylated. Characteristic whole-cell sugars are glucose, mannose, rhamnose, and 6-deoxytalose. The menaquinones are MK-8 and MK-9, with the latter cs the major component. The phospholipid type is type PIII according to Lechevalier et al. (1977), comprising DPG, PG, PC, PI, and PIM. Long-chain fatty acids are primarily straight-chain saturated and monounsaturated ($C_{16:0}$, $C_{16:1}$ ω7c, $C_{18:0}$, $C_{18:1}$ ω9c) in addition to trace of diunsaturated fatty acid ($C_{18:2}$ 6,9c). The DNA G+C content is 61–63.3 mol%. The type species is *Actinomyces bovis*.

Indeed, it remains to conduct additional studies including all currently described *Actinomyces* species to see whether these characters occur in other species to further elucidate their taxonomic affiliation to the genus. Thereafter, a reevaluation of the existing taxonomy will be necessary to reflect an accurate phylogeny of *Actinomyces*.

Genus II. *Arcanobacterium* Collins, Jones and Schofield, 1983, 438^{VP} (Effective publication: Collins, Jones and Schofield, 1982, 1280), emend. Lehnen, Busse, Frölich, Krasinska, Kämpfer and Speck 2006, 864^{VP}, emend. Yassin, Hupfer, Siering and Schumann 2011, 1272^{VP}.

Ar. ca. no. bac. te' ri. um. L. adj. *arcanus*, secret, hidden, secretive; Gr. neut. dim. n. *bakterion*, a small rod; M. L. neut. n. *Arcanobacterium*, secretive bacterium.

Taxonomy, Historical and Current

The genus *Arcanobacterium* was described by Collins et al. (1982b) to accommodate bacterial strains originally isolated from infected American soldiers and previously named "*Corynebacterium haemolyticum*" (MacLean et al. 1946). However, the species exhibits little similarity to typical corynebacteria, and its placement in the genus *Corynebacterium* was questioned by several workers (Cummins and Harris 1956; Barksdale et al. 1957; Barksdale 1970; Jones 1975; Minnikin et al. 1978; Schofield and Schaal 1981; Collins et al. 1982a). In addition, the relationship of "*C. haemolyticum*" to the species "*C. pyogenes*" (Glage) remained unclear. In a study of cell wall compositions in some Gram-positive bacteria, Cummins and Harris (1956) noted that the cell wall compositions of "*C. pyogenes*" and

"*C. haemolyticum*" were obviously similar to one another but differed both in sugar and amino acid composition from the other corynebacteria, since they contain neither species arabinose nor galactose and lysine is the diamino acid of the peptidoglycan, while DAP is absent. On the other hand, Cummins and Harris (1956) found that rhamnose was present in both organisms, and this, together with the fact that alanine, glutamic acid, and lysine were the major amino acid components, led these authors to suggest that the two organisms were related to the streptococci. This view was upheld by Barksdale et al. (1957) who suggested not only that "*C. haemolyticum*" and "*C. pyogenes*" should be reclassified in the genus *Streptococcus*, but also that "*C. haemolyticum*" was a mutant form of "*C. pyogenes*." In the eighth edition of *Bergey's Manual of Determinative Bacteriology*, both taxa were listed in an addendum to the genus *Corynebacterium* (Cummins et al. 1974), and "*C. haemolyticum*" does not appear in the Approved Lists of Bacterial Names (Skerman et al. 1980).

Later, numerical phenetic (Schofield and Schaal 1981) and chemical (Collins et al. 1982a) studies showed that "*C. haemolyticum*" and "*C. pyogenes*" are two distinct taxa. The discovery of tetrahydrogenated menaquinones with ten isoprene units [MK-10(H4)] as predominant component in "*C. pyogenes*" and tetrahydrogenated menaquinone with nine isoprene units [MK-9(H4)] as predominant component in "*C. haemolyticum*" was not in accord with the inclusion of these taxa in the genus *Streptococcus* or the genus *Corynebacterium* (Collins et al. 1982a). The majority of streptococci completely lack respiratory quinones, although some unsaturated naphthoquinones have been detected in a few group D and group N streptococci (Collins and Jones 1979a, b). The menaquinone patterns of C. *pyogenes* and "*C. haemolyticum*" are also incompatible with the retention of these species in the genus *Corynebacterium*. True corynebacteria generally possess dihydrogenated menaquinones with eight [MK-8(H2)] and nine [MK-9(H2)] isoprene units (Yamada et al. 1976; Collins et al. 1977). Tetrahydrogenated menaquinones with ten and nine isoprene units have, however, been reported in the genera *Actinomyces* (Collins et al. 1977) and *Propionibacterium* (Schwartz 1973; Sone 1974), respectively. In addition, the fatty acids data (Collins et al. 1982a) did not support the views of Barksdale et al. (1957) that "*C. haemolyticum*" and "*C. pyogenes*" should be reclassified in the genus *Streptococcus*. "*C. haemolyticum*" and "*C. pyogenes*" contain major amounts of monounsaturated fatty acids of the oleic acid series (18:1 ω9) (synthesized via an aerobic pathway; Collins et al. 1982a), whereas members of the genus *Streptococcus* possess monounsaturated fatty acids of the *cis*-vaccenic acid series (18:1 ω7) (synthesized via an anaerobic pathway; Kroppenstedt and Kutzner 1978). The presence of lysine in the walls of "*C. haemolyticum*" and "*C. pyogenes*" supports the removal of both species from the genus *Corynebacterium* sensu stricto (Keddie and Cure 1978; Minnikin et al. 1978). The absence of mycolic acids and the presence of predominantly straight-chain and monounsaturated (oleic acid series) fatty acids in "*C. pyogenes*" and "*C. haemolyticum*" is, however, compatible with members of the genus *Actinomyces* (Kroppenstedt and Kutzner 1978). Therefore, Reddy et al. (1982) as well as Collins and Jones (1982) proposed that "*C. pyogenes*" should be reclassified in the genus *Actinomyces* as "*Actinomyces pyogenes*."

The taxonomic position of "*C. haemolyticum*" remained equivocal. The results of lipid analyses did not support the view of Barksdale et al. (1957) that "*C. haemolyticum*" is a mutant of "*C. pyogenes*." Phenotypically, "*C. haemolyticum*" is very similar to *A. bovis* and also contains lysine in the cell wall peptidoglycan. The menaquinone composition of "*C. haemolyticum*" is distinct from that of *A. bovis* (Collins et al. 1977) and resembles that of the propionibacteria (Schwartz 1973; Sone 1974), but the results of cell wall and fatty acid analyses do not support this latter relationship. Therefore, on the basis of phenetic, peptidoglycan, fatty acid, menaquinone, and DNA data (Schleifer and Kandler 1972; Schofield and Schaal 1981; Collins et al. 1982a, b) reclassified "*C. haemolyticum*" in a new genus *Arcanobacterium* as *Arcanobacterium haemolyticum*.

The use of molecular phylogenetic methods of classification has resulted in several species being transferred from other genera to the genus *Arcanobacterium* and new taxa have been assigned to it. Thus, in a phylogenetic analysis based on 16S rRNA gene sequences of the genus *Actinomyces*, Pascual Ramos et al. (1997a) reclassified "*Actinomyces pyogenes*" and "*Actinomyces bernardiae*" in the genus *Arcanobacterium* as "*Arcanobacterium pyogenes*" and "*Arcanobacterium bernardiae*," respectively, and described a new species *Arcanobacterium phocae*. Thereafter, further new species, viz., "*A. pluranimalium*," *A. hippocolea*, "*A. abortisuis*," "*A. bialowiezense*," and "*A. bonsai*," were assigned to the genus. However, the observation that the genus *Arcanobacterium* is not monophyletic and that MK-10(H4) was the principal menaquinone found in "*A. pyogenes*," "*A. abortisuis*," "*A. bialowiezense*," and "*A. bonsai*" is not in accord with the inclusion of these species in the genus *Arcanobacterium*. Therefore, Yassin et al. (2011) proposed that the genus *Arcanobacterium* should be restricted to the species *A. haemolyticum*, *A. phocae*, *A. hippocoleae*, and *A. pluranimalium* and to reclassify the other species in a new genus, *Trueperella*. Currently, the genus *Arcanobacterium* comprises five validly published species, namely, *A. haemolyticum*, *A. hippocoleae*, *A. phocae*, *A. pluranimalium*, and *A. canis*.

Molecular Analysis

Similarity values of 16S rRNA gene sequence analyses for members of the genus *Arcanobacterium* range from 95.1 % to 97.4 %. The maximum-parsimony tree (*Fig. 4.1a*) generated based on sequence analysis of the 16S rRNA gene sequences of *Arcanobacterium* species produced a monophyletic clade within the family *Actinomycetaceae* with poor bootstrap support (63 % bootstrap value). Although only poor bootstrap support exists for the *Arcanobacterium* clade as a whole, the lack of support may be due to the poorly resolved position of *Arcanobacterium hippocoleae*, which is sister to all remaining species in the clade (*Fig. 4.1b*). Two major lineages could be recognized. One lineage includes four species, *A. haemolyticum*, *A. canis*,

A. pluranimalium, and *A. phocae*. The second lineage constitutes a single species, *A. hippocoleae*. The phylogenetic coherence of *A. haemolyticum*, *A. canis*, *A. pluranimalium*, and *A. phocae* to the genus *Arcanobacterium* is supported by a group of signature nucleotides (Table 4.1). This include nucleotides at positions 157–164 (U-G), 440 (U), 443 (C), 446–488 (U-G), 598–642 (U-A), 615–625 (G-C), and 1244–1293 (U-A). *A. hippocoleae* share with these species only signature nucleotides at positions 157–164, 598–642, 615–625, and 1244–1293 (Table 4.7).

From a phylogenetic point of view, the genera *Arcanobacterium* and *Trueperella* are sisters (Fig. 4.1a, b); this relationship is strongly supported (96 % bootstrap value). The position of the genus *Actinobaculum* as the basal of the clade containing the genera *Arcanobacterium* and *Trueperella* is poorly supported (bootstrap value 67 %).

Table 4.7

[a]*E. coli* position (Brosius et al. 1978)

Phenotypic Analyses

Gross Morphology

Surface colonies of *A. haemolyticum* on blood agar were described to be small after 24 h of incubation at 36 ± 1 °C, becoming larger upon extended incubation (Collins and Cummins 1986). They are circular, discoid, slightly raised, opaque, and nonpigmented with a butyrous consistency, and they show β-hemolysis. *Arcanobacterium phocae* also produces a potent hemolysin, whereas *A. canis* and *A. hippocoleae* are weakly β-hemolytic, and *A. pluranimalium* was reported to be α-hemolytic.

Cellular Morphology

The cellular morphology of the genus *Arcanobacterium* as described by Collins et al. (1982b) for bacteria formerly named "*Corynebacterium haemolyticum*" is as follows: slender, irregular, bacillary forms predominate during the first 18 h of growth; many cells are arranged at an angle to give V formations (Fig. 4.6a). As growth proceeds, cells become granular and segmented so that they resemble small and irregular cocci. Both rods and coccoid cells are Gram-positive, non-acid-fast, and nonmotile; endospores are not formed.

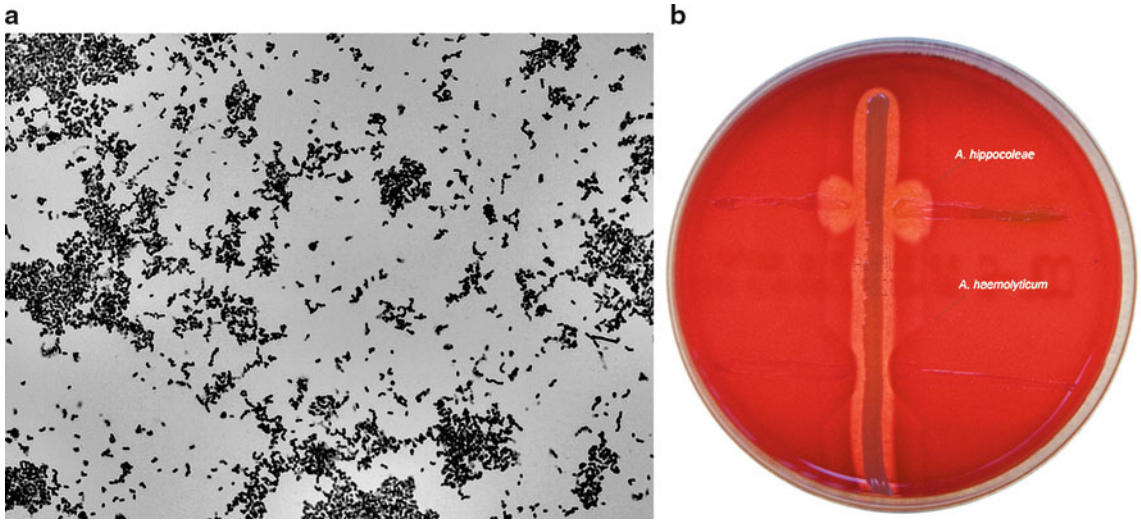

Fig. 4.6
(a) Gram-stained smear from 7-days-old culture of *Arcanobacterium haemolyticum* on Columbia agar with 5% sheep blood showing irregular bacillary forms with V formations. As the growth proceeds cells segmented so that they resembles small irregular cocci. (b) CAMP test showing a positive synergistic result with *Arcanobacterium hippocoleae* DSM15539^T and a positive reverse CAMP test with *Arcanobacterium haemolyticum* DSM20595^T. Staphylococcus aureus ATCC 25923 is streaked down the center of the Columbia agar plate with 5% sheep blood

Biochemical Characteristics

Arcanobacterium species are facultatively anaerobic bacteria having a fermentative type of carbohydrate metabolism. Their growth is considerably enhanced in an atmosphere of increased CO_2 tension. Growth is sparse on ordinary media but enhanced by blood or serum. The optimum temperature for growth is 37 °C. Organisms will not withstand heating at 60 °C for 15 min. Fermentation end products of carbohydrate metabolism are acetic and lactic acids; the amount of succinic acid produced may vary from species to species and may even be difficult to detect. Catalase activity is usually negative, but some strains of *A. haemolyticum* may show weak catalase production. The physiological properties of *Arcanobacterium* species are summarized in *Table 4.8*. Generally, members of the genus *Arcanobacterium* are characterized by a positive CAMP test (*Fig. 4.6b*), but they are negative for nitrate reduction and urease activity.

Interestingly, two biotypes of *A. haemolyticum* that correlates to the site of isolation have been recognized on the basis of colony morphology, β-hemolysis on horse blood agar, β-glucuronidase activity, and ability to ferment sucrose and/or trehalose identified (Carlson et al. 1994b). One, the smooth type, colonies appear smooth, β-hemolytic, and β-glucuronidase negative and often ferment sucrose and/or trehalose, while the other, the rough type, colonies appear rough, nonhemolytic, and β-glucuronidase positive and do not ferment sucrose and trehalose. Both types ferment glucose and maltose. The smooth biotype is more associated with wound infections, while the rough type is more frequently associated with respiratory tract isolates.

Chemotaxonomic Properties

The primary structure of the peptidoglycan of several *Arcanobacterium* species has been determined (Collins et al. 1982a; Lawson et al. 2001a; Schaal et al. 2006; Yassin et al. 2011). This corresponds to peptidoglycan type A5α according to the nomenclature of Schleifer and Seidl (1985). Thus, *A. haemolyticum*, *A. phocae*, *A. pluranimalium*, and *A. hippocoleae* exhibit variation (L-Lys-L-Lys-D-Glu). The muramic acid residue of the glycan moiety is *N*-acetylated. The principal respiratory quinones are tetrahydrogenated menaquinones with eight MK-8(H4) and nine MK-9(H4) isoprene units, with the latter component being the major one (*Table 4.3*).

Reports on the phospholipids found in *Arcanobacterium* species are controversial. Phosphatidylcholine (PC) has been reported as key diagnostic phospholipid in *A. haemolyticum*, *A. phocae* (Schaal et al. 2006), and in *A. canis* (Hijazin et al. 2012b). However, in a comparative chemotaxonomic study of members of the genus *Arcanobacterium*, phosphatidylcholine was not detected in *A. haemolyticum*, *A. phocae*, *A. pluranimalium*, or *A. hippocoleae* (Yassin et al. 2011). Thus, according to Yassin et al. (2011) the phospholipids found in arcanobacteria include diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), and phosphatidylinositol (PI). Nevertheless, in a subsequent emendation of the genus *Arcanobacterium*, Hijazin et al. (2012b) concluded that members of the genus may contain phosphoglycolipid and excluded the presence of PG without referring to the distribution of PC.

The fatty acids profiles are composed of predominantly straight-chain saturated and monounsaturated acids. Major fatty acids are oleic acid ($C_{18:1}\omega9c$) and hexadecanoic acid ($C_{16:0}$). Small amounts of *cis*-vaccenic acid (C18:1ω7c) were detected in *A. haemolyticum*, *A. phocae*, and *A. pluranimalium* (Yassin et al. 2011). Substantial amounts of diunsaturated fatty acids ($C_{18:2}\omega6,9c$) have been detected in all species (Yassin et al. 2011). Methyl-branched-chain (*iso*- and *anteiso*-) were present in minor amounts.

Whole-cell hydrolysates from *A. haemolyticum*, *A. phocae*, *A. pluranimalium*, and *A. hippocoleae* contained rhamnose as diagnostic sugar. Glucose was also detected in these species.

Taxonomic Comments

Arcanobacterium species resemble a variety of other Gram-positive, diphtheroidal, or coccobacillary genera morphologically and/or physiologically. However, recent chemotaxonomic and molecular studies have led to the reevaluation of the genus (Yassin et al. 2011). According to the latter authors the taxonomic circumscription of the genus *Arcanobacterium* established by Collins et al. (1982b) has been modified to emphasize the presence of MK-9(H4) as predominant menaquinone, peptidoglycan type A5α, variation (L-Lys-L-Lys-D-Glu), rhamnose and glucose as diagnostic whole-cell sugars, and phospholipid type PI according to Lechevalier et al. (1977), in addition to a positive CAMP test. These features allowed delimitation of the genus *Arcanobacterium* from the genera *Actinomyces* (as represented by *Actinomyces bovis* the type species of the genus *Actinomyces* sensu stricto), *Actinobaculum*, *Mobiluncus*, *Trueperella*, and *Varibaculum* (*Table 4.3*).

Currently, the genus *Arcanobacterium* comprises five validly published species that form a monophyletic clade in the 16S rRNA gene phylogenetic tree of the family *Actinomycetaceae*. The unresolved placement of *Arcanobacterium hippocoleae* in the phylogenetic tree is due to limited sequence divergence between this species and other members of the genus *Arcanobacterium* (95.1–96.1 % sequence similarity) from one side and members of the genus *Trueperella* (94.1–95.1 % sequence similarity) from the other side. Additionally, there is a potential discrepancy between *A. hippocoleae* and the other species of the genus *Arcanobacterium*, concerning the set of signature nucleotides characteristic for the genus (*Table 4.7*). An obvious explanation for the latter case is that *A. hippocoleae* share with the genus *Trueperella* the set of signature nucleotides at position: 440 (C), 443(U), and 446–488 (A-U). However, the presence of MK-9(H4) as the major menaquinone provides strong evidence that *A. hippocoleae* is specifically related to the genus *Arcanobacterium* and should be retained in the genus.

Besides the chemotaxonomic and phylogenetic evidences, the results of the Christie–Atkins–Munch–Petersen (CAMP) reaction (Christie et al. 1944) are consistent with a distinct phylogenetic group. The CAMP reaction describes the synergistic hemolysis of sheep erythrocytes by the CAMP factor (an extracellular protein) from *Streptococcus agalactiae* and the β-toxin from *Staphylococcus aureus*. All *Arcanobacterium* species are characterized by the production of hemolysis on sheep or horse blood agar and hence display positive CAMP test (*Fig. 4.6b*). This reveals the existence of the gene (*cfa*) that encodes the CAMP factor family protein in the genome of *Arcanobacterium* species, and thus they likely share a common ancestor that already possessed this gene. Although the *cfa* gene has been identified in the only available completed genome sequence of *Arcanobacterium haemolyticum*, the presence of this gene in other species needs to be confirmed.

Definition of the Genus *Arcanobacterium* Sensu Stricto

Cells are slender, irregular, and predominately rod-shaped or arranged at an angle to give V formations during the first 18 h of growth, becoming granular and segmented, resembling small, irregular cocci over time. Both rod-shaped and coccoid cells are Gram-reaction-positive, non-acid-fast, and nonmotile. Endospores are not formed. Strains grow at 37 °C in a 5% CO_2 atmosphere or under anaerobic conditions. Growth is sparse on ordinary media but enhanced on blood- or serum-containing media. The CAMP test is positive with *S. aureus*. The peptidoglycan is of the type A5α, variation L-Lys–L-Lys–D-Glu. The muramic acid residue of the peptidoglycan is *N*-acetylated. The principal menaquinone is MK-9(H_4). Characteristic whole-cell sugars are rhamnose and glucose. The phospholipids comprise DPG and PI but PG and PC may be detected. Mycolic acids are not present. Long-chain fatty acids are primarily straight-chain saturated, monounsaturated, and diunsaturated (C18:2ω6,9c) as well as branched-chain *iso*- and *anteiso*-types. The DNA G+C content is 50–57 mol%. The type species is *Arcanobacterium haemolyticum*.

Identification and Descriptive Characteristics of *Arcanobacterium* Species

The phenotypic characteristics useful for identification of the recognized *Arcanobacterium* species are given in *Table 4.8*.

List of Species of the Genus *Arcanobacterium*

Arcanobacterium haemolyticum (Mac Lean, Liebow, and Rosenberg 1946), Collins, Jones, and Schofield 1983, 438^{VP} (*Corynebacterium haemolyticum* Mac Lean, Liebow, and Rosenberg 1946, 69).

hae. mo. ly' ti. cum. Gr. neut. n. *haema*, blood; Gr. adj. *lyticus*, dissolving, M.L. neut. adj. *haemolyticum*, blood-dissolving, hemolytic.

Surface colonies on blood agar are small (0.75 mm in diameter) after 24 h, becoming large (1.5–2.5 mm in diameter) on extended incubation. Colonies are circular discoid and slightly raised and β-hemolytic. Growth is sparse on ordinary media but is enhanced by blood or serum. Slender, irregular rods predominate during the first 18 h on blood agar; many cells exhibit V forms. Upon extended incubation, organisms become granular and segmented and resemble small irregular cocci. On Loeffler medium, they maintain the slender, irregular, bacillary form but become pleomorphic at 48 h, with numerous club and comma forms. Facultative anaerobi. The optimum temperature for growth is 37 °C. The organism will not withstand heating at 60 °C for 15 min. Acid is produced from glucose, lactose, and some other sugars. Catalase is negative. Extracellular DNase is produced. Gelatin, esculin, and casein are not hydrolyzed. β-Galactosidase and *N*-acetyl-β-glucosaminidase are produced, but β-glucuronidase and α-fucosidase are not. Strain is inhibited by tetracycline (30 pg per disc). The species exhibits the characteristics listed in the definition of the genus *Arcanobacterium* sensu stricto. Other phenotypic features are given in *Table 4.8*.

The mol% G+C of the DNA is 50–52.

Type strain, ATCC 9345 = DSM 20595, isolated from infections among American soldiers.

Arcanobacterium hippocoleae Hoyles, Falsen, Foster, Rogerson and Collins 2002, 619^{VP}.

hip. po. co' le. ae. Gr. masc. and fem. n. *hippos*, horse; Gr. masc. n. koleós, sheath, vagina; M.L. fem. gen. n. *hippocoleae*, of the horse vagina.

Cells are non-branching, irregular-shaped rods which stain Gram-positive, are non-acid-fast, and nonmotile. On Columbia blood agar supplemented with 5% sheep blood, colonies are cirular, entire-edged, convex, shiny, opaque, and gray, surrounded by small zone of beta-hemolysis. Strain is facultatively anaerobic and catalase-negative. Acid is produced from D-glucose and lactose, but not from D-arabitol, L-arabinose, cyclodextrin, glycogen, pullulan, mannitol, melibiose, melezitose, methyl-β-D-glucopyranoside, D-ribose, D-raffinose, sucrose, D-sorbitol, tagatose, trehalose, or D-xylose. Acid may or may not be produced from maltose depending on the test system used. α-Glucosidase, β-galactosidase, β-glucuronidase, leucine arylamidase, and phosphoamidase are detected, but not acid phosphatase, alanine–phenylalanine–proline arylamidase, arginine dihydrolase, chymotrypsin, esterase C-4, ester lipase C8, α-fucosidase, α-galactosidase, β-glucosidase, lipase C14, α-mannosidase, β-mannosidase, pyrrolidonyl arylamidase, pyroglutamic acid arylamidase, pyrazinamidase, trypsin, valine arylamidase, urease, or glycyl-tryptophan arylamidase. *N*-Acetyl-β-glucosaminidase and alkaline phosphatase may or may not be detected depending on the test system used. Esculin (weak reaction) and hippurate are hydrolyzed, but not gelatin. Acetoin is not produced. Nitrate is not reduced to nitrite. The species exhibits the characteristics

listed in the definition of the genus *Arcanobacterium* sensu stricto. Habitat is not known.

The mol% G+C of the DNA has not been reported.

Type strain, CCUG 44697 = CIP 106850, isolated from vaginal discharge from a horse.

Arcanobacterium phocae Pascual Ramos, Foster and Collins 1997, 52^{VP}.

phoc'ae. N.L. gen. n. *phocae*, of *Phoca*, because the organism has been isolated from seals [the genus *Phoca*].

Cells are Gram-stain-positive and non-acid-fast. They are pleomorphic coccbacilli, short rods and dephtheroid. Cells are nonmotile and nonsporeforming. Colonies on blood agar (incubated for 24 h) are white, tiny, circular, low convex, and surrounded by a zone of β-hemolysis which may be two to three times the diameter of the colony. Strain is facultative anaerobic. Growth is not enhanced by increased concentrations of CO_2 (5–10 %). Catalase reaction is variable. Metabolism is strictly fermentative. Acid but not gas is produced from glucose. Acid is produced from glycerol, D-ribose, galactose, D-glucose, D-fructose, *N*-acetylglucosamine, maltose, lactose, sucrose, starch, glycogen, D-turanose, and 5-ketogluconate. Most strains ferment mannose, inositol, trehalose, and melezitose, and a few strains ferment mannitol, D-xylose, D-tagatose, and gluconate. Acid is not produced from erythritol, cellobiose, D-arabinose, L-arabinose, L-xylose, adonitol, β-methyl-D-xyloside, sorbose, rhamnose, dulcitol, D-sorbitol, α-methyl-mannoside, α-methyl-D-glucoside, amygdalin, arbutin, salicin, melibiose, inulin, D-raffinose, xylitol, gentiobiose, D-lyxose, D-fucose, L-fucose, D-arabitol, L-arabitol, and 2-ketogluconate. Nitrate reduction is negative. Gelatin, esculin, and urea are not hydrolyzed. Pyrazinamidase, acid phosphatase, alkaline phosphatase, α-galactosidase, β-galactosidase, α-glucosidase, esterase (C4), esterase–lipase (C8), cystine arylamidase, and leucine arylamidase are produced. Production of trypsin is variable. Pyrrolidonyl arylamidase, lipase (C14), valine arylamidase, chymotrypsin, naphthol-AS-BI-phosphohydrolase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not produced. The species exhibits the characteristics listed in the definition of the genus *Arcanobacterium* sensu stricto. Other phenotypic features are given in ❯ *Table 4.8*.

Arcanobacterium phocae has been isolated from various tissues and fluids of common seals (*Phoca vitulina*) and gray seals (*Halichoerus grypus*), for which its pathological significance is unclear, but it has been recovered in mixed cultures from pneumonic and septicemic seals.

The mol% G+C of the DNA has not been reported.

Type strain, M1590/94/3 = DSM 10002 = CIP 105740, isolated from the lung of common seal (*Phoca vitulina*). The type strain possesses the characteristics of the species except that it is catalase-positive and produces trypsin. M1590/94/3 ferments inositol, mannitol, mannose, melezitose, trehalose, and D-xylose but does not ferment D-tagatose and gluconate.

Arcanobacterium pluranimalium Lawson, Falsen, Foster, Eriksson, Weiss and Collins 2001, 58^{VP}.

plur. a. ni. ma' li. um. L. comp. adj. *plus*, *pluris*, more, a greater quantity; L. gen. pl. n. *animalium*, from animals; M.L. gen. n. *pluranimalium*, from many animals.

Cells are straight to slightly curved, non-branching, slender rods which stain Gram-positive and are non-acid-fast and nonmotile. Strain is facultative anaerobic and catalase-positive. Acid is produced from D-glucose and D-ribose, but not from D-arabitol, L-arabinose, cyclodextrin, glycogen, pullulan, D-sorbitol, tagatose, mannitol, melibiose, melezitose, lactose, raffinose, sucrose, trehalose, or D-xylose. Maltose is variable. Alanine–phenylalanine–proline arylamidase, pyroglutamic acid arylamidase, and β-glucuronidase are detected, but not arginine dihydrolase, alkaline phosphatase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-galacturonidase, *N*-acetyl-β-glucosaminidase, β-mannosidase, or urease. Pyrazinamidase and glycyl-tryptophan arylamidase may or may not be detected. Esculin (weak reaction), gelatin, and hippurate are hydrolyzed. Acetoin is not produced. Nitrate is not reduced to nitrite. The species exhibits the characteristics listed in the definition of the genus *Arcanobacterium* sensu stricto. Other phenotypic features are given in ❯ *Table 4.8*. Habitat is not known.

The mol% G+C of the DNA is 57.

Type strain, CCUG 42575 = DSM 13483, isolated from a dead harbor porpoise and a dead sallow deer.

Arcanobacterium canis Hijazin, Prenger-Berninghoff, Sammra, Alber, Lämmler, Kämpfer, Glaeser, Busse, Hassan, Abdulmawjood and Zschöck 2012, 2203^{VP}.

can'is. L. gen. n. *canis* of a dog.

Cells are Gram stain-positive, nonmotile, and non-sporeforming rods (1–2 µm long and 0.5 µm wide). Growth occurs on sheep blood agar with a weak zone of hemolysis under microaerobic conditions (the zone of hemolysis is less pronounced under aerobic and anaerobic conditions). CAMP reaction is positive with a strain of *Rhodococcus equi*. Acid is produced from D-glucose, D-ribose, maltose, lactose, sucrose, and glycogen, but not from D-xylose or D-mannitol. Activity of the following enzymes is observed: alkaline phosphatase, β-glucuronidase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, DNase, and amylase are positive. Hyaluronidase, pyrazinamidase and pyrrolidonyl arylamidase activities are not detected. Casein, esculin, gelatin and urea are not hydrolyzed. Nitrate is not reduced to nitrite. The menaquinone and polar lipid profiles are typical of the genus. The polyamine pattern contains putrescine, spermine, and spermidine. Cellular fatty acids contain major proportions of $C_{14:0}$, $C_{16:0}$, $C_{18:0}$, $C_{18:1}\omega9c$, and $C_{18:2}\omega6,9c$/anteiso-$C_{18:0}$. Habitat is not known.

The mol% G+C of the DNA has not been reported.

Type strain, CCUG 61573^{T} = CIP 110339^{T}, isolated from canine otitis externa.

Genus III. *Trueperella* Yassin, Hupfer, Siering and Schumann 2011, 1272^{VP}.

Tru. e. pe. rel 'la. N.L. fem. dim. n. *Trueperella*, named after Hans Georg Trüper, the German microbiologist.

Taxonomy, Historical and Current

The genus *Trueperella* was described by Yassin et al. (2011) to accommodate bacterial species previously classified in the genus *Arcanobacterium*. The description of the genus was based on chemotaxonomy and on phylogenetic data of the 16S rRNA gene sequences. To arrive the current taxonomy, members of the genus had undergone a number of taxonomic changes, such as *Trueperella pyogenes*, the type species of the genus, was proposed for the invalidly named species "*Arcanobacterium pyogenes*" proposed by Pascual Ramos et al. (1997a) for the invalidly named species "*Actinomyces pyogenes*," which in turn was reclassified from the invalidly named species "*Corynebacterium pyogenes*" by Reddy et al. (1982) and Collins and Jones (1982) and *Trueperella bernardiae* named for "*Arcanobacterium bernardiae*" proposed by Pascual Ramos et al. (1997a), which in turn was reclassified from the invalidly named species "*Actinomyces bernardiae*" proposed by Funke et al. (1995) for facultative anaerobic, Gram-positive rods that were referred "CDC fermentative coryneform group 2" by workers at the Centers of Disease Control (CDC).

The taxonomic position of "*Corynebacterium pyogenes*" has been always controversial and its retention within the genus *Corynebacterium* has been questioned by several authors (Cummins and Harris 1956; Barksdale et al. 1957; Barksdale; 1970; Jones 1975; Collins et al. 1982a). Cummins and Harris (1956), on the basis of cell wall sugar and amino acid composition, suggested the inclusion of "*C. pyogenes*" and "*C. haemolyticum*" in the genus *Streptococcus*. This view was supported by Barksdale et al. (1957) who further suggested that "*C. haemolyticum*" was a mutant form of "*C. pyogenes*." In the 8th edition of *Bergey's Manual of Determinative Bacteriology*, "*C. pyogenes*" is retained as an addendum to the genus *Corynebacterium* (Cummins et al. 1974), and it appears in the *Approved Lists of Bacterial Names* (Skerman et al. 1980). Later, numerical taxonomic (Schofield and Schaal 1981) and chemical (Collins et al. 1982a) studies indicated that "*C. pyogenes*" and "*C. haemolyticum*" are distinct taxa. The lipid data are not in accord with the views of Barksdale et al. (1957) and Cummins and Harris (1956) that "*C. pyogenes*" should be reclassified in the genus *Streptococcus*. In addition, the discovery of tetrahydrogenated menaquinones with ten isoprene units [MK-10(H4)] predominated in "*C. pyogenes*" is neither in accord with the inclusion in the genus *Streptococcus* nor the retention of this species in the genus *Corynebacterium*. Moreover, the presence of peptidoglycan based on lysine in "*C. pyogenes*" supports this view since this amino acid is present in the peptidoglycan of *A. bovis* (Schleifer and Kandler 1972). Therefore, because of the close chemical and physiological similarity to *A. bovis*, the type species of the genus *Actinomyces*, Collins and Jones (1982) and Reddy et al. (1982) reclassified "*C. pyogenes*" in the genus *Actinomyces* as "*Actinomyces pyogenes*."

Nonetheless, application of phylogenetic analysis based on 16S rRNA gene sequencing of the genus *Actinomyces* revealed that "*A. pyogenes*" along with "*A. bernardiae*" cluster together with *Arcanobacterium haemolyticum* (Pascual Ramos et al. 1997a). Consequently, "*Actinomyces pyogenes*" and "*Actinomyces bernardiae*" have been reclassified and assigned to the genus *Arcanobacterium* as "*Arcanobacterium pyogenes*" and "*Arcanobacterium bernardiae*," respectively. Finally, further study based on comparative chemotaxonomic and phylogenetic analysis of the genus *Arcanobacterium* indicated that members of the genus *Arcanobacterium* clusters in two groups (Yassin et al. 2011). The presence of MK-10(H4) as predominant menaquinone in conjunction with a set of signature nucleotides in one cluster justified the erection of a new genus, *Trueperella*. Currently, the genus *Trueperella* harbors five species, including *Trueperella pyogenes*, *T. abortisuis*, *T. bernardiae*, *T. bialowiezense*, and *T. bonsai*.

Molecular Analyses

Similarity values of 16S rRNA gene sequence analyses for members of the genus *Trueperella* range from 95.4 % to 98.1 %. Phylogenetic analysis based on 16S rRNA gene sequences revealed a strongly supported monophyletic clade (96 % bootstrap value) sister to the genus *Arcanobacterium* (*Fig. 4.1a*) and together, though weakly supported (67 % bootstrap), appeared as potential sister to the genus *Actinobaculum*. The presence of a set of signature nucleotides (*Table 4.1*) in the 16S rRNA gene sequence of all *Trueperella* species underlines the phylogenetic coherence of this group. This includes nucleotides at 157–164 (G-U), 440 (C), 443 (U), 446–488 (A-U), 598–642 (C-A), and 615–625 (G-U).

Phenotypic Analyses

Gross Morphology

Surface colonies of *Trueperella* species incubated for 48 h under anaerobic conditions on blood agar are nonpigmented, pinpoint, smooth, circular, with entire edge, convex, translucent, and surrounded by a zone of β-hemolysis (Collins and Jones 1982; Funke et al. 1995; Lehnen et al. 2006; Reddy et al. 1982). Colony diameters are 0.2–1.5 mm after 48–72 h of incubation. All *T. pyogenes* strains exhibit β-hemolysis on agar media containing bovine or ovine blood (Pascual Ramos et al. 1997a), although strains of porcine origin are generally more hemolytic (Timoney et al. 1988). Some strains of *T. bernardiae* and *T. abortisuis* either are nonhemolytic or possess a very narrow zone of β-hemolysis.

Cellular Morphology

Gram stains of *Trueperella* strains grown on blood agar show slender, irregular bacillary forms. Cells are 0.2 × 2 μm and occur mostly singly and in pairs (V and T formations and

some palisades). Chains of coccoid forms resembling streptococci may be seen but short, diphtheroid forms normally predominate. All forms are Gram-reaction-positive, but cells from older cultures may be Gram-reaction-variable. Cells are nonmotile and non-acid-fast. Endospores are not formed.

Biochemical Characteristics

Of the different biochemical characteristics evaluated for identification of *Trueperella* species, only four tests yield uniform results. These include fermentation of glucose, lack of catalase, and urease activities and inability to reduce nitrate. The ability to liquify gelatin is at present restricted to *T. pyogenes*. Furthermore, *T. pyogenes* has been found to be positive by the CAMP reaction. The major phenotypic features useful in the separation of *Trueperella* species are listed in ❯ *Table 4.9*.

Trueperella are facultatively anaerobic having a fermentative type of metabolism. Metabolic end products of glucose fermentation include succinate, acetate, and lactate.

Chemotaxonomic Properties

The mode of cross-linkage and the amino acid composition of the tetrapeptide bridge of the peptidoglycan layer of *Trueperella* species have been investigated (Collins et al. 1982a; Funke et al. 1995; Yassin et al. 2011). This corresponds to peptidoglycan type A5α according to the nomenclature of Schleifer and Seidl (1985) (❯ *Table 4.3*). However, two peptidoglycan variations could be identified among individual species: variation L-Lys-L-Ala-L-Lys-D-Glu has been identified in *T. pyogenes*, *T. bernardiae*, and *T. bialowiezensis* and variation L-Lys-L-Lys-D-Glu has been characterized in *T. abortisuis* and *T. bonsai*.

Regardless of the variation encountered in the peptidoglycan, the menaquinone pattern of *Trueperella* species consistently correlate with a cohesive group (❯ *Table 4.3*). All species contain tetrahydrogenated menaquinones with nine, ten, and eleven isoprene units, abbreviated MK-9(H4), MK-10(H4), and MK-11(H4), respectively, with MK-10(H4) being the major component (Collins et al. 1982a; Lehnen et al. 2006; Yassin et al. 2011).

Furthermore, *Trueperella* species possess characteristic phospholipid patterns consisting of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphoglycolipids with unknown chemical structure, and a number of incompletely characterized phospholipids. The presence of phosphoglycolipids is considered an important feature to substantiate the genus (Yassin et al. 2011). Although Lehnen et al. (2006) reported the presence of an unknown aminolipid (AL2) and an unknown aminophospholipid in *T. bialowiezensis* and *T. bonsai* and Azuma et al. (2009) reported the presence of phosphatidylethanolamine (PE) in *T. abortisuis*, the distribution of nitrogen-containing phospholipids is considered absent from the genus (Yassin et al. 2011).

The cellular fatty acids of *Trueperella* species are composed of predominantly straight-chain saturated and monounsaturated acids, in addition to trace amounts of diunsaturated ($C_{18:2}\omega6,9c$), methyl-branched-chain (*anteiso-*, *iso-*) fatty acids. Tetradecanoic acid ($C_{14:0}$), hexadecanoic acid ($C_{16:0}$), and oleic acid ($C_{18:1}\omega9c$) predominated in all *Trueperella* species. Additionally, substantial amounts of hexadecenoic ($C_{16:1}\omega7c$) and octadecanoic ($C_{18:0}$) acids were also detected. Moreover, the cellular fatty acid profiles of *T. bialowiezensis* and *T. bonsai* contain traces of $C_{18:1}\omega7c$.

The cell wall of *Trueperella* species is characterized by the presence of rhamnose and glucose as diagnostic sugars (Cummins and Harris 1956; Yassin et al. 2011). The muramic acid residues of the glycan moiety of the cell wall peptidoglycan are *N*-acetylated. The DNA G+C content of member of the genus range from 56 % to 66 % mol% (Yassin et al. 2011).

Identification and Descriptive Characteristics of *Trueperella* Species

The phenotypic characteristics useful for identification of the recognized *Trueperella* species are given in ❯ *Table 4.9*.

List of Species of the Genus *Trueperella*

Trueperella abortisuis Azuma, Murakami, Ogawa, Okada, Miyazaki, and Makino 2009, 1471^{VP}.

(a.bor.ti.su'is. L. n. *abortus*, *abortus*, an abortion; L. n. *sus*, *suis*, a pig, a sow; N.L. gen. n. *abortisuis*, from an abortion of a sow).

Cells are Gram-stain-positive, diphtheroid-shaped rods and may arranged in V-shaped forms or palisades. Colonies on Columbia blood agar are smooth, entire-edged, translucent, and nonhemolytic. Facultatively anaerobic. The strain is catalase-negative. Indole production is negative. Reduces nitrate. Soluble starch is hydrolyzed, but gelatin is not. Produces acid from fructose, galactose, glucose, cellobiose, lactose, maltose, sucrose, trehalose, melezitose, raffinose, inulin, soluble starch, adonitol, and glycerol. Does not ferment arabinose, ribose, xylose, rhamnose, mannose, sorbose, melibiose, amygdalin, arbutin, salicin, dulcitol, erythritol, mannitol, sorbitol, or inositol. Produces α-galactosidase, β-galactosidase, α-glucosidase, and leucine arylamidase but not urease, β-glucosidase, or pyroglutamic acid arylamidase. Fermentation end products are lactic, succinic, and acetic acids. Whole-cell sugars include rhamnose and ribose. Cell wall peptidoglycan contains glutamic acid, alanine, and lysine in the molar ratio of 1:2:1. Major fatty acids are $C_{14:0}$, $C_{16:1}\omega7$, $C_{16:0}$, and $C_{18:1}\omega9$. The major menaquinone is MK-10(H_4). Polar lipids are phosphatidylethanolamine and two unknown phosphatidylinositol mannosides. The interpeptide bridge within the peptidoglycan has not been reported.

The mol% G+C of the DNA is 63.8.

[a]Denote data from A. F. Yassin

Type strain: Murakami^T (= ATCC BAA-1522^T = DSM 19515^T = JCM 14813^T), isolated from a sow's placenta after an abortion.

Trueperella bernardiae (Funke, Pascual Ramos, Fernández-Garayzábal, Weiss, and Collins 1995), comb. nov. Pascual Ramos, Foster, and Collins 1997, 51^{VP} (*Actinomyces bernardiae* Funke, Pascual Ramos, Fernández-Garayzábal, Weiss, and Collins 1995, 59).

(ber. nar' di.ae. N.L. gen. n. *bernardiae*, of Bernard, named after the contemporary Canadian microbiologist Kathryn A. Bernard for her contributions to the study of asporogenous, Gram-positive rods).

Cells are Gram-positive rods, with coccobacilli predominating. Cells are sometimes arranged in clusters, but primary branching is not observed. Cells are nonmotile and do not form spores. Colonies are circular, smooth, and slightly convex with a glassy appearance. Colony diameters range from 0.2 to 0.5 mm after 48 h of incubation in the presence of 5 % CO_2 on sheep blood agar. Catalase is not produced. Acid is produced from glycerol, ribitol, adonitol, D-glucose, D-fructose, maltose, starch, xylitol, D-arabitol, and 5-ketogluconate. Most strains ferment erythritol, ribose, glycogen, and L-arabitol. Acid is not produced from xylose, mannitol, α-methyl-D-mannoside, amygdalin, arbutin, sucrose, and 2-ketogluconate. Activity is detected for leucine arylamidase and α-glucosidase. No activity is detected for alkaline phosphatase, cystine arylamidase, chymotrypsin, trypsin, acid phosphatase, α-galactosidase, β-glucuronidase, β-glucosidase, α-mannosidase, and α-fucosidase. Esculin and urea are not hydrolyzed. Nitrate is not reduced. Palmitic and stearic acids are the main straight-chain cellular fatty acids, while oleic acid is the predominant unsaturated fatty acid. The major menaquinone is MK-10(H_4). The interpeptide bridge within the peptidoglycan is L-Lys-L-Ala-L-Lys-D-Glu (type A 5α).

The mol% G+C of the DNA is 63–66.

Type strain, CCUG 33419 = DSM 9152, isolated from human blood.

Trueperella bialowiezense Lehnen, Busse, Frölich, Krasinska, Kämpfer, and Speck 2006, 864^{VP}.

(bi.a.lo.wi.e.zen'se. N.L. neut. adj. *bialowiezense*, pertaining to Bialowieza, Poland, where the type strain was isolated).

Cells are short pleomorphic rods. After 48 h of growth under aerobic conditions on sheep blood agar, colonies are translucent, convex, approx. 0.5 mm in diameter, and surrounded by a narrow zone of β-hemolysis. Cells are nonmotile (motility agar) and facultatively anaerobic and are catalase- and oxidase-negative. Best growth occurs at 37 °C; no growth at 42 °C. No growth is observed on Gassner or MacConkey agar. Nitrate reduction is negative. Esculin and gelatin are not hydrolyzed. Hippurate hydrolysis is positive. Acid is produced from glycerol, D-glucose, and D-fructose. Acid is not produced from adonitol, D-arabitol, L-arabitol, erythritol, glycogen, inulin, D-lactose, maltose, D-mannitol, raffinose, ribose, D-sorbitol, starch, sucrose, trehalose, and D-xylose. Activity is detected for acid phosphatase, esterase–lipase (C8), naphthol-AS-BI-phosphohydrolase, β-glucuronidase, α-glucosidase, and pyrazinamidase. No activity is detected for alkaline phosphatase, cystine arylamidase, chymotrypsin, α-galactosidase, *N*-acetyl-β-glucosaminidase, β-glucosidase, α-fucosidase, leucine arylamidase, α-mannosidase, pyrrolidonyl arylamidase, trypsin, and urease. The quinone system contains MK-10(H_4) as the predominant compound. The interpeptide bridge within the peptidoglycan has not been reported.

The mol% G+C of the DNA has not been reported.

Type strain, DSM 17162 = NCTC 13354, isolated from the prepuce of a European bison.

Trueperella bonasi Lehnen, Busse, Frölich, Krasinska, Kämpfer, and Speck 2006, 864^{VP}.

(bo. na' si. L. gen. n. *bonsai*, of the European bison (*Bison bonasus*) from which the type strain was isolated).

Cells are short pleomorphic rods. After 48 h of growth under aerobic conditions on sheep blood agar, colonies are translucent, convex, approx. 0.5 mm in diameter, and surrounded by a narrow zone of β-hemolysis. Cells are nonmotile (motility agar), facultatively anaerobic, and catalase- and oxidase-negative. Best growth occurs at 37 °C; no growth at 42 °C. No growth is observed on Gassner or MacConkey agar. Nitrate reduction is negative. Esculin and gelatin are not hydrolyzed. Hippurate hydrolysis is positive. Acid is produced from D-arabitol, L-arabitol, D-fructose, and trypsin. Acid is weakly produced from adonitol, erythritol, and glycerol. Acid is not produced from erythritol, D-glucose, glycogen, inulin, D-lactose, maltose, D-mannitol, raffinose, ribose, D-sorbitol, starch, sucrose, trehalose, and D-xylose. Activity is detected for acid phosphatase, esterase–lipase (C8), lipase (C14), naphthol-ASBI-phosphohydrolase, β-glucuronidase, pyrazinamidase, and pyrrolidonyl arylamidase. No activity is detected for alkaline phosphatase, cystine arylamidase, chymotrypsin, α-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-fucosidase, leucine arylamidase, α-mannosidase, and urease. The quinone system contains MK-10(H_4) as the predominant compound. The interpeptide bridge within the peptidoglycan has not been reported.

The mol% G+C of the DNA has not been reported.

Type strain, DSM 17163 = NCTC 13355, isolated from the prepuce of a European bison.

Trueperella pyogenes (Glage 1903), Pascual Ramos, Foster and Collins 1997, 51^{VP}. (*Bacillus pyogenes* Glage 1903, 1973; *Corynebacterium pyogenes* (Glage) Eberson 1918, 23; *Actinomyces pyogenes* Reddy, Cornell and Fraga 1982, 427). (Gr. neut. n. *pyon*, pus; Gr. v. *gennaein*, to produce; N. L. adj. *pyogenes*, pus-producing).

Cells are Gram-stain-positive coccobacilli or short rods that may occur singly, in pairs or clusters and may arranged in V-forms or T-forms and palisade. Cells are nonmotile and nonsporeforming. Streptococcal forms in small clumps and short crooked chains are occasionally observed. Cells vary in shape and size (0.2 to 0.9 by 0.3 to 2.5 μm) in different media. Cells from old culture (more than 48 hours growth) stain unevenly and may be Gram-variable. The cell wall ultrastructure is typical of Gram-positive bacteria. The cell walls are 29–30 nm

thick and have a characteristic double-track appearance. Pinpoint, β-hemolytic colonies occur on sheep blood agar after 24 h of incubation. The zones of hemolysis are typically two to three times the diameter of the colony. After 48–72 h, the colonies (diameter 0.5–1.5 mm) are convex, circular, opaque, white, and soft with entire edges. Colonies develop faster and are bigger (diameter 1.5–3.0 mm) on SFM agar plates. Good growth occurs under aerobic and strictly anaerobic conditions. Metabolism is strictly fermentative. Acid but not gas is produced from glucose, fructose, galactose, lactose, cellobiose, trehalose, maltose, melezitose, mannose, glycogen, dextrin, xylose, and starch. The fermentation of adonitol, arabinose, erythritol, glycerol, sucrose, mannitol, and sorbitol varies with the strain. No acid is produced from amygdalin, esculin, melibiose, raffinose, rhamnose, or salicin. Alanine, arginine, aspartate, glycine, and threonine are not fermented. Most strains are catalase-negative, although one strain has been reported to be catalase-positive. Acid clotting and digestion of clots in litmus milk and liquefaction of gelatin are characteristic of all strains. Nitrates are not reduced, and indole is not produced. The optimum growth temperature is 37 °C; the temperature range is 20–40 °C.

Lactic acid is the primary metabolic product in Brain Heart Infusion or tryptose broth with no added HCO_3^-; acetate is a minor product. Glucose is fermented in the presence of CO_2/HCO_3^-, and this reaction yields succinate, acetate, formate, and lactate as major end products. For each 1 mol of CO_2/HCO_3^- fixed, 1 mol of succinate, 1 mol of acetate, and 1 mol of formate are produced. In identical media without added bicarbonate or hemin, lactate is the major product, and smaller amounts of acetate, succinate, and formate are produced. CO_2/HCO_3^- is required for growth. Hemin is highly stimulatory or required for growth. Peptides are required for growth even in the presence of a complete complement of 20 amino acids and $(NH_4)_2SO_4$. Inositol can replace the peptide requirement for growth. Riboflavin and nicotinic acid are required for optimal growth. Adenine and uracil are required for optimal growth of some strains. Characteristic cell wall sugar components are rhamnose and glucose. No mycolic acids are present. Culture filtrates are fatal to mice and rabbits after intravenous injection. The soluble hemolysin produced is active against human, guinea pig, sheep, horse, and rabbit erythrocytes. Both toxic and hemolytic activities of crude cell extracts are neutralized by antitoxin.

This organism is frequently isolated from a wide variety of pyogenic disease conditions in many species of domestic animals and in humans. Presumably, *Arcanobacterium pyogenes* occurs as a commensal organism on the mucous surfaces of warm-blooded animals. The interpeptide bridge within the peptidoglycan is L-Lys-L-Ala-L-Lys-D-Glu (Type A5 α). The principal menaquinones are MK-10(H4).

The mol% G+C of the DNA is 56–58.

Type strain, ATCC 19411 = NCTC 5224.

Genus IV. *Actinobaculum* Lawson, Falsen, Åkervall, Vandamme and Collins 1997, 902^{VP}.

Ac. ti. no. ba'cu. lum. Gr. n. *actis actinos*, ray; L. neut. n. *baculum*, rod, stick; N. L. neut. n. *Actinobaculum* ray stick.

Taxonomy, Historical and Current

The genus *Actinobaculum* was introduced by Lawson et al. (2007) to accommodate bacterial strains previously designated as "*Actinomyces suis*" and also some *Actinomyces*-like organisms originated from human sources. Currently, the genus comprises four validly published species: *Actinobaculum massiliense*, *Actinobaculum schaalii*, *Actinobaculum suis*, and *Actinobaculum urinale*. *A. suis*, the type species of the genus, has a convoluted taxonomic and nomenclatural history. In 1957 Soltys and Spratling proposed the name "*Corynebacterium suis*" for an anaerobic diphtheroid bacterium which was associated with cases of cystitis and pyelonephritis in pigs. The generic assignment was based almost exclusively on the diphtheroid morphology of the organism, a common practice at the time. The name "*Corynebacterium suis*" was not included in the Approved Lists of Bacterial Names (Skerman et al. 1980) and hence has no standing in nomenclature.

In a study by Wegienek and Reddy (1982) to determine the taxonomic status of "*Corynebacterium suis*," they found that "*Corynebacterium suis*" strain Soltys 50052 is anaerobic, has rhamnose and lysine as major cell wall components, and produces acetate, formate, and ethanol as major end products of carbohydrate metabolism. According to *Bergey's Manual of Determinative Bacteriology*, 8th ed., the genus *Corynebacterium* includes aerobic or facultatively anaerobic and non-spore-forming organisms that are characterized by arabinose and galactose as the major cell wall sugar components and *meso*-diaminopimelic acid as the major diamino acid (Rogosa et al. 1974). Furthermore, they produce major amounts of acetate, propionate, and formate and variable amounts of other acids as products of carbohydrate metabolism (Reddy and Kao 1978). Thus, Wegienek and Reddy (1982) concluded that "*Corynebacterium suis*" strain Soltys 50052 did not belong to the genus *Corynebacterium* and proposed, despite differences in cell wall composition and DNA base ratios, that the organism should be included in the genus *Eubacterium*. Their proposal was based on a rather limited number of characteristics such as anaerobiosis and morphology, as well as absence of propionate, lactate, and succinate among the end products of carbohydrate metabolism.

In a subsequent phylogenetic study, based on comparative analysis of the 16S rRNA gene sequences, Ludwig et al. (1992) found that "*Eubacterium suis*" is a close relative of "*Actinomyces pyogenes*" (93.8 % sequence similarity), and they also found that the two organisms share a common cell wall composition (lysine is the diamino acid; rhamnose and traces of mannose are the cell wall sugars). Moreover, according to previous studies (Soltys and Spratling 1957; Schaal and Pulverer 1981; Wegienek and Reddy 1982; Schaal 1986b) both "*Eubacterium suis*" and "*Actinomyces pyogenes*" contain cytochrome *c* and have similar DNA G+C contents (55 and 56–58 mol%, respectively). However, differences in the biochemical characteristics of "*Eubacterium suis*" Soltys and Spratling and the species incertae sedis "*Actinomyces*

suis" Franke 1973 indicate that these two organisms are not identical, and since no type strain of "*Actinomyces suis*" Franke is extant, Ludwig et al. (1992) proposed that "*Eubacterium suis*" should be transferred to the genus *Actinomyces* as "*Actinomyces suis*."

In a systematic phylogenetic study of the genus *Actinomyces*, Pascual et al. (1997) noted that the genus *Actinomyces* comprises a phylogenetically diverse group of organisms and is clearly in urgent need of taxonomic revision. One such organism is *Actinomyces suis* which displays approximately 10–14 % 16S rRNA sequence divergence with the *Actinomyces bovis* cluster of species and exhibit somewhat closer affinity with *Arcanobacterium* species (approximately 8–11 % sequence divergence). Considerations of both sequence divergence and tree topology stimulated Lawson et al. (1997) to reclassify *Actinomyces suis* in a new genus *Actinobaculum* as *Actinobaculum suis*. Interestingly, Lawson et al. (1997) also noted that five unknown bacterial isolates from clinical sources possess a specific affinity with *A. suis*. They confidently cluster with this species (bootstrap value of 100 %) and displayed approximately 6 % sequence divergence. Therefore, they concluded that the five clinical isolates represented a distinct species within the new genus as *Actinobaculum schaalii*.

Molecular Analyses

The molecular phylogeny of *Actinobaculum* based on 16S rRNA gene sequence data shows that the genus resolved as a monophyletic clade supported by 73 % bootstrap (*Fig. 4.1a*). Within this clade two genetically distinguishable lineages could be identified: one lineage (supported by 100% bootstrap value) uniting *A. massiliense* and *A. suis*. Both species sharing 95.2% 16S rRNA gene sequence similarity. The other lineage (not supported by bootstrap value) uniting *A. schaalii* and *A. urinale*. The level of 16S gene sequence similarity between the latter two species is 93.6%. This dichotomy was independently supported by molecular signatures in 16S rRNA genes (*Table 4.10*). The two lineages share 92.1–93.6 % similarity. These data imply that the genus *Actinobaculum* represents a paraphyletic assemblage of taxa and need a thorough revision. However, at present time, the small size of the genus (4 species) troubles this attempt to make an infrageneric classification.

Interestingly, phylogenetic analyses resolved a sister relationship between the genus *Actinobaculum* and the genera *Arcanobacterium* and *Trueperella*. However, this relationship is poorly supported (67 % bootstrap value).

Table 4.10
16S rRNA signature nucleotides that define the two lineages of the genus *Actinobaculum*

Phenotypic Analyses

Morphology

Actinobaculum are Gram-positive, non-acid-fast, nonmotile, non-spore-forming straight to slightly curved rods. They grow slowly on blood-containing agar media after anaerobic incubation for 2–3 days. Isolates grew either well or poorly in air with 5 % CO_2 and either poorly or not at all in ambient air. *Actinobaculum suis* produces small, 2–3 mm in diameter, translucent, round, and granular colonies after 2 days growth on Columbia blood agar. After 7 days incubation, colonies flatten and develop a characteristic dry, gray opaque surface with crenated edges, attaining a size of 4–5 mm in diameter after a week of growth (*Fig. 4.7a*). No hemolytic effect is observed around the colonies. The striking colony morphology of *A. suis* easily separates it from other species of the genus. Cells of *A. suis* have coryneform morphology with size varying from 2 to 3 µm in length and from 0.3 to 0.5 µm in width (*Fig. 4.7b*). In contrast to the large, crenate-edged and dry colonies of *A. suis*, colonies of *A. massiliense*, *A. schaalii*, and *A. urinale* are small, <1 mm in diameter, smooth with entire margins, and nonhemolytic (Greub and Raoult 2002; Hall et al. 2003a).

Actinobaculum species are anaerobic bacteria with strict fermentative type of metabolism. Although, acetate has been reported as a basic end product of glucose or maltose catabolism, variations in fermentation end product profiles have been reported.

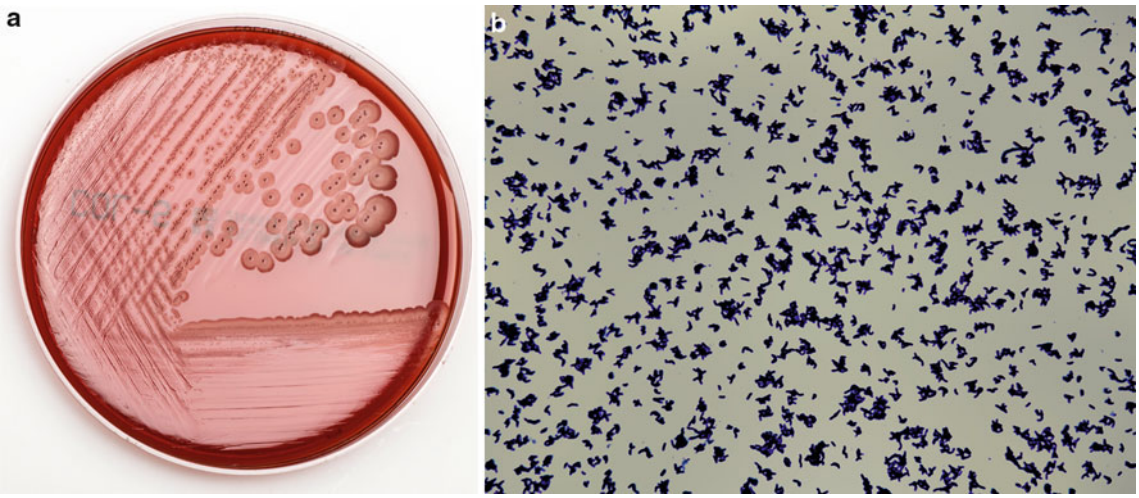

Fig. 4.7
(a) Culture of *Actinobaculum suis* DSM 20639^T on Columbia blood agr with 5% sheep blood The colonies are small, 2-3 mm in diameter, translucent, round and granular. After 7 days incubation, colonies flatten and develop a characteristic dry, gray opaque surface with crenated edges attaining a size of 4-5 mm in diameter. (b) Gram-stained smear from culture of *Actinobaculum suis* DSM20639^T on Columbia agar with 5% sheep blood showing coryneform morphology

A. suis has been reported to produce acetate, ethanol, and formate as main products from maltose fermentation (Wegienek and Reddy 1982) succinate in addition to acetate has been reported to be produced by *A. schaalii* (Lawson et al. 1997), whereas *A. urinale* produces lactate as a major product of glucose catabolism, together with minor amounts of acetate (Hall et al. 2003a). No information is available regarding the fermentation end product profile of *A. massiliense*.

Comprehensive study on the biochemical characteristics of *Actinobaculum* showed that, at present time, three tests yield uniform results for all described species. These include negative reactions for catalase, oxidase, and nitrate reductase. Currently, a positive hippurate hydrolysis test would be useful as a key characteristic of all *Actinobaculum* species. At this time, strains that are both urease and β-glucuronidase positive would be restricted to *A. suis* and *A. urinale*. The general information about the biochemical characteristics of the type strains of *Actinobaculum* species is given in ❯ *Table 4.11*.

Chemotaxonomic Properties

Extensive chemotaxonomic study (Yassin, unpublished) of members of the genus *Actinobaculum* revealed the presence of glucose, rhamnose, and 6-deoxytalose as diagnostic sugars in whole-cell hydrolysates of all species, with the exception of *A. suis* which is characterized by the absence of 6-deoxytalose. The primary structure of the peptidoglycan of the genus *Actinobaculum* belongs to the A5α type. Interestingly, two variations have been identified. Variation (L-Lys-L-Ala-Lys-D-Glu) has been reported in *A. suis* (Ludwig et al. 1992) and variation (L-Lys-L-Lys-D-Glu) has been reported in *A.schaalii* (Lawson et al. 1997). Consistent with the latter variation is the peptidoglycan structure of *A. urinale* (Yassin, unpublished). The muramic acid residue of the glycan moiety of the cell wall peptidoglycan, as far as examined for members of the genus *Actinobaculum*, is *N*-acetylated. The fatty acid profile comprises straight-chain saturated and monounsaturated fatty acids. Respiratory quinones were not detected. The polar lipids pattern contains diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol dimannoside, and choline-containing phosphoglycolipid. The DNA G+C contents range between 55 and 61.1 mol%.

Taxonomic Comment

Originally, the classification of *A. suis* and *A. schaalii* in a separate genus, *Actinobaculum*, is based exclusively on phylogenetic analysis of the 16S rRNA gene sequences (Lawson et al. 1997). Subsequent assignment of new species to the genus was based on its phylogenetic relationships to *A. suis* and *A. schaalii* and differences in biochemical properties. However, the phylogeny-based classification and the placement of new species in the genus have not been justified yet according to chemical features. Evaluation of the phylogenetic and chemotaxonomic data of the genus *Actinobaculum* does not support the continuous inclusion of *A. suis* in the genus. Comparative analysis of the 16S RNA gene sequences shows that *A. suis* appeared to be moderately related to other *Actinobaculum* species (92.7–95.2 % similarity). Moreover, examination of the aligned 16S rRNA gene sequences demonstrated the presence of a set of signature nucleotides that are uniquely and commonly shared by all *Actinobaculum* species, except *A. suis* (❯ *Table 4.10*).

Furtheremore, notable chemotaxonomic differences (Yassin, unpublished) are found between *A. suis* and other members of

Data for *A. suis* from A. F. Yassin; data for *A. schaalii* are from Lawson et al. (1997); data for *A. massiliense* are from Greub and Raoult (2002); data for *A. urinale* are from Hall et al. (2003a)

Symbols + positive/present, – negative/absent, *w* weakly positive, *ND* no data available, *d* differences between strains within one species

the genus. Though *Actinobaculum* species exhibit peptidoglycan type A5α, two distinct variations have been identified. Variation (L-Lys-L-Ala-Lys-D-Glu) has been found in *A. suis*, while *A. schaalii* and *A. urinale* exhibit variation (L-Lys-L-Lys-D-Glu). Besides, analysis of whole-cell hydrolysates revealed that members of the genus are characterized by the presence of glucose, rhamnose, and 6-deoxytalose as diagnostic cell wall sugars. In contrast, 6-deoxytalose is not found in whole-cell hydrolysate of *A. suis*.

Of particular interest is the observation that members of the genus *Actinobaculum* are adapted to different ecological niches. *A. suis* is a well-recognized cause of urinary tract infections and abortion in swine, whereas *A. massiliense*, *A. schaalii*, and *A. urinale* emerged as human pathogens, causing urinary tract infections and systemic diseases. Hence, *A. suis* and all other *Actinobaculum* species represent two different ecotypes. Such adaptations provide a unique opportunity for applying this information for the genus taxonomy. Thus, the genus *Actinobaculum* represents an ecologically diverse clade in the *Actinomycetaceae*.

In this context, the phylogenetic, chemotaxonomic, and ecological evidences argue strongly that *A. massiliense*, *A. schaalii*, and *A. urinale* should at present be excluded from the genus *Actinobaculum* and be elevated to genus rank. However, the decision about whether to retain these species in the genus *Actinobaculum* or to place them in a separate genus depends upon the branching points of other species that will be described and added to this lineage in the future. Such actions to divide *Actinobaculum*, while desirable from the point of view of presenting a more defensible phylogeny, will have considerable epidemiologic repercussions.

Identification and Descriptive Characteristics of *Actinobaculum* Species

The phenotypic characteristics useful for identification of the recognized *Actinobaculum* are given in Table 4.11.

A. massiliense Greub and Raoult 2002, 2025^{VP} mas. si. li. en'se. L. neut. adj. *massiliense*, pertaining to *Massilia*, Latin name of Marseille, where the organism was isolated.

Cells are Gram-positive, non-acid-fast, and straight to slightly curved rods, some of which exhibit branching. Cells are nonmotile. Facultative anaerobe. Catalase- and oxidase-negative. Colonies on sheep blood agar are nonhemolytic, 1 mm in diameter after 72 h of incubation at 37 °C in a 5 % CO_2 atmosphere. Esculin and gelatin are not hydrolyzed. Hippurate hydrolysis is positive. Nitrate is not reduced to nitrite. Acid is produced from glucose, maltose, ribose, xylose, and trehalose, but not from mannose, mannitol, sorbitol, or amidon. Acid production from raffinose is weak. Pyrazinamidase and α-glucosidase activities are positive. Pyrrolidonyl arylamidase, alkaline phosphatase, α-galactosidase, β-glucuronidase, β-galactosidase, *N*-acetyl-β-glucosaminidase, urease, leucine arylamidase, or arginine dihydrolase activity are negative.

The mol% G+C of the DNA has not been reported.

Type strain: CCUG 48898 = CIP 107404 = JCM 15300, isolated from the urine of an 81-year-old woman with cystitis.

Actinobaculum schaalii Lawson, Falsen, Åkervall, Vandamme, and Collins, 1997, 902^{VP} schaalii (N. L. gen. n. schaalii, of Schaal, to honor Klaus P. Schaal, contemporary German microbiologist, for his contributions to actinomycete microbiology).

Cells are straight to slightly curved rods, some of which exhibit branching, nonmotile, non-spore forming, Gram-positive and non-acid-fast. On Columbia blood agar colonies are nonhemolytic, circular, smooth, creamy and with entire edges. A weak CAMP reaction may observed. Facultative anaerobe and catalase-negative. Acetate and succinate are the major end products of glucose fermentation. Acid is produced from glucose, maltose, ribose, and D-xylose. Some strains produce acid from L-arabinose, mannose, starch, sucrose, and trehalose. Acid is not produced from D-arabitol, *N*-acetyl-β-glucosamine, cyclodextrin, glycogen, lactose, mannitol, melezitose, melibiose, methyl-β-D-glucopyranoside, pullulan, raffinose, sorbitol, and D-tagatose. Hippurate is hydrolyzed. Esculin, gelatin, and urea are not hydrolyzed. α-Glucosidase, alanine–phenylalanine–proline arylamidase, and pyroglutamic acid arylamidase are produced. Alkaline phosphatase, arginine dihydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, glycyl-tryptophan arylamidase, and β-mannosidase activities are not detected. Pyrazinamidase and pyrrolidonyl arylamidase activities are shown by some strains. Nitrate is not reduced to nitrite. Acetoin is not produced. The cell wall murein type is type A5a (L-Lys-Lys-D-Glu). The major cellular fatty acids are hexadecanoic, octadecanoic, and *cis*-delta-9-octadecenoic acids.

The mol% G+C of the DNA is 57 mol% G+C.

Type strain, CCUG 27420 = CIP 105739 = DSM 15541 = LMG 1293, isolated from the blood of a 64-year-old male with chronic pyelonephritis.

Actinobaculum suis (Wegienek and Reddy) comb. nov. *Actinobaculum suis* (Eubacterium suis Wegienek and Reddy 1982; "*Corynebacterium suis*" Soltys and Spratling 1957) su'is. L. gen. n. suis, of a hog.

Slender, nonmotile, pleomorphic rods that are 1–3 by 0.5 μm and are arranged singly, in pairs (cells are often at an angle to each other or in palisades), or in small clusters. Cells are Gram-positive, but they are easily decolorized, as culture ages. Not acid fast and nonsporulating; does not survive heating at 80 °C for 10 min. Capsules are not observed by capsule staining; however, a fringelike outer coat external to the cell wall is seen in thin-section electron micrographs. Colonies on blood agar are nonhaemolytic white, circular, granular and have entire to slightly irregular margins after 48 h anaerobic incubation at 37 °C, reaching 0.5–0.3 mm in diameter. Colonies often have slightly raised centers, which gives them a fried-egg appearance. Colonies become flatter reaching 3–5 mm in diamter after 7 days anaerobic incubation at 37 °C. Peptone–yeast extract–starch broth supports excellent growth. The optimal pH is 7–8; no growth occurs at pH 5.0 or less. The optimal temperature is 37 °C; the temperature range for growth is 30–43 °C; and no

growth occurs at 22–23 °C. Cells are anaerobic. Metabolism is strictly fermentative. Maltose, starch, and glycogen are fermented. Acetate, ethanol, and formate are the main end products from maltose fermentation. Adonitol, amygdalin, arabinose, cellobiose, dulcitol, erythritol, esculin, fructose, galactose, glucose, glycerol, inositol, inulin, lactose, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, lactate, pyruvate, and threonine are not fermented. Urease activity is positive. Does not produce catalase, indole, hydrogen sulfide, lipase, or lecithinase; ammonia is not produced from peptone. Hippurate is hydrolyzed. Esculin and gelatin are not hydrolyzed. Meat and milk are not digested. Nitrate is not reduced. Activities of *N*-acetyl-β-glucosaminidase, acid phosphatase, alkaline phosphatase, esterase lipase (C8), α-glucosidase, β-glucuronidase, leucine arylamidase, naphthol-AS-BI-phosphohydrolase, α-mannosidase, pyrrolidonyl arylamidase, and valine arylamidase (weak) are detected. Activities of arginine dihydrolase, esterase (4), α-galactosidase, β-galactosidase, β-glucosidase, pyrazinamidase, lipase (C14), cystine arylamidase, trypsin, α-chymotrypsin, and α-fucosidase are not detected. Major amounts of cytochrome b and minor amounts of cytochrome c are synthesized. Acetoin is not produced. The cell wall sugars are glucose and rhamnose. The cell wall murein type is type A5α (L-Lys-L-Ala-Lys-D-Glu). Exotoxin is not produced.

The G+C content of the DNA is 55 mol%.

Type strain: strain Soltys 50052 = ATCC 331440 = CCUG 19206 = CIP 105361 = DSM 20639 = LMG 18291, isolated from cases of cystitis and pyelonephritis and cases of metritis in pregnant sows.

Actinobaculum urinale Hall, Collins, Hutson, Falsen, Inganäs and Duerden, 2003, 681^{VP}.

u.ri.na'le. N.L. neut. adj. *urinale* pertaining to urine.

Cells are straight to slightly curved Gram-positive rods. Branching is not observed. Cells are non-acid-fast and non-spore-forming. After 48-h anaerobic incubation on Fastidious Anaerobe Agar with 5 % horse blood, colonies are <1 mm in diameter, convex, smooth, entire edged, gray or white, and weakly *β*-hemolytic. Facultative anaerobic and catalase-negative. Lactic acid is the major end product of glucose metabolism, together with minor amounts of acetic acid. Acid is produced from glucose and ribose; acid production from maltose and sucrose is variable and dependent on the test system used. Acid is not formed from D-arabitol, L-arabinose, cyclodextrin, glycogen, lactose, mannitol, mannose, melibiose, melezitose, methyl-*β*-D-glucopyranoside, pullulan, raffinose, sorbitol, tagatose, trehalose, or D-xylose. Urease is strongly positive. Hippurate is hydrolyzed but gelatin and esculin are not. Arginine arylamidase, *β*-glucuronidase, and proline arylamidase are produced. Alanine–phenylalanine–proline arylamidase, arginine dihydrolase, acid phosphatase, alkaline phosphatase, alanine arylamidase, arginine arylamidase, α-arabinosidase, chymotrypsin, trypsin, cysteine arylamidase, esterase C-4, ester lipase C-8, α-fucosidase, α-galactosidase, *β*-galactosidase, *β*-galactosidase-6-phosphate, α-glucosidase, *β*-glucosidase, glycyl-tryptophan arylamidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, glycine arylamidase, histidine arylamidase, leucine arylamidase, leucyl glycine arylamidase, lipase C-14, α-mannosidase, *β*-mannosidase, *N*-acetyl-*β*-glucosaminidase, phosphoamidase, phenylalanine arylamidase, pyroglutamic acid arylamidase, pyrazinamidase, serine arylamidase, tyrosine arylamidase, and valine arylamidase are not detected. Acetoin is not produced. Indole production is negative. Nitrate is not reduced to nitrite. The cellular fatty acids are of the straight-chain saturated and monounsaturated types, with $C_{14:0}$, $C_{16:0}$, $C_{16:1}$, $C_{18:0}$, and $C_{18:1}\omega 9c$ predominating.

The mol% G+C of the DNA has not been reported.

Type strain: CCUG 46093 = CIP 107424 = DSM 15805, isolated from human urine. Habitat is not known.

Genus V. *Varibaculum* Hall, Collins, Lawson, Hutson, Falsen, Inganas, and Duerden, 2003, 627^{VP}.

va.ri.ba'cu.lum. L. adj. *varus*, bent; L. neut. n. *baculum*, small rod; N.L. neut. n. *varibaculum*, small bent rod.

Taxonomy, Historical and Current

The genus *Varibaculum* was introduced by Hall et al. (2003c) to accommodate anaerobic, catalase-negative, Gram-positive diphtheroidal bacteria isolated from human sources. The generic assignment was based exclusively on the biochemical testing, electrophoretic analysis of whole-cell proteins, and phylogenetic analysis of 16S rRNA gene sequences. Currently, the genus comprises only one validly published species: *Varibaculum cambriense*.

Molecular Analyses

Phylogenetic analysis based on 16S rRNA genes conclusively demonstrated that *Varibaculum cambriense* occupies a relatively long and distinct line of descent within the family *Actinomycetaceae* (Hall et al. 2003c). Sequence comparison reveals that *Varibaculum* is equidistantly related to *Actinomyces neuii* (89.9–90.9 % sequence similarity) and *Mobiluncus* species (88.1–88.5 % sequence similarity). The derived phylogenetic tree (Fig. 4.1b) indicates that *Varibaculum cambriense* and *Actinomyces neuii* are sister taxa, a relationship strongly supported by all tree reconstruction methods and 96 % bootstrap. Interestingly, the deduced branching in the phylogenetic tree (Fig. 4.1b) is consistent with the presence of a set of signature nucleotides commonly shared by *Varibaculum cambriense* and *Actinomyces neuii*, but not found in any species of the family *Actinomycetaceae*, and thus provides evidence that they probably descended from a common ancestor. This includes 1239 (U), 1244–1293 (G-C), 1245–1292 (U-G), 1246–1291 (C-G), and 1298 (U). In fact, the placement of *Varibaculum cambriense* and *Actinomyces neuii* as sister group of *Mobiluncus* remains difficult to demonstrate as the 16S rRNA gene-based phylogenetic trees did not resolve the relationships between them with confidence.

Phenotypic Analyses

Morphology

Cells of *Varibaculum cambriense* are Gram-positive, non-acid-fast, nonmotile, non-spore-forming, straight, or curved diphtheroid-shaped rods. The organism grows on blood-containing agar media after anaerobic incubation for 2–3 days. It may grow well or poorly in air containing 5 % CO_2 and either poorly or not at all in ambient air. After anaerobic incubation for 48–72 h on Columbia agar or Fastidious Anaerobe Agar (LabM, Bury, United Kingdom) with horse blood (5 %), colonies are pinpoint, convex, glistening, translucent white or gray, with entire edges, and nonhemolytic.

Varibaculum cambriense is regarded as an anaerobic organism. Like *Actinomyces neuii*, it ferments glucose to a characteristic pattern of metabolic end products consisting of succinic and lactic acid. In contrast to *Actinomyces neuii*, *V. cambriense* is characterized by a negative catalase and synergistic hemolysis (CAMP) test and the inability to produce acid from mannitol.

Chemotaxonomic Properties

The description of the genus *Varibaculum* was chiefly based on phenotypic characteristics derived from biochemical testing and electrophoretic analysis of whole-cell proteins as well as on phylogenetic analysis of 16S rRNA gene sequences. Apart from these phenotypic characteristics and phylogenetic evidence, chemotaxonomic data that provide additional criteria for the delineation of the genus are not available. Comparative chemotaxonomic study (Yassin unpublished) of *Varibaculum cambriense* and *Actinomyces neuii* corroborated the phylogenetic relationships of the two species. Both species have the same chemotaxonomic pattern. This pattern consists of galactose as diagnostic cell wall sugars. The muramic acid residue of the peptidoglycan is *N*-acetylated. The respiratory quinones are [(MK-8(H4)] and nine [MK-9(H4)], with [MK-9(H4)] as the major components. Polar lipids consists of phosphatidylcholine as the characteristic phospholipid, i.e., phospholipid type III sensu Lechevalier et al. (1977), in addition to diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), phosphatidylinositol (PI), and phosphatidylinositol mannosides (PIM). The fatty acid profiles consist of straight-chain saturated, unsaturated, and branched-chain iso- and anteiso-fatty acids. In addition, the G+C contents of the DNA range between 51 and 55 mol%.

Taxonomic Comment

The striking resemblance of the chemotaxonomic profiles of *Varibaculum cambriense* and *Actinomyces neuii* is in complete accordance with the outcome of molecular phylogeny. Thus, it seems likely that *Actinomyces neuii* could be assigned to the genus *Varibaculum* with reasonable confidence. However, in terms of 16S rRNA gene sequence divergence (approximately 10 %), *Varibaculum cambriense* and *Actinomyces neuii* are distantly related and as such, the taxonomic rank of *Actinomyces neuii* is far more problematic. Due to the fact that most generic groupings exhibit a sequence divergence of <6 %, it is obviously evident that *Actinomyces neuii* represents the nucleus of previously unrecognized genus which is closely related to *Varibaculum*.

Identification and Descriptive Characteristics of *Varibaculum* Species

The phenotypic characteristics useful for identification of the genus are previously described by Hall et al. (2003c). Additional descriptive characteristics of the genus are given below (A. F. Yassin unpublished).

Varibaculum

va.ri.ba'cu.lum. L. adj. *varus*, bent; L. neut. n. *baculum*, small rod; N.L. neut. n. *varibaculum*, small bent rod.

Cells consist of short, straight or curved diphtheroid rods which stain Gram-positive and are non-acid fast and nonmotile, nonhemolytic, anaerobic, and catalase-negative. The cell wall contains acetylated muramic acid residues and galactose as diagnostic sugars. The major quinone is menaquinone MK-9(H4). The polar lipids are phosphatidylcholine, phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol and phosphatidylinositol mannosides. The fatty acid profile comprises straight-chain saturated and unsaturated and branched-chain iso- and anteiso-fatty acids. Lactic and succinic acids are the major end products of glucose metabolism. The G+C content of DNA is 51.7 mol%. The type species is *Varibaculum cambriensis*.

Varibaculum cambriensis Hall, Collins, Lawson, Hutson, Falsen, Inganas, and Duerden, 2003, 627^{VP}

cam. bri. en'sis. L. adj. *cambriensis*, pertaining to cambria, the Latin name of Wales.

Cells consists of short, straight, or curved diphtheroid rods which stain Gram-positive and are non-acid-fast and nonmotile. Colonies after 48 h anaerobic incubation on Fastidious Anaerobic Agar with 5 % horse blood are pinpoint, convex, entire edged, glistening, translucent white, or gray. It is nonhemolytic, anaerobic, and catalase-negative. The end products of glucose metabolism are lactic and succinic acids, together with small amounts of acetic acid. Using conventional biochemical testing, acid is formed from D-glucose, sucrose, and D-ribose; acid may or may not be formed from fructose, mannitol, and xylose. Acid is not produced from amygdalin, L-arabinose, cellobiose, lactose,

mannose, D-raffinose, salicin, or trehalose. It is lecithinase and lipase-negative and indole-negative. Esculin, gelatin, and starch are not hydrolyzed. Using API test systems, acid is produced from D-glucose, and most strains ferment sucrose. Some strains produce acid from maltose, D-ribose, trehalose, and D-xylose. Acid is not produced from D-arabitol, L-arabinose, cyclodextrin, glycogen, mannitol, melibiose, melezitose, methyl-β-D-glucopyranoside, lactose, pullulan, D-raffinose, sorbitol, or tagatose. Hippurate is hydrolyzed by most strains, but esculin and gelatin are not hydrolyzed. Activity for α-glucosidase and leucine arylamidase are detected, and some strains display activity for alanine–phenylalanine–proline arylamidase and β-galactosidase (weak reaction). Activity for acid phosphatase, esterase C-4, ester lipase C8, and phosphoamidase is either weakly positive or negative. No activity is detected for arginine dihydrolase, alkaline phosphatase, chymotrypsin, α-fucosidase, α-galactosidase, β-glucosidase, β-glucuronidase, glycyl-tryptophan arylamidase, lipase C14, α-mannosidase, β-mannosidase, *N*-acetyl-β-glucosaminidase, pyrrolidonyl arylamidase, pyroglutamic acid arylamidase, pyrazinamidase, trypsin, valine arylamidase, or urease. Most strains reduce nitrate to nitrite. Acetoin is not produced.

The mol% G+C of the DNA is 51.7.

Type strain, CCUG 44998 = CIP 107344, isolated from human sources, including breast abscess, brain abscess, cheek abscess, submandibular abscess, postauricular abscess, ischiorectal abscess, and intrauterine contraceptive devices.

Genus VI. *Mobiluncus* Spiegel and Roberts 1984, 180^{VP}, emend. Hoyles, Collins, Falsen, Nikolaitchouk, and McCartney, 2004.

Mo.bi.lun'cus. L. adj. *mobilis* capable of movement, active; L. masc. n. *uncus* hook; N. L. masc. n. *Mobiluncus* a motile curved rod.

Taxonomy, Historical and Current

Krönig (1895) reported on the observation of an anaerobic short-curved bacillus in vaginal fluids. Strains were growing in symbiosis with an anaerobic *Streptococcus*, but only survived one generation. Later, Curtis (1913) was the first to isolate an anaerobic curved bacillus in pure culture from the vagina and cervix of a patient with puerperal infection. The strains grown equally well on blood agar made from human, goat, or sheep blood and colonies appeared as a "dustlike coat," minute, translucent, and nonhemolytic. Curtis assumed that the isolated organism is presumably identical with that early observed by Krönig. Due to the curved cellular morphology of the isolate, Curtis classed it with the vibrios. Prévot (1940) in his manual on classification and identification of anaerobic bacteria used the designation "*Vibrio mulieris*" for the vibrio of Curtis.

In the years following the work of Curtis, no further description of curved rod-shaped bacteria from the female genital tract was published, until Moore (1954) isolated and characterized a number of vibrio-like strains seen in wet preparations of vaginal material from women attending a fertility clinic. These strains required a high atmospheric CO_2 tension as well as anaerobiosis for their primary isolation. Similar or identical serum-requiring strains of "vibrions succinoproducteurs" were characterized by Durieux and Dublanchet (1980). They separated these organisms into two groups on the basis of cellular morphology, fermentation of glucose, and reduction of nitrate.

The taxonomic position of these anaerobic curved rods isolated from the human vagina remained uncertain until Spiegel and Roberts (1984) as well as Hammann et al. (1984) proposed to assign them to two species in the genus *Mobiluncus* and the genus *Falcivibrio*, respectively. The two species were named by Spiegel and Roberts (1984) as *M. mulieris* and *M. curtisii*, the latter being further divided into *M. curtisii* subsp. *curtisii* and *M. curtisii* subsp. *holmesii*, whereas Hammann et al. (1984) designated them as *Falcivibrio grandis* and *Falcivibrio vaginalis*. Although the genus designation *Falcivibrio* appeared first in the literature, it was not validated first, so that *Mobiluncus* has priority. In a subsequent polyphasic taxonomic study of members of the genera *Falcivibrio* and *Mobiluncus*, Hoyles et al. (2004) formally proposed to transfer *F. grandis* and *F. vaginalis* to the genus *Mobiluncus* as *M. mulieris* and *M. curtisii*, respectively. *Mobiluncus* species are etiologically involved in a syndrome called bacterial vaginosis (BV), nonspecific vaginitis, "*Haemophilus vaginalis* vaginitis" (Gardner and Dukes 1955), anaerobic vaginosis (Blackwell et al. 1983), or in German "Aminkolpitis".

Taxonomy

Although the Gram reactions of *Mobiluncus* strains are typically Gram-negative or variable, Spiegel and Roberts (1984) noted that the two species of *Mobiluncus*, *M. curtisii* and *M. mulieris*, exhibit a multilayered cell wall, characteristic for Gram-positive bacteria, but lack an outer membrane. The apparent absence of an outer membrane in the cell walls of the Gram-negative curved rod-shaped organisms led these authors to conclude that they more closely resemble Gram-positive organisms than Gram-negative ones. This conclusion is supported by reports that these organisms are resistant to some antimicrobial agents, e.g., colistin and nalidixic acid, which traditionally inhibit Gram-negative microorganisms, and are susceptible to antimicrobial agents, e.g., penicillin and vancomycin, which inhibit Gram-positive bacteria (Durieux and Dublanchet 1980; Sprott et al. 1983). In addition, hydroxy fatty acids, which are commonly found in Gram-negative cell walls, are absent from these organisms (Skarin et al. 1982). Despite the presence of distinct features of Gram-positive bacteria, Spiegel and Roberts (1984) placed *Mobiluncus* in the family *Bacteroidaceae*, the reason being the obvious phenotypic differences to the *Actinomycetaceae* and *Propionibacteriaceae*. However, a more detailed study on the cell walls of *Mobiluncus* confirmed that their composition was not Gram-negative (Carlone et al. 1986). Furthermore, partial reverse transcriptase sequencing of 16S rRNA gene from *Mobiluncus curtisii* and

Mobiluncus mulieris clearly indicated that the genus *Mobiluncus* is not a member of the *Bacteroidaceae* but belongs to the order *Actinomycetales* (Lassnig et al. 1989). The highest degree of relationship was found with the genus *Actinomyces* which is supported by the presence of common physiological properties.

The subdivision of *M. curtisii* into two subspecies, *M. curtisii* subsp. *curtisii* and *M. curtisii* subsp. *holmesii*, was mainly based on differences in migration patterns in soft agar and the ability to reduce nitrate (Spiegel and Roberts 1984). The analysis of surface antigens of *Mobiluncus* using murine monoclonal antibodies (MAbs) in an enzyme-linked immunosorbent assay and indirect immunofluorescence revealed four MAbs and thus surface components that appeared to be subspecies-specific for *M. curtisii* subsp. *curtisii* (Fohn et al. 1988). One MAb reacted with an epitope shared by *M. curtisii* subsp. *holmesii* and *M. mulieris* but not by *M. curtisii* subsp. *curtisii*. However, neither DNA–DNA homology studies (Spiegel and Roberts 1984) nor comparative analysis of partial 16S rRNA gene sequences supported the division of *M. curtisii* in two subspecies (Tiveljung et al. 1996; Hoyles et al. 2004).

Molecular Analyses

The 16S rRNA gene sequence of *Mobiluncus* showed moderate 16S rRNA sequence similarity with members of the family *Actinomycetaceae* (86.2–91.3 %). The highest 16S rRNA similarity values were observed with *Actinomyces hongkongensis* (90.3–91.3 %), members of the genus *Arcanobacterium* (89.5–91.1 %), members of the genus *Trueperella* (89.4–90.7 %), and the two subspecies of *Actinomyces neuii* (89.4–90 %). A significantly lower 16S rRNA similarity (88.1–88.4 %) was observed with *Varibaculum cambriense*. The 16S rRNA gene signatures characteristics for *Mobiluncus* consisted of nucleotides at 114–313 (C-G), 154–167 (G-U), 166 (C), 408 (A), 411 (G), 441 (U), 560 (U), 591–648 (C-G), 613–627 (A-U), 846 (U), 118–1155 (C-G), 1180 (G), and 1245 (A).

The association of the genus *Mobiluncus* with *Actinomyces* and its related taxa has long been recognized (Lassnig et al. 1989). Phylogenetic analyses based on 16S rRNA gene sequences indicate a monophyletic clade within the *Actinomycetaceae*. Phylogenetic tree reconstructed using the maximum-likelihood method resulted in the placement of the genus *Mobiluncus* as sister to the clade comprising all the other genera of *Actinomycetaceae* (Fig. 4.1a). By contrast, the tree reconstructed using the neighbor-joining method shows that the genus *Mobiluncus* cluster as sister to *A. coleocanis–A. europaeus* lineage and to *A. neuii–Varibaculum cambriense* lineage. In addition, the consensus NJ tree produced by bootstrap analysis of 500 resamplings of the 16S rRNA gene sequences produced a tree with several topological changes and thus did not support this association, although strong bootstrap support (98 %) was shown for the association of *Varibaculum cambriense* and to the two subspecies of *A. neuii* as well as the association of *A. coleocanis* and *A. europaeus* (100 % bootstrap support). Moreover, the clustering of *Mobiluncus* with *Varibaculum cambriense* and the two subspecies of *A. neuii* was broken in the maximum-parsimony tree, albeit the association of *Varibaculum cambriense* and the two subspecies of *A. neuii* as well as the association of *A. coleocanis* and *A. europaeus* remain consistently the same for all tree methods. Thus, the phylogenetic position of *Mobiluncus* within the *Actinomycetaceae* appears to remain unsettled, as shown by the different topologies.

Phenotypic Analyses

Morphology

Mobiluncus cells are typically Gram-variable or Gram-negative curved rods with tapered ends that occur singly or in pairs. The cells are motile by means of multiple subterminal flagella (Spiegel and Roberts 1984; Spiegel 1992). *Mobiluncus curtisii* has one to six flagella per cell with a common origin, while *M. mulieris* possesses one to eight flagella with multiple origins (Hammann et al. 1984; Spiegel 1992). *Mobiluncus curtisii* subsp. *curtisii* was reported to migrate through soft (0.25 %) agar, whereas *M. curtisii* subsp. *holmesii* was not; however, migration through soft agar is also variable in *M. mulieris* (Spiegel and Roberts 1984), while this feature was recently shown not to exactly correspond to *M. curtisii* subsp. *curtisii* (Hoyles et al. 2003). Electron micrographs revealed that *Mobiluncus* species possess a multilayered Gram-positive cell wall lacking an outer membrane. The thinness of the walls was considered to be the reason for the tendency of the curved rod-shaped organisms to stain Gram-negative (Spiegel and Roberts 1984). Pili (fimbriae) were not observed (Hammann et al. 1984). Cells of the two *Mobiluncus* species differ considerably in size: While *M. curtisii* cells are <0.5 µm wide and on average 1.7 µm long rods (Fig. 4.8a), *M. mulieris* cells are significantly longer, measuring <0.5 µm in width but 2.9 µm in mean length (Fig. 4.8b). Colonies on Chocolate agar are cream to light brown in color, convex, smooth, and entire after 5-days anaerobic incubation at 37 °C, reaching 2–4 mm in diameter (Hoyles et al. 2004).

Chemotaxonomic Properties

There are no previous reports on the chemotaxonomy of the genus *Mobiluncus* which can be utilized in the clarification of infrageneric taxonomy of the genus. Sporadic reports in the literature have dealt with fatty acids and whole-cell wall carbohydrates. Carlone et al. (1986) reported on the presence of peptidoglycan based on muramic acid and glucosamine. They also demonstrated that analysis of whole-cell carbohydrates revealed the presence of similar amounts of rhamnose and galactose. Besides, they also reported on the absence of lipopolysaccharide (LPS), 2-keto-3-deoxyoctulosonic acid (KDO), and heptose, characteristic components of Gram-negative bacteria.

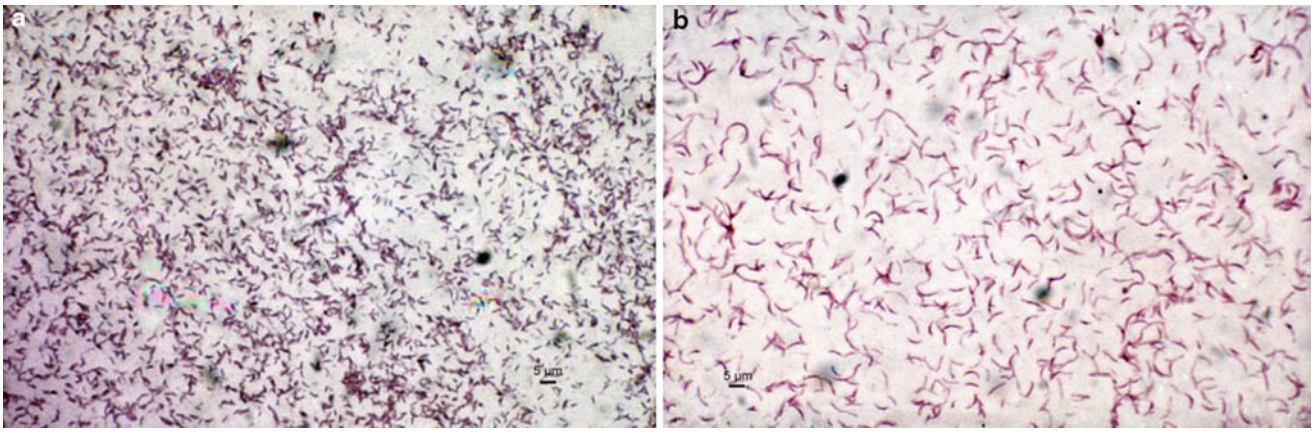

Fig. 4.8
(a) Gram-stained smear from 14-day-old culture of *Mobiluncus curtisii* subsp. *holmesii* on Columbia sheep blood agar incubated under anaerobic condition at 36 °C. Cells measure <0.5 × 1.7 µm. (b) Gram-stained smear from 14-day-old culture of *Mobiluncus mulieris* on Columbia sheep blood agar incubated under anaerobic condition at 36 °C. Cells measure <0.5 × 2.9 µm

Table 4.12
Differential morphological, biochemical and antimicrobial characteristics of *Mobiluncus* species

Characteristic	*Mobiluncus curtisii*		*Mobiluncus mulieris*
	subsp. *curtisii*	subsp. *holmesii*	
Cell length (µm)	1–2	1–2	3–4
Gram reaction	Gram variable	Gram variable	Gram-negative
Growth stimulation by arginine	+	+	–
Reduction of nitrate	–	+	+
Hippurate hydrolysis	+	+	–
Acid production from:			
α-Methyl-D-glucoside	–	–	+
Trehalose	–	–	+
Enzyme activity:			
Arginine dihydrolase	+	+	–
β-galactosidase	+	+	–
Susceptibility to metronidazole	+	+	–

They also assumed that lipoteichoic acids, a cell wall component of Gram-positive bacteria, may be responsible for the intermediate levels of *Limulus* amebocyte lysate (LAL) reactivity (Kessler 1983). The cellular fatty acids profile contained tetradecanoic (14:0), hexadecenoic (16:1ω7c), hexadecanoic (16:0), heptadecanoic (17:0), octadecadienoic (18:2ω6,9c), octadecenoic (18:1ω9c), and octadecanoic (18:0) acids, with 16:0, 18:2, and 18:1 representing more than 50 % of the total fatty acids detected (Carlone et al. 1986). Hydroxylated fatty acids which are commonly found in Gram-negative cell walls are absent from *Mobiluncus* (Skarin et al. 1982; Spiegel and Roberts 1984; Carlone et al. 1986). The G+C content of the DNA of the *Mobiluncus* type strains is 49–52 mol% (Spiegel and Roberts 1984), although values as high as 53.5 ± 0.6 for *M. mulieris* and 55.2 ± 0.6 for *M. curtisii* have been reported (Hammann et al. 1984).

Besides published data, extensive chemotaxonomic investigation of *Mobiluncus* species (Yassin unpublished) indicated that the whole-cell hydrolysates of *Mobiluncus curtisii* subsp. *holmesii*, "*Falcivibrio grandis*," and "*Falcivibrio vaginalis*" were characterized by the presence of galactose and rhamnose as diagnostic sugars (Table 4.3). Analysis of the respiratory quinones of *Mobiluncus curtisii* subsp. *holmesii* revealed the presence of menaquinones with eight (MK-8) and nine (MK-9) isoprene units with MK-9 as the major components (Table 4.3). The polar lipid pattern was phospholipid type V sensu Lechevalier et al. (1977), which is characterized by the presence of *N*-acetylglucosamine in addition to diphosphatidylglycerol and phosphatidylglycerol. The fatty acid profile contained straight-chain saturated and unsaturated fatty acids as well as traces of branched-chain fatty acids of the iso- and anteiso-types (Table 4.3).

Analysis of whole-cell proteins using SDS-PAGE indicated that *Mobiluncus* strains have distinct protein profiles which distinguishes the two species, *M. curtisii* and *M. mulieris* (Baron et al. 1984; Taylor and Owen 1984; Vetere et al. 1987; Schwebke et al. 1990; Drouet et al. 1991; Hoyles et al. 2004). In addition, PAGE-protein analysis allowed defining intraspecies groups association (Drouet et al. 1991; Hoyles et al. 2004). However, this association did not correlate with the biochemical activity of the strains (Drouet et al. 1991). Although, SDS-PAGE analysis of whole-cell proteins is a useful tool for differentiating between the two species of *Mobiluncus* and in intraspecies typing, it is of limited use in subspecies delineation.

Biochemical Characteristics

The genus *Mobiluncus* is divided into two species, *M. curtisii* and *M. mulieris*, on the basis of cell morphology, reaction in Gram's stain, susceptibility to metronidazole, hydrolysis of arginine and hippurate, and β-galactosidase reactions (*Table 4.12*; Spiegel and Roberts 1984; Nord 1984). *Mobiluncus* species are indole, catalase, oxidase, and H_2S negative. *Mobiluncus* strains require extended anaerobic incubation for growth. No growth occurred on media such as CBA incubated in aerobic conditions, or in a candle jar (Vetere et al. 1987). The optimum temperature for multiplication ranges between 33 °C and 37 °C (Spiegel and Roberts 1984; Vetere et al. 1987) and no growth occurs at 20 °C or 42 °C (Holst et al. 1982; Vetere et al. 1987). Scanty growth occurred at pH 4–5 and more enhanced growth occurred at higher pH values above 5, pH >5–8. Furthermore, when grown in peptone–yeast extract–glucose medium (PYG), the metabolic end products of glucose fermentation include succinic, lactic, and acetic acids (Spiegel and Roberts 1984; Vetere et al. 1987).

Phenotypic characterization assays commonly utilized to characterize *Mobiluncus* include carbohydrate fermentations assay. However, the results of individual tests reported in the literature may vary widely, as the performance of such tests are method dependent (Vetere et al. 1987; Spiegel 1992; Hoyles et al. 2004). Therefore, care must be taken when interpreting the results of carbohydrate fermentations assay.

5 The Genus *Arthrobacter*

Hans-Jürgen Busse[1] · *Monika Wieser*[2]
[1]Institute of Bacteriology, Mycology and Hygiene, Veterinary University Vienna, Vienna, Austria
[2]Mycosafe, Vienna, Austria

Abstract

The genus *Arthrobacter* is a member of the family *Micrococcaceae* and compared to other genera of the family, it contains the highest number of species. The genus cannot be considered monophyletic because within the clade embracing all *Arthrobacter* species also members of other genera of the family are present. Based on quinone system and peptidoglycan structure, the genus *Arthrobacter* can be subdivided into two major groups. One group is characterized by a quinone system with monosaturated menaquinone [MK-8(H_2 and/or MK-9(H_2) and peptidoglycan type A3α. The second group contains completely unsaturated menaquinones (MK-8, MK-9, and/or MK-10) and peptidoglycan type A4α. Combining chemotaxonomic and 16S rRNA based data, the genus can be subdivided at least into 11 subgroups. The majority of established species has been isolated from soil and sediments, but some were recovered from clinical specimens, as well. Arthrobacters are heterotrophic bacteria that do not require fastidious growth conditions. Most of them are mesophilic with growth optima below 30 °C, but some strains isolated from cold environments (Arctica, Antarctica, glaciers) are psychrotolerant or even psychrophilic. Numerous arthrobacters have been studied that are able to degrade harmful compounds such as 4-chlorophenol, 4-fluorophenol, 4-nitrophenol, or phenanthrene. Some strains have been identified as a source of enzymes including cold-adapted β-galactosidases. Since the genus *Sinomonas* harbors three former *Arthrobacter* species, its species will be dealt with here without separating from *Arthrobacter* species.

Taxonomy: Historical and Current

Short Description of the Genus

Ar.thro.bac'ter. Gr. n. *arthron* a joint; N.L. masc. n. *bacter* a rod; N.L. masc. n. *Arthrobacter* a joint rod. (Modified from *Bergey's Manual*). The description is an emended version of the description given in *Bergey's Manual*, 2nd edition (Busse et al. 2012).

Most species show a marked rod–coccus cycle when grown in complex media. Cells from the stationary-growth phase are composed entirely or largely of coccoid cells that are 0.6–1.0 μm in diameter. Species that are showing only coccoid shape during the growth cycle are known. Major fatty acids are $C_{15:0\ anteiso}$, $C_{15:0\ iso}$, $C_{17:0\ anteiso}$, and $C_{16:0\ iso}$. $C_{16:0}$ may be another major fatty acid. The quinone system contains as the major compound MK-8, MK-9, MK-10, MK-8(H_2), or MK-9(H_2). The diagnostic diamino acid of the peptidoglycan is L-lysine and the peptidoglycan type is A3α or A4α (Schleifer and Kandler 1972). Numerous variations in the composition of the interpeptide bridge do occur. The majority of species analyzed for polar lipids contain diphosphatidylglycerol, phosphatidylglycerol, and a diglycosyldiacylglycerol (either dimannosyldiacylglycerol/monoacyldimannosylmonoacylglycerol, or digalactosyldiacylglycerol). Monogalactosyldiacylglycerol and trimannosyldiacylglycerol may be present, as well. Cell sugars are galactose, glucose, glucosamine, mannose, rhamnose, ribose, and/or xylose. The G+C content of the genomic DNA is 55–72 mol%.

The genus *Arthrobacter* was proposed by Conn and Dimmick (1947) with the type species *Arthrobacter globiforme* and the species *Arthrobacter tumescens* and "*Arthrobacter helvolum*." While the type species was included to the Approved Lists of Bacterial Names (Skerman et al. 1980) as *A. globiformis* and *A. tumescens*, as well, for unknown reasons "*A. helvolum*" was not. Hence, this name has no standing in nomenclature. Actually, after its description "*A. helvolum*" was mentioned only once in the taxonomic literature (Clark 1951). However, it has to be emphasized that "*A. helvolum*" has not been reclassified as *Pseudoclavibacter helvolum* as asserted by Busse et al. (2012).

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_204,

In the following *A. tumescens* was first renamed *Pimelobacter tumescens* (Suzuki and Komagata 1983) and subsequently *Terrabacter tumescens* (Collins et al. 1989). Certain other species, primarily classified with the genus *Arthrobacter*, were renamed as well. *Arthrobacter duodecadis* (Lochhead 1958) was assigned to the genus *Tetrasphaera* as *Tetrasphaera duodecadis* (Ishikawa and Yokota 2006); *Arthrobacter flavescens* (Lochhead 1958) was first reclassified as *Aureobacterium flavescens* (Collins et al. 1983) and subsequently as *Microbacterium flavescens* (Takeuchi and Hatano 1998); *Arthrobacter radiotolerans* (Yoshinaka et al. 1973) was reclassified as *Rubrobacter radiotolerans* (Suzuki et al. 1989); *Arthrobacter simplex* (Lochhead 1957) was transferred to the genus *Pimelobacter* as *Pimelobacter simplex* (Suzuki and Komagata 1983); *Arthrobacter variabilis* (Müller 1961) was reclassified as *Corynebacterium variabile* (Collins 1987); and *Arthrobacter atrocyaneus* (Kuhn and Starr 1960), *Arthrobacter albidus*, and *Arthrobacter echigonensis* (Ding et al. 2009) were reclassified in the genus *Sinomonas* as *Sinomonas atrocyanea* (Zhou et al. 2009), *Sinomonas albida*, and *Sinomonas echigonensis*, respectively (Zhou et al. 2012). *Arthrobacter picolinophilus* (Tate and Ensign 1974) was identified as a strain of *Rhodococcus erythropolis* (Koch et al. 1995). *Arthrobacter siderocapsulatus* (Dubinina and Zhdanov 1975) was identified as a strain of *Pseudomonas putida* (Chun et al. 2001). A candidate for reclassfication in another genus is *Arthrobacter viscosus* (Gasdorf et al. 1965) which shares highest 16S rRNA gene sequence similarities with members of the proteobacterial genus *Rhizobium* (Heyrman et al. 2005).

At the time of writing, the genus *Arthrobacter* (except *A. viscous*) embraces 66 species. The genus is a member of the actinobacterial family *Micrococcaceae*. Within the genus, several major branches exist (*Fig. 5.1*) and some of these branches show a closer relationship to other genera of the family than to the type species of the genus, *A. globiformis*. This observation indicates that the genus is not monophyletic.

Heterogeneity within the genus regarding peptidoglycan types (A3α or A4α) and quinone system [menaquinone MK-9 (H_2) or MK-8 and/or MK-9] was already discussed by Stackebrandt et al. (1983). These authors designated *Arthrobacter* species with MK-9 (H_2) and peptidoglycan type A3α the "globiformis" group including *Arthrobacter globiformis, Arthrobacter oxydans, Sinomonas atrocyanea* (formerly *Arthrobacter atrocyaneus*), and *Arthrobacter ureafaciens*. *Arthrobacter* species showing MK-8 and/or MK-9 and peptidoglycan type A4α were placed in the "nicotianae" group including *Arthrobacter nicotianae, Arthrobacter mysorens, Arthrobacter protophormiae, Arthrobacter uratoxydans*, and *Arthrobacter sulfureus*. On the same grounds, species of the "globiformis" group together with *Arthrobacter pascens, Arthrobacter histidinolovorans, Arthrobacter ramosus, Arthrobacter ilicis, Arthrobacter aurescens*, and *Arthrobacter crystallopoietes* were considered to represent the *Arthrobacter globiformis/citreus* group whereas the "nicotianae" group was named *Arthrobacter nicotianae* group (Keddie et al. 1986). Komagata and Suzuki (1987) subdivided *Arthrobacter* species into seven groups based on the composition of the interpeptide bride of the peptidoglycan.

Group I shows Lys-Ser-Thr-Ala found in the species *A. oxydans* and *A. polychromogenes*

Group II shows Lys-Ala-Thr-Ala found in *A. aurescens, A. histidinolovorans, A. ilicis, A. nicotinovorans*, and *A. ureafaciens*

Group III shows Lys-$Ala_{1–4}$ found in *A. crystallopoietes, A. globiformis, A. pascens*, and *A. ramosus*

Group IV shows Lys-Ser-$Ala_{2–3}$ found in *Sinomonas atrocyanea* (formerly *Arthrobacter atrocyaneus*)

Group V shows Lys-Thr-Ala_2 found in *A. citreus*

Group VI shows Lys-Ala-Glu found in *A. nicotianae, A. creatinolyticus, A. uratoxydans*, and *A. protophormiae*

Group VII shows Lys-Glu found in *A. sulfureus*

More recently, the genus *Arthrobacter* was subdivided into 11 groups based on combined data from 16S rRNA gene sequences, quinone system, and peptidoglycan structure (Busse et al. 2012). These groups were named

"*Arthrobacter globiformis* group" (*Arthrobacter sensu stricto*) embraces *Arthrobacter globiformis, Arthrobacter pascens, Arthrobacter humicola* and *Arthrobacter oryzae*.

"*Arthrobacter aurescens* group" embraces *Arthrobacter aurescens, Arthrobacter histidinolovorans, Arthrobacter ilicis, Arthrobacter nicotinovorans, Arthrobacter nitroguajacolicus*, and *Arthrobacter ureafaciens*.

"*Arthrobacter oxydans group*" embraces *Arthrobacter chlorophenolicus, Arthrobacter defluvii, Arthrobacter niigatensis, Arthrobacter oxydans, Arthrobacter phenanthrenivorans, Arthrobacter polychromogenes, Arthrobacter scleromae*, and *Arthrobacter sulfonivorans*. *Arthrobacter equi* (Yassin et al. 2011) can be assigned to "*Arthrobacter oxydans* group" as well because it shares highest 16S rRNA gene sequence similarities with representatives of this group and the amino acid composition of the interpeptide bridge of the peptidoglycan (*Table 5.1*).

"*Arthrobacter protophormiae* group" embraces *Arthrobacter ardleyensis, Arthrobacter arilaitensis, Arthrobacter bergerei, Arthrobacter creatinolyticus Arthrobacter mysorens, Arthrobacter nicotianae, Arthrobacter protophormiae, Arthrobacter rhombi, Arthrobacter soli*, and *Arthrobacter uratoxydans*. Assignment of *A. rhombi* should be carefully reconsidered because this species was reported to contain a menaquinone MK-9(H_2) (Chen et al. 2009) which is in contrast to the common trait of this group containing exclusively unsaturated menaquinones (*Table 5.1*).

"*Arthrobacter sulfureus* group" embraces *Arthrobacter antarcticus, Arthrobacter gangotriensis, Arthrobacter kerguelensis, Arthrobacter psychrophenolicus*, and *Arthrobacter sulfureus*. Another species, *Arthrobacter cryotolerans* (Ganzert et al. 2011) proposed recently, can be considered as another species of this group because it shares its chemotaxonomic traits and phylogenetically, it is the deepest branching species of this group (*Fig. 5.1*).

"*Arthrobacter agilis* group" embraces *Arthrobacter agilis, Arthrobacter flavus, Arthrobacter parietis, Arthrobacter subterraneus, Arthrobacter tecti*, and *Arthrobacter tumbae*.

Fig. 5.1

Phylogenetic reconstruction of the genus *Arthrobacter* and related genera based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, a 40% maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Table 5.1
Characteristics of *Arthrobacter* groups as defined by Busse et al. (2012)

Group	*Arthrobacter globiformis* group	*Arthrobacter citreus* group	*Arthrobacter psychrolactophilus* group	*Arthrobacter agilis* group	*Arthrobacter pigmenti* group	*Arthrobacter aurescens* group	*Arthrobacter oxydans* group	*Arthrobacter protophormiae* group	*Arthrobacter sulfureus* group	*Arthrobacter albus/ cumminsii* group
Quinone	MK-9 (H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9 (H_2)	MK-9 (H_2)[a]	MK-8, MK-9	MK-9, MK-10 or MK-8	MK-8(H_2)
Peptidoglycan[b]	A3α (Lys-Ala_{2-3}) A11.5 or A11.6	A3α (Lys-Thr-Ala_2) A11.27	A3α (Lys-Thr-Ala_{1-3} or Lys-Ala_{1-4}) A11.25, A11.26, A11.27, A11.28 or A11.4, A11.5, A11.6 A11.7	A3α (Lys-Thr-Ala_{2-3}) A11.27 or A11.28	A3α (Lys-Ala-Ser-Ala_3 or Lys-Ala_4) unspecified[c] or A11.7	A3α (Lys-Ala-Thr-Ala) A11.17	A3α (Lys-Ser-Thr-Ala) A11.23	A4α (Lys-Ala-Glu) A11.35	A4α (Lys-Glu) A11.54	A4α (Lys-Ala-Glu or Lys-Ser-Glu) A11.35 or A.11.58

[a]Deviating results were reported for *A. phenanthrenivorans* and *A. scleromae* containing predominantly MK-8 and MK-9(H_2) and MK-8(H_2), respectively (Huang et al. 2005; Kallimanis et al. 2009)
[b]Three digit code according to Schleifer and Kandler (1972) and five digit code as provided by the German Collection of Microorganisms and Cell Cultures (http://www.dsmz.de/catalogues/catalogue-microorganisms/specific-catalogues/peptidoglycans.html#c1252)
[c]The interpeptide bridge Lys-Ala-Ser-Ala_3 is not specified at http://www.dsmz.de/catalogues/catalogue-microorganisms/specific-catalogues/peptidoglycans.html#c1252

"*Arthrobacter citreus* group" embraces *Arthrobacter citreus*, *Arthrobacter gandavensis*, *Arthrobacter koreensis*, and *Arthrobacter luteolus*.

"*Arthrobacter psychrolactophilus* group" embraces *Arthrobacter psychrolactophilus*, *Arthrobacter stackebrandtii*, *Arthrobacter psychrochitiniphilus*, and *Arthrobacter alpinus*. Recently, two proposed species, namely, *Arthrobacter livingstonensis* and *Arthrobacter cryoconiti*, were phylogenetically placed in "*Arthrobacter psychrolactophilus* group" and their peptidoglycan compositions (Ganzert et al. 2011; Margesin et al. 2012) are similar to those of representatives of this group (Table 5.1). Hence, placement of these two species in "*Arthrobacter psychrolactophilus* group" is suggested from these data.

"*Arthrobacter pigmenti* group" embraces *Arthrobacter castelli*, *Arthrobacter monumenti* and *Arthrobacter pigmenti*.

"*Arthrobacter albus/cumminsii* group" embraces *Arthrobacter albus* and *Arthrobacter cumminsii*.

"*Sinomonas* group" embraces *Sinomonas albida* (formerly *Arthrobacter albidus*), *Sinomonas atrocyanea* (formerly *Arthrobacter atrocyaneus*), *Sinomonas echigonensis* (formerly *Arthrobacter echigonensis*), and *Sinomonas flava*.

The major characteristics of these groups are listed in Table 5.1.

However, several species were only tentatively assigned to certain groups. *A. crystallopoietes* was placed in "*Arthrobacter globiformis* group" based on high 16S rRNA gene similarities with *A. globiformis* and a similar peptidoglycan composition. Also *A. ramosus* and *A. methylotrophicus* were tentatively placed in "*Arthrobacter globiformis* group" because the interpeptide bridge in their peptidoglycan contains exclusively alanines. Despite close phylogenetic relationship with *A. methylotrophicus*, *A. alkaliphilus* was placed in "*Arthrobacter oxydans* group" because it shares the group-specific peptidoglycan structure, different from that of *A. methylotrophicus*. *A. russicus* was placed in "*Arthrobacter psychrolactophilus* group" because in many phylogenetic trees, it branches at the root of this group and it shows an interpeptide bridge in the peptidoglycan that is similar to that of a representative of the group, *A. stackebrandtii*.

Arthrobacter halodurans was described in 2009 (Chen et al. 2009), but the name was only validated at the end of 2012. This species was shown to group within the *Arthrobacter* clade next related to *A. rhombi* together comprising a separate line of descent within the genus which is branching at the root of species of "*Arthrobacter protophormiae* group" and "*Arthrobacter sulfureus* group." The predominant quinone of *A. halodurans* is menaquinone MK-9(H_2), the peptidoglycan is of the A4α type (Lys-Ala-Glu) and the polar lipid profile contains diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and an unidentified phospholipid. The peptidoglycan type Lys-Ala-Glu in combination with the quinone system, and the polar lipid profile clearly distinguish *A. halodurans* from members of "*Arthrobacter protophormiae* group" and "*Arthrobacter sulfureus* group" which contain a Lys-Ala-Glu or Lys-Glu type peptidoglycan, exclusively unsaturated menaquinones, and lack phosphatidylinositol. Chen et al. (2009) also reported on the quinone system of *A. rhombi* which was found to have menaquinone MK-9(H_2) predominantly which is in accordance with the close relatedness to *A. halodurans*. However, in the phylogenetic tree shown in Fig. 5.1, *A. halodurans* and *A. rhombi* are clearly separated from each other but both being next related to species of "*Arthrobacter sulfureus* group." These observations indicate that reanalyses of the peptidoglycan structure, the quinone systems, and polar lipid profiles of the two species are desirable in order to confirm these traits which are not in agreement with the traits of "*Arthrobacter sulfureus* group." Confirmation of these data would mean that the definition of "*Arthrobacter sulfureus* group" must be reconsidered and their phylogenetic assignment as well.

The species *A. nasiphocae*, *A. roseus*, *A. sanguinis*, and *A. woluwensis* were not assigned to any *Arthrobacter* group because neither phylogenetic studies nor chemotaxonomic characteristics suggest clear relationships.

Molecular Analyses

Phylogeny

Species of the genus *Arthrobacter* are forming a clade with other members of the family *Micrococcaceae* and they are closely related to the type genus of the family, *Micrococcus*. Phylogenetic trees including *Arthrobacter* species and other representatives of the family indicate that the family is polyphyletic. This suggestion is supported also from heterogeneity in chemotaxonomic traits including peptidoglycan composition and quinone system. Despite high intragroup 16S rRNA gene sequence similarities, only a minority of the *Arthrobacter* groups, as defined by Busse et al. (2012), are forming separate clades which are statistically supported from high bootstrap values. Clades with high statistical support are formed by "*Arthrobacter agilis* group," "*Arthrobacter sulfureus* group," "*Arthrobacter albus/cumminsii* group," "*Arthrobacter citreus* group," and "*Arthrobacter psychrolactophilus* group," which are also sharing ≥97 %, intragroup 16S rRNA sequence similarities. However, also among the representatives of the other *Arthrobacter* groups, relatively high intragroup similarities are found: "*Arthrobacter globiformis* group" (>98.0 %), "*Arthrobacter aurescens* group" (>97.0 %), "*Arthrobacter oxydans* group" (>97.0 %) "*Arthrobacter protophormiae* group" (>96.0 %), "*Arthrobacter pigmenti* group" (>96.0 %), and "*Sinomonas* group" (>97.0 %).

DNA-DNA Hybridizations (DDHs)

The first comprehensive study applying DNA-DNA hybridizations (DDHs) between *Arthrobacter* species was published by Stackebrandt and Fiedler (1979). This DDH study already demonstrated the close relatedness of the two "*Arthrobacter globiformis* group" species, *A. globiformis* DSM 20124^T and *A. pascens* ATCC 13346^T (51 % and 55 % DDH similarity).

In contrast, the two species *A. ramosus* CCM 1646^T and *A. crystallopoietes* DSM 20117^T, which were tentatively assigned to "*Arthrobacter globiformis* group" (Busse et al. 2012) like all other strains included in the study did not show significant DDH similarity (<40 %). The same authors showed that *A. oxydans* DSM 20119^T and *A. polychromogenes* DSM 20136 ("*Arthrobacter oxydans* group") are closely related species exhibiting DDH similarity slightly below the threshold value 70 % for species delineation (61 % and 69 %, respectively). This observation is in agreement with phylogenetic analyses (◉ *Fig. 5.1*) and very high 16S rRNA gene similarity (99.3 %). Furthermore, moderate DDH similarities (44–54 %) indicated that the misclassified strain "*Arthrobacter globiformis* DSM 20125" is a close relative of these two species. No significant DDH similarity (<45 %) was found with other strains included in this study. A close relatedness was also found between the "*Arthrobacter aurescens* group" species *A. aurescens* DSM 20116^T and *A. histidinolovorans* DSM 20115^T (50 % and 55 % DDH similarity, respectively). Both strains show no significant DDH similarities with another member of "*Arthrobacter aurescens* group," namely, *A. ureafaciens* nor with other strains included in this study (<40 % DDH similarity). Moderate DDH similarity (39 % and 48 %, respectively) was observed between the two "*Arthrobacter protophormiae* group" species *A. nicotianae* DSM 20123^T and *A. protophormiae* DSM 20168^T. DDH similarities >70 % with strain DSM 20168^T demonstrated that the misclassified patent strains "*Arthrobacter citreus* ATCC 17775" (US Patent 3,533,914), "*Arthrobacter citreus*" ATCC 21348 (US Patent 3,661,711), and "*Arthrobacter citreus*" ATCC 21040" (US Patent 3,532,600) are strains of the species *A. protophormiae* (formerly *Brevibacterium protophormiae*). No relationship with other strains of the study was suggested from DDH similarities. This study also showed that "*Arthrobacter citreus* ATCC 15170" was misclassified and actually is a strain of the "*Arthrobacter sulfureus* group" species *A. sulfureus* (formerly *Brevibacterium sulfureum*; >70 % DDH similarity). No relatedness with other species of this study was found for the type species of "*Arthrobacter citreus* group" species *A. citreus* and "*Sinomonas* group" species *Sinomonas atrocyanea* (formerly *Arthrobacter atrocyaneus*).

In a following study, Stackebrandt et al. (1983) applied DDH for examination of relationship of several strains with the type strains of the species *A. nicotianae, A. protophormiae,* and *A. sulfureus.* These authors showed that the patent strain (US Patent 3,616,215; British Patent 1,158,199) "*Arthrobacter nucleogenes*" ATCC 21279, *Arthrobacter* sp. AC 250, *Arthrobacter* sp. NCIB 9863, "*Brevibacterium*" sp. AJ 1486, and *Corynebacterium liquefaciens* DSM 20579 are strains of *A. nicotianae,* as demonstrated by DDH similarities >80 % and that *Corynebacterium* sp. ATCC 31021, "*Brevibacterium fuscum*" ATCC 15993, the patent strain *Arthrobacter mysorens* ATCC 31021, "*Corynebacterium uratoxydans*" ATCC 21749^T, and "*Corynebacterium uratoxydans*" ATCC 21752 are closely related to *A. nicotianae* (DDH similarity 40–50 %). Furthermore, a close relatedness of the patent strain (US Patent 3,762,999; US Patent 3,709,786; US Patent 3,560,342; US Patent 3,764,472; US Patent 3,586,606) *Arthrobacter* sp. ATCC 21085 with *A. sulfureus* was suggested from 60 % DDH similarity. No close relationships with other species were identified for *A. citreus* DSM 20133^T, *A. globiformis* DSM 20124^T, *Arthrobacter oxydans* DSM 20119, or *A. ureafaciens* DSM 20126^T subjected to DDH analyses. As a result from this study for "*Corynebacterium uratoxydans*" ATCC 21749^T and "*Corynebacterium uratoxydans*" ATCC 21752, which are sharing 100 % DDH similarity, the species *Arthrobacter uratoxydans* was proposed; for "*Brevibacterium sulfureum*" DSM 20167^T the species *Arthrobacter sulfureus* was proposed and *Brevibacterium protophormiae* DSM 20168^T was reclassified as *Arthrobacter protophormiae.*

In a polyphasic study dealing with the classification of two *Arthrobacter oxydans* strains, DSM 419 and DSM 420^T, including analysis of DDH similarity, Kodama et al. (1992) found that these two strains are misclassified. The two strains show less than 45 % DDH similarity with each other, demonstrating that they are not members of a single species. Strain DSM 419 shows less than 20 % similarity with the type strain of *A. oxydans* and also low levels of DDH similarity (<45 %) with the type strains of *A. aurescens, A. histidinolovorans, A. ilicis,* and *A. citreus* but more than 95 % with the type strain *A. ureafaciens.* From these data, the authors concluded that strain DSM 419 should be classified as *A. ureafaciens.* Strain DSM 420 showed less than 60 % DDH similarity with each of above-mentioned reference species. Based on these results, Kodama et al. (1992) proposed for strain DSM 410^T the novel species *Arthrobacter nicotinovorans.*

Two human isolates from blood designated CF46 and CF39 were identified as strains of *Arthrobacter oxydans* based on >80 % DDH similarity (Wauters et al. 2000).

The distinct position of the *Arthrobacter* isolate A6^T and its status as a novel species was determined by DDH hybridization experiments with the close phylogenetic relatives *A. oxydans* and *Arthrobacter polychromogenes.* DDH similarities below 55 % clearly demonstrated that strain A6^T is representing a novel species for which the name *Arthrobacter chlorophenolicus* was proposed (Westerberg et al. 2000).

The type strain of *Arthrobacter defluvii* was hybridized with a second strain 4C1-b which was isolated in the same study and the type strains of closely related *Arthrobacter* species, as indicated from 16S rRNA gene sequence similarities, namely, *A. chlorophenolicus, A. oxydans, A. scleromae, A. polychromogenes,* and *A. sulfonivorans.* DDH similarity with 4C1-b was 93 % and similarities with the reference strains were <40 %, supporting the description of the novel species (Kim et al. 2008).

Despite high 16S rRNA similarity with the type strain of *A. citreus* (98.7 %), an isolate from an infected surgical wound CF25^T was proposed as *Arthrobacter luteolus* (Wauters et al. 2000) because low DDH similarity (44 %) was observed between the two species.

Storms et al. (2003) reported on the description of the novel species *Arthrobacter gandavensis.* Based on DDH similarity (<90 %), the three strains LMG 21285^T, LMG 21286 and LMG 21287, which had been isolated from mastitic milk of dairy cows and from the uterus of a cow, respectively, were identified as strains of the same species. DDH similarities ≤50 % with the

next phylogenetic relatives *A. citreus* and *A. luteolus* confirmed the status of the novel species, *A. gandavensis*. Studies of the genetic relationship of the novel species *Arthrobacter equi* with its close relatives *A. defluvii* and *A. chlorophenolicus* revealed 32.3 % and 53.9 % DDH similarity, respectively, supporting the description of the novel species (Yassin et al. 2011).

The two isolates CA15-8^T and CA15-9 sharing ≥90 % DDH similarity were identified as strains of the novel species *Arthrobacter koreensis*. The two strains share less than 10 % DDH similarity with the type strain of the next phylogenetic relative *A. luteolus* (Lee et al. 2003).

Three strains GIFU 12498^T, GlFU 12499, and GIFU 12500, which share more than 90 % DDH similarity, were described as strains of *Arthrobacter creatinolyticus* (Hou et al. 1998). *A. creatinolyticus* GIFU 12498^T was shown to exhibit less than 35 % DDH similarity with the type strains of *A. aurescens*, *A. globiformis*, *A. ilicis*, *A. nicotianae*, *A. protophormiae*, *A. sulfureus*, and *A. uratoxidans*.

Arthrobacter gangotriensis Lz1y^T and *Arthrobacter kerguelensis* KGN15^T were described as novel species because they exhibited with each other 50 % and with the type species of the nearest relative *A. sulfureus* 54 % and 12 % DDH similarity, respectively (Gupta et al. 2004).

The proposal of *Arthrobacter psychrochitiniphilus*, which shares 97.8 % 16S rRNA gene sequence similarity with its closest relative *Arthrobacter psychrolactophilus*, was supported by 33.8 % DDH similarity between the type strains of the two species (Wang et al. 2009).

Arthrobacter albus was proposed by Wauters et al. (2000) for human isolates CF43^T and CF44 from blood and urine, respectively, which share 88 % DDH similarity. Though CF43^T shares 99.7 % 16S rRNA gene sequence similarity with the type strain of *Arthrobacter cumminsii*, the DDH similarity between the two isolates and *A. cumminsii* is only 54.5 % and 58.6 %, respectively.

Fourteen isolates from the surfaces of different smear-ripened cheeses could be assigned to the two novel species *Arthrobacter arilaitensis* and *Arthrobacter bergerei* based on results from DDH (Irlinger et al. 2005). Based on DDH similarities >70 % with the type strain Re117^T the isolates Po101, Ep104, Cou102, Gor104, Bres102, Po102, Stp101, and Ma107 could be assigned to the species *A. arilaitensis*. The isolates La101, Sne104, Re127, and Ka101 were identified as strains of *A. bergerei* with which they shared >75 % DDH similarity. The type strains of the two species *A. arilaitensis* and *A. bergerei* showed only <45 % DDH similarity with the type strains of their close phylogenetic neighbors *A. nicotianae*, *A. uratoxydans*, *A. protophormiae*, and *A. sulfureus*.

DDH studies between G2-1^T and its closest phylogenetic relatives *A. ilicis* and *A. aurescens* (<45 % DDH similarity) demonstrated that it is the representative of a novel species for which the name *Arthrobacter nitroguajacolicus* was proposed. Furthermore, DDH similarity of 78.2 % identified a second isolate, designated 8/3, as a strain of *A. nitroguajacolicus* (Kotoucková et al. 2004).

The species *Arthrobacter flavus* was proposed despite 77 % DDH similarity with the type strain of *Arthrobacter agilis* (Reddy et al. 2000) which is clearly above the threshold value of 70 % applied for species distinction. This proposal was supported from significant phenotypic differences.

Arthrobacter humicola and *Arthrobacter oryzae* were described by Kageyama et al. (2008). The type strains of the two species showed approximately 50 % DDH similarity and less than 30 % DDH similarity with the type strains of the closely related species *A. globiformis*, *A. pascens*, and *A. ramosus*. These data unambiguously demonstrated the status of separate species for *A. humicola* and *A. oryzae*.

DDH similarity values <45 % with its closest relatives *A. polychromogenes* and *A. oxydans* supported the description of strain Sphe3^T as the species *Arthrobacter phenanthrenivorans* (Kallimanis et al. 2009).

The species *Arthrobacter alpinus* S6-3^T was described because it shared with its next phylogenetic relatives *A. stackebrandtii* and *S. psychrolactophilus* approximately 11 % and 34 % DDH similarity, respectively (Zhang et al. 2010).

Four *Arthrobacter* species were described by Ding et al. (2009), namely, *Arthrobacter alkaliphilus*, *Arthrobacter niigatensis*, *Sinomonas echigonensis* (formerly *Arthrobacter echigonensis*), and *Sinomonas albida* (formerly *Arthrobacter albidus*) including DDH with the next related reference species. *A. alkaliphilus* LC6^T showed 32.1 % DDH similarity with *A. methylotrophus*. The DDH similarity between *A. niigatensis* LC4^T and *A. chlorophenolicus* was determined to be 32.4 %. The closely related strains *Sinomonas echigonensis* LC10^T and *Sinomonas albida* LC13^T shared 25.3 % with each other and with the next related reference species *Sinomonas atrocyanea* (formerly *Arthrobacter atrocyaneus*) 11.2 % and 9.6 % DDH similarity, respectively. The latter three species recently were reclassified in the novel genus *Sinomonas* as *S. echigonensis*, *S. albida*, and *S. atrocyanea* (Zhou et al. 2009, 2012) with the type species *Sinomonas flava* CW 108^T. *S. flavus* and *S. atrocyanea* share 52.2 % DDH similarity (Zhou et al. 2009). Another species, *Sinomonas soli*, shares 58.3 %, 41.8 %, 21.6 %, and 25.5 % DDH similarity, respectively, with the other four species of the genus, *S. atrocyaneus*, *S. flava*, *S. echigonensis*, and *S. albidus*, respectively (Zhou et al. 2012).

Two strains A1-3^T and A19, which had been isolated from the air in the Russian space laboratory Mir, were classified in a single species, *Arthrobacter russicus* (Li et al. 2004). The two strains exhibit 100 % DDH similarity with each other and only 9.8 % DDH similarity with the next relative *A. polychromogenes*.

In the study describing the six species *Arthrobacter monumenti*, *Arthrobacter pigmenti*, *Arthrobacter castelli*, *Arthrobacter tecti*, *Arthrobacter tumbae*, and *Arthrobacter parietis*, the status of the latter five species was substantiated from the results of DDH values obtained between the type strains of selected novel species and the reference species *A. globiformis*, *A. pascens*, *A. agilis*, and *A. ramosus* (Heyrman et al. 2005). *A. parietis* and *A. tumbae* show approximately 50 % DDH similarity, which is reflecting their close relatedness as shown by 16S rRNA gene sequence analyses but less than 12 % DDH similarity with *A. tecti* and the four reference species. DDH similarity of *A. tecti* with *A. parietis*, *A. tumbae*, and the

four reference species is not higher than 16 %. Among the reference species *A. globiformis* and *A. pascens* show highest DDH similarity with each other (approximately 31 %) but less than 14 % with *A. agilis* and *A. ramosus*. DDH similarity of *A. agilis* and *A. ramosus* is less than 6 % and less than 13 % with the three novel species mentioned above and the other two reference species. In the same study, 26 % DDH similarity between the type strains of *A. pigmenti* and *A. castelli* suggested that the two strains belong to different genospecies.

Most recently, the novel species *Arthrobacter cupressi* was described (Zhang et al. 2012). The levels of DDH similarity of the type strains of *A. cupressi* with those of its close relatives *A. oryzae*, *A. humicola*, *A. alkaliphilus*, *A. niigatensis*, and *A. defluvii* were 36 %, 26 %, 21 %, 20 %, and 20 %, respectively.

Multi-locus Sequence Analysis (MLSA)

Multi-locus sequence analyses (MLSA) have not yet been introduced to the taxonomy of the genus *Arthrobacter*. However, a short stretch (360 bp) of the gene *recA* often sequenced in MLSA studies has been applied to selected *Arthrobacter* species for comparative phylogenetic analyses (van Waasbergen et al. 2000). In agreement with relationships deduced from 16S rRNA sequence data, these analyses revealed a close relatedness between *Arthrobacter globiformis* and *Arthrobacter pascens*; between *Arthrobacter uratoxydans*, *Arthrobacter protophormiae*, *Arthrobacter nicotianae,* and more distantly *Arthrobacter sulfureus*; between *Arthrobacter aurescens*, *Arthrobacter nicotinovorans*, *Arthrobacter histidinolovorans*, and *Arthrobacter ureafaciens*; and between *Arthrobacter oxydans* and *Arthrobacter polychromogenes*. Additional *recA* gene sequences from *Arthrobacter* type strains are accessible from the released genome sequences of *Arthrobacter chlorophenolicus* A6^T (CP001341), *Arthrobacter phenanthrenivorans* Sphe3^T (CP002379), and *Arthrobacter arilaitensis* RE117^T (FQ311875). Sequence similarities with the *recA* gene fragments of type strains of recognized *Arthrobacter* species do not support assignment of *A. chlorophenolicus* to "*Arthrobacter oxydans* group" (Busse et al. 2012) but indicate a position between "*Arthrobacter globiformis* group" and "*Arthrobacter oxydans* group." On the other hand, *recA* similarities suggest placement of. *A. phenanthrenivorans* in "*Arthrobacter oxydans* group." In agreement with the grouping proposed by Busse et al. (2012) *A. arilaitensis* RE117^T is placed in "*Arthrobacter protophormiae* group."

Matrix-Assisted Laser Desorption Ionization-Time of Flight Mass Spectrometry (MALDI-TOF MS)

MALDI-TOF MS has been applied for identification of *Arthrobacter* strains that have been isolated from soil contaminated with heavy metals and aromatic solvents (Vargha et al. 2006), from horseradish rhizosphere soil capable to metabolize biphenyl (Uhlik et al. 2011), and halotolerant, phenanthrene-degrading close relatives of *Arthrobacter crystallopoietes* (Prisyazhnaya et al. 2012).

Vargha et al. (2006) studied 16 *Arthrobacter* isolates and showed that the groupings identified on the basis of MALDI-TOF protein profile corresponded well to phylogenetic relationships. Common to all isolates were two peaks at 4,400 and 5,160 *m/z* whereas all other peaks were group specific or even strain specific.

In a study on classification of biphenyl-degrading isolates from horseradish soil applying MALDI-TOF MS and the MALDI Biotyper 2.0 software (Bruker), seven strains were identified at the species level (*A. arilaitensis, A. aurescens, A. chlorophenolicus, A. ilicis, A. oxydans,* and *A. polychromogenes*, respectively), one strain as a member of the group *A. oxydans/A polychromogenes/A. scleromae* and four strains at genus level (Uhlik et al. 2011). Analyses of the 16S rRNA coding genes of the strains confirmed that they are members of the genus *Arthrobacter*. However, 16S rRNA gene comparisons demonstrated that additional three isolates, of which none were identified by the MALDI Biotyper, are members of the genus *Arthrobacter*, as well.

Seven halotolerant *Arthrobacter* isolates capable to degrade phenanthrene were studied by Prisyazhnaya et al. (2012) which are closely related to *A. crystallopoietes*. These authors evaluated the applicability of MALDI-TOF MS for classification and differentiation and compared the results with those from DDH, 16S rRNA gene sequence phylogeny and genomic fingerprints obtained after BOX-PCR. Isolates and *A. crystallopoietes* share 15 MALDI-TOF peaks of which nine peaks (*m/z* 6,020, 6,704, 7,293, 7,344, 7,524, 7,652, 7,998, 8,516, and 9,472) are only found in this group. Two strains of this group are distinguishable from the other strains by the presence of 15 unique peaks whereas the remaining five isolates are characterized by eight unique peaks. These indicated relationships are also reflected in a dendrogram based on MALDI-TOF profiles in which the seven isolates are forming two groups both next related to *A. crystallopoietes* whereas the type strains of ten other *Arthrobacter* species are significantly more distant. These results are well in agreement with results from DDH, BOX fingerprinting, and phylogeny.

In a study investigating the MALDI-TOF profiles of the majority of established *Arthrobacter* species, several most interesting results were obtained (Peter Schumann; unpublished results) since several MALDI-TOF clusters (*Fig. 5.2*) are composed of species which are also phylogenetically forming a group or are placed in an "*Arthrobacter* group" (*Fig. 5.1*) on the basis of 16S rRNA similarity values and/or chemotaxonomic traits. All species of "*Arthrobacter citreus* group," "*Arthrobacter psychrolactophilus* group," "*Arthrobacter pigmenti* group," "*Arthrobacter albus/cumminsii* group," and "*Arthrobacter aurescens* group," respectively, are also forming separate MALDI-TOF groups. Species of "*Arthrobacter oxydans* group" are forming a MALDI-TOF group as well but *A. globiformis* and *A. pascens* are attached to this group, though their peptidoglycan structure is different and their phylogenetic position is clearly separate. The very close phylogenetic relationship between *A. oryzae* and *A. humicola* is reflected by MALDI-TOF spectra

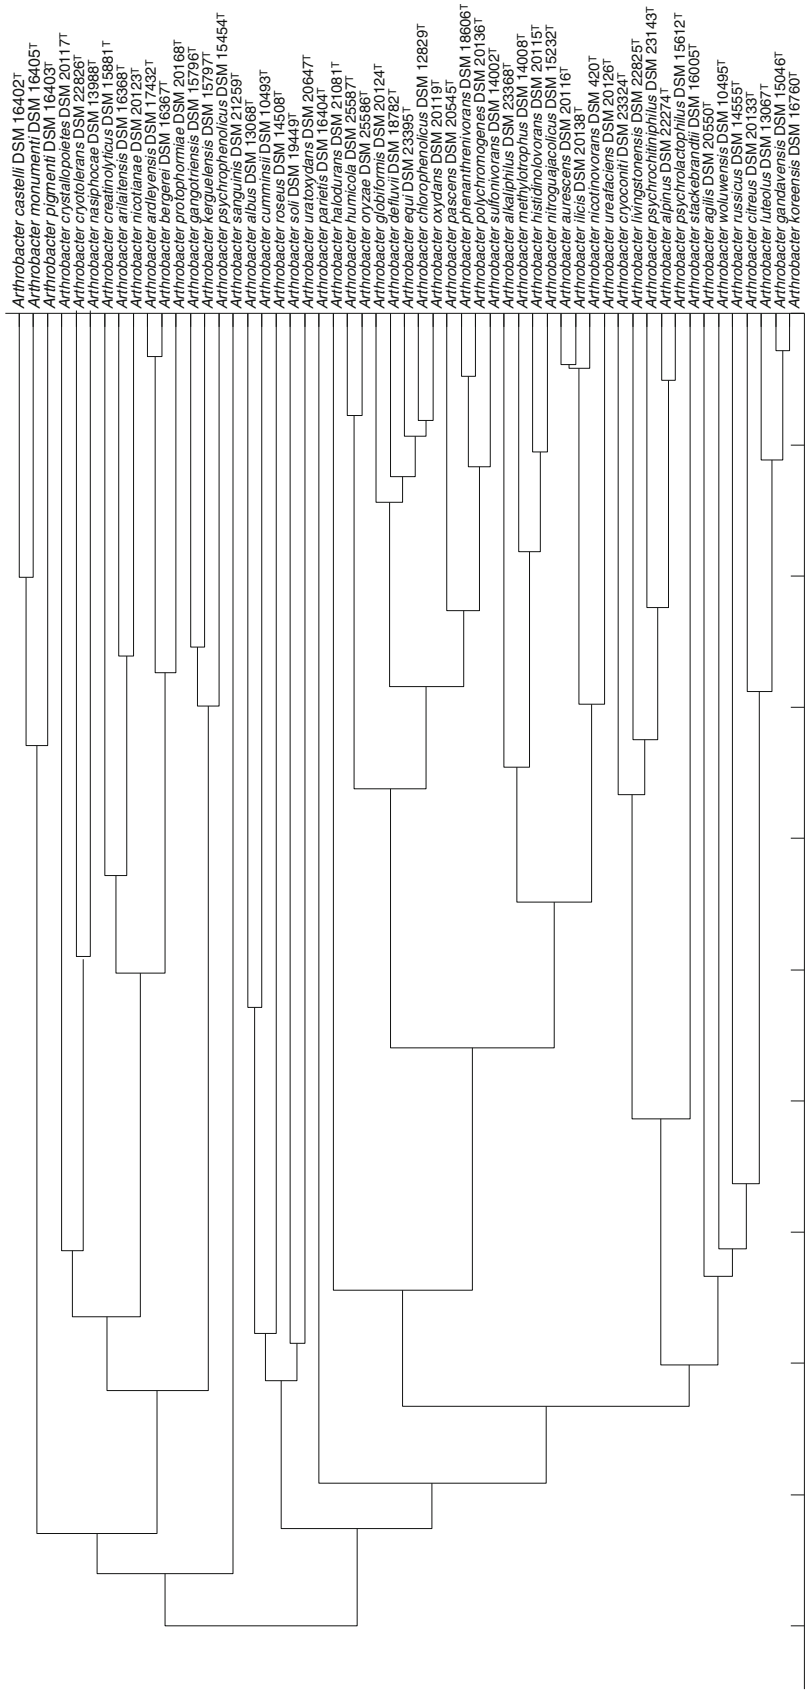

Fig. 5.2
Score oriented dendrogram generated by the Biotyper software (version 3.1, Bruker Daltonics) showing the similarity of MALDI-TOF mass spectra of cell extracts of selected type strains of the genus *Arthrobacter*

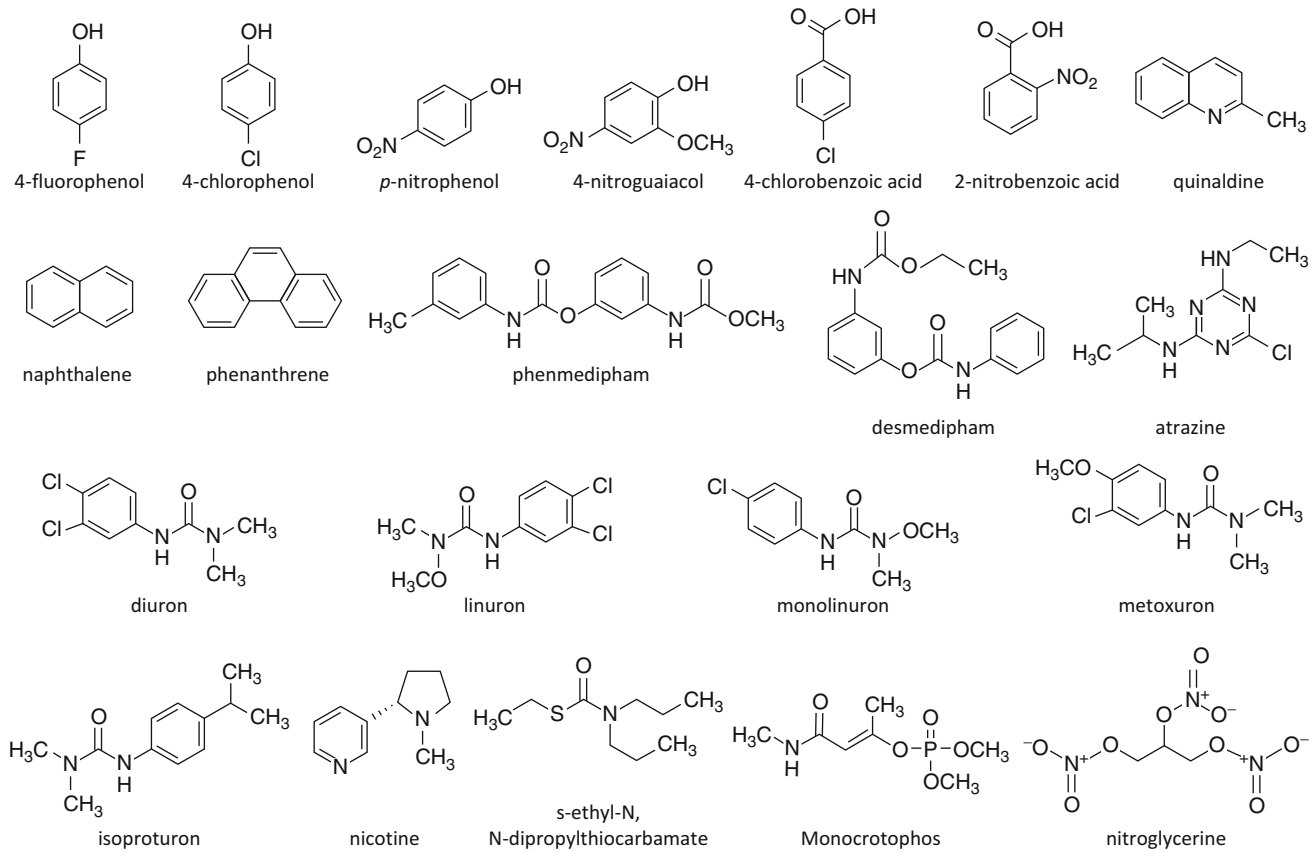

Fig. 5.3
Chemical structures of components attacked by certain *Arthrobacter* strains

as well. Selected species of "*Arthrobacter protophormiae* group" are grouped together by MALDI-TOF profiles except *A. soli* which is clearly separated from this group. Except *A. cryotolerans*, species of "*Arthrobacter sulfureus* group" are also forming a group.

Genomes

So far, nine *Arthrobacter* genomes have been sequenced, including *Arthrobacter globiformis* NBRC 12137^T, *Arthrobacter aurescens* TC1, *Arthrobacter arilaitensis* Re117^T, *Arthrobacter chlorophenolicus* A6^T, *Arthrobacter phenanthrenivorans* Sphe3^T, *Arthrobacter* sp. Rue61a, *Arthrobacter* sp. FB24, *Arthrobacter* sp. strain M2012083, and *Arthrobacter* sp. TB 23. The genomes of *A. chlorophenolicus* A6^T and *A. globiformis* NBRC 12137^T are accessible without associated publications.

The shotgun sequence of the genome of *A. globiformis* NBRC 12137^T (project accession PRJDA71847; accession no. BAEG01000000) comprises 4,954,410 bp, 4,529 coding sequences, three rRNAs, and 50 tRNAs.

The genome of *A. chlorophenolicus* A6^T (project accession PRJNA58969; accession no CP001341) comprises 4,980,870 bp, one chromosome and two plasmids, 4,590 coding sequences, 15 rRNAs, and 88 tRNAs. The G+C content is 66 mol %. The sizes of the chromosome and the two circular plasmids pACHL01 and pACHL02 are 4,395,537 bp, 426,858 bp, and 158,475 bp, respectively.

The 16S rRNA gene sequence of *Arthrobacter* sp. TB23 shares 100 % similarity with the type strain of *Arthrobacter flavus*, and hence, it can be considered to be an authentic member of this species. The shotgun genome sequence of *Arthrobacter* sp. TB 23 (project accession PRJNA170988; accession no ALPM01000000) comprises 3,542,528 bp and the G+C content is 63.3 mol %. The genome contains 3,298 ORFs, and it encodes 46 tRNAs and six rRNA operons. Genes of special interest identified are encoding for type III polyketide synthetase, a non-ribosomal peptide synthetase, and terpene biosynthetic genes (Fondi et al. 2012).

The draft genome of the nicotine-degrading *Arthrobacter* sp. strain M2012083 (accession no AKKK00000000) is 4,629,172 bp long, has a G+C content of 62.0 mol%, and contains 54 genes encoding for tRNAs and 4,312 coding sequences. The genome encodes for 522 proteins involved in carbohydrate metabolism, 59 proteins involved in aromatic compound metabolism, and contains 89 genes involved in stress responses. Genes related to motility are absent (Yao et al. 2012).

Arthrobacter aurescens TC1 was identified (Strong et al. 2002) based on high 16S rRNA sequence similarities with two environmental *A. aurescens* strains, *A. aurescens* TA13 and

strain 51. The complete chromosome of *A. aurescens* TC1 is 4,597,686 bp long and in addition, two circular plasmids are present, pTC1 and pTC2 which are 408,237 bp and 300,725 bp long, respectively (Mongodin et al. 2006). The G+C content is 62.4 mol % which is very close to 61.9 mol % reported for the type strains of *A. aurescens* (Kodama et al. 1992) and *A. nitroguajacolicus* (Kotoučková et al. 2004).

On the chromosome 4,136, open reading frames (ORFs) have been identified of which 2,767 could be assigned to a function. Eighteen ORFs are encoding for rRNA, 54 for tRNA, and one for sRNA; 379 ORFs are assigned to conserved hypothetical proteins, 468 ORFs are encoding for hypothetical proteins, and 522 ORFs are of unknown function.

Eleven genomic islands are present on the chromosome with atypical G+C content. These genomic islands are encoding for 180 genes. In these genomic islands, transposons and related genes, transcriptional regulators, resistance genes, and genes involved in metabolism and transport of substrates are present. On the chromosome 23 sequences are found that are encoding for transposons or insertion sequences. A phage sequence was not detected. Genes coding for flagella synthesis, motility, and chemotaxis are absent. Absence of motility is in agreement with the data published for the type strain of *A. aurescens* by Kodama et al. (1992). The majority of ORFs are associated to the categories energy metabolism (739), encoding for transport and binding proteins (517), related to cell envelope (340) and regulatory functions (332). Additional 186 genes were assigned to cellular processes, 167 genes to protein fate, 141 genes to synthesis of cofactors, prosthetic groups, and carriers, 136 genes to amino acid biosynthesis, 123 genes to protein synthesis, 123 genes to fatty acid and phospholipid metabolism, 117 genes to central intermediary metabolism, 111 genes to DNA metabolism, 89 genes to transcription, 82 genes to purine, pyrimidine, nucleoside, and nucleotides, 54 genes to signal transduction, and 35 genes to mobile and extrachromosomal element function.

The G+C contents of plasmid pTC1 and plasmid pTC2 are 64.6 mol % and 61.3 mol %, respectively. The number of ORFs is 297 and 275, respectively. On plasmid pTC1, a function is assigned to 139 ORFs and on plasmid pTC2 to 275 ORFs; 24 ORFs on pTC1 are encoding for conserved hypothetical proteins and on pTC2 36 ORFs. On pTC1, 104 ORFs are encoding for hypothetical proteins and 30 ORFs are of unknown function. On pTC2 51 ORFs are encoding for hypothetical proteins and 23 ORFs are of unknown function. Except RNA encoding genes on both and protein function related ORFs on pTC2, the two plasmids are harboring at least one gene of each category mentioned above for the genome. Furthermore, a cluster of genes is present on each of the two plasmids encoding for proteins associated with biodegradation of isopropylamine. As already reported earlier (Sajjaphan et al. 2004), the three triazine hydrolase genes *trzN, atzB,* and *atzC* are exclusively located on plasmid pTC1. Also on pTC1, six identical direct tandem repeats of about 16 kb are found. Fourteen ORFs on plasmid pTC1 are encoding for transposons and/or insertion elements. On plasmid pTC2, nine ORFs are encoding for transposons and/or insertion elements.

The chromosomes of *A. aurescens* TC1 and *Arthrobacter* sp. FB24 share 79.1 % similarity at the amino acid level. For a total of 540 genes of *A. aurescens* TC1, no corresponding genes are found on the chromosome of *Arthrobacter* sp. FB24. The two strains share 25 identical proteins of which ten are ribosomal proteins.

Comments on the taxonomy of *Arthrobacter aurescens* TC1: this strain was identified based on highest 16S rRNA gene sequence similarities with *A. aurescens* TA13 (Shimoni et al. 2002; accession number AF467106) and *A. aurescens* strain 51 (Macur et al. 2004; accession number AF388032) but not considering the corresponding sequence of the type strain of the species. Both, strain TA13 and strain 51, share 100 % 16S rRNA sequence similarity with the type strain of *A. nitroguajacolicus* and 99.7 % similarity with the type strain of *A. aurescens*. Hence, it appears to be more likely that strains TA13 and 51 are members of the species *A. nitroguajacolicus* than *A. aurescens*. However, the two environmental isolates TA13 and S1 had been identified at a time when *A. nitroguajacolicus* was not yet described and the best hit for the two 16S rRNA gene sequences actually was that of the type strain of *A. aurescens*. Like the two environmental isolates also, the 16S rRNA gene sequence of *A. aurescens* TC1shows highest similarity with the corresponding sequence of the type strain of *A. nitroguajacolicus* (99.9 %) and that of the type strain of *A. aurescens* (99.7 %). Furthermore, in the *rec*A gene sequence, *A. aurescens* TC1 shows only 91.4 % similarity with the type strain of *A. aurescens* (corresponding sequence of *A. nitroguajacolicus* not available), strongly suggesting that *A. aurescens* TC1has been misclassified. In conclusion from comparison of 16S rRNA and *rec*A gene sequences, it is most likely that *A. aurescens* TC1 is either a strain of the species *A. nitroguajacolicus* or a representative of a so far not described species.

The genome of *Arthrobacter arilaitensis* Re117^T is composed of a circular chromosome and the two plasmids pRE117-1 and pRE117-2 (Monnet et al. 2010). The size of the chromosome is 3,859,257 bp (accession no FQ311875), that of plasmid pRE117-1 is 50,407 bp (accession no FQ311475), and that of plasmid pRE117-2 is 8,528 bp (accession no FQ311476), resulting in total in a genome size of 3,918,192. The size of the chromosome is approximately 0.7–1.3 Mbp smaller than those of the genomes of *Arthrobacter phenanthrenivorans* Sphe3^T, *Arthrobacter globiformis* NBRC 12137^T, *A. aurescens* TC1, *Arthrobacter* sp. FB24, *Arthrobacter chlorophenolicus* A6^T, and *Arthrobacter* sp. strain M2012083 but approximately 0.3 Mbp larger than the chromosome of *Arthrobacter* sp. TB23. The G+C content of the chromosome is 59.2 mol %. The complete genome contains 3,518 genes. The number of rRNA and tRNA genes is 18 and 64, respectively; 3,436 genes are encoding for proteins of which 2,155 are with predicted and 1,281 are without predicted function. In addition, 123 pseudogenes are present in the genome. The organism's genome contains genes that are encoding for proteins associated with repair of DNA lesions, three type I restriction modification systems, a Sec-dependent protein secretion pathway, a twin-arginine translocation pathway, and 356 putative transport proteins. Of the 2,727 gene sequences, 1,210 show highest similarities with corresponding

sequences of *A. aurescens* TC1, *A. chlorophenolicus* A6^T, and *Arthrobacter* sp. FB24. Compared to the latter three strains, the genome of *A. arilaitensis* RE117^T shares with the other three genomes 1,545 coding sequences but 1,246 are unique for *A. arilaitensis* RE117^T. The three reference genomes contain 746 coding sequences which are absent in *A. arilaitensis* RE117^T. The genome encodes for 17 proteins with putative lipase and esterase activity, of which one is a secretory triacylglycerol lipase. This enzyme is considered to contribute significantly to ripening of smear-ripened cheese which is a natural habitat of *A. arilaitensis*. One cluster of genes is associated with the aerobic catabolism of glycerol, including a glycerol uptake protein, a glycerol kinase, and a glycerol-3-phosphate dehydrogenase. Genes encoding enzymes of the β-oxidation pathway are present as well. For five out of 11 putative fatty acid-CoA dehydrogenases and four out of 11 fatty acid-CoA ligases of *A. arilaitensis* RE117^T, no ortholog enzymes are present in the genomes of *A. aurescens* TC1, *Arthrobacter* sp. FB24, and *Arthrobacter chlorophenolicus* A6^T. The genome also contains 30 genes associated with Fe^{3+}/siderophore transporters of which 20 genes do not have orthologs in the genomes of *A. aurescens* TC1, *Arthrobacter* sp. FB24, and *Arthrobacter chlorophenolicus* A6^T. Six putative proteins mediate release of iron from the Fe^{3+}/siderophore complex and five of these proteins are unique compared to *A. aurescens* TC1, *Arthrobacter* sp. FB24, and *Arthrobacter chlorophenolicus* A6^T. The chromosome was found to harbor 4.92 % insertion sequences (109 complete and 35 partial). This is significantly higher than in the chromosomes of the three reference genomes (0.08–0.4 %).

Of 42 ORFs located on plasmid pRE117-1 only 19 genes are encoding for proteins with predicted function. This plasmid contains approximately 10 % insertion sequences. Three sequences are encoding for DNA mobilization proteins, one for a putative secreted peptidase, a single stranded DNA-binding protein, and proteins of unknown function. Five proteins show highest amino acid similarity with proteins encoded from plasmid FB24-2 of *Arthrobacter* sp. FB24. Another five proteins show highest similarity with plasmid proteins of other arthrobacters. Plasmid pRE117-2 harbors 13 gene sequences of which nine are hypothetical proteins whereas two are predicted to encode for mobilization proteins.

The genome of the phenanthrene-metabolizing strain *Arthrobacter phenanthrenivorans* Sphe3^T is composed of a chromosome with 4,250,414 bp (accession no CP002379) and two plasmids with 190,450 bp and 94,456 bp, respectively (Kallimanis et al. 2011). The G+C content of the chromosome is 66 mol % whereas that of the two plasmids is 62 mol %. The genome contains 4,288 putative genes of which 4,212 are encoding for proteins, 76 for RNAs, and 77 for pseudogenes. Four rRNA operons are present. Out of the protein coding genes, 3,167 are assigned to putative function.

The manually annotated genome of *Arthrobacter* sp. FB24 (accession no CP000454), which had been isolated from chromate and xylene enriched soil, is composed of a circular chromosome and the three circular plasmids, p1, p2, and p3 (http://www.genome.jp/kegg-bin/show_organism?org=T00421). The chromosome is 4,698,945 bp long, plasmid p1 is 159,538 bp long (accession no CP000455), plasmid p2 is 115,507 bp long (accession no CP000456), and plasmid p3 is 96,488 bp long (CP000457). The genome encodes for 4,523 protein genes and 69 RNA genes.

The genome of *Arthrobacter* sp. Rue61a comprises a circular chromosome with a length of 4,736,495 bp, the circular plasmid pARUE232 with a length of 231,551 bp, and the linear plasmid pARUE113 with a length of 112,992 bp (Niewerth et al. 2012). The G+C contents are 62.32, 61.58, and 60.88 mol %, respectively. On the genome 4,575 ORFs, six rRNA operons, 53 tRNAs, and nine pseudogenes are found. Out of the total ORFs, 3,382 are assigned to a putative function whereas 1,193 are considered as hypothetical. The genome comprises 303 ORFs that are most similar to genes of phyla other than actinobacteria and 13 putative genomic islands were detected on the chromosome that contains 160 genes. A total of 594 genes are encoding for transporters and binding proteins; 512 of these genes are similar or identical to genes found in the genome of *A. aurescens* TC1. Remaining genes encoding for transporters/binding proteins are found on genomic islands or on plasmid pARUE232. The genome encodes several putative uptake systems for K^+, organic osmoprotectants, and for synthesis of compatible solutes. As indicated by growth experiments, *Arthrobacter* sp. Rue61a encodes proteins that allow utilization of several carbon sources for growth including 4-hydroxybenzoate, protocatechuate, vanillate, hydroxyphenylacetate, homoprotocatechuate, tyrosine, the N-heterocyclic compounds hypoxanthine, xanthine, 1*H*-4-oxoquinaldine, 1*H*-3-hydroxy-4-oxoquinaldine, several sugars, alcohols, organic acids, amines, and amides. Furthermore, genes encoding enzymes are present, allowing the organism to utilize urea, creatinine, and putrescine as sole source of nitrogen and taurine as source of sulfur.

In their study dealing with the complete genome analysis of *Arthrobacter* sp. Rue61a Niewerth et al. (2012) compared the Clusters of Orthologous Groups (COGs) of proteins of the genomes of all available *Arthrobacter* strains. These authors showed that the chromosomes of all *Arthrobacter* strains share only 1,014 homologous genes. Compared to the other genomes, *Arthrobacter globiformis* NBRC 12137^T shows the highest percentage of COG categories related to amino acid transport and metabolism, energy production and conversion, and lowest percentage of the COGs are found related to intracellular trafficking, secretion, and vesicular transport, signal transduction mechanisms, and transcription. In the genome of *A. arilaitensis* Re117^T, the percentage of COGs of the categories replication, recombination, and repair and translation, ribosomal structure, and biogenesis are significantly higher than in the other genomes and category carbohydrate transport and metabolism is the lowest. In the genome of *A. chlorophenolicus*, the percentage of COG category cell motility is approximately sixfold higher than in the other genomes and it also contains the highest percentage of COG category intracellular trafficking, secretion, and vesicular transport. *Arthrobacter* sp. Rue61a shows slightly higher percentages of the COGs carbohydrate transport and metabolism, general function prediction only, lipid transport and metabolism, and transport than the other genomes.

A. phenanthrenivorans Sphe3^T contains the second highest percentage of COG categories replication, recombination, and repair that is still significantly higher than in the remaining five genomes. In the genomes of *A. aurescens* TC1 and *Arthrobacter* FB24, percentages of all COGs are within the average of all genomes.

Bacteriophages

Probably the first report on *Arthrobacter*-lyzing bacteriophages (Conn et al. 1945) was published 2 years earlier than the proposal of the genus *Arthrobacter* (Conn and Dimmick 1947). In this study, Conn et al. (1945) showed that a bacteriophage, which was enriched using a culture labeled "Bact. glob." and showing the typical morphology of "*Bacterium globiforme*", lyzed only cells of the host but not any of some other isolates also regarded as members of *B. globiforme group*. Two bacteriophages of *A. globiformis* were isolated by Gillespie (1960). A bacteriophage reproducing in the type strain of *A. globiformis* was characterized by Einck et al. (1973). This bacteriophage named ΦAG8010 showed a slow adsorption rate to the host cells. On the basis of electron microscopic examination, the bacteriophage was assigned to Bradley's group B (Bradley 1967). It possesses a hexagonal head and an unsheathed tail. Casida and Liu (1974) isolated a virulent bacteriophage named FX-1 which was shown to infect two strains of *A. globiformis,* ATCC 8010^T and ATCC 4,336. These authors found some evidence that the sensitivity of the host cells to the bacteriophage is dependent on the growth phase. Lytic spectra of 11 *Arthrobacter* phage isolates were studied by Germida and Casida (1981) on two strains of *A. globiformis* (ATCC 8010^T and ATCC 4,336), five *Arthrobacter* isolates and several reference strains, of which nowadays only *A. crystallopoietes, A. oxydans*, and *A. ramosus* are still considered as members of the genus. In this study, bacteriophage GAP-15 lyzed only ATCC 8010^T. Bacteriophage GAP-16 lyzed *A. globiformis,* ATCC 8010^T and ATCC 4,336 and bacteriophage GAP-14 lyzed *A. globiformis,* ATCC 8010^T and ATCC 4,336 and *Arthrobacter* isolate SPI-1. This latter isolate was exclusively lyzed by bacteriophage GAP-40. Two bacteriophages, GAP-41 and GAP-42, were shown to cause lysis of the type strain of *A. oxydans*. Two *Arthrobacter* isolates, GSI-5 and GSI-1, were lyzed by bacteriophage GAP-32 and, in addition, *Arthrobacter* isolate GSI-5 was also lyzed by bacteriophage GAP-33. GSI-1 was also lyzed by bacteriophages GAP-30 and GAP-31. *Arthrobacter* isolate GSI-6 was lyzed by two phages, GAP-30 and GAP-34.

Seventeen bacteriophages infecting *Arthrobacter* isolates were recovered from concentrated samples of sewage and river water and nine of which were classified to be distinct (Brown et al. 1978). Based on tail length, these bacteriophages were assigned to Bradley's group B and C, respectively.

A lysogenic bacteriophage hosted by *Arthrobacter polychromogenes* was detected by Schippers-Lammertse et al. (1963) and characterized by Daems (1963). This bacteriophage is composed of a hexagonal head and a long, rigid tail sheath with cross-striations.

Phenotypic Analyses

Arthrobacters are forming colonies of <1–5 mm in diameter depending on medium composition and species examined. Colonies are usually opaque and the majority of arthrobacters are pigmented (light yellow–yellow-orange, creamy, white) or are colorless. Two species, *A. agilis* and *A. roseus*, are red-pink and red-rose pigmented, respectively. *A. polychromogenes* can show different colony pigmentations, depending on the growth medium (colorless, white, grayish, blue or green). Almost all *Arthrobacter* species exhibit a rod–coccus cycle, but *A. agilis* appears always as a coccus and *A. soli* was described to be rod-shaped. The vast majority of arthrobacters are nonmotile, but approximately on third of the species are motile. For some species, peritrichous or lateral flagellae were reported. The majority of species are strictly aerobic, but some are facultatively anaerobic. Catalase is usually produced, whereas oxidase is absent in the vast majority of *Arthrobacter* species. The majority of species are mesophilic, with temperature optima for growth between 20 °C and 30 °C. Usually, growth at 37 °C is slow or even absent. Some species are psychrotolerant, and some may be psychrophilic. The lowest growth temperature reported for *Arthrobacter* species is −6 °C (*A. cryotolerans* and *A. livingstonensis*; Ganzert et al. 2011). Arthrobacters are heterotrophic organisms utilizing a broad range of sugars, amino acids, and organic acids as sole source of carbon and energy. Sugars are utilized oxidatively, but some species are also capable to utilize sugars with production of acid. Some species, e.g., *A. chlorophenolicus, A. defluvii*, and *A. phenanthrenivorans*, are able to degrade toxic compounds such as 4-chlorophenol or phenanthrene.

Fatty acid profiles of arthrobacters are mainly consisting of *iso*- and *anteiso*-methyl branched fatty acids. A typical fatty acid profile of an arthrobacter exhibits the predominant compound *anteiso*-$C_{15:0}$ and usually *iso*-$C_{15:0}$ is the second major compound. Often, relatively high amounts of *iso*-$C_{16:0}$ and *anteiso*-$C_{17:0}$ are present, as well. In few species also significant amounts of the straight-chain fatty acid $C_{16:0}$ were detected. Unfortunately, in the past, fatty acids of arthrobacters were analyzed from biomasses that were not standardized for the physiological age at the point of harvest nor was the same medium composition applied to produce standardized biomasses. Since both, physiological age and medium composition, can influence the fatty acid profile significantly, published data are of little use for species identification or differentiation.

Arthrobacters can be divided into two groups based on differences in the quinone systems. One group contains monosaturated menaquinones whereas the other contains completely unsaturated menaquinones. The majority of established *Arthrobacter* species contain a mono-unsaturated menaquinone with nine isoprenic units in the side chain [MK-9(H_2)]. Three species, *A. scleromae* (Huang et al. 2005), *A. albus,* and *A. cumminsii* (Busse et al. 2012), contain menaquinone MK-8(H_2) and, unique among arthrobacters, *A. phenanthrenivorans* was reported (Kallimanis et al. 2009) to contain a menaquinone system composed of MK-8 and

MK-9(H_2). This quinone system is most surprising. Generally, quinone systems can be considered to be a rather conserved trait and all close relatives of this species comprising "*Arthrobacter oxydans* group" show predominantly menaquinone MK-9(H_2), only. Also unexpected is the observation that the quinone system is composed of a saturated and an unsaturated quinone which differ in the length of the isoprenic side chain. Species with menaquinone MK-9(H_2) were assigned to "globiformis" group (Stackebrandt et al. 1983) or "*A. globiformis/A. citreus group*" (Keddie et al. 1986). The second group contains species which show a quinone system with completely unsaturated isoprenoic units in the side chain with menaquinone MK-8, MK-9, or MK-10 predominating. Members of this group were named by Stackebrandt et al. (1983) the "nicotianae" group and by Keddie et al. (1986) the "*A. nicotianae group*."

The peptidoglycan of all *Arthrobacter* species examined contains lysine as the diagnostic diaminoacid and adjacent peptide side chains are cross-linked via L-lysine of one side chain and D-alanine at position four of the other. The interpeptide bridges contain either mono-carboxylic L-amino acid(s) or a di-carboxylic amino acid. Applying the three digit system of Schleifer and Kandler (1972), these two peptidoglycan types are designated A3α and A4α, respectively. *Arthrobacter* species showing peptidoglycan type A3α were assigned to "globiformis" group (Stackebrandt et al. 1983) or "*A. globiformis/A. citreus group*" (Keddie et al. 1986); species showing peptidoglycan type A4α were assigned to "nicotianae" group or "*A. nicotianae group*." However, large variability is present in the amino acid composition of the interpeptide bridge. On the basis of interpeptide bridge amino acid variability, Komagata and Suzuki (1987) defined seven groups. Group I contains Lys-Ser-Thr-Ala, group II contains Lys-Ala-Thr-Ala, group III contains Lys-$Ala_{1–4}$, group IV contains Lys-Ser-$Ala_{2–3}$, group V contains Lys-Thr-Ala_2, group VI contains Lys-Ala-Glu, and Group VII shows Lys-Glu. By now, two variants of group V have been detected in *Arthrobacter* species. *Arthrobacter agilis* (Koch et al. 1995), *Arthrobacter flavus* (Reddy et al. 2000), *Arthrobacter subterraneus* (Chang et al. 2007), *Arthrobacter tecti, Arthrobacter tumbae* (Heyrman et al. 2005), *Arthrobacter psychrolactophilus* (Loveland-Curtze et al. 1999), and *Arthrobacter alpinus* (Zhang et al. 2010) were shown to exhibit an interpeptide bridge containing of Lys-Thr-Ala_3. Quantitative amino acid analyses of the peptidoglycan of *Arthrobacter psychrochitiniphilus* suggest that the interpeptide bridge is Lys-Thr-Ala (Wang et al. 2009). Furthermore, some so far new amino acid compositions were found in five *Arthrobacter* species. *Arthrobacter castelli* contains Lys-Ala-Ser-Ala_3 in its interpeptide bridge (Heyrman et al. 2005); *Arthrobacter cumminsii* contains Lys-Ser(Gly)-Glu (Funke et al. 1996); *A. nasiphocea* contains Lys-Ala_2-$Gly_{2–3}$-Ala (Gly) (Collins et al. 2002), *Arthrobacter roseus* contains Lys-Gly-Ala_3 (Reddy et al. 2002), and *Arthrobacter woluwensis* contains L-Lys-D-Asp (Funke et al. 1996).

The first report on lipids in an arthrobacter strain was published by Walker and Bastl (1967). These authors showed that in the lipid profile of *Arthrobacter globiformis* strain 616, the glycolipids monogalactosyl diacylglycerol (MGDG), digalactosyl diacylglycerol (DGDG), and dimannosyl diacylglycerol (DMDG) are present. A more complete analysis of the polar lipid profiles of *A. globiformis* strain 616 and the type strains of *Arthrobacter crystallopoietes* and *Arthrobacter pascens* was reported by Shaw and Stead (1971). They confirmed the presence of the three glycolipids MGDG, DGDG, and DMDG in *A. globiformis* strain 616 and detected the same glycolipids in *A. crystallopoietes* and *A. pascens*. Evidence for the presence of trimannosyl diacylglycerol in the three strains was provided, as well and presence of tetramannosyl diacylglycerol was supposed. Furthermore the phospholipids phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), and phosphatidylinositol (PI) were detected in all three strains. Kostiw et al. (1972) were only able to confirm the presence of the glycolipids MGDG and DGDG and the phospholipid PG, DPG, and PI in *A. crystallopoietes*.

In the early1980s, the polar lipid profiles of additional *Arthrobacter* strains were analyzed by 2-dimensional thin layer chromatography (Collins et al. 1981, 1982; Collins and Kroppenstedt 1983) and an overall similarity in the polar lipid profiles was shown. All strains analyzed showed the presence of DPG, PG, and one or more unidentified glycolipids. Except *Arthrobacter nicotianae, Arthrobacter protophormiae,* and *Arthrobacter sulfureus,* all strains also exhibited the presence of PI. Furthermore, it was shown that the chromatographic motility of the unidentified major glycolipid of *A. sulfureus* was clearly different from those of all *Arthrobacter* strains studied. In conclusion from these studies, Keddie et al. (1986) supposed that one major glycolipid of all *Arthrobacter* species is dimannosyl diacylglycerol except *A. sulfureus* which contains the major glycolipid digalactosyl diacylglycerol.

The majority of *Arthrobacter* species, which were also analyzed for their polar lipids, were reported to contain DPG, PG, PI, and one or more unidentified glycolipids. However, reservations have to be expressed concerning polar lipid profiles reported for several *Arthrobacter* species. These reservations are based on the conserved character of polar lipid profiles indicated by the fact that closely related species usually do not show significant differences in their polar lipid profiles. The species *A. phenanthrenivorans* (Kallimanis et al. 2009), *A. antarcticus* (Pindi et al. 2010), *A. flavus* (Reddy et al. 2000), and *A. roseus* (Reddy et al. 2002) were reported to contain phosphatidylethanolamine (PE) and to lack any glycolipid. Within the family *Micrococcaceae*, the ability to synthesize PE appears to be absent whereas common to all *Micrococcaceae* species is the presence of at least one glycolipid. In the case of *A. roseus,* this reservation could be confirmed by 2D-TLC which demonstrated that this species does not contain PE but several glycolipids, of which one shows the chromatographic motility of DMDG (Busse, unpublished results). Also absence of any glycolipid in the polar lipid profiles of *A. tecti, A. tumbae* (Heyrman et al. 2005), and *A. russicus* (Li et al. 2004) is not in accordance with characteristics of their close relatives and re-analysis of the polar lipids would be desirable. A polar lipid profile composed exclusively of PG was reported for *A. livingstonensis* and *A. cryotolerans* (Ganzert et al. 2011). However, in addition to PG, the polar lipid profile of *A. livingstonensis* also contains

DPG, PI, and four unidentified glycolipids and *A. cryotolerans* contains in addition to PG also DPG and an unidentified glycolipid (Kai Mangelsdorf, pers. communication). This additional information concerning the polar lipid profile of *A. livingstonensis* and *A. cryotolerans* is well in accordance with the polar lipid profiles that were reported for related species.

Recently, the chemical structures of the major glycolipids of the type strains of *A. globiformis* and *Arthrobacter scleromae* were analyzed applying more sophisticated methods including matrix-assisted laser desorption/deionization Fourier transform ion cyclotron resonance mass spectrometry (MALDI FT ICR-MS) and 1D and 2D nuclear magnetic resonance (NMR) spectroscopy (Paściak et al. 2010). These studies demonstrated that in both strains, the major glycolipids are acyldimannosyl monoacylglycerol (ADMMG) and monogalactosyl diacylglycerol (MGDG). The presence of ADMMG was also detected in two other representatives of the *Micrococcaceae,* the type strains of *Sinomonas atrocyanea* (formerly *Arthrobacter atrocyaneus*) and *Rothia mucilaginosa* (Niepel et al. 1997; Paściak et al. 2004) whereas analyses of the chemical structure of the major glycolipid of the type strain of *Micrococcus luteus* revealed the presence of a dimannosyl diacylglycerol (Pakkiri et al. 2004).

Isolation, Enrichment, and Maintenance Procedures

The majority of *Arthrobacter* type strains were isolated, applying standard procedures regardless of their source of isolation. Only few of them were recovered applying enrichment procedures, especially those that were shown to degrade certain compounds, e.g., 4-chlorophenol.

Arthrobacter chlorophenolicus was recovered from aridic halplustoll, sandy loam (pH 7.5, 68.6 % sand, 16.1 % silt, 15.3 % clay) after enrichment with 4-chlorophenol (4-CP) (Westerberg et al. 2000). Two grams of soil were added to 300 ml GM medium (l^{-1}: 2.1 g K_2HPO_4, 0.4 g KH_2PO_4,0.5 g NH_4NO_3, 0.2 g $MgSO_4 \times 7H_2O$, 0.023 g $CaCl_2 \times 2H_2O$, 0.002 g $FeCl_2 \times 6\ H_2O$) containing 50 ppm 4-CP. When 30–50 % of 4-CP had disappeared, new 4-CP was added and this procedure was repeated over several times, increasing the concentration up to 350 ppm. Bacteria able to degrade 4-CP were isolated from the enrichment culture on GM agar plates containing 300 ppm 4-CP and 0.3 % yeast extract hardened at a slant with a top layer of GM agar, creating a diffusion gradient of 4-CP. 4-CP resistant bacteria were isolated by cross-streaking against the 4-CP gradient on the agar plates and purified by repeated streaking on GM agar containing 200 ppm 4-CP.

Also the 4-CP degrader *Arthrobacter defluvii* was isolated after enrichment with 4-CP (Kim et al. 2008). A sewage sample supplemented with 50 ppm 4-CP was applied to enrich 4-CP degraders and, after incubation, samples from a dilution series were plated on R2A agar and incubated for 14 days. Creamy white colonies were then selected for further characterization.

Arthrobacter nitroguajacolicus was isolated after enrichment in mineral medium supplemented with 0. 1 mM 4-nitrophenol (Kotoučková et al. 2004). The minimal medium consisted of (l^{-1}): $MgSO_4 \times 7H_2O$, 0.00025 g $FeCl_2 \times 6\ H_2O$, $(NH4)_2SO_4$, 0.42 g K_2HPO_4, 0.17 g KH_2PO_4, 0.88 g $Na_2HPO_4 \times 12\ H_2O$. After incubation on a rotary shaker at 28 °C, an aliquot of the enrichment culture (10 ml) was transferred to 100 ml minimal medium containing 4-nitroguaiacol. After decolonization of the medium, indicating degradation of 4-nitroguaiacol, samples were spread on solid minimal medium supplemented with 4-nitroguaiacol and incubated until appearance of single colonies.

Arthrobacter phenanthrenivorans was isolated from a creosote-polluted soil after enrichment with phenanthrene; 100 ml minimal medium (Sambrook et al. 1989) was supplemented with 0.01 % phenanthrene as the sole source of carbon and energy and incubated for 7 days at 30 °C. After serial dilutions on solid medium, colonies able to grow in the presence of phenanthrene were selected, out of which one was characterized in detail.

Arthrobacter sulfonivorans and *Arthrobacter methylotrophus* were isolated after enrichment with dimethylsulfone as the sole source of carbon and energy (Borodina et al. 2000; 2002). Enrichment was carried out in minimal medium which was composed of (l^{-1}) 7.9 g $Na_2HPO_4 \times 2\ H_2O$, 1.5 g K_2HPO_4, 0.1 g $MgSO_4$, 0.8 g NH_4Cl, and 10 ml trace element solution (Tuovinen and Kelly 1973) and supplemented with 10 mM dimethylsulfone. The medium (100 ml) was inoculated with 10 g soil, and incubation was carried out at 10–15 °C. After serial incubation in fresh medium, samples were spread on agar supplemented with saturated aqueous phenol red in order to detect acid production as a result of the oxidation of dimethylsulfone. Positive colonies were transferred to agar medium and incubated at 25 °C.

Arthrobacter psychrochitiniphilus was isolated from fresh penguin guano samples after enrichment with colloidal chitin (Wang et al. 2009). Agar solidified M9 minimal medium [(l^{-1}) 12.8 g $Na_2HPO_4 \times 7\ H_2O$, 3.0 g K_2HPO_4, 0.5 g NaCl, 0.1 g, 1.0 g NH_4Cl] was inoculated with dilutions of the guano samples. Agar plates were incubated for 7–28 day at 10 °C and colonies were subcultivated for purification.

Arthrobacter creatinolyticus strains were isolated from urine with unusually low creatinine concentrations and due to their ability to hydrolyze creatinine (Hou et al. 1998).

Arthrobacters are not fastidious organisms and since, for long-term conservation, standard procedures can be applied including freezing of cell suspensions in glycerol solution at −80 °C or lyophilization.

Ecology

Arthrobacters are considered to be ubiquitous as they could be found in soil, water, and air. Type strains of the genus were isolated from soil including forest soil, humus soil, rockery soil, paddy soil, soil of the root system, a filtration substrate made from volcanic rock and alpine soil, from wastewater sediments, Antarctic lake sediments and Antarctic sea sediments, from deep surface water, sewage and sea water, from cyanobacterial mats from the Antarctica, from human skins and human clinical

sources, from animals sources like a cattle with mammary and uterine infections, the nose of the common seal, the fly *Protophormia terraenovae*, organs of Greenland halibut, the guano of Adelie penguins, chicken feces and poultry litter, from plant, e.g., cured tobacco leaves, from surfaces of cheese and biofilms, and from the air in the Russian space station Mir.

Arthrobacter strains are commonly detected among cultured strains of microbial communities of terrestrial subsurfaces and are often among the predominant members. Crocker et al. (2000) isolated *Arthrobacter* strains from unconsolidated subsurface sediments. *Arthrobacter*-like strains accounted for 24 % of the 169 isolates obtained. However, the relative proportion of *Arthrobacter*-like isolates varies from one lithology to another. Twenty-nine percent of the 91 strains isolated from lacusterine sediment samples were closely related to *Arthrobacter*, whereas only one out of 47 isolates from the upper paleosol samples was identified *Arthrobacter*-like.

Arthrobacter has also been detected in several other subsurface environments including saturated Atlantic coastal plain sediments (20 % of 187 heterotrophic isolates; Balkwill and Boone 1997; Reeves et al. 1995), deep mine gallery clays (Boivin-Jahns et al. 1995), a karstic aquifer (Rusterholtz and Mallory 1994), a basalt aquifer (Zheng and Kellog 1994), unwelded volcanic tuffs (21 % of 119 isolates; Haldeman et al. 1993), and root domains of mature sugar beet (12 % of 556 isolates; Lilley et al. 1996). Lee and Kim (2003) observed *Arthrobacter* strains to be the dominant population of the biofilm from a Seoul water distribution system at operating day 7.

Members of the genus *Arthrobacter* are usually regarded as obligate aerobes. In order to survive periods of oxygen limitations due to changes in oxygen tension in the upper layer of soil, some *Arthrobacter* species have developed alternative, oxygen-independent growth strategies. For instance, under anaerobic conditions, *Arthrobacter nicotinae* reduces nitrate to ammonia, while *Arthrobacter globiformis* uses nitrate as terminal electron acceptor and is able to carry out mixed acid fermentation (Eschbach et al. 2003).

Members of the genus *Arthrobacter* utilize a wide variety of organic compounds, xenobiotica, and other harmful substances (see applications), and hence, they play a significant role in the transformation of organic matter in natural environment. Certain *Arthrobacter* strains are able to tolerate high concentrations of heavy metals like cadmium and copper or even carry out detoxification by accumulation of the heavy metals in their outer layer which may support degradation of harmful compounds in metal-contaminated soils (Roane and Pepper 2000; Konstantinidis et al. 2003).

Pathogenicity: Clinical Relevance

Arthrobacter spp. are widely distributed in the environment, especially in soil where they are considered to constitute a major part of the community but recently certain species have been recognized as opportunistic pathogens.

Due to difficulties in identifying *Arthrobacter* strains by conventional biochemical assays, the first *Arthrobacter* strains from clinical specimen were identified by using 16S rRNA gene sequence analyses (Funke et al. 1996). After this initial finding, several other studies have been published regarding the appearance of *Arthrobacter* spp. in clinical specimens (Park et al. 2012; Mages et al. 2008; Kim et al. 2007; Huang et al. 2005; Bernasconi et al. 2004; Wauters et al. 2000; Hou et al. 1998; Hsu et al. 1998). Among the 66 established *Arthrobacter* species, six were isolated from clinical sources, namely, *Arthrobacter albus* (Wauters et al. 2000), *Arthrobacter creatinolyticus* (Hou et al. 1998), *Arthrobacter cumminsii* (Funke et al. 1996), *Arthrobacter luteolus* (Wauters et al. 2000), *Arthrobacter woluwensis* (Funke et al. 1996), and *Arthrobacter sanguinis* (Mages et al. 2008). In addition, some strains of *Arthrobacter oxydans* were isolated from blood (Wauters et al. 2000). *Arthrobacter scleromae* (Huang et al. 2005) was isolated from swollen scleromata of a dermatosis patient, *A. protophormiae* from urine, *A. aurescens* from wound swab, and *A. oryzae* from neck abscess (Mages et al. 2008). According to the study from Mages et al. (2008), the most frequently encountered arthrobacter was *Arthrobacter cumminsii*, isolated from urine, wound swab, blood culture, tracheal secretion, cervix, and otitis externa. This investigation is in accordance with the previously published data (Funke et al. 1998; Wauters et al. 2000). Furthermore, *A. oxydans* represented more than 20 % of the clinical strains isolated from wound swab, nasal swab, vaginal swab, eye, blood culture, and lung swab at autopsy. In the study of Wauters et al. (2000), two out of five clinical *Arthrobacter* strains were identified as members of the species *A. oxydans*. The third most frequently found *Arthrobacter* species was *A. aurescens* isolated from wound swab and urine which has not been reported before being isolated from human clinical specimens.

Arthrobacter spp. were identified to be the cause of human diseases, e.g., bacteremia, postoperative endophthalmitis, Whipple's disease-like syndrome, and phlebitis (Bernasconi et al. 2004; Shin et al. 2006; Park et al. 2012). *Arthrobacter cumminsii* might be the bacterial agent responsible for selected cases of urinary tract infections (Mages et al. 2008).

Antibiotica Sensitivity

Only few data are available concerning susceptibility of *Arthrobacter* toward antibiotics. Funke et al. (1996) tested 24 *Arthrobacter* strains, including the type strains of *A. globiformis*, *Sinomonas atrocyanea* (formerly *A. atrocyaneus*), *A. aurescens*, *A. crystallopoietes*, *A. histidinolovorans*, *A. nicotinovorans*, *A. oxydans*, *A. pascens*, *A. ramosus*, *A. ureafaciens*, *A. nicotianae*, *A. protophormiae*, *A. uratoxydans*, *A. cumminsii*, and *A. woluwensis* for susceptibility to the antibiotics amoxicillin-clavulanic acid, ampicillin, ceftriaxone, cefuroxime, cefalothin, chloramphenicol, ciprofloxacin, clindamycin, erythromycin, gentamicin, imipenem, penicillin, rifampin, teichoplanin, tetracycline, and vancomycin. Only the glycopeptide antibiotic teichoplanin suppressed growth of all *Arthrobacter* strains

included in this study. Except *A. woluwensis,* all investigated strains were susceptible to amoxicillin-clavulanic acid, ampicillin, cefalothin, erythromycin, penicillin, and vancomycin. Only *Arthrobacter woluwensis* type strain showed a multidrug resistant pattern, being only susceptible to teichoplanin and moderately susceptible to tetracycline. Mages et al. (2005) investigated the susceptibility patterns of 38 *Arthrobacter* strains from cinical sources. Nearly all strains were susceptible to β-lactam antibiotics, doxycycline, gentamicin, linezolid, rifampin, and vancomycin. In contrast to the result of Funke et al. (1996), strains of *Arthrobacter woluwensis* exhibited no multidrug resistance, indicating that this trait is not characteristic for this species.

Application

Members of the genus *Arthrobacter* are abundant and ubiquitous in soil and are capable of degrading a wide variety of harmful synthetic organic compounds including aliphatic, aromatic, and polycyclic aromatic compounds (*Fig. 5.3*). Hence, they are playing an important role in the bioremediation of soils contaminated with pesticides, herbicides, and insecticides.

The enormous degradation potential of *Arthrobacter* strains seems to be based on the adoption to new environments and numerous biotic and abiotic stresses in the course of evolution. These adoptions might be the result of gene recruitment, gene modifications, and/or horizontal transfer. This notion is strengthened by the fact that degradation genes of many xenobiotics are often plasmid encoded.

Interaction between different degradable compounds can significantly influence their decomposition rates. *Arthrobacter* species MTCC 1553 efficiently degrades phenol, *o*-cresol, and *p*-cresol. In mixtures of phenol and *p*-cresol, degradation of phenol is strongly inhibited rather than *p*-cresol degradation. On the other hand, in a mixture of phenol and *o*-cresol, degradation of phenol is slightly increased whereas degradation of *o*-cresol is unaffected (Kar et al. 1997).

Sinomonas atrocyanea (formerly *Arthrobacter atrocyaneus*) MCM B-425 shows the capability of 93 % removal of the extremely harmful, organophosphorus pesticide Monocrotophos (MCP) from a synthetic medium containing 1,000 mg l^{-1} of the pesticide with the end products phosphates, ammonia, and carbon dioxide (Bhadbhade et al. 2002).

Arthrobacter oxydans strain P52 degrades the phenylcarbamate herbicides phenmedipham and desmedipham co-metabolically (Pohlenz et al. 1992). The degradative enzyme, the phenylcarbamate hydrolase, is a monomer with a molecular weight of 55,000 and, most likely, the corresponding gene is plasmid encoded.

Arthrobacter strain TE1 utilizes s-ethyl-*N*,*N*-dipropylthiocarbamate as a sole source of carbon (Tam et al. 1987). The enzyme is encoded on a 50.5 mDa plasmid. Hayatsu et al. (1999) isolated *Arthrobacter* sp. strain RC100 from carbaryl-treated soil which is capable of utilizing carbaryl (1-naphthyl-*N*-methylcarbamate) as a sole carbon source. The carbaryl degradation pathway of the strain is encoded by two distinct large plasmids. The initial reaction from carbaryl (1-naphthyl-*N*-methylcarbamate) to 1-naphthol is encoded by plasmid pRC1 and the following reactions to salicylaldehyde, salicylic acid, and gentisic acid are encoded by plasmid pRC2. Final reactions leading to the end products CO_2 and H_2O are encoded on the chromosome. *Arthrobacter* sp. GLP-1 and *Sinomonas atrocyaneus* ATCCC 13752 have been shown to utilize the herbicide glyphosate as a sole source of phosphorus and nitrogen (Pipke and Amrhein 1988a, b). However, in contrast to *Arthrobacter* sp. strain GLP-1, *S. atrocyaneus* could only use a rather limited number of organophosphonates as sole source of phosphorus, including aminomethylphosphonic acid, 1-amino-butylphosphonic acid, and glyphosate.

Cullington and Walker (1999) studied an isolate, designated D47, for degradation capabilities of phenylurea herbicides. This isolate was obtained after enrichment of a soil sample with diuron. The latter authors demonstrated that strain D47 was able to utilize the phenylurea herbicides linuron, diuron, monolinuron, metoxuron, and isoproturon as sole source of carbon whereas the derivatives 3-(3,4-dichlorophenyl)-1-methylurea and 3-(3,4-dichlorophenyl)-urea were not. In the following study, Turnbull et al. (2001a) identified strain D47 as a member of the genus *Arthrobacter* and despite the closer relationship to *Arthrobacter citreus* and *Arthrobacter polychromogenes*, the strain was named *Arthrobacter globiformis* D47. In this study, it was also demonstrated that *Arthrobacter globiformis* D47 metabolizes diuron by hydrolysis of the urea side chain at the carbonyl group with accumulation of 3,4-dichloroaniline and loss of carbon dioxide (Turnbull et al. 2001a). In cell-free extracts, it was shown that the degradative activity is optimal at a temperature between 15 °C and 30 °C and a pH between 6.5 and 8.0 whereas salt concentrations >50 mM reduce the activity. Turnbull et al. (2001b) showed that diuron degradative genes are located on a 47 kb plasmid. The diuron degradative enzyme consists of 456 amino acids as predicted from the cloned gene sequence and named phenylurea hydrolase (*puh* gene). Another strain, *Arthrobacter* sp. N2 (CIP 105365), which had been isolated after enrichment with diuron from long-term herbicide treated soil, was shown to metabolize the diuron to 3,4-dichloroaniline (Wideham et al. 2002). Degradation of diuron was shown to be more efficient in the presence of alternative carbon and nitrogen sources. *Arthrobacter* sp. N2 is also able to biotransform the phenylurea herbicides isoproturon and chlorotoluron, resulting in the formation of the corresponding substituted anilines isopropylaniline and 3-chloro-4-methylaniline, respectively (Tixier et al. 2002). Complete diuron degradation was achieved by a mixed culture, consisting of *Arthrobacter* sp. N4 (close to aforementioned N2) and *Delftia acidovorans* W34 (Bazot et al. 2007). Total mineralization of diuron was observed with free cells and with alginate fixed cells.

Rousseaux et al. (2001) isolated three *Arthrobacter crystallopoietes*–related strains from three geographically different soils in France that are capable of atrazine degradation. These strains are not able to mineralize the atrazine ring as

indicated from the accumulated intermediate compound cyanuric acid. The three strains harbor the genes *atz*B and *atzC* both of which sharing high gene sequence similarity with the corresponding genes of the well-known atrazine degrader *Pseudomonas* sp. ADP. These genes are encoding enzymes catalyzing degradation of hydroxyatrazine to *N*-isopropylammelide and cyanuric acid, respectively. In addition, evidence for presence of a gene similar to *atz*A was provided that shows only low sequence similarity with the corresponding gene of *Pseudomonas* sp. ADP. On the other hand, *atz*D found in *Pseudomonas* sp. strain ADP is absent in the three *A. crystallopoietes* similar strains. In a following study, Rousseaux et al. (2002) reported the presence of a gene homologous to the triazine hydrolase *trz*N gene in the three *A. crystallopoietes*-related strains.

Arthrobacter aurescens strain TC1 uses diverse s-triazine ring compounds as the sole source of nitrogen, carbon, and energy, including the herbicides atrazine, ametryn, atratone, cyanazine, prometryn, and simazine. Moreover, atrazine substrate analogs containing fluorine, mercaptan, and a cyano group in place of the chlorine substituent are also used as growth substrates. *A. aurescens* strain TC1 also metabolizes compounds containing chlorine plus N-ethyl, N-propyl, N-butyl, N-isobutyl, or N-t-butyl substituents on the s-triazine ring. Atrazine is metabolized to alkylamines and cyanuric acid, consuming up to 3 mg atrazine per liter (Strong et al. 2002). Strain TC1 contains the genes *atzB*, *atzC*, and *trzN* but not *atz*A. Sajjaphan et al. (2004) showed that *Arthrobacter aurescens* strain TC1 contains two large plasmids pAA1 and pAA2, and suggested that the genes *trzN*, *atzB* and *atzC* are located on plasmid pAA1.

Cai et al. (2003) isolated *Arthrobacter* sp. strain AD1 from industrial waste water from a herbicide production facility in china. On the basis of high 16S rRNA sequence similarity (>99.8 %), *Arthrobacter* sp. strain AD1 was identified as a close relative of *Arthrobacter ureafaciens*. *Arthrobacter* sp. strain AD1 degrades atrazine very efficiently. It utilizes sucrose and sodium citrate as carbon sources and atrazine as a sole nitrogen source. Bioremediation experiments using soil experimentally contaminated with up to 1 mg/g of atrazine resulted in 96 % of atrazine removal by strain AD1 at 30 °C within 4 weeks. In a control experiment, only 83 % of atrazine was removed by *Pseudomonas* sp. strain ADP.

Chlorinated benzoic acids (CBAs) are known to be intermediates in the metabolism of herbicides and chlorinated biphenyls (Abramowicz 1995; Komancová et al. 2003; Pettigrew et al. 1990). Hydrolytic dehalogenation of 4-CBA has been described for *Arthrobacter* TM-1 which can use this component as sole source of energy and carbon (Marks et al. 1984). In the initial step, 4-CBA is dehalogenated to 4-hydroxybenzoate and further metabolized to protocatechuate. In cell extracts, 4-fluoro- and 4-bromobezoate are dehalogenated as well.

Schmitz et al. (1992) reported 4-CBA dehalogenation in cell extracts and intact cells of *Arthrobacter* sp. strains TM1 and SU. Cell-free extracts of strain TM1 also dehalogenated 3- and 2-CBA but with less efficiency. However, 3-CBA was only dehalogenated by intact cells if 4-CBA was added as a co-substrate whereas intact cells did not metabolize 2-CBA under any condition. In strains TM1 and SU, 4-CBA is hydrolytically dehalogenated to *p*-hydroxybenzoate, requiring ATP and CoA, suggesting involvement of 4-CBA-CoA ester. As also reported for *A. globiformis* KZT1 (Zaitsev et al. 1991), the dehalogenese genes of *Arthrobacter* sp. strain SU are encoded on a plasmid (pASU) and organized in an operon containing three open reading frames (ORFs). Two of these genes exhibit high sequence similarity to corresponding genes of *Pseudomonas* sp. strain CBS3 encoding for 4-CBA-CoA-ligase (*fchA* gene) and 4-CBA-CoA-delagogenase (*fcbB* gene), whereas no significant sequence similarity was found for the third ORF (*fcbC* gene) supposed to encode for a thioesterase. In substrate activity experiments with the purified FcbC protein of strain SU, Zhuang et al. (2003) identified the enzyme as a 4-hydroxybenzoate-CoA thioesterase. Since no plasmid could be detected in strain TM1, obviously, genes mediating dehalogenation of 4-CBA are encoded on the chromosome.

Evidence was provided that also in other 4-CBA-degrading *Arthrobacter* isolates, the corresponding dehalogenation gene cluster is either located on the chromosome or a plasmid. Yi et al. (2000) isolated three *Arthrobacter* strains from upland and rice-field soils in South Korea which are capable to utilize 4-CBA. *Arthrobacter* sp. strain HR15 (devoid of any plasmid) was able to degrade 4-CBA, 4-bromobenzoic acid, and benzoic acid; *A. protophormiae* strain HR17 (carrying one plasmid) utilized 4-CBA and benzoic acid; *A. globiformis* strain HR19 (devoid of any plasmid) utilized 4-CBA, 4-iodobenzoic acid and 4-bromobenzoic acid.

The type strain of *Arthrobacter chlorophenolicus* A6^T was isolated from a soil suspension after enrichment with 4-chlorophenol (4-CP). During adaptation (165 day) to 4-CP, the ability of strain A6^T to degrade 4-CP and the rate of degradation increased from 50 to 350 ppm 4-CP and 8.0 to 33.2 ppm d^{-1} Strain A6^T utilizes 4-CP as sole source of carbon and energy and removed 4-CP completely from the medium. It can also grow on phenol, *p*-bromophenol, *p*-nitrophenol, and *p*-fluorophenol. Strain A6^T retains 4-CP-degradation ability even when serially cultivated on non-selective medium. Since no plasmid could be detected in A6^T, it is assumed that the degradative genes are chromosomally encoded (Westerberg et al. 2000).

Successful bioremediation of soil contaminated with high concentrations of 4-chlorophenol (175µg l^1 dry weight) with the 4-CP adapted strain *Arthrobacter chlorophenolicus* A6 was described by Elväng et al. (2001). The 4-CP was completely degraded in soil to background level after incubation for 7 days. Therefore, this strain is promising for bioremediation of field sites contaminated with high concentrations of 4-CP. Jernberg and Jansson (2002) applied a variant of *Arthrobacter chlorophenolicus* A6, chromosomically tagged with the firefly luciferase gene *luc* (strain A6L), for monitoring changes in the population of strain A6L corresponding to biodegrading of 4-CP and members of the indigenous microbiota and was found to have a significantly higher abundance is soils contaminated with 4-CP.

Another taxonomically sufficiently characterized 4-CP degrader, *Arthrobacter defluvii*, was described by Kim et al. (2008). The two isolates assigned to the species *A. defluvii* were

recovered from 4-CP stimulated sewage in Korea. The isolates removed 100 ppm 4-CP completely from the medium and were resistant at up to 200 ppm 4-CP.

A new pathway of 4-chlorophenol (4-CP) degradation was found in the isolate *Arthrobacter ureafaciens* strain CPR706 (Bae et al. 1996). Strain CPR706 degrades 4-CP via a hydroquinone pathway, in which the chloro-substituent is eliminated in the first step and hydroquinone is produced as a transient intermediate. Compared to other 4-CP-degrading bacteria carrying out hydroxylation of 4-CP to form chlorocatechol, this strain exhibited much higher substrate tolerance and degradation rate. In addition to 4-CP, strain CPR706 also degrades other para-substituted phenols such as 4-nitro, 4-bromo, 4-iodo, and 4-fluorophenol) via the same pathway.

A 4-fluorophenol degrading *Arthrobacter* sp. strain IF1 was isolated by Ferreira et al. (2008) after enrichment from soil samples that are contaminated with halogenated aliphatic compounds. The isolate IF1 showed highest 16S rRNA gene sequence similarity with the type strain of *Arthrobacter nitroguajacolicus*. The strain grows on catechol, hydroquinone, hydroxyquinol, benzoate, phenol, 4-fluorocinnamic acid, and 4-nitrophenol as substrates but not with 2-fluorophenol, 3-fluorophenol, 4-chlorophenol, 4-bromophenol, 4-iodophenol, fluoroacetate, trifluoroacetate, fluoroacetamide, trifluoroethanol, or on 2-bromoethanol. In batch culture, it is able to mineralize 5 mM 4-fluorophenol and to use it as the sole source of carbon and energy. It is suggested that strain IF1 degrades 4-fluorophenol, starting with removal of fluorine, yielding benzoquinone by a monooxygenase which is subsequently reduced to hydroquinone and in the following step, the hydroquinone is hydroxylated to hydroxyquinol which is then converted to maleylacetate and subsequently to 3-oxoadipate.

Ferreira et al. (2009) showed that *Arthrobacter* sp. strain IF1 harbors two gene clusters (clusters A and B). Cluster A contains four ORFs encoding for putative proteins associated with 4-fluorophenol degradation, *fpdA1, fpdD, fpdE,* and *fdpT1*. Cluster B contains the ORFs *fpdA2, fpdB, fpdC, fpdR, fpdT2,* and *fdpX*. Interestingly, in both gene clusters, ORFs are found encoding for a monooxygenase (*fpdA1* and *fdpA2*). At the deduced amino acid level, the two enzymes are sharing 98.9 % sequence similarity. The two sequences share highest similarity with a 4-nitrophenol monooxygenase of *Arthrobacter* sp. strain JS443 and the hydrolase component of 4-chlorophenol monooxygenase of *Arthrobacter chlorophenolicus* A6. Open reading frames *fpdD* and *fpdE* (cluster A) show some sequence similarity with a maleylacetate reductase of *Arthrobacter* sp. strain JS443 which is involved in degradation of *p*-nitrophenol and to α/β-hydrolase fold family enzyme, respectively. The putative reductase (*fpdB* ORF) is only present in cluster B. The deduced protein shares highest amino acid sequence similarities with the reductase component of the monooxygenase systems of *Arthrobacter* sp. strain JS443 (92 %) and *Arthrobacter chlorophenolicus* A6 (86 %) that reduce FAD to $FADH_2$ (flavine reductase). ORF *fpdC* encodes a putative protein with a high similarity to hydroxyquinol dioxygenase which is involved in 4-chlorophenol degradation in *Arthrobacter chlorophenolicus* A6. ORF *fpdX* is assumed to encode a putative periplasmic binding protein. In ORF *fpdR*, a nucleotide-binding domain and a helix-turn-helix (HTH) motif are present that are similar to putative regulator genes encoded in *p*-nitrophenol and 4-chlorophenol degradation gene clusters found in *Arthrobacter* sp. strain JS443 and *Arthrobacter chlorophenolicus* A6. So far, ORF *fpdT2* is of unknown function. It is located at a similar position like a corresponding ORF in the *p*-nitrophenol gene cluster in *Arthrobacter* sp. strain JS443.

The isolate *Arthrobacter protophormiae* RKJ100 was recovered from a soil sample after enrichment with *p-nitrophenol* (Chauhan and Jain 2000). RKJ100 was shown to utilize *o*-nitrobenzoate as the sole source of nitrogen, carbon, and energy. The degradation of *o*-nitrobenzoate is an oxygen-insensitive reductive catabolic pathway and yields *o*-hydroxylaminobenzoate and anthranilic acid as the terminal aromatic intermediate. Experimental data suggested that the corresponding genes are located on a 65 kb plasmid.

A *p*-nitrophenol-degrading isolate, *Arthrobacter* strain JS443, was described by Jain et al. (1994). The 16S rRNA gene sequence of strain JS443 (accession no: ef078488; Perry and Zylstra 2007) shares highest similarities (>99 %) with the type strains of *Arthrobacter ureafaciens* and *Arthrobacter nicotinovorans,* placing it in the "*Arthrobacter aurescens* group." Mainly on the basis of growth experiments, Jain et al. (1994) supposed that strain JS443 transforms *p*-nitrophenol to 1,2,4-benzenetriol, via 4-nitrocatechol and 4-nitroresorcinol and, after ring fission to maleylacetic acid, degradation follows the β-ketoadipate pathway.

A deviating catabolic pathway was proposed by Perry and Zylstra (2007) for degradation of *p*-nitrophenol by *Arthrobacter* strain JS443. These authors identified in strain JS443 a gene cluster designated *rpd*. The gene cluster harbors the genes *npdA1, npdA2 npdB, npdC, npdR, npd X,* and *orf6*. Based on cloned genes, sequencing, and comparison with genes of *Arthrobacter chlorophenolicus* encoding enzymes of the 4-chlorophenol degradation pathway, *npdA1* was identified to encode a putative NADH-dependent flavin reductase and *npdA2* a putative *p*-nitrophenol monooxygenase belonging to the two-component flavin-diffusible monooxygenase family. Gene *npdB* encodes a hydroxyquinol 1,2-dioxygenase, gene *npdC* a putative maleylacetate reductase, and *npdR* is assumed to be a regulatory gene. No function was assigned to the genes *npdX* and *orf6*. On the basis of genes putatively identified in JS443 and degradation experiments, Perry and Zylstra (2007) proposed that in the first reaction, the NADH-dependent flavin reductase catalyzes the release of nitrite and transformation of *p-nitrophenol* to 2-hydroxy-1,4-benzoquinone via 1,4-benzoquinone which is then reduced by an unidentified reductase to 1,2,4-hydroxyquinol. The hydroxyquinol 1,2-dioxygenase catalyzes cleavage of 1,2,4-hydroxyquinol to maleylacetate reduced to β-ketoadipate. As indicated by the appearance of 4-nitrocatechol in the reactions in a sideway, an unknown oxygenase may convert *p*-nitrophenol to 4-nitrocatechol and NADH-dependent flavin reductase catalyzes the release of nitrite and formation of 2-hydroxy-1,4-benzoquinone.

Arthrobacter strain JS443 has been successfully applied for development of a whole cell amperometric biosensor for *p*-nitrophenol (Lei et al. 2003). The biosensor measures the oxidation current of the intermediates of *p*-nitrophenol degradation, namely, 4-nitrocatechol and 1,2,4-hydroxyquinol (1,2,4-benzenetriol). Under optimized conditions, the biosensor measured as low as 5 nM *p*-nitrophenol.

Three *Arthrobacter* strains were isolated from the microbial community in soil surrounding an outdoor coal storage pile which were capable of growth with naphthalene as sole carbon source at low pH values (Dore et al. 2003). Phylogenetically, one strain was placed in the vicinity of "*Arthrobacter aurescens* group" (isolate 5), whereas the other two strains clustered next to "*Arthrobacter psychrolactophilus* group" (isolates 4 and 13). They showed a range of acid and heavy-metal tolerances (pH 3–7, mercury tolerance: 6–20µg/ml). None of the genes related to naphthalene degradation were found in the three isolates: neither *nahAc, nahAd, phnAc, nahH, xylE,* nor *GST.* However, evidence was provided that these *Arthrobacter* isolates do not mineralize naphthalene completely.

A phenanthrene degrading strain, *Arthrobacter* sp. P1-1, was isolated from a PAH contaminated soil collected from Hilo, Hawaii (USA), after enrichment. The strain was identified as a member of the genus *Arthrobacter* on the basis of highest sequence similarity with another strain, *Arthrobacter* sp. BS20 (Seo et al. 2006). A pre-grown culture (optical density 0.05 at 540 nm) of *Arthrobacter* sp. P1-1 completely degrades 40 mg l^{-1} of phenanthrene in a minimal medium shake culture at 28 °C within 7 days, suggesting that it utilizes this compound as a sole source of carbon and energy. Metabolic analyses suggest that the degradation starts with dioxygenation on 1,2-, 3,4-, and 9,10-C of phenanthrene. Intermediate degradation products indicated that phenanthrene-1,2- and −3,4-diols undergo *meta*-cleavage, but to a limited extent also *ortho*-cleavage may occur. Naphthalene-1,2-diol is then formed via 1-[(*E*)-2-carboxyvinyl]-2-naphthoic acid, naphthalene-1,2-dicarboxylic acid, and 1-hydroxy-2-naphthoic acid. Naphthalene-1,2-diol is then further degraded through the phthalic acid and salicylic acid pathways.

Even higher phenanthrene concentrations are degraded by *Arthrobacter phenanthrenivorans* Sphe3^T (Kallimanis et al. 2007). This strain catabolizes 90 % of 400 mg/l phenanthrene in a minimal medium within 4 days. Vandera et al. (2012) identified in strain Sphe3 two gene loci for 1-hydroxy-2 naphthoic acid dioxygenases which are associated with phenanthrene utilization. The *diox1* gene is located on a plasmid and the *diox2* gene on the chromosome. At the amino acid level, the two enzymes share 93 % sequence homology but only 85 % with the corresponding protein of a *Nocardioides* strain. Both genes are induced in the presence of phenanthrene in the medium, but only minimal expression occurs in the presence of glucose or glucose + phenanthrene. The *diox2* gene is twofold higher upregulated than the *diox1* gene. The occurrence of two genes encoding 1-hydroxy-2 naphthoic acid dioxygenases in Sphe3 renders the strain more advantageous for PAH biodegradation and hence more adjustable to polluted environments. These duplicates may provide an advantage for microbial adaption to environment changes.

Promising results of phenanthrene degradation in soils after inoculation with a phenanthrene-degrading *Arthrobacter* strain were obtained by Schwartz and Scow (1999) and Schwartz et al. (2000). These authors carried out experiments with *Arthrobacter* strain RP17, which had been isolated from soil after enrichment with phenanthrene as a sole carbon source in Forbes soil, which contained a microbial community unable to rapidly degrade phenanthrene. After inoculation with a culture of the nonindigenous *Arthrobacter* strain RP17, a significant decrease of phenanthrene in the soil could be measured, suggesting phenanthrene degradation.

Quinaldine is utilized by *Arthrobacter nitroguajacolicus* Ru61a^T as a sole source of carbon and energy via the anthranilate pathway (Parschat et al. 2003, 2007). Genes for quinaldine degradation are encoded on the linear catabolic plasmid pAL1 (Overhage et al. 2005), and they are organized in two operons. Evidence was provided that quinaldine is converted to anthranilate via 1*H*-4-oxoquinaldine, 1*H*-3-hydroxy-4-oxoquinaldine, and *N*-acetylanthranilic acid involving the enzymes quinaldine 4-oxidase (Qox), 1*H*-4-oxoquinaldine 3-monooxygenase (Moq), 1*H*-3-hydroxy-4-oxoquinaldine 2,4-dioxygenase (Hod), and *N*-acetylanthranilate amide hydrolase. It is hypothesized that anthranilate is then degraded by two different routes. Detection of the intermediate catechol and the ability of a pAL1-deficient mutant of Ru61a^T to grow on anthranilate and catechol as carbon sources strongly suggest that degradation proceeds via the β-ketoadipate pathway. However, genes encoding for the catechol-generating enzymes anthranilate 1,2-dioxygenase and a catechol dioxygenase were not detected on the plasmid but might be encoded by the chromosome. Presence of a second route for anthranilate degradation is assumed by relatively high amino acid sequence similarities of proteins deduced from OFRs abd encoded on plasmid pAL1. These proteins indicate degradation of anthranilate via 2-aminobenzoyl-CoA and 2-amino-5-oxo-cyclohex-1-ene-carbonyl-CoA.

Arthrobacter nicotinovorans (Kodama et al. 1992) has the ability to use the tobacco alkaloid nicotine as its sole carbon and energy source (Decker et al. 1961; Eberwein et al. 1961; Gherna et al. 1965; Hamm and Decker 1978). Corresponding genes are encoded by plasmid pAO1, including a heterotrimeric 6-hydroxypseudooxynicotine dehydrogenase and 2,6-dihydroxypyridine 3-hydroxylase (Baitsch et al. 2001). Gabor and Brandsch (2003) identified on the plasmid the genes for a nicotine dehydrogenase, a 6-hydroxy-L-nicotine oxidase, a ketone dehydrogenase, and an L-nicotine uptake system.

Arthrobacter ureafaciens SP1b-5 isolated from soil of a wash water soakway at a disused nitroglycerin manufacturing plant in Somerset West, South Africa, after enrichment is capable to utilize nitroglycerin as its sole nitrogen source (Marshall and White 2001). Strain SP1b-5 converts nitroglycerin (glycerol trinitrate) to 1,2-glyceroldinitrate and 1,3-glyceroldinitrate in a ratio of approximately 2–1, but mononitrates were not detected during the course of the experiment. Detection of transient intermediates and simultaneous adaptation studies

with potential intermediates indicated that the degradation pathway involves the conversion of nitroglycerin to glycerol via 1,2-dinitroglycerin and 1-mononitroglycerin, with concomitant release of nitrite. Glycerol then serves as the source of carbon and energy. Another strain of *Arthrobacter*, strain JBH1, was isolated after selective enrichment from a nitroglycerin contaminated soil at a facility that formerly manufactured explosives after 8 months. Partial 16S rRNA gene sequence similarity identified strain JBH1 as a close relative of *Arthrobacter pascens*. Strain JBH1 degraded 1,2-dinitritroglycerol, 1,3-dinitroglycerol, and 1-mononitroglycerol, respectively, as sole source of carbon but not 2-mononitroglycerol (Husserl et al. 2010). Enzyme assays with crude extracts from strain JBH1 indicated that the conversion of nitroglycerin to 1,2 dinitroglycerin is NADPH dependent with concomitant release of nitrite, whereas the transformation of 1-mononitroglycerin is ATP dependent and neither nitrate nor nitrite is released (Husserl et al. 2012). Most likely, 1-mononitroglycerin is then phosphorylated at carbon 3 and the nitrite is released by subsequent reactions.

Arthrobacter sp. strain G1 has been isolated after enrichment with 4-fluorocinnamic acid and 4-fluorobenzoic acid from a site in the Netherlands which was contaminated with chlorobenzene and halogenated aliphatic compounds (Hasan et al. 2011). *Arthrobacter* sp. strain G1, a close relative of *Arthrobacter nitroguajacolicus*, is able to degrade 4-fluorocinnamic acid to 4-fluorobenzoic acid and uses the two-carbon side chain for growth. Further degradation does only occur in co-culture with *Ralstonia* sp. strain H1.

Arthrobacter strain D9 plays a special role in degradation of the herbicide 2,4-dichlorophenoxyacetic acid in co-culture with *Alcaligenes eutrophus* JMP134 in a cadmium/2,4-dichlorophenoxyacetic acid–polluted soil (Roane et al. 2001). *Arthrobacter* strain D9 is cadmium resistant but is not able to degrade 2,4-dichlorophenoxyacetic acid, whereas *Alcaligenes eutrophus* JMP134 is cadmium sensitive and able to degrade 2,4-dichlorophenoxyacetic acid. In a laboratory soil microcosm, co-inoculated with the two strains and co-contaminated with both, cadmium and 2,4-dichlorophenoxyacetic acid, 500 $\mu g\ l^{-1}$ of the herbicide could not be detected after 6 weeks of incubation. In broth co-culture, the herbicide was almost undetectable after 5 days of incubation. These results indicate that strain D9 carries out detoxification of the environment from accessible cadmium. Accumulation of cadmium in the outer layer suggests that the metal is bound to the exopolysaccharide which is produced by strains D9.

However, when arthrobacters are applied to remediate xenobiotic compounds from soils, the ability of certain *Arthrobacter* strains to produce antibiotics and antagonistic effects on other members of the community should be considered. Kamigiri et al. (1996) described *Arthrobacter* strain YL-02729S which was recovered from soil collected from West Kalimantan (Indonesia). This strain is producing a quinolone antibiotic with activity against Gram-positive bacteria including multiple resistant strains of *Staphylococcus aureus* and *Staphylococcus epidermidis*.

Seven *Arthrobacter* isolates collected at different geographical Arctic sites (copepod, surface water, sea ice, deep sea, and melt water) were described by Wietz et al. (2012). These *Artrhobacter* strains shared almost identical 16S rRNA gene sequences and are identical or almost identical to that of *Arthrobacter russicus*. The seven isolates were shown to produce arthrobacillins A, B, and C under different culture conditions. Also other unidentified compounds were detected which may contribute to the antagonistic action of these strains, as well.

Formation of Added-Value Products

Microorganisms play an important role in ripening of the surface of smear cheeses and other cheeses, as well. Species of the genus *Arthrobacter* are major components in the smear microflora of surface-ripened chesses and also of mold surface-ripened cheeses, such as Brie and Camembert. They belong to the group of principal secondary microorganisms contributing to cheese ripening. The most important function of these microorganisms is the production of extracellular enzymes and deacidification of the cheese (Sousa et al. 2001). In a study on analysis of the microbial flora of the smears of Austrian Tilsit cheeses and three varieties of soft cheeses among the members of the microbial smear flora in addition to species of the genera *Brevibacterium* and *Corynebacterium*, also strains of the species *Sinomonas atrocyanea* (formerly *Arthrobacter atrocyaneus*), *Arthrobacter citreus*, *Arthrobacter globiformis*, *Arthrobacter nicotianae*, *Arthrobacter protophormiae*, *Arthrobacter uratoxydans*, and *Arthrobacter* spp. were identified (Eliskases-Lechner and Ginzinger 1995).

Arthrobacter nicotianae is a typical species present in the bacterial smear of surface ripened cheeses. *Arthrobacter nicotianae* 9458 produces two extracellular serine proteinases, P1 and P2 (Smacchi et al. 1999a). Another proteinase of *A. nicotianae* 9458 was identified as an extracellular proline iminopeptidase (Smacchi et al. 1999b). These enzymes are well active at conditions applied during cheese ripening and may contribute to proteolysis of the cheese during ripening. *A. nicotianae* 9458 also produces an extracellular esterase (Smacchi et al. 2000). This enzyme shows highest activity on β-naphthyl butyrate at pH 7.0 and 30 °C and as well may play an important role in cheese ripening.

Results from Bockelmann and Hoppe-Seyler (2001) showed that the red-brown or orange pigments are most likely due to the yellow pigmented *Arthrobacter* sp. in the surface flora. The successful use of a defined five strain starter culture consisting of *Debaryomyces hansenii*, *Brevibacterium linens*, *Arthrobacter nicotianae*, *Corynebacterium ammoniagenes*, and *Staphylococcus sciuri* for Tilsit cheese ripening was demonstrated and *Arthrobacter* sp. is involved in the flavor and color development.

Smit et al. (2004) analyzed *Arthrobacter* sp. used in dairy fermentations such as cheese making for their potential to convert leucine into flavor components, most notable 3-methylbutanal. Flavor formation in cheese and other fermented dairy products results mainly from catabolism of milk proteins, sugar,

and lipids. It was demonstrated that *Arthrobacter nicotianae* strains are involved in the formation of very diverse flavors in dairy products.

Arthrobacter aurescens TA13 is capable of utilizing *t*-anethole, anisic acid, anisaldehyde, and anisic alcohol as the sole carbon source. These findings provide new routes for environmental friendly production processes of valuable aromatic chemicals via bioconversion of phenylpropenoides. Valuable aroma compounds are produced as intermediates in the degradation pathways of such phenylpropenoides. *t*-Anethole is the major component of several essential oils, including star anise, anise seed oil, and sweet fennel. Hence, microorganisms capable of utilizing *t*-anethole may be applied to produce intermediates as 4-methoxylated aromatic flavor and fragrance compounds, including anisic alcohol, anis aldehyde, or anisic acid. Shimoni et al. (2002) developed a biotransformation process for valuable aromatic chemicals, indicating that a high yield transformation of various phenylpropenoides such as eugenol, estragol, and safrole into valuable aromatic compounds will be possible.

Arthrobacter sp. DS7 was isolated from a heavy-oil contaminated soil (D'Addario 1996) as a desulfurizer. *Arthrobacter* sp. DS7 is able to cleave C-S bonds from organosulfur hetercyclic compounds such as thiobenzothiophene (Serbolisca et al. 1999). The desulfurization operon was found to be located in a large plasmid that also bears the genes conferring cadmium and arsenic resistance. The desulfurization capacity of the strain depends on the activity of the 4-S pathway enzymes already described for other bacteria. The sequence of the *sox*-operon is completely identical to that of *Rhodococcus* sp IGTS38. Since there is a considerable interest in lowering sulfur levels in petroleum distillates, *Arthrobacter* sp. DS7 may be applied for this purpose because it appears to be already adapted to this special environment.

Enzymes

Arthrobacter ilicis isolated from the marine sponge *Spirastrella* sp. produces extracellular serine type acetylcholine esterase. The maximum enzyme activity was found at 45 °C and pH 8.0 (Mohapatra and Bapuji 1998). The microbial production of this enzyme was also shown for *Arthrobacter globiformis* (Shmeleva et al. 1989).

Arthrobacter psychrolactophilus was described to produce an extracellular α-amylase (Loveland-Curtze et al. 1999; Trimbur et al. 1994). This amylase is thermally labile, calcium dependent, and has an optimum activity temperature of 50 °C for a synthetic substrate, a property associated with mesophilic enzymes rather than with psychrophilic enzymes. The relatively high temperature optimum was assumed likely to be induced by the synthetic substrate applied for the experiments and does not accurately reflect the catalytic efficiency at low temperatures. The amylase possesses a raw starch-binding domain which could make it useful for processes where uncooked starch granules need to be hydrolyzed at ambient temperatures. In crude concentrations, the amylase initially hydrolyzes raw starch at 30 °C at about the same rate as an equal number of units of barely α-amylase, but it loses most of its activity after only a few hours (Smith and Zahnley 2005).

A *β*-fructofuranosidase with wide range of acceptor specificities has been isolated from *Arthrobacter globiformis* IFO 3062 which is applicable for the production of heterooligosaccharides (Win et al. 2004). The enzyme has a molecular mass of 60 kDa and its activity for sucrose is 101 U mg^{-1}. The enzyme exhibits maximum activity at pH 6.8 and still 90 % activity is found at pH between 5.5 and 9.5. Temperature optimum is 37 °C and >90 % activity remains at 40° C. By fructosyl transfer to cellobiose and cellotriose, the enzyme catalyzes the formation of nonreducing oligosaccharides, such as *O*-*β*-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl- (1→2)-α, *β*-D-fructofuranoside and *O*-*β*-D-glucopyranosyl-(1→4)-*β*-D-glucopyranosyl-(1→4)-α-D-glucopyranosyl-(1→2)-α, *β*-D-fructofuranoside, respectively. The two oligosaccharides resist heating at 100 °C for 30 min even at pH 2.0.

The psychrotrophic *Arthrobacter* strain B7 was isolated from Pennsylvania farmlands (Loveland-Curtze et al. 1999). Strain B7 produces three different cold-active-β-galactosidase isozymes when grown with lactose as the sole carbon source. The sizes of the three different β-galactosidase isozymes are 111kDa, 71kDa, and 52 kDa, respectively. Due to high homology with the *lacZ* from *E. coli*, the gene encoding the largest β-galactosidase was designated *lacZ*, as well. The protein sequence deduced from the nucleotide sequence contains the conserved acid–base and nucleophilic sites involved in catalysis and typically found in *lacZ* enzymes. The enzyme exhibits a temperature optimum about 20 °C below that of the *E. coli* β-galactosidase (Trimbur et al. 1994). The gene encoding the medium-sized isozyme lacks significant homology with the *lacZ* site but shows homology with isozymes from the thermophile *Geobacillus stearothermophilus* (formerly *Bacillus stearothermophilus*) and the mesophile *Bacillus circulans*. The enzyme shows homology to the acid–base sites of the *lacZ* family but not with the nucleophilic region. It was assigned to a new β-galactosidase family designated *lacG* which corresponds to glycosyl hydrolase family 42 (Henrissat and Bairouch 1993). The temperature optimum is between 45 °C and 50 °C (Gutshall et al. 1995). The smallest β-galactosidase exhibits homology with the lysosomal acid β-galactosidases from human and mice and with an enzyme of *Xanthomonas manihotis* (Gutshall et al. 1997) and in agreement with this observation, phylogenetic analysis of the amino acid sequence led to the unexpected clustering within the eukaryotic clade. The enzyme hydrolyzes substrates with either a β-2,4 or a β-1,3 linkage with an temperature optimum similar to the temperature optimum of the *E. coli lacZ* β-galactosidase. Meanwhile strain B7 has been described as the type strain of *Arthrobacter psychrolactophilus* (Loveland et al. 1994).

Arthrobacter strain SB was isolated from Antarctic Dry Valley soil. On the basis of 16S rRNA gene analysis, strain SB was identified as a close relative of *Arthrobacter sulfonivorans*. The strain was tested positive for β-galactosidase activity. The corresponding gene (*bgaS*) shows highest sequence similarities with *lacZ*-like genes of *Arthrobacter* sp. C2-2 (71 %) and *Arthrobacter psychrolactophilus* B7 (66 %). These results suggest that the

β-galactosidase of strain SB belongs to the *lacZ* family β-galactosidases. The enzyme is cold active with an optimal activity at 18 °C, retaining 50 % activity at 0 °C. It is heat labile as it can be inactivated by incubation for 10 min at 37 °C (Coker et al. 2003).

Arthrobacter psychrolactophilus F2 is able to hydrolyze lactose at a temperature below 5 °C. Only one type of cold-active β-galactosidase could be identified in this strain (Nakagawa et al. 2003). This β-galactosidase exhibits a high activity at 0 °C, its temperature and pH optima are 10 °C and 8.0, respectively. It is inactivated rapidly at 45 °C within 5 min (Nakagawa et al. 2006).

Arthrobacter sp. 32c was isolated from Antarctic soil due to its ability to hydrolyze the chromogenic lactose analog X-Gal. Analysis of its 16S rRNA gene sequence identified strain 32c as a close relative of *Arthrobacter oxydans* and *Arthrobacter polychromogenes* (Hildebrandt et al. 2009), placing it in the "*Arthrobacter oxydans* group" (Busse et al. 2012). The β-D-galactosidase gene encodes a protein consisting of 694 amino acids and a deduced mass of 76 kDa. The β-D-galactosidase gene sequence shares highest similarities with those of *Arthrobacter* sp. FB24 (77.1 %) and *Arthrobacter aurescens* TC1 (71.8 %). However, comparison with newly accessible genome sequences identifies *Arthrobacter phenanthrenivorans* Sphe3 (82.5 %) and *Arthrobacter chlorophenolicus* A6 (82.3 %) harboring highest similar sequences. The enzyme shows highest activity at pH 6.5 and 50 °C, approximately 60 % activity is retained at 25 °C and 15 % at 0 °C.

A strain isolated from a soil sample near the Great Wall Station in Antarctica and designated *Arthrobacter* ON14 was described recently (Xu et al. 2011). Phylogenetically, strain ON14 is closely related to *Arthrobacter psychrochitiniphilus* and *A. psychrolactophilus,* suggesting its placement in the "*Arthrobacter psychrolactophilus* group" (Busse et al. 2012). It was shown to contain two genes encoding different β-galactosidases which were designated *galA* and *galB*. The *galA* gene is highly expressed at low temperature (4 °C) and repressed at high temperature (28 °C). The corresponding enzyme GalA shows highest amino acid homology (97.3 %) to BglA of *Arthrobacter psychrolactophilus* strain F2. The maximum activity is at 15 °C and pH 8.0. The *galB* gene is repressed at low temperature and induced at high temperature. Its maximum activity is at 37 °C. The GalB isozyme shows highest amino acid homology (42.4 %) with the 71 kDa β-galactosidase isozyme of *A. psychrolactophilus* B7, and hence, it is assigned to the *lacG* family.

The Antarctic *Arthrobacter* sp. D10 produces two extracellular alkaline phosphatases, designated D10A and D10B. Enzyme D10A shows a pH optimum between 7 and 11 and a maximum at pH 9.5. Enzyme D10B shows calcium-dependent maximum activity at pH 9 and a minimum at pH 10. Both enzymes are heat labile (de Prada et al. 1996).

A D-threonine aldolase was purified and characterized from *Arthrobacter* sp. DK-38. The enzyme catalyzes the cleavage of D-threonine into glycine and acetaldehyde and the reaction is reversible. The molecular mass of the enzyme is approximately 51 kDa and requires pyridoxal 5′-phosphate and divalent cations such as Co^{2+}, Ni^{2+}, Mn^{2+}, or Mg^{2+} for its activity. Both D-threonine and D-allothreonine act as substrates for the enzyme. The aldolase also cleaves other D-β-hydroxy-α-amino acids (Kataoka et al. 1997).

Arthrobacter nicotianae 9458 produces three extracellular proteases, two serine proteinases (P1 and P2), and a proline iminopeptidase (Smacchi et al. 1999a, b). The molecular masses of the two serine enzymes are approximately 54 kDa and 71 kDa, respectively. They differ in respect of temperature optimum which is 55–60 °C and 37 °C, respectively. Both enzymes tolerate NaCl concentrations higher than 5 %, show optimum activity at pH 9.0–9.5, and are still active at pH 6.0. The extracellular proline iminopeptidase shows a temperature optimum of 37 °C and a pH optimum of 8. It is completely inactivated by heating at 80 °C. However, a very high acitivity of the enzyme is observed at 10 °C, pH 7.0, and 5.0 % NaCl concentration; approximately 60 % of the activity is retained at 13 °C, pH 6.5, 3.75 % NaCl, and 13 °C, pH 6.5, 6.25 % NaCl concentration, respectively. *A. nicotianae* 9458 also produces an extracellular esterase (Smacchi et al. 2000). This enzyme shows highest activity on β-naphthyl butyrate at pH 7.0 and 30 °C.

6 The Family *Beutenbergiaceae*

Moriyuki Hamada
Biological Resource Center, National Institute of Technology and Evaluation (NBRC), Kisarazu, Chiba, Japan

Abstract
The family *Beutenbergiaceae* is a member of the order *Micrococcales* and comprises the monospecific genera *Beutenbergia*, *Miniimonas*, *Salana*, and *Serinibacter*. Cells of members of the family are irregular rods and cocci and may exhibit a rod–coccus life cycle. All the species are Gram-stain-positive, catalase-positive, non-motile, non-acid fast, and do not contain mycolic acids. Oxidase activity is variable, and endospores are not formed. Members of the family are defined by a wide range of chemotaxonomic properties. Cross-linkage of the peptidoglycan is of the A type with an L-serine residue at position 1 of the peptide subunit (with the exception of the genus *Beutenbergia*); the diagnostic diamino acids are either L-lysine (*Beutenbergia* and *Serinibacter*) or L-ornithine (*Salana* and *Miniimonas*). The interpeptide bridge contains L-glutamic acid. The predominant menaquinone is MK-8(H_4). The cellular fatty acid profiles consist of iso- and anteiso-branched fatty acids. Saturated straight-chain fatty acids may be present as major components. The G + C content of the genomic DNA ranges between 71 mol% and 75 mol%. The phylogenetic neighbors are the families *Bogoriellaceae*, *Ruaniaceae*, *Jonesiaceae*, and *Actinomycetaceae*.

Taxonomy: Historical and Current

Short Description of the Family

The family description is mainly based on its phylogenetic position and the pattern of its 16S rRNA gene sequence signatures.

Beutenbergiaceae: Zhi, Li, and Stackebrandt 2009, 597^{VP} Emend Hamada, Iino, Tamura, Iwami, Harayama, and Suzuki 2009, 2813^{VP} Emend Ue, Matsuo, Kasai, and Yokota 2011, 125^{VP}

Beu′ten.ber.gi.a.ce′a.e. N.L. fem. n. *Beutenbergia* type genus of the family; *-aceae* ending to denote a family; N.L. fem. pl. n. *Beutenbergiaceae* the family of *Beutenbergia*.

The pattern of 16S rRNA gene sequence signatures consists of nucleotide positions 144:178 (C–G), 280 (U), 293:304 (G–U), 668:738 (A–U), 1003:1038 (G–U), 1027:1034 (U–A), and 1414:1486 (U–A) (Hamada et al. 2009).

The family is a member of the order *Micrococcales* (Busse 2012) within the class *Actinobacteria* (Stackebrandt et al. 1997) and contains the type genus *Beutenbergia* (Groth et al. 1999) and the genera *Miniimonas* (Ue et al. 2011), *Salana* (von Wintzingerode et al. 2001), and *Serinibacter* (Hamada et al. 2009).

Phylogenetic Structure of the Family

A phylogenetic tree, based on 16S rRNA gene sequences, showing the positions of the members of the family *Beutenbergiaceae* is shown in ❯ *Fig. 6.1*. The phylogenetic tree indicates that the members of the family form a monophyletic and reliable cluster within the order *Micrococcales*. The family is moderately related to the families *Bogoriellaceae*, *Ruaniaceae*, *Jonesiaceae*, and *Actinomycetaceae* according to a RaxML 16S rRNA gene tree of the All-Species Living Tree Project (Yarza et al. 2008).

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_172,

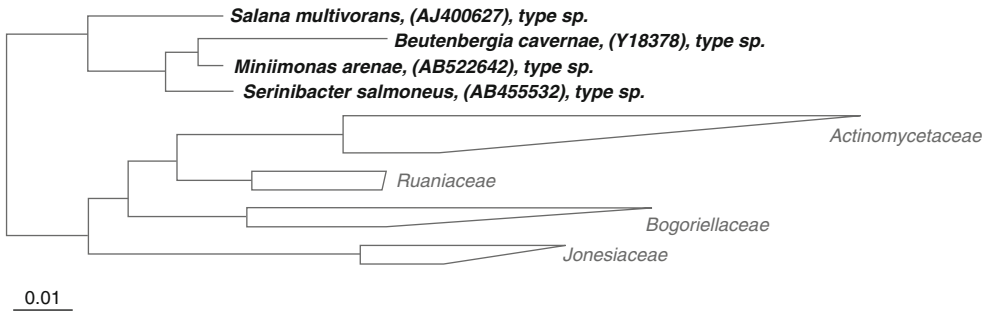

Fig. 6.1
A maximum likelihood phylogenetic tree derived from the 16S rRNA gene sequences of the members of the family *Beutenbergiaceae* and its taxonomic neighbors. The tree was constructed using the RAxML algorithm (Stamatakis 2006)

The family *Beutenbergiaceae* was established for the genera *Beutenbergia*, *Salana*, and *Georgenia* (Altenburger et al. 2002) by Zhi et al. (2009) on the basis of phylogenetic position and the presence of a unique set of 16S rRNA gene sequence signature nucleotides. Later, the genus *Serinibacter* was proposed by Hamada et al. (2009) as a new genus of the family *Beutenbergiaceae* with the emendation of the families *Beutenbergiaceae* and *Bogoriellaceae*. They reevaluated these families based on phylogenetic position and a set of signature nucleotides and concluded that the genus *Georgenia* should be transferred from the family *Beutenbergiaceae* to the family *Bogoriellaceae*. Based on their study, the family *Beutenbergiaceae* was amended to accommodate the genera *Beutenbergia*, *Salana*, and *Serinibacter*, whereas the genus *Georgenia* was placed in the family *Bogoriellaceae*. Recently, the genus *Miniimonas* was described by Ue et al. (2011). They confirmed the results of Hamada et al. (2009) and placed the genus *Miniimonas* in the family *Beutenbergiaceae*. In addition, the family description was emended to change the nucleotide pair at position 131:231 to A–G and not C–G as per Zhi et al. (2009). This time, the family *Beutenbergiaceae* is defined on the basis of a unique set of 16S rRNA gene signature nucleotides, i.e., nucleotides at positions 144:178 (C–G), 280 (U), 293:304 (G–U), 668–738 (A–U), 1003:1038 (G–U), 1027:1034 (U–A), and 1414:1486 (U–A) (Hamada et al. 2009).

Molecular Analyses

MALDI-TOF (matrix-assisted laser-desorption/ionization time-of-flight) mass spectrometric analysis of the members of the family *Beutenbergiaceae* and their phylogenetic neighbors shows a wide range of spectra similarities (*Fig. 6.2*). The type strains of the family *Beutenbergiaceae* form a coherent cluster; however, all the strains have major differences in their spectra when compared with each other (Hamada unpublished). The only study to include the ribotyping method was that of von Wintzingerode et al. (2001). The three isolates of *Salana multivorans* (Se-3111^T, Se13111, and Se1311A) and their closest phylogenetic neighbor *Beutenbergia cavernae* DSM 12333^T were ribotyped using the restriction enzyme *Pvu*II. The similarity values between the ribotype patterns of the three isolates ranged from 65 % to greater than 95 % as compared with less than 20 % similarity to the ribotype pattern of *Beutenbergia cavernae* DSM 12333^T. Thus, it was concluded that the novel isolates were genotypically very similar and represent a single species. DNA–DNA hybridization, riboprinting, and multilocus sequence analysis have not been performed for any members of the family *Beutenbergiaceae*.

Genome Analyses

Beutenbergia cavernae HKI 0122^T is the only strain of the family *Beutenbergiaceae* for which the complete genome sequence has been released (INSDC ID: CP001618) (Land et al. 2009). The genome of the strain is 4,669,183 base pairs long and comprises a circular chromosome with 73.12 % G + C content. This G + C content is slightly higher than that determined originally by HPLC (71 mol%; Groth et al. 1999). The sequences of the two 16S rRNA gene copies in the genome of strain HKI 0122^T are identical but differ by 4 nucleotides from the previously published 16S rRNA gene sequence determined from DSM 12333^T (Y18378). Of the 4,278 genes predicted, 4,225 were protein-coding genes and 53 were RNA genes. Twenty-eight pseudogenes were also identified. The majority of the genes (74.3 %) were assigned a putative function. The percentage of genes assigned to clusters of orthologous groups (COGs) was 72.67 %. The remaining genes were annotated as hypothetical proteins. The classification of the genes into COG functional categories showed that a higher number of genes are involved in carbohydrate transport and metabolism (546 genes; 12.9 %), followed by involvement in transcription (384 genes; 9.1 %), amino acid transport and metabolism (264 genes; 6.3 %), inorganic ion transport and metabolism (183 genes; 4.3 %), and translation, ribosomal structure, and biogenesis (169 genes; 4.0 %). Sixty-two genes (1.5 %) were found to code for secondary metabolite biosynthesis, transport, and catabolism. The details are provided in Land et al. (2009).

A dendrogram generated by the BioTyper (version 2.0; Bruker Daltonics) software showing the similarity of MALDI-TOF mass spectra of cell extracts from type strains of the family *Beutenbergiaceae* and some related taxa

Phenotypic Analyses

The genera belonging to the family *Beutenbergiaceae* are mainly characterized by differences in chemotaxonomic features such as peptidoglycan type, polar lipids, and cellular fatty acids. The major characteristics of the genera *Beutenbergia*, *Miniimonas*, *Salana*, and *Serinibacter* are indicated in Table 6.1. Specifically, members show diversity in terms of their peptidoglycan structures. Cross-linkage of the peptidoglycans is of the A type and the diagnostic diamino acids are either L-lysine (*Beutenbergia* and *Serinibacter*) or L-ornithine (*Salana* and *Miniimonas*). Furthermore, it has been reported that L-serine occupies position 1 of the peptide subunit of the members of the genera *Salana* and *Serinibacter* (von Wintzingerode et al. 2001; Hamada et al. 2009). Detailed peptidoglycan analyses of the members of the family revealed that the peptidoglycan structure of the genus *Miniimonas* is identical to that of the genus *Salana* (Table 6.2). Specifically, it was concluded that the peptidoglycan of the genus *Miniimonas* was of the A4β type with an L-serine residue at position 1 of the peptide subunit (Hamada unpublished).

Beutenbergia: Groth, Schumann, Schuetze, Augsten, Kramer, and Stackebrandt 1999, 1738^{VP}

Beu.ten.ber′gi.a. N.L. fem. n. *Beutenbergia* referring to Beutenberg, the geographical location of the institute in which the soil sample was studied.

Cells are irregular rods, and cocci occur singly, in pairs, short chains, or clusters and exhibit a rod–coccus growth cycle. Gram-stain-positive, non-acid fast, non-motile, no formation of spores. Aerobic to microaerophilic. Oxidase-negative, catalase-positive. The peptidoglycan type is A4α with an L-Lys–L-Glu interpeptide bridge. The acyl type is acetyl. The major menaquinone is MK-8(H_4). The polar lipids are phosphatidylinositol, diphosphatidylglycerol, and three unknown phospholipids. The major fatty acids are iso-$C_{15:0}$ and anteiso-$C_{15:0}$.

The type strain of *Beutenbergia cavernae* HKI 0122^T was isolated from a soil sample collected in a cleft between the rocks of the Reed Flute Cave near Guilin, Guangxi, China. It shows the following additional properties. Cell sizes in rods vary from 1.0 to 3.1 μm in length. The diameters of the cocci are 0.7–1.0 μm. Colonies are 0.7–1.8 mm in diameter, cream to bright yellow colored, circular, convex. Acids are produced from L-arabinose, D-cellobiose, dextrin, D-fructose, D-galactose, D-glucose, glycerol, inulin, maltose, D-mannose, D-raffinose, L-rhamnose, D-ribose, salicin, sucrose, starch, trehalose, and D-xylose. There is no acid production from D-glucitol, lactose, or D-mannitol. Acetate, aconitate, benzoate, citrate, formate, malate, succinate, and DL-tartrate are not utilized. Nitrate is reduced to nitrite and H_2S is produced, whereas indole is not produced. Methyl red and Voges–Proskauer reactions are negative. Casein, aesculin, gelatin, and potato starch are decomposed; adenine, hippurate, hypoxanthine, xanthine, Tween 80, and tyrosine are not decomposed. Urease activity is negative. NaCl in combination with R medium is well tolerated up to a concentration of 4 % (w/v). Good growth occurs at 28 °C, growth is weak at 37 °C, and no growth occurs at 42 °C. Cells are susceptible to ampicillin (10 μg), chloramphenicol (30 μg), erythromycin (15 μg), neomycin (30 μg), oxytetracycline (30 μg), penicillin G (2 IU), and rifampin (2 μg). Susceptibility to polymyxin B (300 IU) is weakly expressed, and there is no susceptibility to ciprofloxacin (5 μg), gentamicin (10 μg), kanamycin (30 μg), lincomycin (2 μg), nitrofuran (300 μg), oxacillin (5 μg), streptomycin (10 μg), and sulfonamide. Based on the API ZYM enzyme assay, strain HKI 0122^T is positive for

phosphatase alkaline, esterase (C4), esterase lipase (C8), leucine arylamidase, cystine arylamidase, phosphatase acid, naphthol-AS-BI-phosphohydrolase, α-galactosidase, *p*-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase, and negative for lipase (C14), valine arylamidase, trypsin, chymotrypsin, β-glucuronidase, and β-glucosidase. The DNA G + C content of the type strain is 71 mol%.

Miniimonas: Ue, Matsuo, Kasai, and Yokota 2011, 125[VP]

Mi.ni.i.mo′nas. L. adj. *minius* cinnabar-red, vermilion; L. fem. n. *monas* a unit, monad; N.L. fem. n. *Miniimonas* vermilion monad, referring to the cell mass color.

Gram-stain-positive, non-motile, coccoid- to rod-shaped, oxidase-negative, and catalase-positive. Growth occurs under both aerobic and anaerobic conditions. The peptidoglycan is of the A4β type with an L-Orn–L-Glu interpeptide bridge and an L-Ser residue at position 1 of the peptide subunit. The acyl type of muramic acid is acetyl. The major menaquinone is MK-8(H_4). The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and one unknown phospholipid. The fatty acid pattern is of the iso- and anteiso-branched and straight-chain saturated type. The major fatty acids are anteiso-$C_{15:0}$ and $C_{16:0}$. The whole-cell sugars are galactose, xylose, and ribose. Mycolic acids are absent.

The type strain of *Miniimonas arenae* YM18-15^T was isolated from sea sand in Teguma fishing harbor in Nagasaki, Japan. It shows the following additional properties. Rod-shaped cells are 0.6–3.7 μm in length. Cells exhibit a rod–coccus cycle.

The diameters of the cocci are 1.0–1.7 μm. Growth occurs weakly at 25–30 °C. The pH range for growth is 5–11, with optimum growth at pH 7–7.5. Cells grow in the absence of NaCl, but tolerate up to 5 % NaCl (w/v). When grown aerobically for 7 days on LB agar or IL8 medium agar, the type strain forms a vermilion-colored cell mass and does not form spores. Cells form circular and smooth colonies that are 1–4 mm in diameter after 7 days at 30 °C on LB agar. Nitrate is reduced to nitrite. H_2S is not produced. Hydrolysis of starch is negative. The type strain forms vermilion-colored colonies. Based on API ZYM tests, cells are positive for esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, α-glucosidase, and β-glucosidase, but negative for alkaline phosphatase, lipase (C14), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Cells are weakly positive for esterase (C4) and acid phosphatase. Cells utilize the following substrates as sole carbon sources: L-arabinose, D-mannose, D-xylose, D-glucose, D-fructose, L-rhamnose, and maltose monohydrate. The strain does not utilize D-mannitol. The API 20A test for the anaerobic formation of acid is positive for glucose, sucrose, maltose, D-xylose, L-arabinose, D-mannose, raffinose, L-rhamnose, and trehalose; weakly positive for cellobiose; and negative for D-mannitol, lactose, salicin, glycerol, melezitose, and D-sorbitol. Based on API 20A tests, cells are anaerobically positive for the hydrolysis of aesculin, but negative for the hydrolysis of gelatin and for the production of indole, arginine dihydrolase, and urease. The DNA G + C content of the type strain is 74.2 mol%.

Salana: von Wintzingerode, Göbel, Siddiqui, Rösick, Schumann, Frühling, Rohde, Pukall, and Stackebrandt 2001, 1659[VP]

Sa.la′na. N.L. fem. n. *Salana* referring to the German river Saale, the source of the bioreactor culture.

Cells form irregular rods and cocci and sometimes club-like forms. They are Gram-stain-positive and facultatively anaerobic bacteria. A variety of organic electron donors may be utilized. The peptidoglycan is of the A4β type with an L-Orn–L-Glu interpeptide bridge and an L-Ser residue at position 1 of the peptide subunit. The major menaquinone is MK-8(H_4). The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and several unidentified phospholipids in minor amounts. The fatty acid pattern is of the iso- and anteiso-branched and straight-chain saturated type. The major cellular fatty acids are anteiso-$C_{15:0}$ and $C_{14:0}$.

The type strain of *Salana multivorans* Se-3111^T was isolated from an anaerobic dechlorinating consortium enriched from river sediment. It shows the following additional properties. Cells are 0.4–0.7 μm wide and 1.2–3.1 μm long. Growth occurs under both aerobic and anaerobic conditions. Under aerobic conditions, optimal growth occurs at pH 7.5 and 30 °C or 37 °C. Under anaerobic conditions, cells reduce selenate to elemental selenium. Gelatin and aesculin are not hydrolyzed. Indole is not formed and urease is negative. According to API ZYM reactions, alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, cystine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and valine arylamidase are positive, whereas trypsin, chymotrypsin, α-fucosidase, and β-glucuronidase are negative. Acid is formed under aerobic conditions (according to API 50CH) from L-arabinose, galactose, D-glucose, D-fructose, D-mannose, maltose, melibiose, sucrose, trehalose, D-raffinose, D-turanose, and D-lyxose, but not formed from erythritol, L-xylose, adonitol, L-sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, methyl *a*-dglucoside, *N*-acetylglucosamine, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, and 5-ketogluconate. Acid production from amygdalin, D-arabinose, gentiobiose, glycerol, inulin, methyl β-D-xyloside, ribose, xylitol, and D-xylose is variable. Anaerobically, acid is produced from arabinose, cellobiose, glucose, glycerol, lactose, maltose, mannitol, mannose, melezitose, raffinose, rhamnose, salicin, sorbitol, trehalose, and xylose. The DNA G + C content of the type strain is 75 mol%.

Serinibacter Hamada, Iino, Tamura, Iwami, Harayama, and Suzuki 2009, 2813[VP]

Se.ri.ni.bac′ter. N.L. n. *serinum* serine; N.L. masc. n. *bacter* rod; N.L. masc. n. *Serinibacter* a rod with serine in the cell wall.

Cells are irregular, rod-shaped, Gram-stain-positive, and non-endospore-forming. Growth occurs under both aerobic and anaerobic conditions. The cell-wall peptidoglycan is of the A4α type with an L-Lys–L-Glu interpeptide bridge and an L-Ser residue at position 1 of the peptide subunit. The acyl type of muramic acid is *N*-acetyl. The major menaquinone is MK-8(H_4), and the major polar lipids are phosphatidylethanolamine and phosphatidylglycerol. The fatty acid profile consists of iso- and anteiso- branched and straight-chain fatty acids. The major cellular fatty acids are anteiso-$C_{15:0}$ and $C_{16:0}$. The major cell-wall sugar is galactose. Mycolic acids are absent.

The type strain of *Serinibacter salmoneus* Kis4-28^T was isolated from the intestinal tract of sillago fish (*Sillago japonica*) collected from Kyonan beach on the coast of Tokyo Bay, Japan. It shows the following additional properties. Cells are 0.4–0.5 × 1.0–2.0 μm and non-motile. Colonies are circular, smooth, and yellowish orange, but cells grown in liquid culture are yellowish pink. Catalase-positive and oxidase-negative. The Voges–Proskauer test is positive, while the methyl red test is negative. Growth occurs at the NaCl concentrations of 0–10 % (w/v) but not at 15 % NaCl, and the optimal NaCl concentration range for growth is 0–5 %. The temperature range for growth is 10–37 °C, and the optimal temperature for growth is 28 °C. The pH range for growth is 6.0–9.0, and the optimal pH is 7.0. Acid is produced from *N*-acetylglucosamine, cellobiose, D-fructose, D-galactose, gentiobiose, D-glucose, glycogen, lactose, maltose, D-mannose, methyl α-D-glucopyranoside, methyl

β-D-xylopyranoside, starch, sucrose, trehalose, and D-xylose. Esterase lipase (C8), leucine arylamidase, acid phosphatase, α-galactosidase, β-galactosidase, α-glucosidase, pyrazinamidase, and pyrrolidonyl arylamidase are present, whereas alkaline phosphatase, lipase (C4), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, arginine dihydrolase, lysine- and ornithine decarboxylases, and tryptophan- and phenylalanine deaminases are absent. H_2S and indole are not produced. Aesculin is hydrolyzed, while gelatin, urea, and DNA are not hydrolyzed. Nitrate is not reduced. The DNA G + C content of the type strain is 70.7 mol%.

Isolation, Enrichment, and Maintenance Procedures

Beutenbergia cavernae HKI 0122^T (Groth et al. 1999) was isolated from a soil sample collected from a cleft between the rocks of the Reed Flute Cave near Guilin, Guangxi, China. One gram of soil sample was suspended in 10 ml sterile phosphate buffer (pH 7.2) and thoroughly mixed by shaking. Soil particles were allowed to sediment, and then the liquid phase was serially diluted and spread onto casein mineral medium (Altenburger et al. 1996) containing 0.6 g/l K_2HPO_4, 0.5 g/l $Na_2HPO_4 \cdot 2H_2O$, 0.05 g $MgSO_4 \cdot 7H_2O$, 0.1 g $MgCl_2 \cdot 7H_2O$, 0.2 g/l KNO_3, 0.01 g/l $FeCl_3 \cdot 6H_2O$, 0.8 g/l casein, and 0.4 g/l yeast extract (pH 7.0). Another strain, HKI 0132, was isolated from the same sample on PY-BHI agar (Yokota et al. 1993) containing 10.0 g/l peptone, 2.0 g/l yeast extract, 2.0 g/l Bacto brain heart infusion (Difco), 2.0 g/l NaCl, and 2.0 g/l glucose (pH 7.0).

Miniimonas arenae YM18-15^T (Ue et al. 2011) was isolated from sea sand from the Teguma fishing harbor in Nagasaki Prefecture, Japan. Isolation was performed at 25 °C for 30 days on H medium (Ue et al. 2011).

Salana multivorans Se-3111^T (von Wintzingerode et al. 2001) was isolated from an anaerobic bioreactor. Samples were taken from a fluidized bed reactor inoculated with an anaerobic, trichlorobenzene-dechlorinating consortium enriched from sediment of the River Saale near Jena, Germany (Selent 1999). Within the fluidized bed reactor, the dechlorinating consortium was immobilized on polyurethane foam cubes. For enrichment of anaerobic, selenate-reducing bacteria, the foam cubes were removed from the bioreactor using sterile forceps and transferred to reduced RAMM medium (Shelton and Tiedje 1984). After a 7-day incubation at 30 °C under anaerobic conditions (GasPak anaerobic jars, Anaerogen), enrichment cultures were set up by transferring 1 foam cube each to an Erlenmeyer flask with Se medium (Macy et al. 1989) containing 2.2 g/l NaCl, 0.3 g/l KCl, 0.3 g/l NH_4Cl, 0.2 g/l KH_2PO_4, 0.15 g/l $CaCl_2 \cdot 2H_2O$, 0.4 g/l $MgCl_2 \cdot 6H_2O$, 0.6 g/l $NaHCO_3$, 3.78 g/l Na_2SeO_4, 3.78 g/l potassium acetate, 10 ml/l trace-metal solution SL8, 10 ml/l vitamin solution, and 800 µl/l methanol. After 5 days of anaerobic incubation in anaerobic jars (CO_2, N_2, and H_2 atmosphere), a red precipitate was visible and served as an inoculum for subcultures in modified Se medium (Se medium supplemented with 1.2 g/l NaCl, 1–4 g/l yeast extract, 0.3 g Na_2SO_4, and 2.02 g/l KNO_3). Pure cultures were obtained by repeated streaking on agar plates containing the above medium.

Serinibacter salmoneus Kis4-28^T (Hamada et al. 2009) was isolated from the intestinal tract of a fish species (Japanese sillago; *Sillago japonica*) collected from Kyonan Beach on the coast of Tokyo Bay, Chiba Prefecture, Japan. The sillago was dissected, and an intestinal tract sample of approximately 1 g was used for the isolation of bacteria. Suspensions of the intestinal tract in 10 ml saline were serially diluted and spread onto LYPm agar (Iino et al. 2007) containing 10 g/l α-lactose, 20 g/l NaCl, 10 g/l yeast extract, 5 g/l polypeptone, 0.025 g/l Tween 80, 5 ml/l salt solution, and 15 g/l agar (pH 6.0). The salt solution contained 40 g/l $MgSO_4 \cdot 7H_2O$, 2.0 g/l $MnSO_4 \cdot 4H_2O$, 2.0 g/l $FeSO_4 \cdot 7H_2O$, and 2.0 g/l NaCl. The inoculated plates were cultivated at room temperature (approximately 20–25 °C) in a sealed nylon bag with an O_2-absorbing and CO_2-generating agent (Anaero-Pack, Mitsubishi Gas Chemical) for at least 1 month. Visible colonies on the agar plates were picked up and then transferred to fresh LYPm agar in aerobic conditions. Pure cultures were obtained by repeated streaking on LYPm agar.

Members of the family *Beutenbergiaceae* grow readily in complex liquid or on solidified media, i.e., Bacto nutrient agar, Bacto tryptic soy agar, and NBRC medium 802 containing 10 g/l polypeptone, 2.0 g/l yeast extract, and 1.0 g/l $MgSO_4 \cdot 7H_2O$ (pH 7.0). Members of the family do not require special procedures for maintenance and preservation. Cultures of the members can be maintained by serial transfers onto appropriate solid media. Growth on agar slants can be kept at 4 °C for about 1 month. Medium-term preservation is in 12–15 % (v/v) glycerol suspensions at −80 °C. Long-term preservation of liquid cultures supplemented with 12–15 % (v/v) glycerol or 7 % (v/v) dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−150 °C). Freeze-drying and L-drying methods can also be applied for long-term storage.

Ecology

Members of the family *Beutenbergiaceae* were isolated from cave soil, river sediment, sea sand, and the intestinal tract of a fish. However, ecological information is insufficient because most species are defined only by a type strain. Further studies are required in order to elucidate the ecological niches and the functions of the members of the family. The NCBI taxonomy browser lists several unnamed strains and clones affiliated to the family *Beutenbergiaceae*, e.g., *Beutenbergia* sp. 91196 (accession number AY996854), an uncultured *Beutenbergiaceae* bacterium clone 741-8-06 from endosphere of hybrid poplar (Ulrich et al. 2008) (AM489678), and two uncultured *Salana* sp. clones OT44-13 and F5OHPNU07INO5B from an organic household waste in anaerobic reactor (Cardinali-Rezende et al. 2009) (FJ982876) and a tailing pond (Ramos-Padrón et al. 2011) (HQ091860), respectively.

Pathogenicity and Clinical Relevance

Pathogenicity has not been reported in any strains belonging to the family *Beutenbergiaceae*. *Beutenbergia cavernae* cells are susceptible to ampicillin (10 μg), chloramphenicol (30 μg), erythromycin (15 μg), neomycin (30 μg), oxytetracycline (30 μg), penicillin G (2 IU), and rifampin (2 μg). The cells demonstrate weak susceptibility to polymyxin B (300 IU), and are resistant to ciproflaxin (5 μg), gentamicin (10 μg), kanamycin (30 μg), lincomycin (2 μg), nitrofuran (300 μg), oxacillin (5 μg), streptomycin (10 μg), and sulfonamide. No information on antibiotic sensitivity and resistance is available for *Miniimonas arenae*, *Salana multivorans*, and *Serinibacter salmoneus*.

Application

It has been reported that strains of *Salana multivorans* are capable of selenate reduction (von Wintzingerode et al. 2001).

Abstract
Brevibacterium constitutes a ubiquitous range of species for which only the halotolerant sulfur aroma production has been utilized in the dairy food industry. Recently, however, a wide range of new isolates from different environments including soil, sediment, and seawater has been assigned to this genus. Since these isolates show quite diverse metabolic properties, they pave the way to new applications such as metal processing or bioremediation. Despite its long-time industrial use, especially as inoculants in the cheese-making industry, the genomic era for this genus has just started, with the first genomes of *B. aurantiacum* ATCC9174 (an industrial strain), *B. massiliense* DSM23039 (a pathogenic strain), and, finally, *Brevibacterium* sp. JC43 (a human gut strain) being released recently. Other genome sequences of *Brevibacteriaceae* are on their way. This includes the genome sequences from several strains of the industrially used *B. linens* (ATCC9172 and OC2 strains) and the genital pathogen *Brevibacterium mcbrellneri*. Genomic data should open investigation of the valuable but not yet fully deciphered metabolic properties of species and, on the other side, allow a better understanding of the specialization of distinct species within this genus as pathogens. Genetic manipulation of members of this genus is also not yet fully developed and tools remain to be derived from the genomic information. The recently obtained but still limited genomic data should be screened carefully with special focus on genetic elements such as genomic islands and plasmids. In addition, the investigation of mechanism underlying lateral gene transfer will also give novel insights and potentially applicable genetic tools for this genus.

Taxonomy, Historical and Current State

In 1953, Breed first established the genus *Brevibacterium* with *B. linens* as the type species. The genus' name comes from the Latin *brevis*, short, and the Greek βακτερια, rod. Classically, the genus has presented taxonomists with difficulties because of its close morphologic resemblance with other genera including *Corynebacterium*, *Arthrobacter*, and *Rhodococcus*. Recognized as a genus in the seventh edition of the *Bergey's Manual of Determinative Bacteriology*, it was listed as *incertae sedis* in its 8th edition. Numerical taxonomy has demonstrated that *Brevibacterium* indeed constitutes a distinct genus. Although remaining in continuous reclassification on the basis of 16S rRNA gene sequencing and DNA/DNA hybridization, *Brevibacterium* today remains the unique genus of the *Brevibacteriaceae* family located in the order *Micrococcales*, class *Actinobacteria*. The genus shows, however, an extreme heterogeneity in physiological, biochemical, and chemical features, resulting today in the delineation of 28 *Brevibacterium* species which were isolated from habitats as diverse as dairy products, poultry skin, insects, soil, mural paintings, wall, clinical samples, the human microbiome, brown algae, and salt-lake, marine, or beach sediments (*Table 7.1*). Historically, *B. linens* and *B. iodinum* were the first species described within this genus (Collins et al. 1980), followed by *B. casei* (Collins et al. 1983), *B. epidermidis* (Collins et al. 1983), *B. mcbrellneri* (McBride et al. 1993), *B. otitidis* (Pascual et al. 1996), *B. avium* (Pascual and Collins 1999), *B. paucivorans* (Wauters et al. 2001), *B. luteolum* (Wauters et al. 2003), *B. sanguinis* (Wauters et al. 2004), *B. celere* (Ivanova et al. 2004), *B. permense* (Gavrish et al. 2004), *B. picturae* (Heyrman et al. 2004), *B. samyangense* (Lee 2006), *B. ravenspurgense* (Mages et al. 2008), *B. album* (Tang et al. 2008), *B. marinum* (Lee 2008), *B. oceani* (Bhadra et al. 2008), *B. massiliense* (Roux and Raoult 2009), *B. sandarakinum* (Kämpfer et al. 2010), *B. salitolerans* (Guan et al. 2010),

+ positive, *nd* no data, *w* weakly positive, *v* variable

B. pityocampae (Kati et al. 2010), *B. siliguriense* (Kumar et al. 2011), *B. ammoniilyticum* (Kim et al. 2012), *B. daeguense* (Cui et al. 2013), and *B. yomogidense* (Tonouchi et al. 2013). In addition to the description of novel species, other resulted from the reclassification of heterogeneous ones. This was the case for the species *B. linens* which showed heterogeneity in DNA/DNA hybridization properties. In 2004, Gavrish and collaborators split this species into three new species: *B. linens*, *B. antiquum*, and *B. aurantiacum* (Gavrish et al. 2004). Moreover, our own work suggests that the cheese strain of economic interest, CNRZ918, should be reclassified as *B. antiquum* (Forquin et al. 2009). The list of *Brevibacteriaceae* is not extensive, and

novel species have to be defined from novel metagenomic approaches as shown for the gut microbiome for instance. Indeed a *Brevibacterium* sp. JC43 was lately isolated from the cultivable microbiome of human feces (Lagier et al. 2012) that is not yet classified within known *Brevibacterium* species although it presents a 16S sequence close to the one from the recently described *B. yomogidense*. New species of *Brevibacteriaceae* are thus shortly expected. Alternatively, some species were recently removed from the *Brevibacteriaceae* such as *Brevibacterium stationis* which was first described in 1944 as "*Achromobacter stationis*" (ZoBell and Upham 1944) and later assigned to the genus *Brevibacterium* by Breed (Breed 1953). This species was recently reclassified as *Corynebacterium stationis* comb. nov. (Bernard et al. 2010). Classification of *Brevibacterium* remains ambiguous, and a number of strains described as *Brevibacterium* in the literature or public generalist or dedicated databases have to be reclassified. The phylogenetic relationships of the 28 described species of *Brevibacterium* at the time of publication, built from 16S rRNA gene sequences, are shown in *Fig. 7.1*.

Molecular Analyses

The classification and typing of *Brevibacterium* have been done using DNA/DNA hybridization (Fiedler et al. 1981; Stackebrandt and Fiedler 1979), 16S rRNA gene sequence typing (Gavrish et al. 2004; Stackebrandt et al. 1997), or spectroscopic methods such as FT-IR (Oberreuter et al. 2002), DNA restriction enzyme analysis (ARDRA), pulsed-field gel electrophoresis (PFGE), and ribotyping (Hoppe-Seyler et al. 2007; Lima and Correia 2000). Nowadays, the identification is based mainly on classical molecular methods such as 16S DNA sequencing coupled with phenotypic characterization. Recently, a study developed and used both Multilocus Sequence Typing (MLST) and Comparative Genomic Hybridization approaches (CGH) to study the genomic variability of cheese-related *Brevibacterium* strains (Forquin et al. 2009). This study showed that MLST can be efficiently used to identify and type *Brevibacterium* species in a single step. CGH appears also interesting for screening purposes of specific metabolic routes but its use remains restricted to the analysis of the diversity of *B. aurantiacum* isolates (Forquin et al. 2009). Indeed, such tools were up to now developed from the only completed *B. aurantiacum* ATCC9174 genomic sequence. Specific tools should however soon be derived from the increasing number of released genomic sequences of *Brevibacteriaceae* genomes.

Until recently, a few data are available regarding *Brevibacterium* sp. genomes, plasmids, and even gene sequences. Released public information is briefly resumed in *Table 7.2*. Most available *Brevibacterium* sequence data corresponds to 16S rDNA genes. Regarding plasmids, data still remain scarce. Some *Brevibacteriaceae* have been reported as not harboring plasmids while several distinct plasmids, generally circular and of smaller sizes, were identified in others (Nardi et al. 2005). In addition, a large, linear plasmid (which is typically a characteristic of *Streptomyces*, *Arthrobacter*, *Nocardia*, and *Rhodococcus*) of 436 kb has recently been reported in an environmental *Brevibacterium* sp. isolated in Argentina (Dib et al. 2010). Historically, a first multicopy plasmid of a size of 7.75 kb, designated pBL100, has been isolated from *B. linens* DSM 20158 (Sandoval et al. 1985). Further, a plasmid designated pBL33 (7.3 kb) has been isolated from *B. aurantiacum* ATCC 9174 which, interestingly, showed a restriction map very similar to that of the pBL100 plasmid. It also appeared identical to plasmids previously isolated by Kato et al. (1989) from a range of *Brevibacteriaceae*. Small plasmids with similar restriction profiles were further confirmed in six strains of *B. linens* (Holtz et al. 1992) suggesting that small, putatively conjugative plasmids with potentially wider host ranges within the genus may exist in *Brevibacteriaceae*. It has been indicated in older studies that some of these plasmids encoded extracellular proteases. This has to be confirmed by modern sequence data analysis such as the one from the *B. linens* OC2 genome. Indeed, plasmid is likely to be harbored by the currently sequenced *B. linens* OC2 genome (our unpublished data), but this has to be confirmed after gap closure. Systematic genome sequencing in the genus is thus aimed at increasing the knowledge and the characterization of *Brevibacteriaceae* plasmids for which maintenance, replication, and transfer mechanisms are not yet fully understood. Some findings on plasmid biology were indeed published for strains which were nowadays reclassified as *Rhodococcus* sp. or *Corynebacterium* sp. and no systematic plasmid screening has been performed until recently. In addition, plasmids classically used for the genetic manipulation of *Corynebacterium* sp. were derived from strains like "*B. lactofermentum*" or "*B. flavum*" that are all nowadays reclassified as *C. glutamicum*. The lack of tools necessary to perform genetic modifications in this species, for long, hindered the systematic genetic investigation of *Brevibacteriaceae* metabolism (Nardi et al. 2005). Thus, traditionally, selection under pressure rather than genetic manipulation has been used for industrial strain improvement but also for evident reasons as food safety and public acceptance, explaining the lack of interest for the development of genetic engineering tools. Difficulties for genetic manipulation may also have arisen from the lack of knowledge on DNA methylation or CRISPR-like defense mechanisms of *Brevibacteriaceae* against foreign DNA (Roux et al. 2012).

Nowadays, several sequencing projects of *Brevibacterium* genomes have started (*Table 7.2*). One *B. casei* S18 *Brevibacterium* genome project is listed on the NCBI website and other projects are on their way including the genome sequence of *B.marinum*, *B. casei*, *B epidermidis*, *B. picturae*, *B. permense*, *B. antiquum*, and *B linens* (T. Vallaeys, M.P. Forquin-Gomez, F. Irlinger; J Kalinowski, unpublished information).

Three draft genomes are available on the NCBI website. The draft genome of *B. mcbrellneri* consists of 96 contigs, has a total length of 2.56 Mb with a G+C content of 58 %, and 2,490 genes are predicted that encode 2,432 proteins. The draft genome of *B. massiliense* DSM23039 has just been released (Roux et al. 2012). It contains 7 scaffolds and 27 contigs (>1,500 bp) and a total length of 2.36 Mb. Its G+C content was 62.3 %.

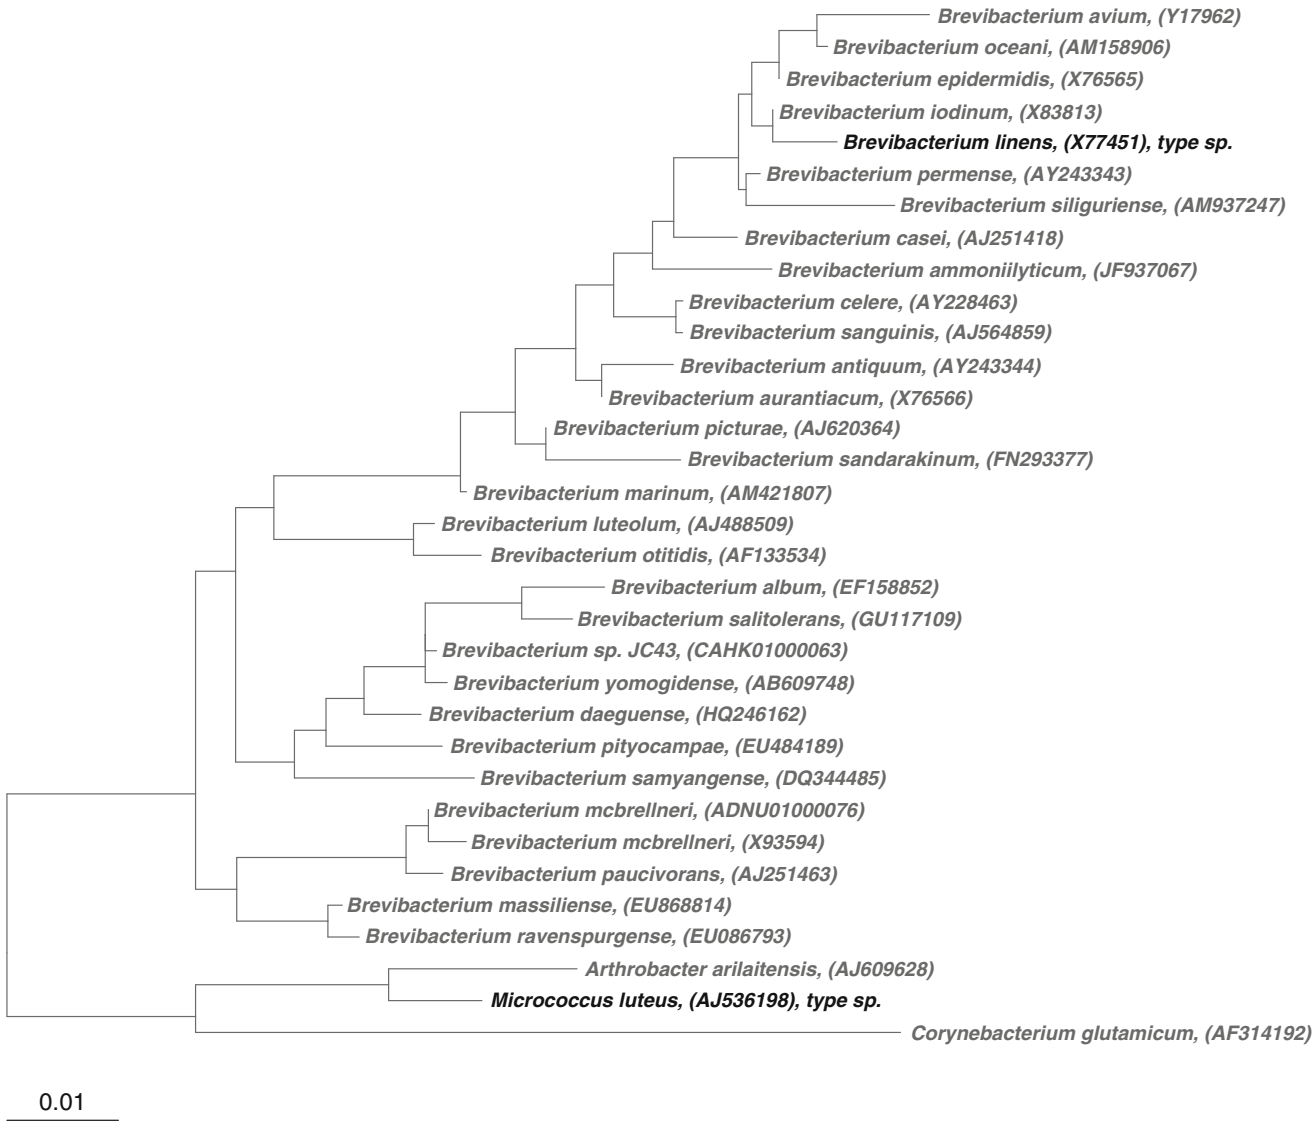

Fig. 7.1

Phylogenetic reconstruction of the family *Brevibacteriaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

The genome contains 43 tRNA genes and encodes 2,154 putative proteins. The last draft genome sequence available belongs to *Brevibacterium* sp. JC43 (accession number CAHK01000000). This *Brevibacterium* was isolated from the cultivable microbiome of humans, and this strain is apparently related to *B. yomogidense*. The genome of *B. aurantiacum* ATCC9174 has been completely determined (Forquin-Gomez et al., unpublished). The genome consists of a circular chromosome of 4.4 Mb and one plasmid of 7.3 kb. The entire genome with a G+C content of 62.3 % contains 4,104 predicted protein-coding genes (4,097 in the chromosome and 7 on the plasmid) and 48 tRNA genes. Four rDNA operons were identified on the chromosome, organized in the order 16S-23S-5S. The annotation was performed and protein functions according to the COG (Clusters of Orthologous Groups) classification have been assigned. The categories "unknown function" and "general function prediction only" represent 38 % of the genes in the genome. The analysis showed that the highest number of predicted functions (8 %) belongs to the category "amino acid metabolism" and 7 % of genes are involved in transcription. The category carbohydrate metabolism represents only 4 % of the protein-coding genes in the genome. Similar data

were obtained for *B. linens* OC2, this draft genome has been assembled in 4 scaffolds which G+C content is 62.3 % (unpublished data).

Phenotypic Analyses

Brevibacterium are gram-positive coryneform bacteria and strictly aerobic; nonmotile, except for *B. album* (Tang et al. 2008) and *B. iodinum* (Collins et al. 1980); non-spore forming; catalase positive; and frequently halotolerant bacteria (5 % NaCl is a standard but up to 20 % NaCl is tolerated by given environmental isolates). Their optimal growth temperatures range from 20 °C to 30 °C for the environmental or food-derived strains and up to 37 °C for the human isolates (Table 7.1). However, given *Brevibacteriaceae* were reported to grow at temperatures below 12 °C (Table 7.1). *Brevibacterium* strains grow from pH 5.8 on with an optimum at pH 7. *Brevibacterium* sp. usually alkalinizes its growth medium (up to pH 9.5). Interestingly, in complex media, *Brevibacterium* exhibits a typical distinct rod-coccus cycle. In exponential phase, the cells are rod-shaped, becoming

coccoid-shaped in the stationary phase (3–7 days old cultures). Cell length is thus variable but remains within the range of 0.6–1 μM. The typical arrangement of cells seen under the microscope is V-shaped with cells adherent at one side with an angle resulting from an unequal rupture of the cell walls after cell division. The cell-wall peptidoglycan of *Brevibacterium* is based on cross-linked meso-diaminopimelic acid (Schleifer and Kandler 1972), and complex teichoic acids assembling neutral sugars, amino sugars, and sugar alcohols (Anderton and Wilkinson 1980; Fiedler et al. 1981). Cellular fatty acids are typically branched and long chained, belonging to the anteiso- and iso-methyl types, with 12-methyltetradecanoic and 14-methylhexadecanoic acids predominating (Bousfield et al. 1983; Collins et al. 1980, 1983). Although some strains synthesize phosphatidylinositol (Collins et al. 1980, 1983), diphosphatidylglycerol, phosphatidylglycerol, and dimannosyl-diacylglycerol constitute major polar lipids. Menaquinones constitute the sole respiratory quinones detected in the cellular membrane of *Brevibacteriaceae* with preponderant dihydrogenated menaquinones carrying eight isoprene units (MK- 8[II-H2]) (Collins et al. 1980, 1983).

Production of volatile sulfur compounds (VSCs) such as methanethiol, dimethyl disulfide (DMDS), dimethyl trisulfide (DMTS), or *S*-methyl thioesters are among the major characteristics of *Brevibacterium*, especially for strains of industrial use. A number of *Brevibacteriaceae* typically convert methionine into methanethiol via a unique one-step reaction using methionine γ-lyase. This compound is then oxidized into VSCs. The VSCs of *B. linens* and *B. aurantiacum* have been well described (Bonnarme et al. 2000, 2001; Dias and Weimer 1998a, b; Forquin et al. 2011; Weimer et al. 1999). Interestingly, VSC production is not limited to strains of industrial importance, and *B. mcbrellneri* (McBride et al. 1993), *B. sanguinis* (Wauters et al. 2004), *B. epidermidis*, *B. casei*, *B. marinum*, *B. celere*, and *B. picturae* (Heyrman et al. 2004) also produce some VSCs (Forquin-Gomez, personal observations). *B. antiquum* and *B. aurantiacum* are also able to produce *S*-methyl thioesters using short-chain fatty acids or branched-chain amino acids as precursors (Sourabié et al. 2012). VSCs production by *B. casei* and *B. epidermidis* is also suspected to be responsible for unpleasant body odors (Jones and Keddie 1986).

A number of *Brevibacteriaceae* are producing pigments, constituting another phenotypic characteristic of the genus. The color of mature colonies varies from clear white beige or grey (*B. epidermidis*, *B. casei*) to orange (*B. linens*) and cream with purple dots (*B. iodinum*) (*Table 7.1*). This typical dark red coloration is due to the secretion of purple crystals of a derivative of the phenazine derivative iodine by *B. iodinum*, which gave the name to the species. Orange colors result from carotenoids, the production of which has been reported to be enhanced by light. Novel metabolic characteristics reported in lately described isolates of environmental *Brevibacteriaceae* include heavy metal metabolism and degradation of long-chain aliphatics (crude oil) and aromatic carbon for which pathways remain mostly undeciphered (Ng et al. 2010; Verma et al. 2013). Such characteristics pave the way to the setting up of new culture media for the selective isolation of this for long-neglected group of environmental *Brevibacteriaceae*.

Isolation, Enrichment, and Maintenance Procedures

Brevibacterium globally comprises easy cultivable species. Its diversity of habitats, originally thought to be restricted to dairy products, has long been masked by the lack of attempts to isolate it from other sources. *Brevibacteriaceae* are indeed grown easily on most peptone-yeast extract agars as well as on brain-heart infusion agars under aerobic conditions as long as salt is added (up to 4 % NaCl is suitable). They are relatively fast growers and can be isolated after incubation at ambient temperatures (mostly 20–25 °C) for 3–5 days. Higher temperatures select for those species living on the human skin and for animal isolates while temperatures of 10–20 °C are preferable for the isolation and culture of soil-inhabiting and marine strains. *Brevibacterium* species are mainly aerobic but growth in microaerophilic conditions, and even weak growth in anaerobic conditions, has been reported (Roux and Raoult 2009). No selective media are available and apart from microscopic characteristics such as the so-called coryneform morphology, 16S sequencing is the method of choice for their identification. Extended metabolic analysis resulting from genome sequences may however soon fill the gap by elaboration of more selective or at least enriching growth media.

Ecology

Brevibacteriaceae are typically halotolerant bacteria and are predominantly found in habitats with increased salt concentrations, including marine environments and salted foods (*Table 7.1*). Indeed, several species are related to saltwater. *B. oceani* has been isolated from deep-sea sediments, *B. samyangense* from beach sediments, *B. salitolerans* from salt-lake sediment, *B. marinum* from seawater, *B. siliguriense* from river water, and *B. celere* from brown algae. *Brevibacterium* species were also recently isolated from lagunal samples and salines in southern France and Tunisia (Abbes and Vallaeys, unpublished data). Similarly, other strains were isolated from saline terrestrial environments: *B. album* was isolated from a saline soil, but *B. antiquum* and *B. permense* were isolated from permafrost soils. However, a *B. antiquum* relative was also isolated from cheese (Forquin et al. 2009). Salted foods constitute another preferential habitat for *Brevibacteriaceae*: *B. aurantiacum and B. linens* are major components of the microflora of surface-ripened cheese such as Munster, Limburger, Tilsiter, and Romadour (Brennan et al. 2002; Feurer et al. 2004a, b; Mounier et al. 2005, 2009), however, sharing the smear niche with other coryneforms such as *Arthrobacter*, lactic acid bacteria, and yeasts (Feurer et al. 2004a, b). Interestingly, a strain of *B. linens* T4 has been found to represent over

96 % of the assigned cloned 16S rDNA sequences obtained from a library constructed from total DNA extracted from the curd of a farm house-produced *Fourme de Montbrison* suggesting either increased competitiveness or antibacterial and antifungal activity for this strain (Vallaeys unpublished data). Similarly, *B. casei* has been isolated from cheese curd and cheddar cheese but also from milk. Interestingly, some strains of this species were isolated from human clinical specimens. Further, *Brevibacterium* appears as a ubiquitous species colonizing a wide range of natural but also human-shaped habitats. Two species were indeed isolated form indoor environments: *B. sandarakinum* from a wall and *B. picturae* from a damaged mural painting at the Saint-Catherine chapel of Castle Herberstein in Austria. An extended diversity of habitats is further suggested by recent studies: *B. iodinum* was originally isolated from milk and *B. avium* was isolated from poultry skin, *B. yomogidense* from poultry manure. *B. ammoniilyticum* and *B. daeguense* have been isolated from the sludge of a wastewater treatment plant. *B. luteolum* has been isolated from environmental and human clinical samples. Nowadays, more and more species are isolated from humans, *Brevibacterium epidermidis* forms part of the resident human skin microflora, and *B. sanguinis*, *B. mcbrellneri*, *B. ravenspurgense*, *B. paucivorans*, *B. otitidis*, and *B. massiliense* were also isolated from humans, suggesting that given *Brevibacterium* species could present an infective potential.

Pathogenicity, Clinical Relevance

Until relatively recently, *Brevibacteriaceae* were not associated with human infections. However, it seems that *Brevibacteriaceae* have recently emerged as background opportunistic pathogens, affecting immunocompromised patients. Of the nine known species of *Brevibacterium* isolated from human clinical samples, *B. casei* is the most frequently reported species from clinical specimens. Indeed, several human infections involving *B. casei* have been reported (Brazzola et al. 2000; Cannon et al. 2005; Gruner et al. 1994; Janda et al. 2003; Kumar et al. 2011; Ulrich et al. 2006). Cases involving *B. epidermidis* (Manetos et al. 2011) and *B. otitidis* (Dass et al. 2002; Ulrich et al. 2006; Wauters et al. 2000) were also published. Moreover, *B. mcbrellneri* was isolated from genital hair of patients infected with white piedra in association with *Trichosporon beigelii* (McBride et al. 1993). *B. luteolum* (Wauters et al. 2003), *B. paucivorans* (Wauters et al. 2001), and *B. sanguinis* (Wauters et al. 2004) were also associated to human infections. Isolates belonging to the *Brevibacterium* genus have been also implicated in corneal ulcers (Ghosheh et al. 2007) but also bacteremia (Ulrich et al. 2006). Implications of *Brevibacterium* in pericardial infections (Cannon et al. 2005), endocarditis (Dass et al. 2002), peritonitis (Antonoiu et al. 1997; Wauters et al. 2000), osteomyelitis (Neumeister et al. 1993), and even brain abscess (Kumar et al. 2011) were reported. Recently, *B. massiliense* has been isolated from a human ankle discharge. However, for long *Brevibacterium* infections were almost exclusively described in immunocompromised patients. Only three patients with *Brevibacterium* bacteremia were not immunocompromised in a classical sense, but still suffered from severe diseases. One can thus consider that given members of the *Brevibacteriaceae* constitute opportunistic pathogens rather than pathogens of clinical relevance.

General Metabolism

General metabolic characteristics of the genus are detailed in *Table 7.3*. Historically, the main metabolic studies in *Brevibacterium* sp. were related to cheese production. *Brevibacterium* strains are indeed known to produce volatile sulfur compounds that are key aromas of cheese flavor (Dias and Weimer 1998a, b; Forquin et al. 2011; Sourabié et al. 2012, 2011; Weimer et al. 1999). Industrial *Brevibacterium* species, mainly related to *B. linens* and *B. aurantiacum* but also *B. antiquum* (Forquin et al. 2009), convert methionine into methanethiol by means of methionine γ-lyase (Dias and Weimer 1998a; Forquin et al. 2011), which then is converted to dimethyl disulfide (DMDS), dimethyl trisulfide (DMTS), and *S*-methylthioesters (Sourabié et al. 2012). The expression of genes encoding methionine γ-lyase and a methionine low-affinity transporter is induced in the presence of methionine, in combination with a significant increase in production of volatile sulfur compounds (Forquin et al. 2011).

The *Brevibacteriaceae* can produce different types of proteinases or peptidases which are extracellular, intracellular, or cell wall associated (see Rattray and Fox 1999 for a review). Various studies have shown the ability of proteinases from *Brevibacteriaceae* to hydrolyze milk caseins (Coskun and Sienkiewicz 1999; Frings et al. 1993; Rattray et al. 1995, 1996) (*Table 7.3*). Extracellular proteinolytic activity has been detected in 15 strains of *Brevibacterium* (Foissy 1974), and six extracellular proteases have been purified and characterized, showing high variability in optimal temperatures and pH (Rattray and Fox 1999). *The Brevibacteriaceae* additionally produce several intracellular proteinases (Fernández et al. 2000; Rattray and Fox 1997b) and cell-wall-associated proteinases, whose activities are relatively low when compared to those of the extracellular enzymes (Rattray and Fox 1999). Interestingly, the genome analysis of *B. aurantiacum* ATCC 9147 shows the presence of 17 aminopeptidases, 10 carboxypeptidases, 7 endopeptidases, and 4 serine proteases. (Forquin et al. Unpublished Data) suggesting the major role of amino acids in *Brevibacterium* life environment.

Brevibacterium also produces lipases. The lipolytic activity has been demonstrated to be mainly cell associated, with a maximal activity at 37 °C and alkaline pH (Adamitsch and Hampel 2000; Adamitsch et al. 2003). However, lipase activity appears to be distributed heterogeneously in the genus and even within the species. Early studies performed on *B. linens* showed, indeed, an extracellular lipase activity in selected isolates, while others appeared to be restricted to the intracellular compartment.

Esterase activity is also found in *Brevibacteriaceae*. Intracellular esterase activity was reported early using α-naphthyl acetate, β − naphthyl butyrate, or tributyrin, *o*-nitrophenyl, and *p*-nitrophenyl derivatives of acetic and butyric acids as substrates (Foissy 1974). One esterase was purified and characterized. Its pH and temperature optima were 7.5 and 35 °C, respectively (Rattray and Fox 1997a).

Catabolism of aromatic compounds is another typical metabolic characteristic of the given members of the genus playing a major role in the formation of flavors and their precursors, especially through the metabolism of aromatic amino acids that were suspected to be actively transported through the membrane by three high affinity permeases in *B. linens*. Phenol and indole are indeed both found at elevated concentration in red smear cheeses. Transamination was then early suspected to constitute the first step in the utilization of aromatic amino acids that could be used as sole nitrogen sources in *B. linens* (Rattray and Fox 1999) and aromatic amino acid aminotransferase activity was detected. Aromatic ring cleavage is then carried out by dioxygenases, and the involvement of a 3,4-dihydroxyphenylacetate 2,3-dioxygenase was early proposed although catechol 2,3-dioxygenases are principal enzymes involved in the breakdown of non-substituted aromatics (Topp et al. 1997). These early data have thus to be confirmed by modern genomic approaches.

Some *Brevibacteriaceae* are also characterized by the fact that they produce a typical orange to red pigmentation. Pigments involved in the orange color were identified as aromatic carotenoids: the isorenieratene, 3-hydroxy-isorenieratene, and, finally, 3,3′-dihydroxyisorenieratene. The genes encoding the synthesis pathway of these pigments were identified in *B. aurantiacum* DSM20426 and are part of the *crt* cluster (Krubasik and Sandmann 2000). The formation of these compounds from isopentenyl pyrophosphate (IPP) occurs by the successive action of IPP isomerase, Idi; a geranylgeranyl pyrophosphate (GGPP) synthase, CrtE; a phytoene synthase, CrtB; β-carotene desaturase, CrtU; and finally a cytochrome P450 (Dufossé and de Echanove 2005; Krubasik and Sandmann 2000).

Brevibacterium has been reported to produce a variety of bacteriocins and antimicrobial substances. Three of the compounds have been characterized in detail. Some strains of *B. linens* produce a bacteriocin, Linocin M18, active against species of the actinobacterial genera *Arthrobacter*, *Corynebacterium*, and *Micrococcus* as well as to those of Firmicutes such as *Bacillus* and *Listeria* (Valdes-Stauber and Scherer 1994). The Linencin A is only active against some other *B. linens* strains but not against other species of the genera *Brevibacterium*, *Corynebacterium*, and *Micrococcus* (Kato et al. 1991). Finally, *B. linens* strain OC2 produced a bacteriocin designated Linenscin OC2, which is different from the two other bacteriocins Linecin A and Linocin M18 (Maisnier-Patin and Richard 1995). Linenscin OC2 inhibits growth of gram-negative bacteria by altering outer membrane permeability and gram-positive bacteria (*Staphylococcus aureus* and *Listeria monocytogenes*) (Boucabeille et al. 1998). More genome sequencing projects to be carried out in the future are expected to further enlighten typical and strain-specific metabolic characteristics of strains from the genus *Brevibacterium*.

Applications

Brevibacterium has for long been recognized for its major industrial potential in dairy production, particularly in the maturation of surface-ripened cheeses, including Munster, Cheddar, and Camembert. *Brevibacteriaceae* produce multiple flavor compounds that include compounds derived from lipolysis, fatty acids, and volatile sulfur compounds (Dias and Weimer 1998a, b; Ganesan et al. 2004; Ummadi and Weimer 1996, 2001; Weimer et al. 1999). In *Brevibacteriaceae*, the proteolytic and lipolytic abilities are also used to accelerate cheese ripening (Weimer et al. 1997). *Brevibacterium* species are also thought to produce specific antibacterial molecules to control growth of food pathogens (Boucabeille et al. 1998; Maisnier-Patin et al. 1992; Motta and Brandelli 2002), as well as production of orange pigmentation (Guyomarc'h et al. 2000; Krubasik and Sandmann 2000). All these characteristics contribute to give *Brevibacterium* a major role in the elaboration of the organoleptic properties of cheese. These properties brought industrials and scientists to screen for *Brevibacteriaceae* strains, investigate their sulfur metabolism, protease production, pathways involved in pigment production, and finally, their genomes. Bacteriocin production but also, potentially, antibiotic production constitute also alternatives, especially, in the latter case if given *Brevibacteriaceae* appear as potential carriers of large, linear, (Makarova et al. 2006) Streptomycete-like plasmids (Dib et al. 2010). More recently, this somehow restricted range of applications has extended. Some indigenous *Brevibacterium* strains of heavy metal-contaminated Kuwaiti soils showed, along with indigenous *Agrobacterium* and *Corynebacterium* strains, a high tolerance to heavy metal pollution and hydrocarbon pollutions (Ali et al. 2012). Even further, *Brevibacterium linens* strains were shown able to grow using *n*-alkanes as carbon substrates. An obvious application for these metabolisms is to be used to clean up crude oil contamination. Whether the presence of some contaminants like sodium arsenate or cadmium sulfate facilitates this metabolic pathway is yet unclear but the direct crude oil consumption rate seemed promising. Such data underline the potential of given indigenous *Brevibacteriaceae* to constitute an interesting source of organisms for bioremediation of mixed organic–inorganic pollutions. This also includes *B. casei* that has been used to produce gold and silver nanoparticles (Kalishwaralal et al. 2010) and to detoxify hexavalent chromium (Ng et al. 2010; Verma and Singh 2013) as well as pentachlorophenol (Verma and Singh 2013). Bioremediation may thus very soon emerge as a novel application for a range of environmental *Brevibacteriaceae* that have been generally neglected up to now.

Abstract
The suborder *Catenulisporineae* (Cavaletti et al. 2006) has recently been elevated to the order level (Ludwig et al. 2012) in the course of an adjustment of higher ranks within *Actinobacteria* (Stackebrandt et al. 1997). This order forms an independent lineage within class I *Actinobacteria*, phylum Actinobacteria. The order comprises the two families *Catenulisporaceae* (Busti et al. 2006a) and *Actinospicaceae* (Cavaletti et al. 2006) and two genera, *Catenulispora* and *Actinospica* which harbor five and two species, respectively. The two families share moderate 16S rRNA gene sequence relatedness of 93.1 % similarity among each other and less than 92.5 % similarity with any other, mainly mycelium-forming members of class I. Strains of both genera, including the type strains of *C. acidiphila, A. robiniae and A. acidiphila*, possess genes coding for non-ribosomal peptide synthases and polyketidsynthases I and II, indicative of antimicrobial activity. Isolated mainly from forest soil, paddy fields and rhizophere and at least *Catenulispora* strains appear globally distributed.

Taxonomy, Historical and Current

Short Description of the Families

Despription of the Order *Catenulispora*les

The order contains the families *Catenulisporaceae* and *Actinospicaceae*. The pattern of 16S rRNA gene signatures consists of nt 127: 234 (G–C), 138: 225 (U–A), 139: 224 (C–G), 140: 223 (C–G), 141: 222 (A–U), 157: 164 (G–C), 449 (C), 589: 650 (C–G), 602: 636 (R–U), 603: 635 (A–U), 694 (G) and 1251 (G) (Busti et al. 2006a). The type genus of the order is *Catenulispora*.

Description of the Family *Catenulisporaceae*

Ca.te.nu.li.spo.ra'ce.ae. N.L. fem. n. *Catenulispora* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Catenulisporaceae* the *Catenulispora* family. The pattern of 16S rRNA gene signatures consists of nt 127: 234 (G–C), 129: 232 (U–A), 449 (C), 580: 761 (U–A), 586: 755 (U–A), 591: 648 (C–G), 824: 876 (A–U), 825: 875 (A–U), 834: 852 (G–U), 838: 848 (U–G), 952: 1229 (U–A), 999: 1041 (U–U) and 1000: 1040 (U–U). The type genus is *Catenulispora* (Busti et al. 2006a).

Description of the Family *Actinospicaceae*

(Ac.ti.no.spi.ca'ce.ae. N.L. fem. n. *Actinospica* type genus of the family; -aceae ending to denote a family; N.L. fem. pl. n. *Actinospicaceae* the *Actinospica* family).

The pattern of 16S rRNA gene signatures consists of nt 127: 234 (G–C), 129: 232 (C–G), 344 (G), 449 (C), 450: 483 (C–G), 560 (U), 576 (G), 590: 649 (C–G), 591: 648 (U–R), 859 (G), 952: 1229 (C–G), 1122: 1151 (G–C), 1123: 1150 (U–G), 1124: 1149 (A–U). An insert of seven to nine extra nucleotides is present between positions 1134 and 1140. The type genus is *Actinospica* (Cavaletti et al. 2006).

Despite their remote relatedness members of the two families share several common morphological and chemotaxonomic features. With respect to fatty acid, polar lipid and menaquinone composition members of the two genera are similar (*Table 8.1*), though differences exist in the quantitative

composition, even among species of the same genus. The fatty acid composition given for the various *Catenulispora* species description is somewhat confusing and may be due to differences in growth conditions and methods used for generating their profiles and interpretation. Most authors find iso-C16:0 and anteiso-C17:0 fatty acids (Busti et al. 2006a; Tamura et al. 2007, 2008), though Lee et al. (2011) in their description for *C. graminis* could not verify the high amounts of antesio-C17:0. Morphologically strains are defined by a non-fragmentary vegetative mycelium and the formation of aerial mycelium. Members of both genera form straight to slightly flexuous hyphae which are arranged in tufts in members of *Actinospica*. In aged aerial mycelium hyphae septate into chains of cylindrical arthrospores. Of the properties traditionally used to separate actinobacterial genera it is mainly the composition of the amino acid composition of the peptidoglycan in which members of the two genera differ (*Tables 8.1* and *8.3*). *Actinospica* strains possess hydroxyl-diaminopimelic acid (Dpm) and traces of meso-Dpm (Dpm) (peptidoglycan type A1γ, see www.peptidoglycan-types.info). As in members of *Actinoplanes* and *Micromonospora* (Schleifer and Kandler 1972), glycine has replaced L-alanin bound to muramic acid. Strains of *Catenulispora*, on the other hand, possess meso-Dpm and glycine forms the interpeptide bridge; this type (A3γ) is found for example in members of *Streptomycetaceae, Nocardioides, Luteococcus, Marmoricola and in Propionibacterium.*

Phylogenetic Structure of the Family and Its Genera

According to the original descriptions of the genera, the two families are moderately related (93.1 % 16S rRNA gene sequence similarity) and share less than 92.5 % similarity with *Sporychthya polymorpha, Cryptosporangium arvum* (Busti et al. 2006a; Cavaletti et al. 2006). These two genera are not included in the phylogenetic dendrogram of Lee et al. (2011), though *Micromonospora, Nakamurella* and other genera defined by mycelium forming organisms are also found as nearest neighbors.

The type strains of two species of *Actinospica*, *A. robiniae* and *A. acidophila* are closely related, sharing 97.5 % sequence similarity. Of the five species of *Catenulispora C. rubra* Aac-30^T and *C. acidophila* ID139908^T are highly related (99.4 %). The similarities between *C. subtropica* 99-48^T, *C. yoronensis* TT N02-20^T,

and *C. acidiphila* ID139908^T and *C. rubra* Aac-30^T ranged between 97.4 and 98.7 % (Tamura et al. 2008). *C. graminis* BR-34^T (its sequence has not yet been included in the LTP database) appears as most unrelated species of the genus, sharing less than 97.4 % with any other type strain (*Fig. 8.1*).

Molecular Analyses

DNA reassociation studies using the fluorimetric method of Ezaki et al. (1989) have been performed on a few *Catenulispora* strains to confirm either the strain affiliation to the same species (Tamura et al. 2008) or to verify the species status. In any pair wise comparison similarity values were lower than 50 % (Tamura et al. 2008; Lee et al. 2011).

The level of phylogenetic distinctness of 29 *Catenulispora* and 34 *Actinospica* isolates was assessed by capillary electrophoresis of PCR amplified ITS spacer regions (Busti et al. 2006b). Twelve strains with unique patterns were identified which were further analyzed by 16S rRNA gene sequence analysis and screened for the presence of non-ribosomal peptide synthases and polyketidsynthases (PKS) I and II, Primers used for the amplification of the latter genes and modifications of the PCR protocol of Courtois et al. (2003) as well as phylogenetic analysis of translated gene fragment sequences are indicated by Busti et al. (2006b).

The genome sequences of *Catenulispora acidophila* DSM 44928^T has been generated in the frame of the GEBA (*Genomic **E**ncyclopedia of **B**acteria and **A**rchaea*) Project (Copeland et al. 2009). The genome is 10.6 Mb and comprises one circular chromosome. The DNA G+C content is 69.8 mol% GC content, hence 1.7 mol% lower than reported in the original description of the species. 9,056 genes coding for proteins were identified, 66 genes code for RNAs, and 142 pseudogenes were found. Of the identified genes 68.2 % and 31.8 % of the identified genes were assigned with a putative function and annotated as hypothetical proteins, respectively. Of the 5,707 genes associated with the general COG functional categories, 265 genes are associated to

[a]Trace

secondary metabolites biosynthesis, transport and catabolism. Among the easily recognizable clusters within the genome are those for the biosynthesis of leinamycin-, thiopeptide- and actinorhodin-related compounds (S.D., unpublished). The latter is probably dedicated to the synthesis of the isochromanequinone GTRI-BB described by Busti et al. (2006b). The genome sequence corroborates the finding of Busti et al. (2006b) on the antibiotic producing ability of the taxon; *Streptosporangium roseum* DSM 43021^T, a known antibiotic-producing strain with a similar genome size contains 315 of such genes (Nolan et al. 2010). On the other hand, only 50 such genes have been reported to be present in the, albeit lower, 4.1 Mb genome of *Cellulomonas flavigena* DSM 20109^T, a rod-shaped actinobacterium for which no such potential has been described (Abt et al. 2010). The genome size has been determined for two additional strains of *Catenulispora* and one *Actinospica* strain, using pulsed-field electrophoresis of *Ase*I, and *Dra*I restriction fragments. The genome size estimated from the fragment sizes obtained from the two enzymes ranged between 8.3–8.6 and 8.3–9.9 Mb for *Catenulispora* isolates (Neo1 and Neo2, respectively) and 8.3–8.8 for *Actinospica* strain Gamma 3 (Busti et al. 2006b).

Phenotypic Analyses

The main phenotypic properties distinguishing *Catenulispora* and *Actinospica* as well as the type strains of the five *Catenulispora* species are indicated in Tables 8.1 and 8.3, respectively. Cultural characteristics for all members of the families were tested on ISP2, ISP3, ISP4, ISP5, ISP6 and ISP7 agar plates (Shirling and Gottlieb 1966), acidified to pH 4.5–5.5. Type strains of both genera differ from each other in the combination of characteristics determined for each medium. Detailed information is available in the original descriptions. *Actinospica* type strains did not exhibit enhanced growth in the presence of carbon sources added to CMM supplemented (Busti et al. 2006a) ISP9 medium and ISP4 medium (omitting starch and pH adjusted to 5.0–5.5); carbon utilization can therefore not be determined for these type strains, nor compared to the reactions available for *Catenulispora* type strains.

Catenulispora Busti et al. 2006, 1745^{VL}, emend Tamura et al. 2008

Ca.te.nu.li.spo'ra. L. fem. n. catenula small chain; Gr. fem. n. spora seed; N.L. fem. n. *Catenulispora* a thin chain of spores).

The emendation of the genus was based on four species and not all of the morphological properties have been determined for all strains. These are Gram-positive, non-acid-fast, and aerobic. The vegetative mycelium does not fragment and the branching aerial hyphae start to septate in chains of cylindrical arthrospores during aging. Motile elements are not produced. Most strains are acidophilic but one type strain tolerates growth at pH 8.0. The peptidoglycan contains LL-A_2pm with glycine as the interpeptide bridge. Iso-$C_{16:0}$ and anteiso-$C_{17:0}$ are present as major cellular fatty acids in most strains. Whole cell sugar composition and polar lipid composition are variable. Menaquinones MK-9(H6) and MK-9(H8) are predominant in most strains. The G+C content of the DNA is 69–72 mol%. The type species is *Catenulispora* acidiphila.

Differentiating metabolic reactions are indicated in Table 8.2. In contrast to *Actinospica* strains most *Catenulispora* strains are metabolically active as they are able to utilize a wide range of carbohydrates and are enzymatically active. All strains hydrolyse starch and do not utilize methyl β-xylopyranoside (Lee et al. 2011). As not all strains have been tested by the same commercial kits we refrain from listing addition positive and negative reactions and refer the reader to the original species descriptions. As judged from the data indicated in Tables 8.1 and 8.2, *C. graminis* appears to be more diverse than the other four type strains, supporting the deepest branching 16S rRNA lineage within the genus.

Actinospica Cavaletti et al. 2006, 1751^{VL}

Ac.ti.no.spi'ca. Gr. n. actinos a ray; L. fem. n. spica tuft; N.L. fem. n. *Actinospica* an actinomycete with tufts of aerial hyphae.

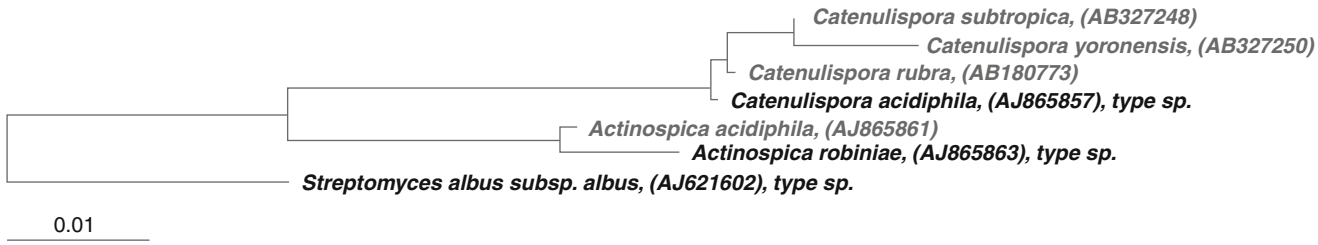

Fig. 8.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of *Catenulisporales*. present in the LTP_106 (Yarza et al. 2010). Representative sequences from close relative genera were used to stabilize the tree topology. In addition, a 40 % maximum frequency filter was applied to remove hypervariable positions from the alignment. *Scale bar* indicates estimated sequence divergence

In addition to properties indicated in *Table 8.2*, the following traits were recorded (Cavaletti et al. 2006): Gram-positive, aerobic, mesophilic, acidophilic and catalase positive. Non-fragmenting vegatative hyphae. Tufts of straight to slightly flexuous hyphae originating from very short sporophorous branching in few sporogenous hyphae. Hyphae form chains of cylindrical arthrospores in aging cultures. Motile elements are not produced. Growth is not supported at pH values higher than 6.2. Grow better on acidic yeast extract–malt extract agar (ISP2) and acidic oatmeal agar (ISP3)

The two type strains share moderate 16S rRNA gene sequence similarity but they are very similar otherwise (*Table 8.3*). As each species is defined by a single strain only even these differences may be strain-, rather than species—specific, such as differences in tolerance towards 1 % NaCl (w/v), starch hydrolysis, size of cylindrical spores and cultural appearance on different ISP media.

Isolation, Enrichment and Maintenance Procedures

The isolation procedure described for members of the two genera varied widely. While *C. graminis* BR34^{T} was isolated on acidified (pH5.5) ISP medium (Lee et al. 2011), *C. subtropica* TT99-48^{T} and *C. yoroensis* TT N02-20^{T} were isolated by using the yeast extract/SDS method (Hayakawa and Nonomura 1989) on humic acid/vitamin (HV) agar (Hayakawa and Nonomura 1987), containing per litre 20 mg nalidixic acid and 50 mg cycloheximide (Tamura et al. 2008). The cultivation medium for *C. rubra* Aac-^{30T} consisted of equal parts of a glucose/yeast extract agar medium pH.5.0 and a mineral salt broth, pH about 4.0 (Tamura et al. 2007). *C. acidiphila* ID 39908^{T} (Busti et al. 2006a), and *A. robiniae* GE134769T and *A. acidiphila* GE 134766*T* (Cavaletti et al. 2006) were isolated from a dried soil sample which was resuspended in a 18.2 mM citric acid, 164 mM Na_2HPO_4 buffer (pH7). Serial dilutions were spread onto a soil extract, gellan gum, $CaCl_2$ medium, supplemented with traces of a vitamin solution. The precise protocol is given by Busti et al. (2006a). Colonies of the latter isolates were picked after 8 weeks of growth.

Strains can be maintained on ISP 2 agar or in GYM *Streptomyces* medium (http://www.dsmz.de/microorganisms/medium/pdf/DSMZ_Medium65.pdf). Medium-term preservation is done at −86 °C in the presence of 20 % (v/v) glycerol, while freeze-drying or storage under N_2 vapor is recommended for long term preservation (DSMZ information).

Ecology

Habitat

Acidic forest soil appears to be the main habitat though strains have been isolated from other soil samples and a rice paddy field as well. The functional role and possible interactions with other organisms is unknown. Busti et al. (2006b) noted, citing a more general observation by Sait et al. (2002), that members of the two genera have not been reported before in the decades long search for antibiotic-producing mycelium-forming actinomycetes (Williams et al. 1971; Khan and Williams 1975; Kim et al. 2003, 2004), especially as these organisms can be isolated on standard ISP 2 medium. On the other hand, within a short period of 5 years two genera with seven species has been added to the actinobacteria proper. In addition to the described type strains several other undescribed isolates cluster with either *Catenulispora* or *Actinospica* species. Within *Catenulispora* there are the six unnamed Neo isolates from acidic soils from Italy and Nicaragua which were included in their study on antibiotic-producing ability (Busti et al. 2006b). Of these, Neo 3 became later the type strain of *C. acidiphila*. Similarly highly related (>99 %) are the so called "Ellin" strains from soil (for Dairy Research Institute, Ellinbank, Victoria, Australia (38°14.55′S, 145°56.11′E) (Joseph et al. 2003) and other unidentified isolates, e.g., strain 12202 [AY639903]; and IMER-B1-10 [FJ796419] from a nonspecified habitats as well as several strains from Cliff soil: CR3-AC11 [FM998837], CR3-AC10 [FM998836], or CR3-AC7T [FM998835], tentatively named "*Catenulispora cavernae*." Using a 16S rRNA gene based PCR protocol for the specific detection of members of *Catenulispora*, Busti et al. (2006b) were able to detect signals in 33 % of those 100 different soil samples from Europe, Africa and America which had a pH of 5.5 or lower.

Clustering adjacent to the two type strains of *Actinospica* are more than 20 isolates from acidic soils (Tamura and Sakane

unpublished) as well as the so called Gamma strains included in the study by Busti et al. (2006b). The phylogenetic position of some of these isolates from both genera is shown by Cavaletti et al. (2006). It is noteworthy that there are hardly any records of environmental clone sequences falling into the phylogenetic radiation of the members of the two genera. Clone ncd2045h10c1 (JF176612) from an international skin consortium (Kong et al. unpublished) and clone mat161 (JN590556) of white lupin cluster roots (Weisskopf et al. 2011) are the only two records found after BLAST search. A 16S rRNA gene fragment sequence found in a clone library from DNA retrieved from acidic grasslands was moderately similar to the homologous gene sequence of *Actinospica acidiphila* (Jenkins et al. 2009). As a result of their study of community dynamics on plots of long-termed managed grassland undergone different fertilizing regimes, these authors also stress the prevalence of members of *Streptomyces*, *Acidimicrobium* and *Actinospica* in acidic soils thriving in.

Pathogenicity, Clinical Relevance

All members of the families are categorized as risk group 1 organisms by the DSMZ-internal risk assessment.

The antimicrobial activities of some *Catenulispora* (Neo) and *Actinospica* (Gamma) strains were evaluated by Busti et al. (2006b). Few bioactive metabolites have been reported from *Actinospica* and *Catenulispora* strains. Busti et al. (2006b) reported that strain Neo3 (the *C. acidiphila* type strain) produced a compound with anti-staphylococcal activity that showed UV–VIS maxima and a 629 $[M-H]^-$ *m/z* signal identical to those of isochromanequinone GTRI-BB (Yeo et al. 2002), although no further characterization was reported. As mentioned above, the *C. acidiphila* genome contains a gene cluster highly related to those involved into isochromanequinone biosynthesis. After prediction from genome analysis, *C. acidiphila* was demonstrated to produce the class III lantipeptide catenulipeptin, a 27-amino acid peptide containing two labionin bridges (Wang and van der Donk 2012). Catenulipeptin was apparently devoid of antimicrobial activity, but was able to stimulate aerial mycelium formation in surfactin-treated *Streptomyces coelicolor* (Wang and van der Donk 2012). Busti et al. (2006b) also reported that *Actinospica* strain Gamma22, an isolate with 16S highly related to that of *A. robiniae*, produced an unidentified compound with antimicrobial activities. Recent work has shows that this strain produces the new metabolite 6-hydroxychrolactomycin, along with minor amounts of chrolactomycin (Iorio et al. in preparation).

9 The Family *Cellulomonadaceae*

Erko Stackebrandt · Peter Schumann
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
Cellulomonadaceae, a family within the order *Actinomycetales*, embraces the genera *Cellulomonas, Oerskovia, Paraoerskovia* (including *Koreibacter*), *Actinotalea*, and *Tropheryma*. Irrespective of algorithms applied to the set of 16S rRNA gene sequences of type strains, *Tropheryma whipplei* and *Actinotalea fermentans* branch deeply and have *Cellulomonas bogoriensis* as their phylogenetic neighbor. Based upon the fragmentary phenotypic data on *Tropheryma whipplei* and comparative analysis of full genome sequences of some members of the suborder *Micrococcineae*, the position of the genus *Tropheryma* must be considered tentative. Members of the family are defined by a wide range of morphological and chemotaxonomic properties, such as polar lipids, fatty acids, amino acids of peptidoglycan, and whole cell sugars which are used for the delination of genera and species. Members of the family are mainly found in soil, but they have been isolated from patient material and the marine environment as well. Many species are described for their ability to decompose not only plant-derived macromolecules such as cellulose, starch, and xanthan but also chitin, DNA, and gelatine. Some strains of the genera *Cellulomonas* and *Oerskovia* are opportunistic pathogens. This contribution is a modified and updated version of previous family descriptions (Stackebrandt E, Schumann P, Prauser H (2006) The family *Cellulomonadaceae*. In: Dworkin M, Falkow S, Rosenberg E, Schleifer K-H, Stackebrandt E (eds) The prokaryotes, 3rd edn. Springer, New York, pp 983–1001; Stackebrandt E, Schumann P (2012) *Cellulomonadaceae*. In: Whitman WB, Goodfellow M, Kämpfer P, Busse H-J, Trujillo ME, Garrity G, Ludwig W, Suzuki K-I (eds) Bergey's manual of systematic bacteriology, vol 6, 2nd edn. Springer, New York, p 699).

Taxonomy: Historical and Current

Short Description of the Family

Phylogenetically a member of the order *Micrococcales* (Busse 2012), phylum Actinobacteria. The family contains the type genus *Cellulomonas* (Bergey et al. 1923; emended by Clark 1953; Stackebrandt et al. 1982), *Oerskovia* (Prauser et al. 1970; emended by Lechevalier 1972), *Actinotalea* (Yi et al. 2007), *Paraoerskovia* (Khan et al. 2009), and *Koreibacter* (Lee and Lee 2010). *Tropheryma* (La Scola et al. 2001) is included in this family in several communications and databases (e.g., http://www.bacterio.cict.fr/), but its membership to the family is doubtful (see comment below). Gram-positive but many of the older cells stain Gram-negative. Morphological forms vary from slender irregular rods of varying length, which may show primary branching, short filaments and coccoid forms may occur in late exponential phase cultures; or vegetative mycelia with the oldest parts of the mycelium fragmenting into sections of different size and more or less irregular shape; fragmentation may continue to yield rod-like cells of coryneform appearance and arrangement. Aerial mycelium is not formed. Motile by means of one or several polar or subpolar flagella, or peritrichous flagella; some species are nonmotile. Aerobic to facultatively anaerobic, producing acid from a variety of carbohydrates. Cross-linkage of the peptidoglycan is by the A type; diagnostic diamino acids

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_223,

For Abbreviations see *Table 9.2*.

are either ornithine or lysine. Interpeptide bridges contain either aspartic acid or glutamic acid; L-Thr in combination with a dicarboxylic amino acid occurs in one genus. 12-Methyltetradecanoic (anteiso(ai)-$C_{15:0}$) is the prominent fatty acid; $C_{16:0}$, i-$C_{15:0}$, $C_{14:0}$, and ai-$C_{17:0}$ may also occur. Menaquinone MK-9(H4) is the predominant isoprenoid quinone (*Table 9.1*). The set of 16S rRNA gene sequence signature nucleotides is comprised of position 120 (A), 131:231 (A–G), 196 (C), 342–347 (C–G), 444–490 (A–U), 580–761 (C–G), 602–636 (C–G), 670–736 (A–U), 822–878 (U–C), 823–877 (A–C), 826–874 (U–G), 827 (G), 843 (C), 950–1231 (U–A), 1047–1210 (G–C), 1109 (C), 1145 (G), 1309–1328 (G–C), 1361 (G), and 1383 (C).

If analyzed, polar lipids are diphosphatidylglycerol and phosphatidylglycerol besides unidentified lipids, phospholipids, and phosphoglycolipids. Mycolic acids, diagnostic whole cell sugars, and teichoic acids are absent. G+C values of DNA range between 68 and 76 mol%. Usually found in soil, compost, and cellulose-enriched environments such as decaying plant materials, bark, wood, sugar fields, rumen, and activated sludge; occasionally isolated from various clinical specimens. Members of two genera have been isolated from marine environment.

Comment on *Tropheryma*: The members of the subcommittee on the taxonomy of the suborder *Micrococcineae* did not consider the genus *Tropheryma* La Scola et al. 2001 a member of the family *Cellulomonadaceae* because of insufficient arguments for this classification (Schumann et al. 2009). These authors preferred to list this genus under genera incertae sedis. In the NCBI taxonomic browser (http://www.ncbi.nlm.nih.gov/ Taxonomy/Browser), this genus is listed under unclassified *Micrococcineae*. In the recent description of *Cellulomonadaceae* (Stackebrandt and Schumann 2012), neither *Tropheryma* nor *Demequina* was originally considered to be members of this family; both genera were included by the editors of *Bergey's Manual of Systematic Bacteriology*, vol 2 (Whitman et al. 2012). In this communication, *Tropheryma* will be dealt with only in the context of phenotypic and genomic comparison with members of *Cellulomonadaceae* (see also below).

Phylogenetic Structure of the Family and Its Genera

According to the phylogenetic branching of actinobacterial type strains in the RaxML 16S rRNA gene tree of the Living Tree Project (Yarza et al. 2010), the family is moderately related to the families *Promicromonosporaceae*, *Sanguibacteraceae*, and *Rarobacteraceae*. A phylogenetically broad group containing *Micrococcaceae*, *Actinomycetaceae*, and several other less species-rich families appear as a sister clade of these four families, while a clade embracing *Microbacteriaceae* and *Bifidobacteriaceae* is branching slighly deeper.

16S rRNA cataloguing (Stackebrandt et al. 1980a; Stackebrandt and Woese 1981) indicated *Cellulomonas* species to be related to members of *Arthrobacter*, *Micrococcus*, and related taxa. This relationship was supported by 5S rRNA analysis performed on *Cellulomonas biazotea* and a variety of coryneform bacteria (Park et al. 1987) and later by almost complete sequences of 16S rRNA gene sequences, characteristic indels in protein sequences analyzed from completely sequenced genomes (Gao and Gupta 2005), and recently from the fully sequenced genome of *Cellulomonas flavigena* (Abt et al. 2010).

Based upon phylogenetic evidence, the genera *Cellulomonas* and *Oerskovia* were united into the genus *Cellulomonas* (Stackebrandt et al. 1982). When the high correlation between phylogenetic clustering and chemotaxonomic distinctness within the actinobacteria became apparent, the phenotypic properties of cellulomonads and *Oerskovia*e were reevaluted. As a consequence, the generic status of *Oerskovia* was reconfirmed, *Cellulomonas cellulans* was excluded from *Cellulomonas* and reclassified as *Cellulosimicrobium cellulans*, while *Promicromonospora enterophila* was reclassified as *Oerskovia enterophila* (Stackebrandt et al. 2002).

Cellulomonas, *Oerskovia*, *Promicromonospora*, and *Jonesia* were members in the original description of the family *Cellulomonadaceae* (Stackebrandt and Prauser 1991, 480^{VL}, effective publication Stackebrandt and Prauser 1991, 263, emend. Stackebrandt et al. 1997, 484, emend. Stackebrandt and Schumann 2000, 1284). With the availability of sequences of several newly described type strains, the phylogenetic branching pattern of the family was refined (Rainey et al. 1995). Consequently, the genera *Promicromonospora* and *Jonesia* were excluded in the description of a new hierarchic structure of the *Actinobacteria* classis nov. (Stackebrandt et al. 1997) and the families *Promicromonosporaceae* (Rainey, Ward-Rainey and Stackebrandt) and *Jonesiaceae* (Stackebrandt, Rainey and Ward-Rainey), respectively, were described for the two genera. The emended family *Cellulomonadaceae* (Stackebrandt et al. 1997), described on the basis of phylogenetic position and signature nucleotides of 16S rRNA gene sequences, was affiliated to the suborder *Micrococcineae*, order *Actinomycetales* (Stackebrandt et al. 1997). The family then contained the genera *Cellulomonas*, *Oerskovia*, and *Rarobacter* (Yamamoto et al. 1988). Shortly afterward, several new genera were described as new members of the suborder *Micrococcineae* (Groth et al. 1997a, b, 1999; Martin et al. 1997); the addition of new 16S rRNA gene sequences to the database of actinomycete species changed the phylogenetic position of a few taxa while stabilizing other taxa. New families were described, i. e., *Rarobacteraceae*, *Bogoriellaceae*, *Dermacoccaceae*, and *Sanguibacteraceae* (Stackebrandt and Schumann 2000). 16S rRNA gene sequence signatures given in these family descriptions were adjusted according to novel sequences included in recent descriptions of *Cellulomonas* (Rivas et al. 2004; An et al. 2005; Brown et al. 2005; Jones et al. 2005; Kang et al. 2007) and *Oerskovia* species (Stackebrandt et al. 2002). A full update and revision of the signature-based hierarchic structure (Stackebrandt et al. 1997) of *Actinobacteria* was published by Zhi et al (2009) who included the genera *Actinotalea* (Yi et al. 2007), *Tropheryma* (La Scola et al. 2001), and *Demequina* (Yi et al. 2007) into *Cellulomonadaceae*. The latter genus was excluded from this family as a family of its own, *Demequinaceae* (Ue et al. 2011), on the basis of chemotaxonomic differences and the pattern of 16S rRNA signatures. The highly related genera *Paraoerskovia* and *Koreibacter* were described in 2009 (Khan et al. 2009) and 2010 (Lee and Lee 2010), respecively, but only *Paraoerskovia* has been formally included into *Cellulomonadaceae*. In the phylogenetic dendrogram given in the original description of *Koreibacter* (Lee and Lee 2010), the type strain K. algae DSW-2^T branched between the genera *Sanguibacter* and *Demequina*. The type strain of *Paraoerskovia* marina CTT-37^T, published 1 year earlier, was not included in the analysis of *Koreibacter algae*, hence excluding detection of a possible high phylogenetic relatedness. Blast analysis of the 16S rRNA gene sequences for the type strains of *K. algae* (FM995611) and *P. marina* (AB445007) resulted in a similarity of 100 %. The agreement in chemotaxonomic properties (peptidoglycan type A4α L-Lys-L-Ser-L-Glu, major menaquinone MK-9(H4), major fatty acids anteiso (ai)-$C_{15:0}$, ai-$C_{17:0}$, $C_{16:0}$, $C_{18:0}$), and the DNA-DNA similarity of 94 % led to the reclassification of the type strain DSW-2^T of *K. algae* as a strain of *P. marina* (Schumann et al. 2013).

The genus *Oerskovia* with its four species forms a monophyletic cluster. In the maximum likelihood (◉ *Fig. 9.1*) and parsimony (not shown) trees, 15 of the 18 *Cellulomonas* species form a coherent cluster, while *C. bogoriensis*, *C. hominis*, and *C. denverensis* cluster outside the *Cellulomonas*/*Oerskovia*/*Paraoerskovia* group. The species *Cellulomonas phragmiteti*, described recently (Rusznyák et al. 2011), will be added in the next update of the LTP tree. Its nearest phylogenetic neighbor is *C. flavigena*.

Molecular Analyses

DNA-DNA Hybridization Studies

Almost all descriptions of *Cellulomonas* and *Oerskovia* species include results of DNA-DNA hybridization (DDH) studies and a few species only were found to be closely related (>40 % similarity), e.g., *Cellulomonas biazotea* and *C. fimi*, and a cluster comprising *C. uda*, *C. flavigena*, *C. persica*, and

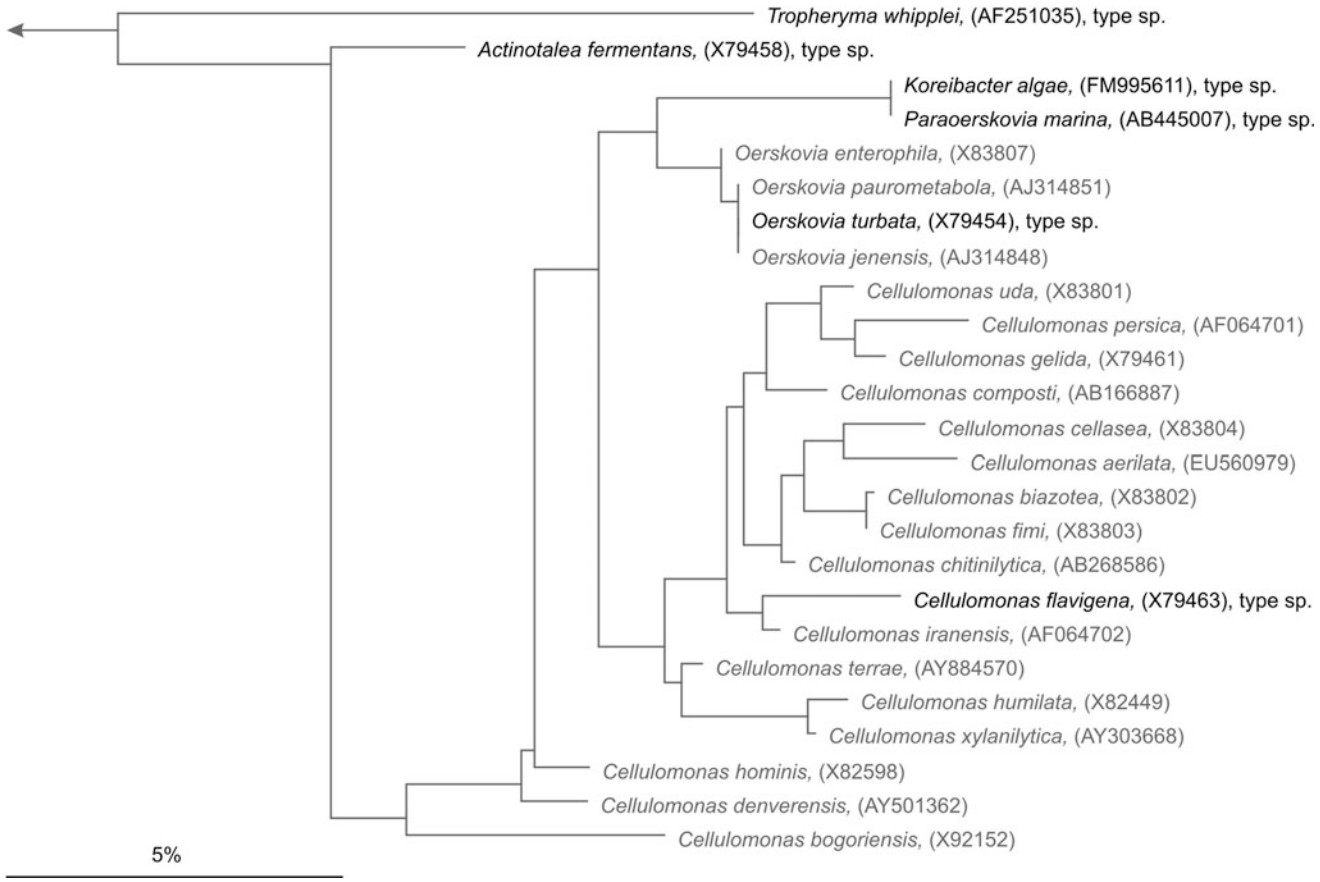

Fig. 9.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the family *Cellulomonadaceae* present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences List of type strains used for dendrogram construction: *Actinotalea fermentans* DSM 3133^T, *Cellulomonas aerilata* 5420S-23^T, *C. biazotea* DSM 20112^T, *C. bogoriensis* 69B4^T, *C. cellasea* DSM 20118^T, *C. chitinilytica* X.bu-b^T, *C.composti* TR7-06^T, *C.* denverensis W6929^T, *C. fimi* DSM 20113^T, *C. flavigena* NCIMB 8073^T, *C. gelida* NCIMB 8076^T, *C. hominis* DMMZ CE40^T, *C. humilata* NCTC 25174^T, *C. iranensis* O^T, *C. persica* I^T, *C. terrae* DB5^T, C. uda DSM 20107^T, *C. xylanilytica* XIL 11^T, *Koreibacter algae* DSW-2^T, *Oerskovia enterophila* DSM 43852^T, *Oerskovia jenensis* DSM 46000^T, *Oerskovia paurometabola* DSM 14281^T, *Oerskovia turbata* NCIMB 10587^T, *Paraoerskovia marina* CTT-37^T, *Tropheryma whipplei* Twist-Marseille^T. *Cellulomonas carbonis* T26^T, *C. soli* Kc1^T and *C. oligotrophica* Kc5^T are not included because of their recent descriptions (see genus description)

C. iranensis (Stackebrandt and Kandler 1979; Elberson et al. 2000). Others were more distantly related such as those reported for the type strains of *C. xyl*anilytica and *C. humilata* (37 %; An et al. 2005), between *C. cellasea* (<35 %) and some other *Cellulomonas* strains, between *C. denverensis* and *C. hominis* (24–33 %, Brown et al. 2005), between *C. aerilata* and related strains (16–28 %, Lee et al. 2008), between *C. chitinilytica* and other cellulomonads (7–23 %, Yoon et al. 2008) as well as between *C. soli* and *C. oligotrophica* and 13 type strains of *Cellulomonas* (<35 %, Hatayama et al. 2012). Moderate DDH relatedness of 37–40 % between type strains of *Actinotalea* (then [*Cellulomonas*] *fermentans* and *C. uda*, Bagnara et al. 1985), however, is no proof for intrageneric membership as shown by the later exclusion of *C. fermentans* from *Cellulomonas* and its reclassification as *Actinotalea fermentans* on the basis of chemotaxonomic properties. Discrimination of the type strains of the four *Oerskovia* species by DDH revealed similarity values below 70 %, indicative of members of the separate genomospecies. DDH values are moderately high with values ranging between 55 % and 75 % similarity. *Oerskovia paurometabola* and *O. jenensis* are close neighbours, as strains of these species share between 64% and 75 % DNA similarity (Stackebrandt et al. 2002).

The description of *Paraoerskovia* gen. nov. was substantiated by a moderate DDH value determined for the type specis *Paraoerskovia marina* and *Oerskovia enterophila* JCM 7350T (10–12 %). The necessity of the transfer of *Koreibacter* algae DSW-2^T into the species *Paraoerskovia marina* has been indicated by a DNA-DNA similarity of 94 %.

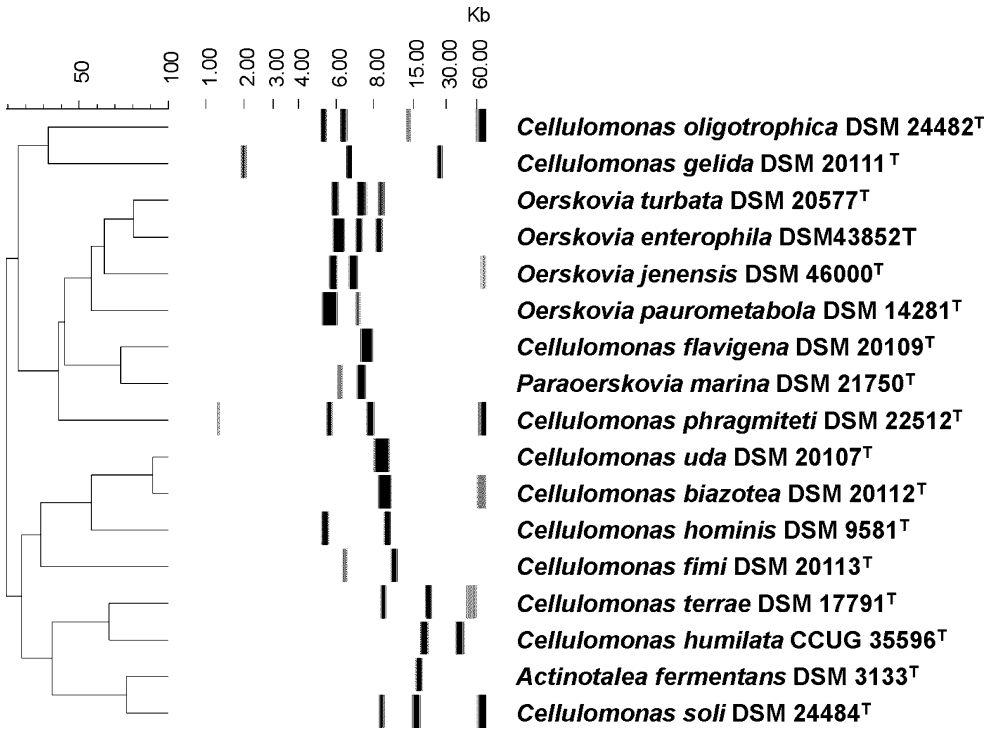

Fig. 9.2

RiboPrint patterns of those type strains of the family *Cellulomonadaceae* species which are cut by *Pst*I. The dendrogram has been generated with the BioNumerics software (Applied Math, Kortrijk, Belgium)

Riboprinting and Ribotyping

The presence of restriction sites for different nucleases and the presence of conserved regions next to more highly variable ITS regions and flanking regions have made the rrn operons an ideal target for species characterization. While the automated robot RiboPrint® system works with entire rrn operons and flanking DNA regions, the ribotype approach usually works with PCR amplified 16S rRNA genes which are then subjected to restrictions and one-dimensional gel electrophoresis. Because the RiboPrint system targets the entire rrn operons at the genome level, its discrimination is superior.

RiboPrint pattern of strains of members of *Cellulomonadaceae* are routinely generated and used in the authentication process of the DSMZ collection. However, as the standard restriction enzyme *Eco*RI does not cut at all and as the cleavage sites of enzymes *Pvu*II and *Pst*I are not present in all members of the family, two subsets need to be generated. *Figure 9.2* shows the *Pst*I patterns of the *Oerskovia* and some *Cellulomonas* species (Stackebrandt et al. 2002), as well as those of the type strains of *Paraoerskovia* marina and *Actinotalea fermentans*. *Figure 9.3* displays the second set of strains in which the patterns were generated with *Pvu*II (*Paraoerskovia marina* is cut by both enzymes *Pvu*II and *Pst*I). The highest RiboPrint similarity of over 90 % is seen between the type strains of *C. uda* and *C. biazotea* (*Fig. 9.2*). This relationship is neither supported by an exclusively high 16S rRNA gene sequence similarity nor for DDH similarities between *C. uda* and *C. biazotea* for which these data are available. These results reinforce the notion that RiboPrint analyses are not indicative of intrageneric relationships.

Riboprinting and ribotyping of members of *Cellulomonadaceae* have been generated in taxonomic studies (Stackebrandt et al. 2002), in a molecular epidemiology study of *Oerskovia turbata* causing endocarditis and *Cellulomonas hominis* (McNeil et al. 2004) and on a single *Oerskovia* strain isolated from paper mill pulps (Suihko and Skyttä 2009).

MALDI-TOF

A recent introduction into the molecular tool box is the MALDI-TOF (matrix-assisted laser desorption/ionization time-of-flight) mass spectrometric approach, a cheaper and faster way of strain characterization than the generation of riboprints. This method compares the mass spectra recorded in the range of 2.000–20.000 m/z of biomolecules (mainly ribosomal proteins) extracted from the microbial cells by a simple sample preparation (Tóth et al. 2008). These mass spectrometric fingerprints are used for the reliable species identification of bacteria, yeasts, and fungi by comparison with reference databases. Dendrograms based on the similarity of MALDI-TOF mass spectra provide an insight into the phylogenetic relationship of species in good agreement with results obtained by sequence comparison of housekeeping genes (Schumann, unpublished).

The MALDI-TOF analyses of type strains of *Cellulomonadaceae*, also routinely performed in the DSMZ collection for

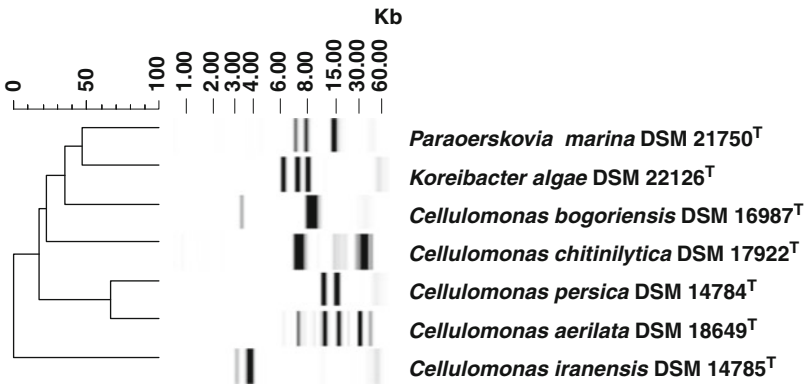

Fig. 9.3

RiboPrint patterns of those type strains of the family *Cellulomonadaceae* species which are cut by *Pvu*II. The dendrogram has been generated with the BioNumerics software (Applied Math, Kortrijk, Belgium)

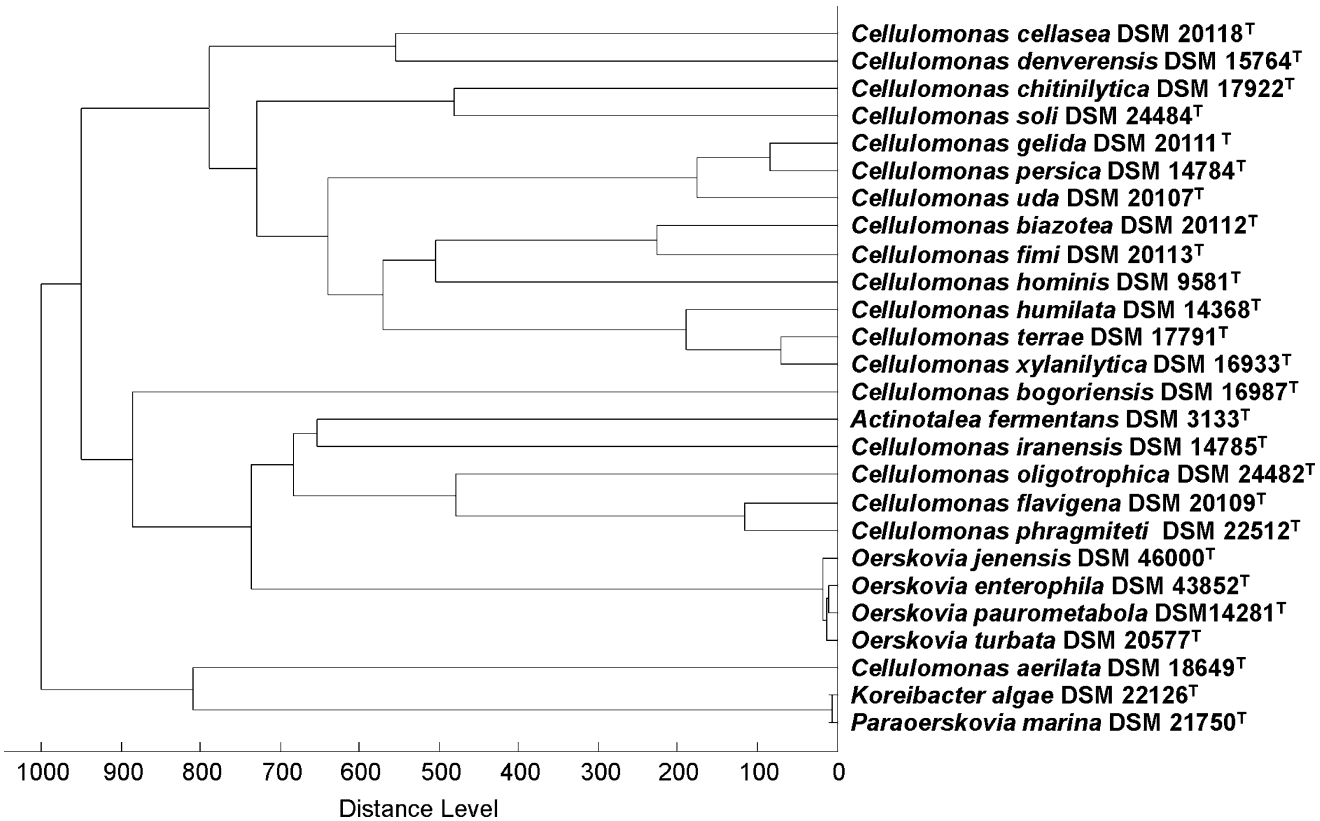

Fig. 9.4

Score oriented dendrogram generated by the BioTyper software (version 2.0, Bruker Daltonics) showing the similarity of MALDI-TOF mass spectra of cell extracts of selected type strains of the family *Cellulomonadaceae*

authentication purposes, display a wide range of spectral similarities. Similar to the 16S rRNA gene sequence, dendrogram type strains of *Oerskovia* as well as *Paraoerskovia marina* and *Koreibacter algae* (see below) are highly related (Fig. 9.4). *Cellulomonas* strains do not form a coherent cluster, but the strains branching outside the main cluster are different to those in the 16S rRNA gene tree. However, several clusters of *Cellulomonas* species agree in the 16S rRNA gene sequence and MALDI-TOF MS–based dendrograms: *C. gelida*/*C. persica*/*C. uda*, *C. fimi*/*C. biazotea*, *C. flavigena*/*C. phragmiteti*, *C. xylanilytica*/*C. terrae*/*C.*

humilata. The MALDI-TOF approach has been mainly used for functional studies such as on carbohydrate-binding modules of xylanase from *Cellulomonas fimi* (Boraston et al. 2001; Boraston et al. 2003) and on studies of mannose from *C. fimi* (Hekmat et al. 2010).

Genome Comparison

The complete genome sequences of two species branching within the 16S rRNA gene tree of *Cellulomonadaceae* have been released. The genome of the type strain of *Cellulomonas flavigena* DSM 20109T (Abt et al. 2010).(GOLD ID Gc01326) is 4,123,179 bp long, contains 3.788 genes, including six copies for the 16S rRNA gene, and the mol% G+C of DNA is 74.3 %. The latter value falls into the range of 72.7–74.8 mol% determined for the species (*Table 9.2*) by HPLC and thermal denaturation. Annotation of the 3.735 genes coding for proteins gene sequences revealed the presence of several proteins related to the synthesis of carotenoids (similar to those found in *Beutenbergia cavernae*, *Leifsonia xyli* subsp. *xyli*, and *Sanguibacter keddii*). The highest number of genes associated with general COG functional categories is found for carbohydrate transport and metabolism, followed by transcription (272 and 270, respectively) and amino acid transport and metabolism (209). In accordance with the species description of *C. flavigena* is the absence of genes related to flagellum structure and flagellum biogenesis (though eight genes are listed to be responsible for cell motility), as well as the presence of several genes involved in the degradation of xylane and cellulose. The presence of a chitinase points toward the ability of *C. flavigena* to degrade chitin though this property has never been reported.

The second species is *Tropheryma whipplei* with the genomes of two strains (strain Twist and TW08/27) fully sequenced. These two strains are highly related as their ANI (average nucleotide identity) value is 99.3 %, thus above the 95 % threshold value determined to separate different species (Konstantinidis and Tiedje 2005) and the presence of about 900 genes shared at the nucleotide level and 773 genes share at the amino acid level (AAI) (Konstantinidis, personal communication). These two genomes are, however, not closely related to the genomes of *C. flavigena*, *Brevibacterium linens and Beutenbergia cavernae*, as indicated by the very low number of less than 10 shared genes at the nucleotide level and about 500 shared genes at the aminoacid level. The ANI values are as low as about 83 % and unreliable because of the low number of shared genes. At the amino acid level, *Tropheryma* strains shows 48 % AAI to either of the other three genomes compared, indicating that *T. whipplei* is not closer related to *Cellulomonas flavigena* than it is to the type strains of *Beutenbergia cavernae* or *Brevibacterium* linens. As mentioned above, the membership of *Tropheryma* to the family is a moot point, a notion that is confirmed by the genome analyses.

Phages

The set of phages proposed to be specific of the genus *Oerskovia* (Stackebrandt and Prauser 1991; Prauser 1984, 1986; Prauser and Falta 1968) are phages O2 (DSM 49109) (host *O. turbata* DSM 43878), O3 (DSM 49138) (host *O. jenensis* DSM 46000 T), and O6 (DSM 49111) (host *O. turbata* DSM 20577 T). The hosts for phages O5 (DSM 49112) and O13 (DSM 49139) described originally as *Cellulomonas cellulans* (DSM 43881 and DSM 46215, respectively) have been reclassified as *Cellulosimicrobium cellulans*.

Phenotypic Analyses

The main features of members of *Cellulomonadaceae* are listed in *Tables 9.1–9.3*.

Cellulomonas Bergey et al. 1923, 154, emend. mut. char. Clark 1952, 504^{AL}.

Cellu.lo.mo'nas. M.L. n. cellulosa cellulose; Gr. n. monas a unit, monad; M.L. fem. n. *Cellulomonas* cellulose monad.

Young cultures of *Cellulomonas* consist of slender, irregular rods ranging between ~0.4 and 0.8 μm in diameter. The rods vary considerably in length and may appear as short filaments in late exponential phase cultures (24 h) when examined by the methods described by Cure and Keddie (1973). They may also show primary branching. As growth proceeds, the rods become shorter and V formations become more obvious. One-week old cultures or older cultures are usually composed mainly of short rods but a proportion of the cells may be coccoid. When placed on fresh solid medium, growth of coccoid cells occurs by elongation from one or sometimes two parts of the cell to give rods which appear club-shaped or jointed. However, they do not show the marked rod-coccus cycle characteristic of *Arthrobacter* and *Brevibacterium*. Only *Cellulomonas humilata* forms a mycelium with true branching that fragments into diphtheroid and coccoid elements (Collins and Pascual 2000).

Moderate growth occurs in air at 30 °C on meat extract, peptone agar or yeast-extract, peptone-based agar media at near neutral pH (Keddie and Jones 1981). Colonies on such media are opaque, usually convex, ~1–3 min in diameter, and usually yellow, but sometimes white. *C. humilata* forms branched, filamentous microcolonies (Gledhill and Casida 1969). Some strains grow at 10 °C, some at 5 °C, and the maximum temperatures are in the range 36–43 °C (cited in Stackebrandt and Keddie 1986). If tested, strains do not survive heating at 63 °C for 30 min (Keddie et al. 1966). All strains grow best aerobically and most give markedly reduced growth under anaerobic conditions (Keddie 1974; Keddie and Cure 1977). *C. soli* and *C. oligotrophica* can grow anaerobically on basal medium agar without Fe(III)-nitrilotriacetic acid (Hatayama et al. 2012). *C. humilata* is microaerophilic (Gledhill and Casida 1969). Glucose, maltose, and sucrose are fermented by all species, while a few species fermented one or two of the carbohydrates

mannitol, xylose, dextrin, ß-methyl-xyloside, rhamnose, and gluconat. The main products of glucose dissimilation in resting cell suspensions of several type strains are acetic acid, L-lactic acid, formic acid, succinic acid, ethanol, and CO_2. End products of aerobic glucose dissimilation are mainly CO_2 and either acetate or acetate and L-lactate (Stackebrandt and Kandler 1979, 1980a, b). Lactic acid is the main endproduct of sugar dissimilation by *C. humilata* (Gledhill and Casida 1969) while end products were not determined for strains described in the past years. The major route for glucose dissimilation is the Embden-Meyerhof-Parnas pathway; a small amount of glucose is metabolized via the hexose monophosphate pathway (Stackebrandt and Kandler 1974; 1980b). This finding is supported by determination of respective key enzyme activities of these pathways in *C. flavigena* (Kim 1987) and C. uda (Marschoun et al. 1987). Under anaerobic conditions, resting cells produce mainly CO_2, acetate, lactate, and ethanol as well as smaller amounts of succinate and formate. As shown with *C. flavigena*, gluconate is catabolized via the Entner-Doudoroff (ED) pathway and HMP shunt (Kim 1987).

Biotin and thiamine are the only exogenous organic growth factors required by the type strains of *C. flavigena*, *C. biazotea*, *C. cellasea*, *C. gelida*, and *C. uda* (Keddie et al. 1966); when provided with these vitamins, growth occurs in suitable mineral media with glucose as carbon + energy source and an ammonium salt (or nitrate for most strains) as nitrogen source (Owens and Keddie 1969).

Cellulomonas species have been extensively characterized with respect to chemotaxonomic properties. The diagnostic amino acid in position 3 of the peptide subunit of the peptidoglycan is ornithine with the interpeptide bridge containing either D-aspartic acid (*C. flavigena*, *C. phragmiteti*, *C. iranensis*, *C. persica*) or D-glutamic acid (all other species) (*Table 9.2*). Rhamnose is the major diagnostic cell wall sugar in most strains. Menaquinone MK-9(H4) is the predominant isoprenoid quinone (Collins and Jones 1981; Collins and Pascual 2000). 12-Methyltetradecanoic (ai-$C_{15:0}$) and hexadecanoic ($C_{16:0}$) acids are the dominant components of fatty acid patterns of cellulomonads, other branched-chain (e.g., i-$C_{15:0}$, ai-$C_{17:0}$) and straight-chain (e.g., $C_{14:0}$, $C_{15:0}$) fatty acids occur in lower amounts (Funke et al. 1995; no data are available on cellular fatty acids of *C. iranensis*, *C. persica*, and *C. humilata*). Phosphatidylglycerol (Lechevalier et al. 1981), diphosphatidylglycerol, and phosphoglycolipid are the major polar lipids (Minnikin et al. 1979). No data are available on isoprenoid quinones and polar lipids of *C. iranensis*, *C. persica*, *C. humilata*, and *C. hominis*.

Chemotaxis toward cellobiose and hemicellulose hydrolysis products, e.g., cellotriose, D-glucose, xylobiose, and D-xylose as well as other sugars, has been observed in *C. gelida* ATCC 486 (Hsing and Canale-Parola 1992). Two types of separately regulated cellobiose receptors (Cb1 and Cb2) were described, allowing the motile organism to migrate toward

plant containing cellulose and hemicellulose by swimming up concentration gradients of cellobiose and other sugars. While one receptor Cb1 was inducible and bound to cellobiose and xylobiose, receptor Cb2 was synthesized constitutively and bound to cellobiose, cellotriose, xylobiose, and D-glucose. In a following paper, the authors (Hsing and Canale-Parola 1996) described that L-methionine is required for normal cell motility and chemotaxis and that S-adenosylmethionin is involved in sugar chemotaxis. Methylation occurred posttranslationally, increased upon addition of sugar

attractants and decreased after removal of the stimulating sugars. The cellulolytic enzymes are controlled by catabolic repression, as activity against carboxymethyl cellulose is only low during growth on glucose or cellobiose (Stoppok et al. 1982; Choi et al. 1978)

All cellulomonads are able to grow under aerobic and microaerophilic conditions and *C. uda* ATCC 21399 (Dermoun et al. 1988) grows under strictly anaerobic conditions as well. Glucose uptake of whole cell suspension of an unidentified *C. fimi* isolate was two-fold higher under aerobic condition than under N_2 or H_2; cellobiose negatively affected glucose uptake (Khanna 1993).

The three *Cellulomonas* species described recently, not included in ❯ *Fig. 9.1*, show the following 16S rRNA gene sequence relatedness to other species: *C. carbonis* T26^T is moderately related to *C. bogoriensis* DSM 69B4^T (69.4 % similarity) in trees obtained with various algorithms, forming a sister clade to the other *Cellulomonas* type strains (Shi et al. 2012). *C. soli* Kc1^T and *C. oligotrophica* Kc5^T, sharing 97.8 % sequence similarity between each other, display highest similarities with *C. terrae* DB5^T (98.1–98.4 %) (Hatayama et al. 2012).

Oerskovia Prauser et al. 1970, 534^{AL} emend Stackebrandt et al. 2002.

Oers.ko'vi.a M.L. dim. *-ia* ending; M.L. fem.n. *Oerskovia* in honor of J. Øerskov who first described this organism.

*Oerskovia*e are typical nocardioforms but may show a coryneform appearance depending on the particular strain, the age of the culture, and the external growth conditions. In general, they are characterized by extensively branching vegetative hyphae (ca. 0.5 µm in diameter) which grow on the surface of the agar or penetrate into it. The substrate hyphae fragment into bacillary and coccoid or spore-like elements, which can be motile by differently arranged flagella, i.e., subpolar tufts of one to three flagella (Higgins et al. 1967) and monotrichous flagella (for short cellular elements) and peritrichous flagella (for longer cells) (Sukapure et al. 1970). All elements, motile and nonmotile, resulting from fragmentation, may give rise to new mycelia independent of their size. No aerial mycelium is formed. The growth appears bacteroid in smears. Colonies are lemon-yellow to whitish. Their consistency is smooth and the surface is glistening with a tendency to dull. Edges show mycelial or at least hyphal character, resembling those of other nocardioforms.

The most straightforward placement of an unidentified strain into the genus *Oerskovia* is a combination of 16S rRNA gene sequence analysis and determination of the peptidoglycan type A4α. Teichoic acids are lacking (Evtushenko et al. 1984b). The cytochromes belong to the a, b, and c types (Seidl et al. 1980).

While *Oerskovia enterophila* DSM 43852^T utilizes a broad range of BIOLOG compounds (76 of 95 substrates), *O. paurometabola* DSM 14281 reacts mostly negative toward the BIOLOG substrate panel (28 of 95) (❯ *Table 9.3*). *O. turbata* and *O. jenensis* are metabolically similar (Stackebrandt et al. 2002). Differentiating phenotypic properties are displayed in ❯ *Table 9.2*. All *Oerskovia* strains were positive in the following reactions API "coryne" reactions: oxidase, catalase, nitrate reduction, pyrazimidase, α-glucosidase, *N*-acetyl-ß-glucosidase, ß-glucosidase, and fermentation of glucose, ribose, xylose, maltose, and saccharose. All strains were negative in the following reactions: pyrrolidonyl arylamidase, ß-glucuronidase, and fermentation of mannitol and lactose.

All strains utilized the following Biolog GP substrates: ß-cyclodextrin, dextrin, glycogen, Tween 40, *N*-acetyl glucosamine, D-gluconic acid, α-D-glucose, maltose, maltotriose, mannose, ribose, salicin, sucrose, trehalose, turanose, D-xylose, methyl-pyruvate, glycerol, adenosine, 2-deoxy adenosine, inosine, thymidine, uridine, and adenosine-5′-monophosphate. The following substrates were not utilized by any *Oerskovia* strain: inuline, D-arabitol, melizitose, *p*-hydroxyphenyl acetic acid, α-keto glutaric acid, alaninamide, D-alanine, L-alanine, L-alanyl-glycine, glucose-1-phosphate, and glucose-6-phosphate.

All *Oerskovia* strains were positive in the following reactions API "coryne" reactions: oxidase, catalase, nitrate reduction, pyrazimidase, α-glucosidase, *N*-acetyl-ß-glucosidase, ß-glucosidase, and fermentation of glucose, ribose, xylose, maltose, and saccharose. All strains were negative in the following reactions: pyrrolidonyl arylamidase, ß-glucuronidase, and fermentation of mannitol and lactose.

All strains utilized the following Biolog GP substrates: ß-cyclodextrin, dextrin, glycogen, Tween 40, *N*-acetyl glucosamine, D-gluconic acid, α-D-glucose, maltose, maltotriose, mannose, ribose, salicin, sucrose, trehalose, turanose, D-xylose, methyl-pyruvate, glycerol, adenosine, 2-deoxy adenosine, inosine, thymidine, uridine, and adenosine-5'-monophosphate. The following substrates were not utilized by any *Oerskovia* strain: inuline, D-arabitol, melizitose, *p*-hydroxyphenyl acetic acid, α-keto glutaric acid, alaninamide, D-alanine, L-alanine, L-alanyl- glycine, glucose-1-phosphate, and glucose-6-phosphate. ❯ *Table 9.3* lists the differentiating-phenotypic properties of *Oerskovia* species.

Actinotalea, Paraoerskovia, and *Koreibacter* are monospecific genera. Some of their salient properties have been covered unter "short description of genera" and in ❯ *Table 9.1*.

Paraoerskovia Khan et al. 2009, 2094^{AL}. emend. Schumann et al. 2013.

Pa.ra.oer.sko'via. Gr. prep. *para* beside; N.L. fem.n. *Oerskovia* a bacterial genus name; N.L. fem. n. *Paraoerskovia* beside or close to *Oerskovia*.

Koreibacter alga is a later heterotypic synonym of *Paraoerskovia marina* and the unification required the emendation of *Paraoeroskovia. Paraoerskovia marina* (Khan et al. 2009) is catalase-positive and oxidase-negative. Cells are 0.4–0.6-µm wide and 1.0–1.6-µm long. Colonies on HSMA or ISP2 plates after 3–5 days of incubation at 28 °C are creamy yellow-coloured colonies, 1–2 mm in diameter. Carotenoid-type pigments are present. Growth occurs at 10–35 °C (optimum at 28 °C) and pH 6.0–10.0 (optimum pH 7.0–8.0). Growth occurs at 0–8 % NaCl (w/v).

According to the API 50CH system, it is positive for acid production from starch, glycogen, cellobiose, sucrose, trehalose, gentiobiose, maltose, L-arabinose, D-fructose, D-galactose, D-glucose, D-mannose, D-xylose, esculin ferric citrate, glycerol, turanose (type strain) and negative for 33 other tests of the

panel. Positive for the degradation of CM-cellulose and starch and negative for the degradation of casein, cellulose, chitin, and gelatin. In the API ZYM system, positive for leucine arylamidase, α- and β-glucosidase, lipase *N*-acetyl-ß glucosaminidase, and esterase (type strain) and negative for all other enzymes included in the test panel. For the type strain, menaquinones MK-9 and MK-9(H2) are detected in addition to the major menaquinone MK-9(H4). Traces of xylose occur in addition to the major cell-wall sugar galactose.

Actinotalea Yi et al. 2007, 155^{AL}.

Ac.ti.no.tal'e.a. Gr. n. actis, actinis ray; L. fem. n. talea a slender staff, rod, stick; N.L. fem. n. *Actinotalea* ray stick.

Actinotalea fermentans (Bagnara et al. 1985) was isolated as *Cellulomonas fermentans* from a methanogenic enrichment culture from a municipal dumping ground of unrecorded origin in France. The type strain M^T exhibits a coryneform polymorphism, 0.2–0.5 by 0.6–1.7 µm. Colonies are white with an undulate margin, 2–3 mm in diameter. A zone of cellulose digestion around colonies is observed in cellulose agar. Anaerobic, but shows growth under aerobic conditions without any apparent benefit. Growth on arabinose, cellulose, fructose, galactose, glucose, glycogen, lactose, maltose, mannose, mannitol, raffinose, starch, sucrose, trehalose, xylose, and xylan but not on asparagine, arbutine, glycerol, inulin, melibiose, melezitose, pectin, rhamnose, ribose, pyruvate, salicin, sorbitol, and urea. Fermentation products are acetic acid, formic acid, ethanol, occasionally L-(+)-lactic acid, and, in smaller amounts, carbon dioxide and succinic acid. No growth under aerobic conditions on butanol, butyrate, citrate, ethanol, gluconate, lactate, propanol, propionate, or succinate but grows slowly on acetate. Yeast extract (0.05 %) and casamino acids (0.2 %) support only slight growth. Growth factors other than biotin and thiamine together are required and can be provided by 0.05 % yeast extract. Gelatin is liquefied, nitrate reduction positive, NH_3 is produced from peptone. Neither acetyl methyl carbinol nor indole is produced. Catalase- and urease-negative. Optimum temperature between 30 °C and 37 °C. No growth at 50 °C. Optimum pH around 7.4. Growth rate decreases substantially when pH is under 7 and over 8. Cell wall sugars are glucose, rhamnose, and ribose.

Isolation, Enrichment, and Maintenance Procedures

Members of the family *Cellulomonadaceae* grow on a wide range of media as do many other soil bacteria. The main problem in their isolation is the exclusion of organisms that cover large areas of the isolation plates, e.g., swarming bacilli, pseudomonads, and hyphal fungi, as well as the suppression of the numerous streptomycetes, which may be confused at first sight with young stages on the isolation plates and which may possibly antagonize the *Oerskoviae*. Cultures may be enriched in a mineral-based medium containing a low (0.05-0.1 %) concentration of yeast extract to provide the necessary organic growth factors, and filter paper as cellulose source (Stackebrandt and Keddie 1986). This is followed by plating on a similar solid medium but containing cellulose in dispersed form. Cellulolytic bacteria produce colonies surrounded by zones of clearing. Direct plating on cellulose agar, or R2A medium (Reasoner and Geldreich 1985) without previous enrichment, may also be used. The methods are not selective for *Cellulomonas* and isolates must be screened for those with a coryneform morphology, followed by molecular characterization.

Suspensions or macerates of the material being examined, soil, compost, etc., may be streaked directly onto the surface of cellulose agar (Stewart and Leatherwood 1976) of the following composition (g/100 ml of distilled water): $NaNO_3$, 0.1; K_2HPO_4, 0.1; KCl, 0.05; $MgSO_4$, 0.05; yeast extract, Difco, 0.05; agar, 1.7; ball-milled filter paper, 0.1; glucose 0.1; pH 7.0. To prepare the ball-milled filter paper, a 3 % (w/v) aqueous suspension of filter paper (Whatman No. 1) is ball-milled for 3 days. Other suitable sources of dispersed cellulose may be used, e.g., microcrystalline cellulose (Avicel, FNIL) at a concentration of 0.1 % (w/v) (Kaufmann et al. 1976), Avicel, Solka floc, CF11 cellulose, carboxymethyl cellulose, or phosphoric acid-treated cellulose (Kauri and Kushner 1985). In other similar versions of the medium, the glucose is omitted. The plates are incubated at 30 °C for 5–7 days; colonies showing zones of clearing are replated on the same medium until pure cultures are obtained. Yellow to yellowish isolates which show a coryneform morphology in combination with cellulolytic activity are presumptive members of the genus *Cellulomonas*.

Cellulomonas enrichments may be prepared by a method similar to that described by Han and Srinivasan (1968). A liquid version of the cellulose agar described above is used but with the glucose omitted and with strips of filter paper replacing the finely divided cellulose. Other mineral bases may be used, e.g., that of Han and Srinivasan (1968); Owens and Keddie (1969); Bagnara et al. 1985; Malekzadeh et al. (1993). Moderate growth occurs on meat extract, peptone agar, or media based on yeast extract or peptone at around neutral pH. Growth-promoting factors in yeast extract are, in part, thiamine and biotin. These factors can be supplemented by adding a few drops of a sterile commercially available multivitamin solution (e.g., Multibionta, Merck). Other strains grow on Trypticase soy agar (TSA) or nutrient agar at 30 °C. Xylanic strains may be isolated on XED medium (xylan, 0.7 %; yeast extract, 0.3 %; agar, 2.5 %) (Rivas et al. 2004). *C. phragmiteti* has been isolated and cultivated on Kings B medium adjusted to pH 9.0 (Rusnyak et al. 2011) while *C. aerilata* was enriched and maintained on R2A agar (Lee et al. 2008).

C. soli and *C. oligotrophica* from soil were enriched anaerobically on basal medium agar (Lovley et al. 1984), supplemented with Fe(III)-nitrilotriacetic acid (Roden and Lovley 1993), but are able to grow aerobically on TSA and R2A agar. The same media support growth of *C. carbonis*, isolated from a coal mine (Shi et al. 2012), which was enriched on a chemically defined medium (Weeger et al. 1999).

Strains from clinical specimen were cultured on Columbia agar or Trypticase soy agar (Becton Dickinson Microbiology Systems, Cockeysville, Md.) with 5 % sheep blood at 37 °C in

a 5 % CO_2 atmosphere (Funke et al. 1995). *C. humilata* can be cultivated on brain heart infusion agar at 30 °C (http://www.atcc.org/) but does not grow well at 37 °C, in chemically defined media or in those lacking organic nitrogen and in anaerobic conditions (Collins and Pascual 2000).

Alkaliphilic cellulomonads may be enriched at 37 °C on an alkaline casein medium containing the following (g l^{-1}): glucose (10), Difco peptone (5), Difco yeast extract (5), K_2HPO_4 (1), $MgSO_4.7H_2O$ (0·2), NaCl (40), Na_2CO_3 (10), casein (20), and agar (20) (Jones et al. 2005). Cultivation is achieved in glucose alkaline medium consisting of two parts. Solution A contained the following, dissolved in 800-ml distilled water and sterilized: glucose (10 g), Difco peptone (5 g), Difco yeast extract (5 g), K_2HPO_4 (1 g), and $MgSO_4.7H_2O$ (0·2 g). Solution B contained 40 g NaCl and 10 g Na_2CO_3 dissolved in 200-ml distilled water and sterilized. The two solutions were then mixed. Solid medium was prepared by adding agar (2 %, w/v) to solution A before sterilization (Duckworth et al. 1996).

Procedures and media used for the isolation of members of the genus *Promicromonospora* (Stackebrandt and Prauser 1991) can also be recommended for *Oerskovia*e. Tapwater agar (1.5 % crude agar in tap water; Lechevalier and Lechevalier 1989) may also be used to isolate *Oerskovia*e.

Paraoerskovia marina, isolated from marine sediment, was enriched on half strength marine agar (Khan et al. 2009), while a second strain was isolated from seaweed, enriched on starch-casein sea water medium (for composition see Lee and Lee 2010).

Actinotalea fermentans is the only member of the family *Cellulomonadaceae* that is able to grow under strict anaerobic conditions: The basal medium used had the following composition: K_2HPO_4, 2.21 g; KH_2PO_4, 1.50 g; $FeS0_4$ solution (0.5 % [wt/vol]), 0.25 ml; yeast extract, 5 g; and distilled water to bring the final volume to 1 l. The pH was adjusted to 7.4 with 8 N NaOH.

For isolation purposes, the basal medium was supplemented with 4.0 % (w/vol) ball-milled MN300 cellulose and 2.0 % agar and used by the Hungate roll-tube technique (Hungate 1969).

For anaerobic cultures in liquid medium, 10 ml of sterile cysteine-hydrochloride solution (5.0 %) and 10 ml of sterile sodium bicarbonate solution (8.0 %) per liter were added after autoclaving. The anaerobic culture technique used was that of Hungate (1950) as modified by Bryant (1972).

When carbon sources were soluble carbohydrates, they were autoclaved separately (30 min, 110 °C) and added just before inoculation. For culture maintenance, the basal medium was supplemented with 0.5 % MN300 cellulose and dispensed in 10-ml volumes into Hungate tubes under an O_2-free argon atmosphere. All cultures were incubated at 30 °C without agitation.

For short-term preservation, stab cultures in semisolid medium should remain viable for several months at room temperature. Serial transfers on nutrient agar at 4-week intervals followed by maintenance at 4 °C are recommended for medium-term storage as is maintenance of cells as 20 % (w/v) lycerol suspensions in an appropriate medium at −20 °C and at −80 °C. Long-term preservation methods include freeze-drying in skim milk and maintenance in liquid nitrogen at −196 °C.

Ecology

Habitat

The main habitat of cellulomonads appears to be the soil, including decayed wood, cellulose-containing material, compost, and municipal waste from which the original cultures were isolated (Kellerman et al. 1913; Bergey et al. 1923; Kauri and Kushner 1985; Stackebrandt and Keddie 1986). This applies also to *Cellulomonas* species described or reclassified recently: *C. persica* and *C. iranensis* were isolated from forest soils (Elberson et al. 2000), *C. terrae* (An et al. 2005) and *C. humilata* (basonym *Actinomyces humiferus*) originated from organically rich soils (Collins and Pascual 2000), *C. soli* and *C. oligotrophica* (Hatayama et al. 2012) were isolated from wet to most Japanese soils, while *C. carbonis* was found in subsurface soil of a chinese coal mine Shi et al. 2012. *C. xylanilytica* was isolated from a decayed elm tree (Rivas et al. 2004). Cattle-farm compost has been the source of *C. chitinilytica* (Yoon et al. 2008), and *C. composti* (Kang et al. 2007) while *C. aerilata* was found in an air sample (Lee et al. 2008). Two species have been isolated from alkaline environment, i.e., *C. bogoriensis* (Jones et al. 2005) from the litteral zone of Lake Bogoria and *C. phragmiteti* (Rusznyák et al. 2011) from reed growing in a soda pond in Hungary. Reports on the occurrence of cellulomonads in natural environments are rare and they almost never are found as a dominating population. Emphasis placed on the cellulolytic activity of these organisms has resulted in the successful isolation of *Cellulomonas* strains from activated sludge (Ramasamy et al. 1981), and cellulose-enriched environments such as bark and wood (Deschamps 1982; Przybyl 1979), coffee beans (Silva et al. 2000), soils enriched on flax or sisal fibres (Lednicka et al. 2000) and sugar fields (de Leon and Joson 1980). A strain of *C. flavigena* has been isolated from the great spruce bark beetle, *Dendroctonus micans* (Yaman et al. 2010), and culture and culture-independent studies demonstrated the presence of cellulomonads in the gut of the turpentine beetle, *Dendroctonus valens LeConte* (Morales-Jiménez et al. 2009). Cellulolytic culturable bacteria closely related to strains of the genus *Cellulomonas* as revealed by 16S rDNA sequence comparison have been isolated from refuse of a landfill (Pourcher et al. 2001), from an agricultural encatchment (Ulrich and Wirth 1999), and they were found among other endophytic bacteria on growing shoot tips of banana (Thomas and Soly 2009) and among populations associated with rice seeds (Cottyn et al. 2001). A high number of uncharacterised *Cellulomonas* strains have been isolated from mature coffee beans of *Coffea arabica* in Brazil (Silva et al. 2000). Under dry conditions, cellulomonads dominated the population of Gram-positive organism. Their role, however, has not been elucidated.

Cellulomonads were found among a halophilic oil-utilizing community in the Arabian Gulf cost (Al-Awadhi et al. 2007) and as hydrocarbonoclastic bacteria in mangrove sediments in Brazil (Brito et al. 2006). They were part of the dominating cultrable population in a 2,347-year-old permafrost soil from Spitsbergen (Hansen et al. 2007).

C. hominis and *C. denverensis* were the first representatives of the genus which were isolated from human clinical samples: *C. hominis* from cerebrospinal fluid (Funke et al. 1995) and *C. denverensis* and *C. hominis* from blood, cerebrospinal fluid, homograft valve, lip wound, and pilonidal cyst (Brown et al. 2005). Recently, Ohtaki et al. (2009) reported *C. denverensis* as the cause of an acute cholecystitis.

*Oerskovia*e were randomly and rarely isolated from various types of soils from different geographical regions, composts, decaying plant materials, and occasionally from various clinical specimens (Cruickshank et al. 1979; Reller et al. 1975; Sottnek et al. 1977). *Oerskovia enterophila* (*Promicromonospora enterophila*) constitutes the major part of the actinomycete microflora of the intestines and feces of litter-inhabiting millipedes, e.g., *Chromatoiulus projectus* (Dzingov et al. 1982; Jáger et al. 1983; Szabó et al. 1983, 1986). The species occurs also in the feces of the cave-inhabiting blind isopode *Mesoniscus graniger* (Bodnar et al. 1989). A large homogenous population of facultatively anaerobic *Oerskovia*-type nocardioforms was also found in the gut contents of adult specimens of the common earthworm *Lumbricus polyphemus* (Ravasz et al. 1987; Szabó et al. 1986). None of these *Oerskovia*e could be isolated from the surrounding feeding habitats of the animals. Moreover, the inability of the gut and feces nocardioforms to survive in the natural soil and litter habitat could be demonstrated (Márialigeti et al. 1985). However, among 311 culturable cellulolytic bacterial isolates from soil of an agricultural encatchment, 13 strains were found to show 99.6 % 16S rRNA gene similarity to *Oerskovia enterophila* (Ulrich and Wirth 1999), classified as "*Paramicromonospora enterophila*" by the authors. Similarly, the name *Oerskovia xanthineolytica* is frequently used even in the recent literature while this organism has been reclassified as *Cellulolomicrobium cellulans* (Schumann et al. 2001). *Oerkovia turbata* has frequently been associated with endocarditis (see below).

The habitat of members of the monospecific genera and of those species for which only a single strain, the type strain, is available must be considered tentative.

As pointed out by Abt et al. (2010) for *Cellulomonas flavigena*, a survey of metagenome libraries do not, until 2010, provide information about the presence of close relatives in any of the environments tested. Also, 16S rRNA based studies did hardly point toward the presence of cellulomonads in soil environments such as grassland soils (Felske et al. 1998), Amazonan soil Borneman and Triplett (1997), or arid soil (Kuske et al. 1997). One of the rare reports demonstrating the presence of four clone sequences related to *Cellulomonas* spp. comes from the analysis of grass pasture in the UK (McCaig et al. 1999). Apparently, cellulomonads and *Oerskovia*e are not dominating in soil habitats (though they have been isolated therefrom) but are more affiliated to the gut environment of invertebrates like earthworms and termites and in close contact with decaying plant material.

Pathogenicity: Clinical Relevance

Strains of *Cellulomonas denverensis* and *Cellulomonas hominis*, rare human pathogens, were isolated from blood and cerebrospinal fluid, and some other specimen (Brown et al. 2005; Funke et al. 1995).

Oerskovia turbata, Cellulomonas strains described until 1995, and *C. hominis* are susceptible to tetracycline and vancomycin and, except of *Oerskovia turbata*, also subsceptible *to* rifampicin (Funke et al. 1995). Rifampicin and vancomycin were also suitable antimicrobial agents for *C. denverensis* (Brown et al. 2005). Additionally, clarithromycin, clindamycin, imipenem, and minocycline were considered active against *C. hominis* and *C. denverensis* strains (Brown et al. 2005). Two isolates from blood cultures from patients at the Gaziantep University Hospital (south-east Turkey) that were identified as members of the genus *Cellulomonas* were susceptible to teicoplanin, rifampicin, vancomycin, gentamicin and ampicillin-sulbactam (Balci et al. 2002). The environmental type strain of *C. bogoriensis* (Jones et al. 2005) is susceptible to ampicillin (25 μg), chloramphenicol (25 μg), erythromycin (5 μg), fusidic acid (10 μg), methicillin (10 μg), novobiocin (5 μg), streptomycin (10 μg), tetracycline (25 μg), sulphafurazole (100 μg), oleandomycin (5 μg), polymyxin (300 IU), rifampicin (2 μg), vancomycin (30 μg) and bacitracin (10 IU) and resistant to gentamicin (10 μg), nitrofurantoin (50 μg), nalidixic acid (30 μg), sulphamethoxazole (50 μg), trimethoprim (2·5 μg), penicillin G (1 IU), neomycin (30 μg) and kanamycin (30 μg) (Jones et al. 2005). A similar sensitivity spectrum was determined for the type strain of *C. carbonis* (Shi et al. 2012). *C. terrae* is resistant to ampicillin (30 μg), tetracycline (15 μg), streptomycin (15 μg) and kanamycin (2 mg) (An et al. 2005). *Paraoerskovia marina* is sensitive to vancomycin (50 μg), and resistant to bacitracin (10 μg), gentamycin (30 μg), kanamycin (30 μg), nalidixic acid (30 μg), nitrofurantoin (300 μg), nystatin (100 IU) and streptomycin (10 μg) (Khan et al. 2009). Other members of *Cellulomonadaceae* have not yet been tested for antibiotic resistance and susceptibility.

C. flavigena ATCC 482, *C. gelida* ATCC 488, *C. uda* ATCC 491, *C. fimi* ATCC 15724 and *Cellulomonas* sp. ATCC 21399 were subjected to toxicity test by injecting cell extracts as well as viable cells in fertile chicken eggs and some rodents, respectively. Neither were cell extracts lethal to the embryos, nor did the viable cells cause generalized or local infections in rats, mice or rabbits. The sexual maturity, fertility and organs of adult rats as well as the vitality of their progeny were not affected by feeding 10 % protein from the test strains (Dey and Fields 1995).

C. hominis was isolated from cerebrospinal fluids of a male and a female patient (Funke et al. 1995). Although no patients'

records were available for the evaluation of the clinical significance of the isolates, this was the first report on members of the genus *Cellulomonas* that were isolated from clinical specimens. Three additional clinical isolates from cerebrospinal fluid (strain W7335), pilonidal cyst (strain W7336) and a lip wound (strain W7387) were identified as *C. hominis* mainly on the basis of DNA-DNA hybridization (Brown et al. 2005). Two isolates from a patient with endocarditis from Denver (W6929^T from blood and W6124 from a homograft valve) and a blood isolate (strain W6117) from a patient from Ohio differed in their ability to fermentation of sorbitol and low DNA-DNA similarity values sufficiently from *C. hominis* to be classified in a new species, *C. denverensis* (Brown et al. 2005). Although it is difficult to differentiate between true infection and contamination and to identify *Cellulomonas* strains unambiguously by phenotype-based commercial diagnostic test systems, the role of members of the genus *Cellulomonas* as potential pathogens in clinical cases especially of immunocompromised patients must be taken into consideration. A recent review on infective endocarditis and osteomyelitis by cellulomonads has been published by Lai et al. (2009).

When reading the literature care must be taken in the interpretation of strains reported to be either *Oerskovia* or *Cellulosimicrobium* species. According to Betancourt Castellanos et al. (2011) there are four *Oerskovia* cases of peritoneal infection published, caused by *O. xanthineolytica* or *O. turbata*. The authors then conclude on the basis of published literature that these two species are currently known as *Cellulosimicrobium cellulans* (Rowlinson et al. 2006) and *Cellulosimicrobium funkei* (Brown et al. 2006), respectively. The latter authors however did not reclassify *O. turbata* as *Cellulosimicrobium funkei* but only a set of strains formerly assigned to *O. turbata*. Indeed, the majority of cases are assigned to *Cellulosimicrobium* [*xanthineolytica*] *cellulans*.

The pathogenic potential of *Oerskoviae* was first described by Reller et al. (1975). Strains identified as *O. turbata* were frequently isolated from the blood taken from a patient suffering from endocarditis after homograft replacement of the aortic valve. The source of *O. turbata* remained speculative although contamination of harvested heart valves with *O. turbata* have been reported (Reller et al. 1975). The occurrence of *Oerskoviae* in various clinical sources was documented (Sottnek et al. 1977) when a large number of motile, Gram-positive, non-sporeforming, yellow-pigmented organisms could be allocated to *O. turbata* and to the former *O. xanthineolytica* (now *Cellulosimicrobium cellulans*). Nine of 31 clinical isolates, collected by the Bacteriology Division, Centers for Disease Control (CDC) over a period of 20 years, were identified as *O. turbata*. The source of the *O. turbata* isolates was heart tissues, heart valves, blood, and tissues. Since no satisfactory case history for any of the isolates was available, their clinical significance could not be elucidated.

Vancomycin-sensitive *Oerskovia* strains have been frequently isolated from the commensal bowel flora in humans, where they may cause opportunistic infections. The *van*A gene, coding for vancomycin and teicoplanin resistance has been sequenced from the clinical isolate *Oerskovia* sp. strain 892 (Power et al. 1995). The sequence of the plasmid-born gene was found to be highly similar to that of *Arcanobacterium haemolyticum* and *Enterococcus faecium*. Sialidase (neuraminidase) activity has been detected in culture collection strains of *O. turbata* and strain isolated from a liver abscess (Müller 1995). Some of the non-type strains have been reclassified as the new species *O. jenensis* (Stackebrandt et al. 2002).

Application

Waste Treatment and Removal

The ability of cellulomonads to attack cellulose and wheat straw under microaerobic or even anaerobic conditions has been used in mixed cultures to provide nitrogen-fixing strains of *Bacillus macerans* and *Azospirillum brasilense* with energy-yielding products (Halsall and Gibson 1985, 1986; Halsall and Goodchild 1986). Good nitrogen-fixing rates have been reported for the pair *Azospirillum brasilense* ATCC 29145 and *Cellulomonas* sp. strain CS117. The latter is a mutant strain selected for its increased production of cellulase and reduced sensitivity to inhibition or repression by accumulated cellobiose and glucose (Haggatt et al. 1978).

Of the large variety of hydrolytic starch, xylan, and cellulose-degrading enzymes, detected in *Cellulomonadaceae*, the cellulases are the most salient ones. In a comparative study *C. biazotea* produced the highest filter-paper cellulase and endo-glucanase activities, followed by *C. flavigena*, *C. cellasea*, and *C. fimi* (Rajoka and Malik 1997). However, most of the molecular work on cellulase and xylanase genes was determined with *C. fimi*.

Like other cellulose- and hemicellulose-degrading organisms, *Cellulomonas* strains have been considered potential candidates for waste disposal (Ramasamy et al. 1981; Dunlap and Callihan 1974), and composting flax and sisal fibres (Lednicka et al. 2000), bagasse (Richard and Peiris 1981), pith, leaves of sugar canes (Diaz and Guirola 1983; Richard and Peiris 1981; Rajoka and Malik 1986), dried palm oil mill effluent (Agamuthu and Tan 1985), shredded newspapers (Rapp et al. 1984), or even as producers of chemicals from low-cost substrates. Mutants of *C. flavigena*, showing elevated xylanase and carboxymethyl cellulase acitivity, were able to use a larger portion of sugar cane bagasse than their wild type strains (Ponce-Noyola and de la Torre 1995; Mayorga-Reyes and Ponce-Noyola 1998). The isolation of cellulomonads from a landfill of domestic refuse, e.g., *Actinotalea fermentans, C. hominis*, *C. biazotea*/ *C. fimi* and *C. flavigena*/*C. uda* (the latter two pairs of organisms were indistinguishable by numerical analysis, Pourcher et al. 2001) or strains isolated from cattle compost indicate their potential to degrade solid cellulolytic waste. *Cellulomonas* sp. strain DOT 21, isolated from

a domestic refuse (Bichet-Hébé et al. 1999), has been used to estimate paper degradation by reduction of a whiting fluorescent agent added to white paper prior to the degradation process.

Bioremediation

The bioremediating abilities have been investigated in a few cases. *C. flavigena* strain HR5, was isolated from agricultural soil in South Korea, contaminated with 4-chlorobenzoate. This plasmid-bearing strain was also able to utilize well 4-bromobenzoic acid, benzoic acid and less well 4-iodobenzoic acid, but not 3-chlorobenzoic acid and 2,4-dichlorophenoxyacetic acid (Yi et al. 2000). A bench scale experiment with *Cellulomonas* sp. strain ES6 resulted in the reduction of Cr(VI) and Fe(III) without continuous nutrient supply in the subsurface thus offering a viable and economical alternative technology for in situ remediation of Cr(VI)-contaminated groundwater through formation of permeable reactive biobarriers (Viamajala et al. 2008).

Formation of Added-Value Products

Cellulomonas strains ATCC 482, ATCC 488, ATCC 491, ATCC 15392 and ATCC 21399 were found to contain high protein and essential amino acid values (Dey 1976) and different strains have been used for single-cell protein production from a variety of waste products, such as sugar cane bagasse (Han et al. 1971; Rodríguez et al. 1993) and rice straw (Han et al. 1971), hemstock (Jedar et al. 1987) and ground corn and stalks (Fields et al. 1991).

Cellulolases from *Cellulomonas* sp. YJ5 has been used to hydrolyse suspensions of *Chlorella* with favorable results concerning yield of soluble proteins, peptides, Fe(2+) chelating ability, antioxidation capacity and reducing power (Yin et al. 2010).

Mixed cultures consisting of *Cellulomonas* sp. ATCC 21399, *Desulfovibrio vulgaris* strain J.J., and *Methanosarcina barkeri* 227 were highly efficient in converting xylan to methane via hydrolysis and acidogenesis (strain ATCC 21399), acetogenesis (strain J.J.), and methanogenesis (strain 227) (Guyot 1986). The same *Cellulomonas* strain has also been used in mixed cultures with *Rhodopseudomonas capsulata* to photoevolve molecular hydrogen by the nitrogenase system of the phototrophic strain with cellulose as the sole carbon source (Odom and Wall 1983).

The ability of *Actinotalea fermentans* to degrade cellulose and to produce acetate has been used by Bayer et al. (2009) to construct a consortium consisting of this cellulomonad and a recombinant strain of *Saccharomyces cerevisiae* to turn raw cellulolytic material into methyl halide which can be easily converted to fuel. This inexpensive process works at low temperature using unprocessed switchgrass, corn stover, sugar cane bagasse and poplar as feed for *A. fermentans*. *S. cerevisiae* with its cloned methyl halide transferase gene from turtleweed transfers the acetate into methyl halide which can be converted into gasoline, benzene, toluene, xylene, ethylene, propylene, methanol or dimethyl ether.

Enzymes

The earlier literature has been summarized by Stackebrandt and Prauser (1991). Different kinds of cellulose preparations and derivatives had been tested, including amorphous (Dermoun and Belaich 1985), swollen, phosphoric-acid-treated (Kauri and Kushner 1985), microcrystalline (Vladut-Talor et al. 1986; Dermoun and Belaich 1988; Poulsen and Petersen 1988), and carboxymethyl cellulose (CMC). As reported by Kauri and Kushner (1985), degradation of cellulose does not depend on cell-to-fiber contact, but cellulases from three *Cellulomonas* strains were active even when they were physically separated from the fibers. Microcrystalline cellulose (Avicel pH 101, Cellulose MN300, Whatman cc41) appears to be less efficiently attacked than amorphous cellulose (phosphoric-acid-treated Whatman cc41 cellulose) (Dermoun and Belaich 1985). Under anaerobic conditions, celluloses with varying degrees of crystallinity were hydrolized by *C. uda* ATCC 21399 with the same efficiency as by aerobically grown cells though the growth yield was reduced significantly (Dermoun et al. 1988). Optimal liquefaction of CMC gels occurred in a synthetic medium at 40 °C at pH of 7.0–7.5 (Thayer et al. 1984).

A wide range of carbohydrate-binding modules, carbohydrate esterases and glycoside hydrolases have been studied in detail at the molecular level. Several enzymes have been identified to be involved in the hydrolysis of xylane (endo-1,4-xylanases [Mayorga-Reyes et al. 2002; Horcasitas et al. 1998]), cellulose (endo-1,4-glucanases [Gutiérrez-Nava et al. 2003] ß-glucosidase, cellobiohydrolases), chitine (exo-*N*,*N*'-diacetylchitobiohydrolase [Chen et al. 1997] chitinase) and mannan (ß-mannanase). Most of the species studied were *C. flavigena* and *C. fimi*. The earlier molecular data on these enzymes were compiled by Stackebrandt et al. (2002) and the reader is asked to read the chapter of Bayer (Bayer et al. 2000) and his contribution in this edition.

As indicated above, the annotation of the recently fully sequenced genome of *C. flavigena* DSM 20109^T revealed that 9.6 % of encoded proteins are classified into the COG category "carbohydrate transport and metabolism"; among these are genes coding for xylan degrading enzymes; 14 genes coding for putative endo-1,4-β-xylanases belonging to glycoside hydrolase family 10, and five genes encoding β-xylosidases. Also identified were two genes coding for endo-1,4-β-glucanases (Cfla_0016, Cfla_1897), three genes encoding 1,4-β-cellobiohydrolases (Cfla_1896, Cfla_2912, Cfla_2913) and three genes coding β-glucosidases (Cfla_1129, Cfla_3027, Cfla_2913).

10 The Families *Conexibacteraceae*, *Patulibacteraceae* and *Solirubrobacteraceae*

Luciana Albuquerque[1] · *Milton S. da Costa*[2]
[1]Center for Neuroscience and Cell Biology, University of Coimbra, Coimbra, Portugal
[2]Department of Life Sciences, University of Coimbra, Coimbra, Portugal

Abstract
Three families will be here discussed, *Conexibacteraceae*, *Patulibacteraceae*, and *Solirubrobacteraceae*, which are members of the order *Solirubrobacterales* together in this chapter. Members of this order are Gram-positive, mesophilic, and the peptidoglycan contains meso-diaminopimelic acid (*meso*-Dpm) as diagnostic diamino acid. The pattern of 16S rRNA signatures consist of nucleotides at positions 63 : 104 (G-C), 70 : 98 (G-C), 370 : 391 (C-G), 580 : 776 (U-A), 657 : 749 (U-A), 670 : 736 (A-U), 681 : 709 (U-A), 941 : 1342 (A-U), 953 : 1228 (G-C), 954 : 1226 (G-C), 1051 : 1207 (G-C), 1118 : 1155 (U-A) and 1311 : 1326 (A-U). The three families of the order *Solirubrobacterales* are monogeneric: The family *Conexibacteraceae* contains two species, *Conexibacter woesei* and *C. arvalis* (Monciardini et al., Int J Syst Evol Microbiol 53:569–576, 2003; Seki et al., Int J Syst Evol Microbiol 53:2400–2404, 2012); the family *Patulibacteraceae* contains three species, *Pautulibacter minatonensis*, *P. americanus*, and *P. ginsengiterrae* (Kim et al., Int J Syst Evol Microbiol 62:563–568, 2012; Takahashi et al., Int J Syst Evol Microbiol 56:401–406, 2006; Reddy et al., Int J Syst Evol Microbiol 59:87–94, 2009) and the family *Solirubrobacteraceae* comprises three species, *Solirubrobacter pauli*, *S. soli* and *S. ginsenosidimutans* (An et al., Int J Syst Bacteriol 61:2606–2609, 2011; Kim et al., Int J Syst Evol Microbiol 57:1453–1455, 2007; Singleton et al., Int J Syst Evol Microbiol 53:485–490, 2003). These organisms are phylogenetic neighbors of the families *Gaiellaceae*, *Rubrobacteraceae*, and *Thermoleophilaceae* (Albuquerque et al., Syst Appl Microbiol 34:595–599, 2011; Reddy and Garcia-Pichel, Int J Syst Evol Microbiol 59:87–94, 2009).

Taxonomy: Historical and Current

Short Description of the Families and Genera

Conexibacteraceae Stackebrandt 2005; Emend. Zhi et al. 2009

Conexibacteraceae (Co.ne.xi.bac.te.ra.ce'a.e. N.L. masc. n. *Conexibacter*, type genus of the family; suff. -aceae, ending to denote a family; N.L. fem. pl. n. *Conexibacteraceae*, the *Conexibacter* family).

The members of the family *Conexibacteraceae* of the order *Solirubrobacterales* stain Gram-positive. Form rod-shaped cells and endospores are not formed. These organisms are strictly aerobic and chemoorganotrophic. The peptidoglycan contains *meso*-Dpm as diagnostic diamino acid. The peptidoglycan type is A1γ' (based on *meso*-A_2pm, directly cross-linkage). Unsaturated straight chain and iso-fatty acids are present. The major respiratory lipoquinone is MK-7 or derivatives. The pattern of 16S rRNA signatures consist of nucleotides at positions 52 : 359 (U-A), 127 : 234 (G-C), 139 : 224 (G-C), 144 : 178 (U-A), 145 : 177 (U-A), 291 : 309 (U-A), 293 : 304 (G-C), 377 : 386 (C-G), 408 : 434 (A-U), 418 : 425 (U-A), 590 : 649 (U-A), 600 : 638 (U-G), 823 : 877 (G-C), 906 (A), 955 : 1225 (U-A), 999 : 1041 (G-U), 1115 : 1185 (C-G) and 1410 : 1490 (U-A). The type and only genus of this family is *Conexibacter* (Monciardini et al. 2003; Reddy and Garcia-Pichel 2009; Seki et al. 2012; Zhi et al. 2009).

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_200,

Patulibacteraceae Takahashi et al. 2006; Emend. Zhi et al. 2009; Emend. Kim et al. 2012

Patulibacteraceae (Pa.tu.li.bac.te.ra.ce'a.e. N.L. masc. n. *Patulibacter* type genus of the family; suff. –aceae, ending to denote a family; N.L. fem. pl. n. *Patulibacteraceae*, the *Patulibacter* family).

A family of the order *Solirubrobacterales*. Cells are Gram-positive and form rod-shaped cells. Endospores are not formed. Strictly aerobic and chemoorganotrophic. The peptidoglycan contains *meso*-Dpm as diagnostic diamino acid. The peptidoglycan type is A1γ'. Unsaturated straight chain and anteiso-fatty acids are present. The major respiratory quinone is MK-7 or derivatives. The pattern of 16S rRNA gene sequence signature nucleotides of members of the family consists of 52 : 359 (C-G), 98 (A), 127 : 234 (G-C), 139 : 224 (G-C), 144–178 (C-G), 291 : 309 (U-A), 293 : 304 (G-C), 377 : 386 (C-G), 408 : 434 (G-C), 502 : 543 (G-C), 590 : 649 (U-A), 600 : 638 (U-G), 823 : 877 (A-U), 906 (A), 955 : 1225 (U-A), 999 : 1041 (U-A), 1115 : 1185 (C-G), 1354 : 1368 (U-G) and 1410 : 1490 (A-U). The type and only genus of this family is *Patulibacter* (Kim et al. 2012; Reddy and Garcia-Pichel 2009; Takahashi et al. 2006; Zhi et al. 2009).

Solirubrobacteraceae Stackebrandt 2005; Emend. Zhi et al. 2009

Solirubrobacteraceae (So.li.ru.bro.bac.te.ra.ce'a.e. N.L. masc. n. *Solirubrobacter*, type genus of the family; suff. -*aceae*, ending to denote a family; N.L. fem. pl. n. *Solirubrobacteraceae*, the *Solirubrobacter* family).

A family of the order *Solirubrobacterales*. Cells are Gram-positive and form rod-shaped cells. Endospores are not formed. Strictly aerobic and chemoorganotrophic. The peptidoglycan contains *meso*-Dpm as diagnostic diamino acid. The peptidoglycan type is A1γ'. Unsaturated straight chain and iso-fatty acids are present. The major respiratory quinone is MK-7 or derivatives. The pattern of 16S rRNA signatures consists of nucleotides at positions 52 : 359 (C-G), 127 : 234 (G-C), 139 : 224 (A-U), 144 : 178 (C-G), 145 : 177 (C-G), 293 : 304 (G-C), 408 : 434 (G-C), 590 : 649 (C-G), 600 : 638 (C-G), 823 : 877 (G-C), 906 (A), 955 : 1225 (U-A), 999 : 1041 (U-A), 1115 : 1185 (C-G) and 1410 : 1490 (U-A). The family comprises the type and only genus *Solirubrobacter* (An et al. 2011; Kim et al. 2007; Reddy and Garcia-Pichel 2009; Singleton et al. 2003; Stackebrandt 2004; Zhi et al. 2009).

Phylogenetic Structure of the Family and Its Genera

The order *Solirubrobacterales* comprises three monogeneric families, namely, *Conexibacteraceae*, *Patulibacteraceae*, and *Solirubrobacteraceae* which form a monophyletic clade at a level of about 92–93 % 16S rRNA gene sequence similarity (*Fig. 10.1*). They are most closely related to the species of the genus *Thermoleophylum* (family *Thermoleophylaceae*) with sequence similarity of about 89–90 %. The three validly named species of the genus *Solirubrobacter* have 16S rRNA gene sequence similarities varying from 96.4 % between

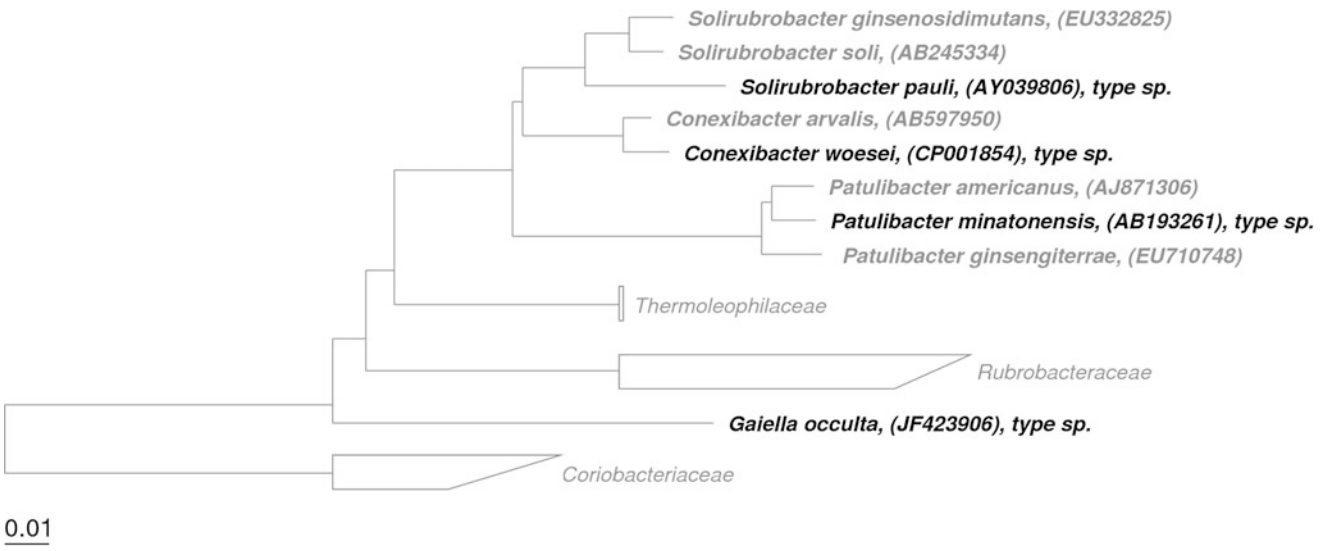

Fig. 10.1

Phylogenetic reconstruction of the families *Conexibacteraceae*, *Patulibacteraceae*, and *Solirubrobacteraceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

S. ginsenosidimutans BXN5-15^T (EU332825) and *S. pauli* B33D1^T (AY039806) and 98.4 % between *S. soli* Gsoil 355^T (AB245334) and *S. pauli* B33D1^T (AY039806).

The species *Conexibacter arvalis* KV-962^T (AB597950) and the type species *C. woesei* ID131577^T (CP001854) share 98.6 % 16S rRNA sequence similarity, while the species of the genus *Patulibacter*, namely, *P. americanus* CP177-2^T (AJ871306) and *P. ginsengiterrae* P4-5^T (EU710748), share 98.6 % and 98.5 % 16S rRNA gene sequence similarity with the type strain of the genus, *P. minatonensis* KV-614^T (AB193261), respectively.

The close relationship in phylogeny deduced from 16S rRNA gene sequence analysis is confirmed by similar chemotaxonomic characteristics, namely, the respiratory quinones, peptidoglycan type, and fatty acid composition, indicating that the *Conexibacteraceae*, *Patulibacteraceae*, and *Solirubrobacteraceae* are closely related (see Chap. 19 on the Family *Gaiellaceae*).

Phenotypic Analyses

The main features of the families *Conexibacteraceae*, *Patulibacteraceae*, *and Solirubrobacteraceae* are listed in Table 10.1. The main features of *Conexibacter woesei* and *Conexibacter arvalis* are listed in Table 10.2. The main features of *Patulibacter minatonensis*, *Patulibacter americanus*, and *Patulibacter ginsengiterrae* are listed in Table 10.3. The main

Table 10.2

Phenotypic and chemotaxonomic properties of members of the genus *Conexibacter*. All of the organisms are catalase positive and reduce nitrate. All of the strains hydrolyze gelatin and utilize D-trehalose. All of the organisms are urease and arginine dihydrolase negative, and do not produce indole. None of the strains utilize methyl-αD-mannopyranoside, methyl-αD-glucopyranoside and D-cellobiose. In Api ZYM tests, all organisms are positive for esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase and negative for α-chymotrypsin, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase. All organisms are sensitive to amikacin, gentamicin, chloramphenicol, tetracycline, vancomycin, polymyxin B and resistant to aztreonam, ceftazidime, ciprofloxacin, norfloxacin, oxacillin

features of *Solirubrobacter pauli*, *Solirubrobacter soli*, *and Solirubrobacter ginsenosidimutans* are listed in *Table 10.4*. All organisms of the three families are strictly aerobic, chemoorganotrophic, and mesophilic with an optimum growth pH between about 6.5 and 7.5, except for *Conexibacter arvalis*, which is reported to have an optimum pH for growth of 7.0–9.0. The peptidoglycan is of the A1γ' type with *meso*-Dpm; the predominant respiratory lipoquinone is menaquinone 7 (MK-7 or derivates of MK-7). The predominant fatty acids of the families *Conexibacteraceae*, *Patulibacteraceae*, and *Solirubrobacteraceae* are unsaturated straight chain, and iso- and anteiso-branched chain fatty acids. The G+C content of the DNA is around 71–75 %.

Conexibacter Monciardini et al. 2003

Conexibacter (Co.nex.i.bac'ter. L. part. adj. *conexus* bound, tied; N.L. masc. n. *bacter* from Gr. N. *baktron* rod; N.L. masc. n. *Conexibacter* a rod that is bound).

Conexibacter forms rod-shaped cells. Motile by long flagella. Mesophilic. Catalase positive and oxidase variable. The Biolog GP2 and GN2 microplates were used to assess the carbon metabolism of the species *Conexibacter woesei*, while the API 50 CH system was used to assess the single carbon source assimilation of the species *Conexibacter arvalis*. Some assimilations of *C. woesei* were also performed by Seki et al. (2012). *C. woesei* and *C. arvalis* were negative for glucose fermentation. The optimum pH for growth varies from about 7.0 to 7.5 in *C. woesei* and between pH 7.0 and 9.0 in *C. arvalis*. Mycolic acids are absent. The major isoprenoid respiratory lipoquinone is a fully saturated menaquinone 7, tetrahydrogenated menaquinone 7 [MK-7(H_4)]. The polar lipid pattern consists of phosphatidylinositol (PI) and an unknown phospholipid (PL). The major fatty acids are $C_{18:1}\omega9c$, $C_{17:1}\omega6c$ and iso-$C_{16:0}$. The G+C content of the DNA is in the range 71–75 mol%. The type species is *Conexibacter woesei*. The type strain ID131577^T (=DSM 14684^T =JCM 11494^T) was isolated from a temperate forest soil in Gerenzano, Italy (Monciardini et al. 2003). *Conexibacter arvalis* is the second species of this genus; the type strain is KV-962^T (=DSM 23288^T =NBRC 106558^T), isolated from soil collected from a field in Japan. Strain KV-963, isolated from the same source, is a reference strain of *C. arvalis* (Seki et al. 2012).

Patulibacter Takahashi et al. 2006; Emend. Reddy and Garcia-Pichel 2009; Emend. Kim et al. 2012

Patulibacter (Pa.tu.li.bac'ter. L. adj. *patulus*, spreading; N.L. masc. n. *bacter*, a rod; N.L. masc. n. *Patulibacter* bacterium with spreading growth).

Patulibacter forms rod-shaped cells; motility is variable. Mesophilic. Catalase positive and oxidase variable. The Biolog GP2 microplates were used to assess the carbon metabolism of the species *Patulibacter minatonensis*, the classical single carbon and energy source assimilations were used to assess the carbon source assimilation of the species *Patulibacter americanus*, and the API 50 CH and the API 20 NE systems were used to assess the carbon source assimilations of the species *Patulibacter ginsengiterrae* making comparisons of assimilation patterns impossible. Acid production was only examined in *P. ginsengiterrae* using the API 50 CH, being negative for all carbohydrates. *P. minatonensis* was reported to be negative for the fermentation of glucose, which was the only sugar examined.

Table 10.3

Phenotypic and chemotaxonomic characteristics of members of the genus *Patulibacter*. All of the organisms are catalase positive, and hydrolyze tween 20 and tween 80. All of the strains are DNAse, β-galactosidase, lysine decarboxylase, phenylalanine deaminase, methyl red, voges-proskauer negative, do not reduce nitrate, and do not produce indole and H_2S. None of the strains hydrolyze gelatin, esculin, and starch. All organisms are sensitive to polymyxin B, vancomycin, gentamicin and resistant to aztreonam

[c]Kim et al. 2012

Cell-wall peptidoglycan contains *meso*-diaminopimelic acid as diagnostic diamino acid along with alanine and glutamic acid. Major fatty acids are $C_{18:1}\omega9c$ and anteiso-$C_{15:0}$. Mycolic acids are absent. The predominant isoprenoid respiratory lipoquinone is a demethylmenaquinone 7 (DMK-7) or is a fully saturated menaquinone 7 [MK-7(H_2)]. Major polar lipids include phosphatidylglycerol (PG) and diphosphatidylglycerol (DPG). The DNA G+C content is in the range 72–75 mol%. The type species is *Patulibacter minatonensis*. The type strain, KV-614^T (=NRRL B-24346^T=JCM 12834^T =NBRC 100761^T), was isolated from soil (Takahashi et al. 2006). *Patulibacter americanus* is other species and the type strain is CP177-2^T (=ATCC BAA-1038^T =DSM 16766^T), isolated from biological soil crusts from the Colorado Plateau, USA. Strain CP153-3 (=ATCC BAA-1037), isolated from the same source, is a reference strain of *P. americanus* (Reddy and Garcia-Pichel 2009). Another species

Table 10.4

Phenotypic and chemotaxonomic characteristics of members of the genus *Solirubrobacter*. All of the organisms are catalase positive. All of the strains are urease and arginine dihydrolase negative, do not reduce nitrate, and do not produce indole and H_2S. None of the strains utilize citrate and malate. In Api ZYM tests, all organisms are positive for esterase (C4), esterase lipase (C8), leucine arylamidase, α-glucosidase, β-glucosidase and negative for lipase (C14), trypsin, α-chymotrypsin, α-galactosidase, β-glucuronidase, α-fucosidase

is *Patulibacter ginsengiterrae* and the type strain is P4-5^T (=KCTC 19427^T =CECT 7603^T), isolated from soil of a ginseng field in Republic of Korea (Kim et al. 2012).

Solirubrobacter Singleton et al. 2003

Solirubrobacter (So.li.ru.bro.bac'ter. L. n. *solum*, soil; N.L. n. *Rubrobacter*, a bacterial genus; N.L. masc. n. *Solirubrobacter*, a *Rubrobacter*-like bacterium from soil).

Solirubrobacter forms rod-shaped cells and nonmotile. Mesophilic. Catalase positive and oxidase variable. One species *Solirubrobacter pauli* grows on common sugars, polyols, organic acids, and amino acids as sole carbon sources. The API 20 NE and the API ID32 GN systems were used to assess the carbon metabolism of the species *Solirubrobacter soli* and *Solirubrobacter ginsenosidimutans*. None of the strains produce acid from glucose. Major fatty acids are $C_{18:1}\omega9c$ and iso-$C_{16:0}$. The major respiratory isoprenoid lipoquinone is a fully saturated menaquinone 7 [MK-7(H_4)]. The DNA G+C content is approximately 71 mol%. The type species is *Solirubrobacter pauli*. The type strain is B33D1^T (=ATCC BAA-492^T =DSM 14954^T) and was isolated from a burrow of the epigeic earthworm *Lumbricus rubellus* in an agricultural soil (Singleton et al. 2003). The genus *Solirubrobacter* also includes two additional species: *Solirubrobacter soli*, the type strain is Gsoil 355^T (=KCTC 12628^T =LMG 23485^T) that was isolated from soil from a ginseng field in Daejeon, South Korea (Kim et al. 2007); *Solirubrobacter ginsenosidimutans*, the type strain is BXN5-15^T (=KACC 20671^T =LMG 24459^T) that was isolated from soil of a ginseng field of Baekdu Mountain, China (An et al. 2011).

Isolation, Enrichment, and Maintenance Procedures

Conexibacter woesei was isolated from a temperate forest soil in Gerenzano, Italy, by Monciardini et al. (2003). Soil was plated on half-strength humic acid vitamins agar (HV/2 medium) (Hayakawa and Nonomura 1987) following dilution in water. Single colonies were transferred on Internacional Streptomyces Project medium 3 (ISP3, Oatmeal agar: 20 g oatmeal, 18 g agar, 1 L deionized water) (Küster 1959; Shirling and Gottlieb 1966). Colonies were serially transferred on HV/2, ISP3, and Todd–Hewitt agar (THA, Difco) plates until a pure culture was obtained. The strain was also cultured on brain heart infusion agar (BHI, Difco), Luria-Bertani (LB, Difco), tryptic soy agar (TSA, Oxoid), R2A agar (Difco), and Internacional Streptomyces Project medium 2 (ISP2, Yeast extract-malt extract agar: 4 g bacto yeast extract, 10 g bacto malt extract, 4 g bacto dextrose, 20 g agar, 1 L deionized water) (Pridham et al. 1956–57; Shirling and Gottlieb 1966). For liquid cultures, Todd–Hewitt medium, BHI, tryptone soy broth (TSB, Oxoid), and R2A medium were used.

Conexibacter arvalis was isolated from a soil sample collected from a field in Saitama, Japan, by Seki et al. (2012). Soil was plated on 1/5-strength nutrient agar (1/5 NA, Difco) with 0.002 % benlate (Dupon) and incubated at 27 °C for 21 days. The strain was cultured on 1/5 NA, NA, ISP medium 5 (DAIGO; Nihon Pharmaceutical), brain heart infusion agar (BHI, Difco), 1/5 strength brain heart infusion agar (1/5 BHI), R2A agar (Difco), 1/5 strength R2A agar (1/5 R2A agar), tryptic soy agar (TSA, Difco), Todd–Hewitt agar (THA, Difco), 1/5 strength Todd–Hewitt agar (1/5 THA), and GPM agar [1 % (w/v) glucose, 0.5 % (w/v) peptone, 0.5 % (w/v) meat extract, 0.3 % (w/v) NaCl, 1.2 % (w/v) agar, pH 7.0] at 27 °C for 14 days.

Patulibacter minatonensis was isolated from a soil sample collected at Minato-Ku, Tokyo, Japan, (Takahashi et al. 2006) using an agar medium supplemented with superoxide dismutase (SOD) following the method of Takahashi et al. (2003). GPM agar medium, consisting of 1 % (w/v) D-glucose, 0.5 % (w/v) peptone, 0.5 % (w/v) meat extract, 0.3 % (w/v) NaCl, and 1.2 % (w/v) agar supplemented with 30 U ml^{-1} *Escherichia coli* SOD (Sigma), was used for strain isolation. The strain was cultured on 1/5 strength nutrient agar (1/5 NA, Difco), ISP3 medium (Küster 1959; Shirling and Gottlieb 1966), heart infusion agar, R2A agar, and Todd–Hewitt agar (THA, Difco) and Yeast

extract/glucose agar [YD agar: 1 % (w/v) yeast extract, 1 % (w/v) glucose and 1.2 % (w/v) agar] for 7 days at 27 °C. Trypticase soy broth (TSB, BBL) was used for liquid culture.

Patulibacter americanus was isolated from a biological soil crusts (BSC) collected from the Colorado Plateau (Reddy and Garcia-Pichel 2005; Reddy and Garcia-Pichel 2009). The medium used for isolation was BG11-PGY [10 % (v/v) BG11 mineral medium, 0.25 % (w/v) peptone, 0.25 % (w/v) yeast extract, 0.25 % (w/v) glucose, 1.5 % (w/v) agar]. The composition of BG11 base was: 1.5 g $NaNO_3$, 40 mg $K_2HPO_4.3H_2O$, 75 mg $MgSO_4.7H_2O$, 36 mg $CaCl_2.2H_2O$, 6 mg citric acid, 6 mg ferric ammonium citrate, 1 mg EDTA (disodium magnesium), 20 mg Na_2CO_3, 1 ml trace metal solution in 1 L Milli-Q water, pH 7.4 [the composition of the trace metal solution is as given in Rippka et al. (1979)]. Initially, 0.5 g of crust sample was suspended in Ringer's solution (9 g NaCl, 0.042 g KCl, 0.025 g CaCl2, and 100 mL deionized water) (Reddy et al. 2006) and vortexed for 30 min. The suspension was allowed to settle and then 100 mL supernatant was plated on BG11-PGY and incubated at room temperature for 15 days. Pink-colored colonies were isolated, purified on 1/10-strength BG11-PGY (1/10 BG11-PGY) by streaking, and maintained on the same medium.

Patulibacter ginsengiterrae was isolated from soil of a ginseng field located in Geumsan Country, Republic of Korea, by Kim et al. (2012). The soil sample was diluted serially in sterile deionized water, and samples of each serial dilution were spread on 1/10 strength nutrient agar (1/10 NA, Difco) and incubated at 25 °C for 4 weeks. One colony was selected and purified by subculturing on the same medium. The strain was routinely cultured on trypticase soy agar (TSA, Difco) or in trypticase soy broth (TSB, Difco) at 25 °C for 3 days.

Solirubrobacter pauli was isolated from a burrow of the epigeic earthworm *Lumbricus rubellus* in an agricultural soil (Furlong et al. 2002), on a plate composed of 50 % nutrient broth medium (NB, Difco) at 23 °C. Isolates were allowed to grow for 2 weeks before colonies were picked. One pink colony was selected from a dilution series and maintained on the same medium. The strain was routinely cultured on NB at 30 °C.

Solirubrobacter soli was isolated by direct plating of serially diluted soil sample from a ginseng field in Daejeon, South Korea, on R2A agar (Difco) by Kim et al. (2007). Single colonies from these plates were transferred to new plates and incubated for 5 days at 30 °C. The strain was routinely cultured on R2A agar at 30 °C.

Solirubrobacter ginsenosidimutans was isolated from soil of a ginseng field of Baekdu Mountain in China (An et al. 2011). The soil sample was suspended in 50 mM phosphate buffer (pH 7.0) and spread on modified xylan-nutrient agar (0.02 g tryptone, 0.02 g yeast extract, 0.02 g malt extract, 0.02 g beef extract, 0.02 g casaminoacid, 0.02 g soytone, 1 g xylan, 0.1 g sodium pyruvate, 0.3 g K_2HPO_4, 0.05 g $MgSO_4$, 0.05 g $CaCl_2$, 15 g agar, and 1 L deionized water, pH 7.0) plates after serial dilution with 50 mM phosphate buffer (pH 7.0). The plates were incubated at 30 °C for 1 month. The strain was routinely cultured on R2A agar (Difco) at 25 °C.

Members of this family do not require special procedures for maintenance and long-term storage. Generally, strains are maintained on the isolation medium at 4 °C for a few days and can be stored frozen at −70 °C in medium containing 15 % glycerol without loss of viability. Long-term preservation is by lyophilization.

Ecology

Habitat

All species of the genera *Conexibacter*, *Patulibacter*, and *Solirubrobacter* originate from soil samples, indicating that the members of the three genera inhabit soils with generally low temperatures and neutral pH. Since none of the species seem to tolerate or necessitate high salt media for growth, it is unlikely that these organisms inhabit saline environments.

Environmental 16S rRNA gene sequences closely related to the species of the genera *Conexibacter*, *Patulibacter* and *Solirubrobacter* corroborate the hypothesis that most of the members of the order *Solirubrobacteriales* inhabit soil habitats. Sequences with 98 % similarity or higher to the species of *Solirubrobacter*, namely, JF176876, JF176927, HM845968, and HM845830, were recovered from human skin. Other clone sequences such as JX133394, HQ119173, and HQ397109 were encountered in soil. The same habitat seems to be true of the species of *Conexibacter* which are mostly recovered from soil (JF806520, EU223949). Clone sequences or strains closely related to *Patulibacter* spp. were detected in the intestine of an earthworm (FJ542906) and an endophytic habitat (JQ660040).

[2]INRA, AgroParisTech, Jouy-en-Josas, France
[3]Redx Anti-infectives Ltd, Alderley Edge, UK

Abstract
Coriobacteriaceae is a family within the order *Coriobacteriales* (phylum Actinobacteria), which includes 30 species belonging to 14 genera: *Adlercreutzia*, *Asaccharobacter*, *Atopobium*, *Collinsella*, *Coriobacterium* (type genus), *Cryptobacterium*, *Denitrobacterium*, *Eggerthella*, *Enterorhabdus*, *Gordonibacter*, *Olsenella*, *Paraeggerthella*, *Parvibacter*, and *Slackia*. These bacteria are normal dwellers of mammalian body habitats such as the oral cavity, the gastrointestinal tract, and the genital tract. In the gut, *Coriobacteriaceae* carry out functions of importance such as the conversion of bile salts and steroids as well as the activation of dietary polyphenols. However, they can also be considered as pathobionts, because their occurrence has been associated with a range of pathologies such as bacteremia, periodontitis, and vaginosis. *Coriobacteriaceae* are usually nonmotile, nonspore-forming, nonhemolytic, and strictly anaerobic bacteria that grow as small rods; stain Gram-positive; are negative for oxidase, urease, and indole production; and are characterized by a high G+C content of DNA (around 60 mol%). Many species are asaccharolytic and possess a variety of aminopeptidases. Typical cellular fatty acids are $C_{18:1}$w9c as well as saturated fatty acids ($C_{14:0}$, $C_{16:0}$, $C_{18:0}$) and derivatives thereof. The production of menaquinone-6 homologues of vitamin K_2 seems also to be an attribute of the family. Taking into account the aforementioned metabolic functions of *Coriobacteriaceae*, their clinical relevance and the fact that an increasing number of novel species have been described very recently, this bacterial family will surely gain an increasing attention in the field of host/bacteria interactions in the near future.

Taxonomy, Historical and Current

The proposal to create the family *Coriobacteriaceae* (Co.ri.o.bac.te.ri.a'ce.ae. M.L. neut. n. *Coriobacterium* type genus of the family; *-aceae* ending to denote a family; M.L. fern. pl. n. *Coriobacteriaceae* the *Coriobacterium* family) was first published in 1997 by Stackebrandt et al. who reported a novel hierarchic classification of the phylum Actinobacteria according to 16S ribosomal RNA (rRNA) gene-based phylogeny (Stackebrandt et al. 1997). The type genus of the family, *Coriobacterium*, includes only one species, *Coriobacterium glomerans*, originally cultured from the intestine of a red soldier bug (Haas and König 1988).

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_343,

Only five of the current members of the family were isolated before the advent of molecular phylogeny in the mid-1980s. All of them have been subjected to amended description: *Atopobium minutum* (formerly *Bacteroides minutum*, *Eubacterium minutum*, or *Lactobacillus minutus*) (Collins and Wallbanks 1992), *Atopobium parvulum* (formerly *Peptostreptococcus parvulus* or *Streptococcus parvulus*) (Collins and Wallbanks 1992), *Collinsella aerofaciens* (formerly *Bacteroides aerofaciens*, *Eubacterium aerofaciens*, or *Pseudobacterium aerofaciens*) (Kageyama et al. 1999a), *Eggerthella lenta* (formerly *Bacteroides lentus*, *Eubacterium lentum*, or *Pseudobacterium lentum*) (Wade et al. 1999), and *Slackia heliotrinireducens* (formerly *Peptococcus heliotrinreducans* or *Peptostreptococcus heliotrinreducens*) (Wade et al. 1999). The main phenotypic traits still used nowadays for the identification of most family members are as follows: Gram-positive staining; nonmotile (with the exception of *Gordonibacter pamelaeae*); nonspore-forming; nonhemolytic; mesophilic (typically with a relatively narrow range of growth temperatures around the optimum of 37 °C); usually neutrophilic and acidotolerant; strictly anaerobic, albeit some members reported to be aerotolerant (*Eggerthella lenta*, *Enterorhabdus*, and *Parvibacter* spp.) and others microaerophiles (*Olsenella* spp.) or facultative anaerobes (*Atopobium vaginae*); grow as small rods or coccobacilli that mostly occur as single cells, pairs, or chains (e.g., *Adlercreutzia equolifaciens*, *Collinsella aerofaciens*, *Collinsella tanakaei*, *Coriobacterium glomerans*, *Eggerthella* spp., *Olsenella umbonata*, *Paraeggerthella hongkongensis*); grow usually to low optical density in liquid medium (with the exception of *Atopobium*, *Collinsella*, and *Olsenella* spp.); enhanced growth in the presence of arginine (e.g., *Cryptobacterium*, *Eggerthella*, *Gordonibacter*, and *Slackia* spp.) or Tween 80 (e.g., *Atopobium* and *Olsenella* spp.); positive for arginine dihydrolase and a variety of aminopeptidases; and negative for indole production, oxidase, and urease. Many species are asaccharolytic or convert a very limited number of sugars, e.g., *Adlercreutzia equolifaciens*, *Asaccharobacter celatus*, *Eggerthella* spp., *Enterorhabdus* spp., *Paraeggerthella hongkongensis*, *Parvibacter caecicola*, and all *Slackia* species.

Researchers who isolated strains of *Coriobacteriaceae* in the early days focused mainly on the description of isolates from feces, wounds, abscesses, and gingival crevices, which drew attention to the pathogenic potential of these bacteria. To date, however, nearly all species within the *Coriobacteriaceae* are known as commensal members of mammalian microbiota. The last 5 years have seen a bloom in the number of newly described bacteria belonging to the family: 11 of the 30 known species with a standing name in nomenclature have been described since 2008 (Maruo et al. 2008; Minamida et al. 2008; Clavel et al. 2009, 2010, 2013; Matthies et al. 2009; Würdemann et al. 2009; Jin et al. 2010; Nagai et al. 2010; Kraatz et al. 2011). In light of these novel descriptions, chemotaxonomic features have emerged as important parameters for reliable taxonomic classification of isolates. Most members of the *Coriobacteriaceae* contain a high proportion of saturated cellular fatty acids (e.g., $C_{14:0}$, $C_{16:0}$, or $C_{18:0}$ and dimethyl acetal thereof) and/or $C_{18:1}$w9c. The major menaquinones hitherto reported are menaquinone-6 (MK-6) (e.g., in *Eggerthella lenta*, *Gordonibacter pamelaeae*, and *Paraeggerthella hongkongensis*), monomethylmenaquinone-6 (MMK-6) (e.g., in *Eggerthella sinensis*, *Enterorhabdus* spp., and *Parvibacter caecicola*), and dimethylmenaquinone-6 (DMMK-6) (e.g., in *Adlercreutzia equolifaciens*, *Eggerthella* spp., and *Enterorhabdus caecimuris*). The latter group of quinones seems to be unique to the *Coriobacteriaceae* (Würdemann et al. 2009). So far analyzed peptidoglycan structures are of type A4*a*, A4*b*, as well as A4*g* or A1*g* based on the presence of LL- or *meso*-diaminopimelic acid, respectively. In all species examined for the presence of polar lipids, phosphatidylglycerol and diphosphatidylglycerol as well as up to four glycolipids and three phospholipids were detected.

Molecular Analyses

Phylogenetic Structure of the Family and Its Genera

A 16S rRNA gene sequence-based phylogenetic tree of the 30 members of the family is shown in ❯ *Fig. 11.1*. The trees were reconstructed by using a subset of sequences representative of most closely related genera to stabilize the tree topology.

The first phylogenetic description of the family *Coriobacteriaceae* was published by Stackebrandt et al. (1997). Due to newly described species within the phylum Actinobacteria and the availability of their 16S rRNA gene sequences, an emended description of the family was recently published based on the analysis of 2,642 actinobacterial sequences with >1,300 unambiguous nucleotides (between position 100 and 1,400) (Zhi et al. 2009). The authors reported that the order *Coriobacteriales* (and thus *Coriobacteriaceae*, the sole family within this order) constitutes one of the deepest branches within the phylum Actinobacteria together with the lineages of the order *Rubrobacterales* (e.g., *Thermoleophilaceae*, *Conexibacteraceae*) and *Acidimicrobiales*. The pattern of 16S rRNA signatures of *Coriobacteriaceae* consists of nucleotides at positions 242 : 284 (C–G), 291 : 309 (C–G), 316 : 337 (U–G), 819 (A), 952 : 1229 (U–A), and 1115: 1185 (C–G). Before the first description of the family by Stackebrandt et al. (1997), 16S rRNA-based phylogeny had already played an important role for the sake of emended description of several misclassified member species, including *Lactobacillus minutus*, *Lactobacillus rimae*, and *Streptococcus parvulus* (Collins and Wallbanks 1992). The genus *Atopobium* has then served, together with *Coriobacterium*, as a phylogenetic core of the *Coriobacteriaceae* and has been used to demonstrate that the inclusion of a broad range of physiologically diverse bacteria and thoughtful selection of out-groups are essential prerequisites for drawing proper phylogenetic conclusion (Rainey et al. 1994; Stackebrandt and Ludwig 1994). Thereafter, 16S rRNA gene-based phylogenetic evidence has largely contributed to the reclassification of additional members of the *Coriobacteriaceae*, e.g., *Atopobium fossor*, *Collinsella aerofaciens*, *Eggerthella lenta*, *Slackia exigua*, and *Slackia heliotrinireducens* (Kageyama et al. 1999a, b; Wade et al. 1999).

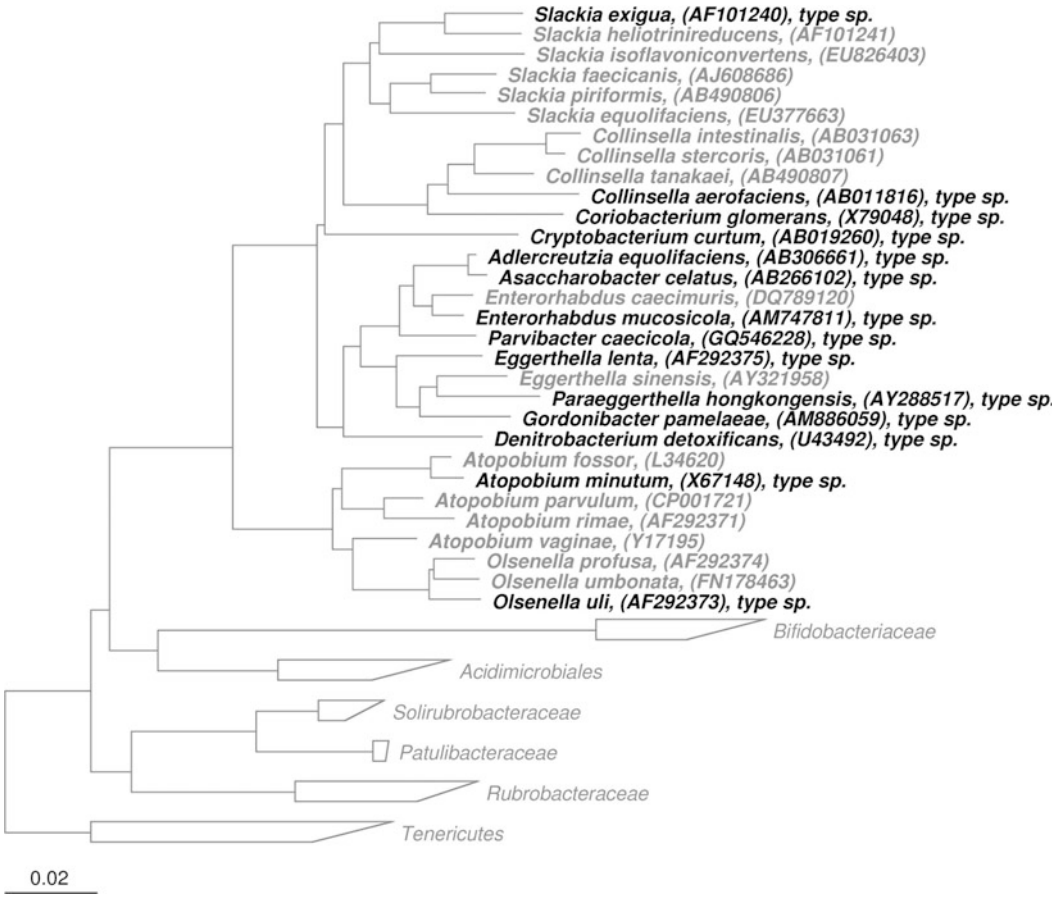

Fig. 11.1

Phylogenetic reconstruction of the family *Coriobacteriaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality-type strain sequences proportionally distributed amongst the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

According to information retrieved from the Ribosomal Database Project, 749 isolates that relate to the *Coriobacteriaceae* family have been described (full and partial 16S rDNA length), most of them from the *Atopobium* genus (337) and unclassified *Coriobacteriaceae* (117), followed by *Olsenella* (94), *Collinsella* (63), *Cryptobacterium* (39), *Eggerthella* (25), *Slackia* (22), *Paraeggerthella* (20), *Coriobacterium* (10), *Adlercreutzia* (9), *Gordonibacter* (6), *Denitrobacterium* (4), *Enterorhabdus* (2), and *Asaccharobacter* (1). Even though the number of 16S rRNA operons varies greatly between species (from 1 operon to 7 in *Collinsella aerofaciens*), their average number is low (2.4) since most of the sequenced strains have only one to two 16S rRNA operons.

DNA-Based Analysis and Genome Comparison

With the exception of *Atopobium* spp. and *Cryptobacterium curtum*, family members are characterized by a high G+C content of DNA (approximately 60 mol% and above). All DNA-DNA relatedness values available in the literature for members of the *Coriobacteriaceae* are given in *Table 11.1*.

Table 11.2 gathers most relevant information on genome sequencing projects focused on members of the *Coriobacteriaceae*. Representative genomes are available for 24 species belonging to 8 of the *Coriobacteriaceae* genera: *Atopobium* ($n = 6$ genomes), including *Atopobium parvulum*, *Atopobium rimae*, and *Atopobium vaginae* (3 strains); *Collinsella* ($n = 4$ genomes), including *Collinsella aerofaciens*, *Collinsella intestinalis*, *Collinsella stercoris*, and *Collinsella tanakaei*; *Coriobacterium glomerans* ($n = 1$ genome); *Cryptobacterium curtum* ($n = 1$ genome); *Eggerthella lenta* ($n = 4$ genomes from 3 strains); *Gordonibacter pamelaeae* ($n = 1$ genome); *Olsenella* ($n = 2$ genomes), including *Olsenella uli* and *Olsenella* sp. oral taxon 809; *Slackia* ($n = 4$ genomes), including *Slackia exigua*, *Slackia heliotrinireducens*, and *Slackia piriformis* (2 strains); and unclassified *Coriobacteriaceae* ($n = 1$ genome; *Coriobacteriaceae* bacterium JC110).

A complete genome is available for eight of the sequenced organisms, whereas the others are whole genome shotgun under completion. Fourteen of the 24 sequenced species are human isolates; four of them were isolated from diseased patients (caries, periodontitis, or bacteremia). Genome size ranges from 1,418,601 (*Atopobium vaginae* DSM 15829^T) to 3,632,260 bp (*Eggerthella lenta* DSM 2243^T). No plasmids have been described. One chromosome has been described for each of the sequenced strains. The number of genes is lowest in the *Atopobium* genus and highest in *Eggerthella lenta* DSM 2243^T. On average, 73.2 % of genes can be assigned to Clusters of Orthologous Groups (COGs). This ranges from 66.5 % in *Collinsella* spp. (min. 60.0 % in *Collinsella stercoris*) to 80.7 % in *Coriobacterium glomerans* PW2. In *Eggerthella* sp. YY7918, Yokoyama et al. reported an incomplete carbohydrate metabolic pathway in KEGG, supporting the observation that members of this genus are known to be asaccharolytic (Yokoyama et al. 2011). Several phage-related genes have been described in the genomes of all members of the family (*Table 11.3*). The highest number of phage-related genes is observed in the genome of *Atopobium rimae* ATCC 49626 ($n = 20$) and *Collinsella stercoris* DSM 13279 ($n = 16$). However, no phages have been described to lyse or infect strains of the *Coriobacteriaceae*.

The complete genomes of six sequenced strains were compared to the biggest genome of the family, i.e., *Eggerthella lenta* DSM 2243^T, using RAST (Aziz et al. 2008) (*Fig. 11.2*). Genes were annotated to proteins and results were computed using BLASTP (uni- and bidirectionally) to compare every protein in the reference genome (*Eggerthella lenta*) to every protein in the comparison genomes. Out of the 3,308 total proteins in *Eggerthella lenta*, 115 proteins were shared with the six other sequenced strains at a threshold of 60 % similarity. A major part of these genes were related to ribosomal proteins. Proteins that were not directly related to ribosomal proteins ($n = 73$) belonged to several COGs family, but originated mainly from the family J (translation, ribosomal structure, and biogenesis), L (DNA replication, recombination, and repair), O (posttranslational modification, protein turnover, chaperones), and R (general function prediction only). As expected, the genome of *Eggerthella* sp. YY7918 was the most closely related to that of *Eggerthella lenta*, followed by *Slackia heliotrinireducens*.

Phenotypic Analyses

Unless otherwise stated, all so far described species are Gram-positive, nonspore-forming, nonmotile, strictly anaerobic small rods or coccobacilli (*Fig.11.3*) that are negative for oxidase, urease, hemolysis, and indole production. The main

discriminative features of *Coriobacteriaceae* at the genus level are listed in *Table 11.4*. Many species possess a range of amino-peptidases likely to be important for amino acid release from the environment, N cycling processes, ammonia production, and which are useful selective parameters for the classification of *Coriobacteriaceae*. Thus, information on arginine dihydrolase and amino acid arylamidases is summarized at the species level in *Table 11.5*.

Adlercreutzia Maruo et al. (2008)

Ad.ler.creut'zi.a. N.L. fem. n. *Adlercreutzia* named after H. Adlercreutz (Emeritus Professor, University of Helsinki, Finland), for his contributions to research on the effects of phytoestrogens on human health.

The genus is represented only by the type species *Adlercreutzia equolifaciens* (e.quo.li.fa'ci.ens. N.L. n. *equol-olis*

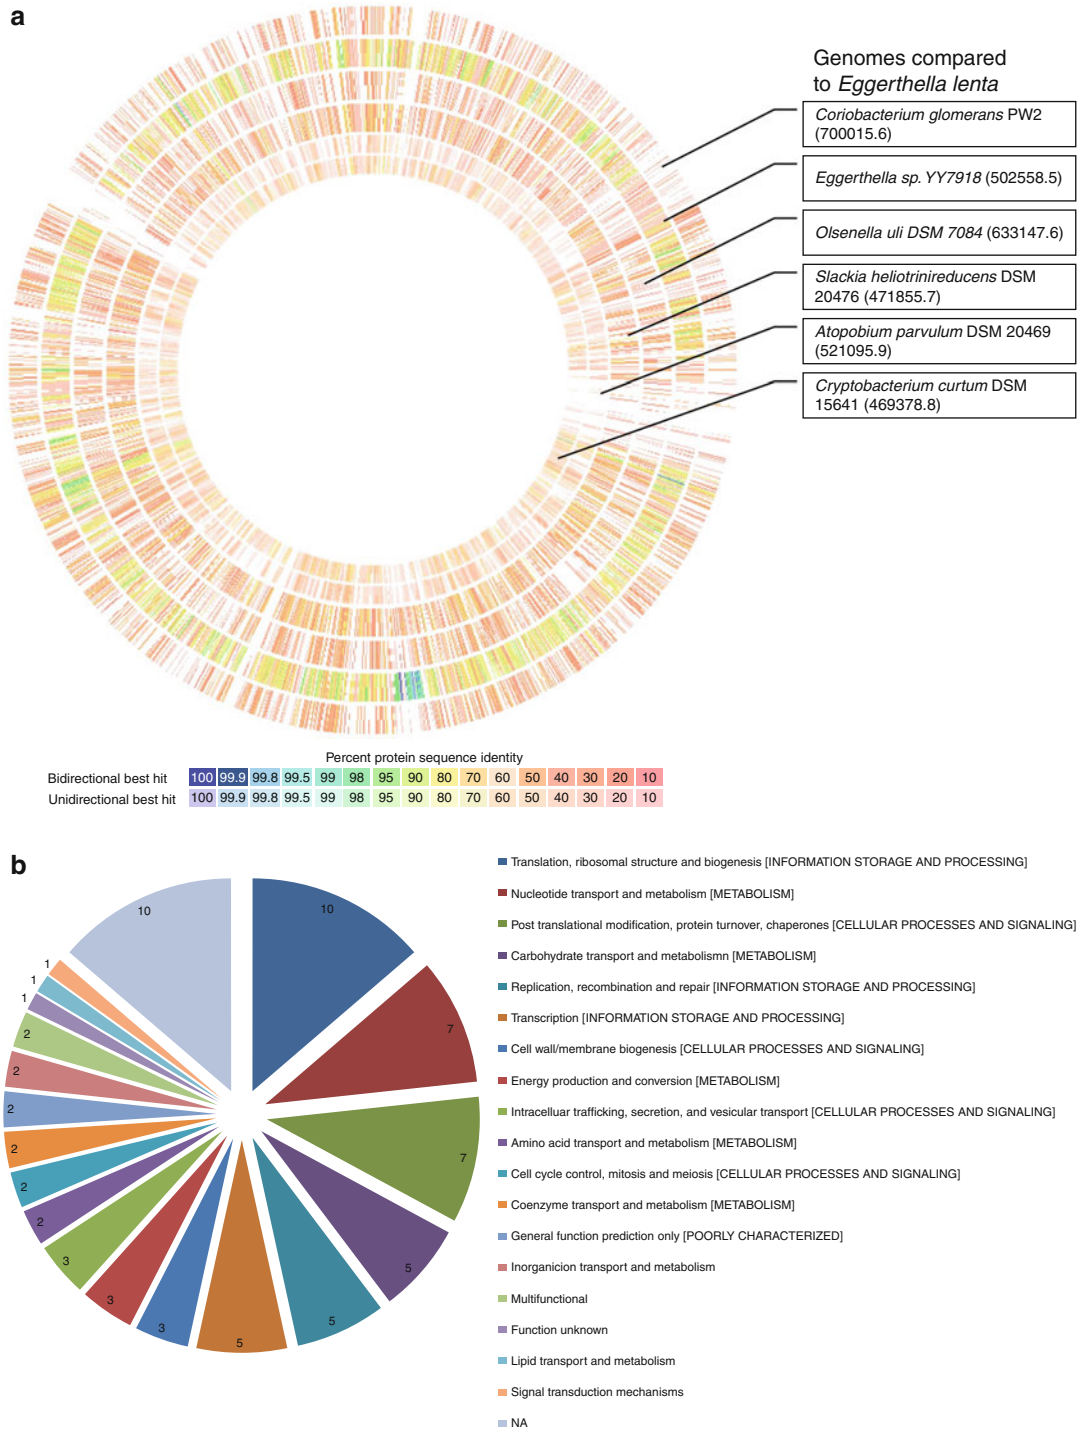

Fig. 11.2

Comparative genome analysis of *Coriobacteriaceae*. (a) Circular map of proteins encoded by the different compared genomes with percent similarity to the reference genome *Eggerthella lenta* (the order of proteins refers to the order of the contigs/genes in the reference genome). The amino acid identity of the query genomes relative to the reference is color coded on a logarithmic scale following the visible spectrum. (b) Functional category distribution of non-ribosomal proteins ($n = 73$) shared by the seven *Coriobacteriaceae* genomes

equol; L. part. adj. *faciens* making; N.L. part. adj. *equolifaciens* equol-producing). Cells are coccobacilli (0.6–0.7 × 1.5–2.7 μm) arranged in chains. Colonies on blood agar are 1–2 mm in diameter, grey to off-white grey, circular, entire, slightly convex, and smooth. The species does not grow in 20 % bile. It is asaccharolytic and positive for arginine dihydrolase as well as arginine and leucine arylamidase. No metabolic end product is detected in peptone-yeast extract medium

supplemented with glucose. Growth is stimulated by arginine. Nitrate is not reduced. *Adlercreutzia equolifaciens* converts the isoflavone daidzein into equol. Its cell wall contains A1*g*-type peptidoglycan with an (L-Ala)–D-Glu–m-Dpm peptide subunit. The diamino acid in the peptidoglycan is *meso*-diaminopimelic acid. The principal respiratory quinone is DMMK-6 (70–96 %). MMK-6 is a minor component (1–29 %). The major cellular fatty acid is $C_{18:1}$*cis*9. The G+C content of DNA is 64–67 mol% (64 mol% for the type strain). The description is based on the study of four strains: FJC-A10, FJC-B9, FJC-B20, and FJC-D53. The type strain is FJC-B9^T (= JCM 14793^T = DSM 19450^T = CCUG 54925^T).

Asaccharobacter Minamida et al. (2008)

A.sac.cha.ro.bac'ter. Gr. pref. *a-* not; Gr.n.*saccharon* sugar; N.L. masc. n. *bacter* a rod; N.L. masc. n. *Asaccharobacter* rod that does not digest sugar.

The genus is represented only by the type species *Asaccharobacter celatus* (ce.la'tus. L. masc. adj. *celatus* conceal, hide, keep secret). This species is phylogenetically closely related to *Adlercreutzia equolifaciens* FJC-B9^T and strain Julong 732 (>99 % similarity) based on partial 16S rRNA gene sequence analysis. DNA-DNA hybridization analysis of these three isolates has not been performed so far. In contrast to *Adlercreutzia equolifaciens*, *Asaccharobacter celatus* can grow in 20 % bile, is negative for leucine arylamidase, and is characterized by the presence of a dominant lipoquinone that is not MK, MMK, DMMK, ubiquinone, or rhodoquinone. Cells are rod-shaped (0.45 × 2.3–2.7 μm). Colonies are smooth, clear, and colorless on GAM agar, reaching 1 mm in diameter after 2 days at 37 °C. Growth is enhanced in the presence of arginine, but not Tween 80. The species does not reduce nitrate, is asaccharolytic, and produces trace amounts of organic acids (lactic, acetic, and succinic acid) in medium containing peptone, yeast extract, and glucose. It is capable of converting the isoflavone daidzein to equol. Cells do not produce acid from/show negative test results in the API 50 CH system with the following substrates: glycerol, glucose, erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, methyl *b*-D-xyloside, galactose, fructose, mannose, sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, methyl *a*-D-mannoside, methyl *a*-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, and 5-ketogluconate. Cells show strong naphthol-AS-BI-phosphohydrolase activity, medium acid phosphatase activity, and weak alkaline phosphatase and esterase (C4) activities. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid, alanine, and glutamic acid. The predominant cellular fatty acid is $C_{18:1}$*cis*9. The G+C content of DNA is 63 mol%. The type strain is do03^T (= JCM 14811^T = DSM 18785^T = AHU 1763^T).

Atopobium fossor, *Coriobacterium glomerans*, and *Denitrobacterium detoxificans* were not included in the table since, to the best of our knowledge, no information is available in the literature on any of the listed enzymes for these species

Symbols and abbreviations: + positive, – negative, *v* variable depending on strains, *ND* not determined

Atopobium Collins and Wallbanks (1992)

A.to.po'bi.um. Gr. adj. *atopos* having no place, strange; Gr. neu. part. used as noun; *bion* living thing; N.L. neu. n. *Atopobium* strange living thing.

The genus name *Atopobium* was initially proposed in 1992 following the pioneering 16S rRNA-based phylogenetic analysis of 40 lactic acid bacteria by Collins and Wallbanks. The genus was created to accommodate the species formerly classified as follows: (a) *Lactobacillus minutus* (synonyms: *Bacteroides minutum*, *Eubacterium minutum*) → *Atopobium minutum* comb. nov. (mi.nu'tum. L. neut. adj. *minutum* little, small); (b) *Lactobacillus rimae* → *Atopobium rimae* comb. nov. (L. gen. n. *rimae* of a fissure, here pertaining to the gingival crevice); and (c) *Streptococcus parvulus* (synonym: *Peptostreptococcus parvulus*) → *Atopobium parvulum* comb. nov. (L. neut. dim. adj. *parvulum* very small) (Collins and Wallbanks 1992). The genus also includes *Atopobium vaginae* (va.gi'nae. L. n. *vagina* vagina; L. gen. n. *vaginae* of the vagina) (Rodriguez Jovita et al. 1999) and *Atopobium fossor* (fos'sor. L.n. *fossor*, a digger, delver), originally described as [*Eubacterium fossor*] (Bailey and Love 1986; Kageyama et al. 1999b). The type species of the genus is *Atopobium minutum*. Of note, Olsen et al. published already in 1991 an amended description of [*Lactobacillus minutus*] and [*Streptococcus parvulus*] (Olsen et al. 1991), which were originally described in 1937 (Hauduroy et al. 1937; Weinberg et al. 1937). The transfer of [*Peptostreptococcus parvulus*] to the genus *Streptococcus* was published by Cato in 1983 (Cato 1983).

Symbols: *v* variable (number of positive strains/total number of strains tested)

The growth of *Atopobium* spp. is usually stimulated by the presence of Tween 80. Cells consist of short rods, often with central swellings, or small cocci that may appear to be elliptical. Cells occur singly, in pairs, or short chains. The major fermentation products from glucose are lactic acid, together with acetic and formic acid; trace amounts of succinic acid may also be formed. H_2 is not produced. Gelatin is not liquefied; meat is not digested. These bacteria are usually strictly anaerobic, but *Atopobium vaginae* can also grow under aerobic conditions (5 % CO_2). The G+C content of DNA is 35–46 mol%. Discriminative features of *Atopobium* spp. are shown in *Table 11.6*.

Collinsella Kageyama et al. (1999c), Emend. Kageyama and Benno (2000)

Col.lin.sel'la. M.L. fem. dim. ending *-ella*, M.L. fem. n. *Collinsella* named to honor Matthew D. Collins, a contemporary English microbiologist, for his outstanding contribution to microbial taxonomy and phylogeny.

The genus *Collinsella* was created in 1999 to accommodate [*Eubacterium*] *aerofaciens* (ae.ro.fa'ci.ens. Gr. n. *aer* gas; L. v. *facere* to make, to produce; M.L. part. adj. *aerofaciens* gas-producing), which had been previously published as *Bacteroides aerofaciens* (Eggerth 1935). The proposal to create *Collinsella* gen. nov. was based on 16S rRNA gene sequence analysis showing that three strains of [*Eubacterium*] *aerofaciens* (JCM 10188^T, JCM 7790, and JCM 7791) formed a cluster closest to *Atopobium* spp. and *Coriobacterium glomerans*. The three strains were also characterized by higher G+C content of DNA (60–61 vs. 45–47 mol%) when compared with *Eubacterium* sensu stricto (*Eubacterium limosum*, *Eubacterium barkeri*, *Eubacterium callanderi*). The genus currently comprises four species: *Collinsella intestinalis* (in'test.in.alis. N. L. adj. *intestinalis* pertaining to the intestine) (Kageyama and Benno 2000), *Collinsella stercoris* (ster'co.ris. L. n. *stercus* feces; L. gen. n. *stercoris* of feces, referring to the source of the isolate) (Kageyama and Benno 2000), *Collinsella tanakaei* (ta.na.ka'e.i. N.L. masc. gen. n. *tanakaei* of Tanaka, to honor Ryuichiro Tanaka, a Japanese microbiologist, for his contribution to increased knowledge about human intestinal microbiota and probiotics) (Nagai et al. 2010), and the type species *Collinsella aerofaciens*. *Collinsella* spp. occur in chains of rod-shaped cells (0.5–1.0 × 1–3 μm). Fermentation products of glucose are H_2, ethanol, formate, and lactate. All strains are positive for naphthol-AS-BI-phosphohydrolase, acid from glucose and D-mannose. They are negative for *a*-arabinosidase, *a*-fucosidase, *a*-galactosidase, *a*-mannosidase, chymotrypsin, esterase (C4), esterase lipase (C8), glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, lipase (C14), pyroglutamic acid arylamidase and acid from L-arabinose, glycerol, D-mannitol, melezitose, raffinose, L-rhamnose, D-sorbitol, and D-xylose. It has been reported that the growth of *Collinsella* is stimulated by Tween 80 (Dewhirst et al. 2001; Maruo et al. 2008), but this characteristic is absent from the single description of all *Collinsella* species (Kageyama et al. 1999a; Kageyama and Benno 2000; Nagai et al. 2010). Cells of *Collinsella tanakaei* are resistant to 20 % bile (no data available for the other species). The cell wall contains a A4-type peptidoglycan. Respiratory quinones are not detected. The G+C content of DNA is

CFA cellular fatty acids

60–64 mol%. All strains were isolated from human feces. Discriminative features of the *Collinsella* spp. are shown in *Table 11.7*.

Coriobacterium Haas and König (1988)

Co.ri.o.bac.ter'i.um. Gr. fem. n. *koris* bug; Gr. neut. n. *bakterion* a small rod; M.L. neut. n. *Coriobacterium* rodlet associated with bugs.

The genus is represented only by the type species *Coriobacterium glomerans* (glo'me.rans. L. part. adj. *glomerans* agglomerating; the cells form flocculent, wooly sediments with a clear supernatant in fluid media). Cells grow as long chains (>150 μm) of pear-shaped to irregularly shaped rods (0.44–1.80 μm long). Spherical involution forms are common. The filamentous cell chains are attached to the epithelia in the intestine of bugs. The organisms grow on Columbia blood agar, supplemented Schaedler agar (BBL), and TPY agar at 25 and 30 °C. When grown in TPY medium, the fermentation products of glucose (−7.8 μmol/mL) are acetic acid (7.5 μmol/mL), L-lactic acid (6.5 μmol/mL), ethanol (6.1 μmol/mL), CO_2, and H_2. D-Lactic acid, formic acid, volatile short-chain alcohols, or other volatile fatty acids are not formed. The cells ferment glucose, L-arabinose, D-xylose, D-ribose, mannose, sucrose, maltose, cellobiose, mannitol, and salicin. Lactose, melibiose, raffinose, inulin, starch, and inositol are not fermented. The cells have an electron-dense Gram-positive 40-nm-wide cell wall. The peptidoglycan belongs to the Lys-Asp type. The G+C content of the DNA is 60–61 mol%. The type strain is PW2^T (= DSM 20642^T = ATCC 49209^T = JCM 10262^T). The species was originally reported to occur in the third bulbous midgut portion of all stages of the red soldier bug (*Pyrrhocoris apterus*), except the eggs. However, recent in situ hybridization experiments and sterilization of eggs revealed that vertical transmission of *Coriobacterium glomerans* occurs via the egg surface (Kaltenpoth et al. 2009).

Cryptobacterium Nakazawa et al. (1999)

Crypt.o.bac.te'ri.um. Gr. n. *kryptos* hidden; Gr. n. *bakterion* a small rod; M.L. neut. n. *Cryptobacterium* a hidden rod-shaped bacterium.

The genus is represented only by the type species *Cryptobacterium curtum* (cur'tum. L. neut. adj. *curtum*

shortened, a shortened cell of this organism). Cells are asaccharolytic short rods. On BHI-blood agar, minute, circular, convex, and translucent colonies less than 1 mm in diameter are formed, even after prolonged incubation. Growth in broth media is poor with or without carbohydrates. Starch is not hydrolyzed and no liquefaction of gelatin occurs. Ammonia is produced from arginine (Uematsu et al. 2006). Adonitol, amygdalin, arabinose, cellobiose, erythritol, fructose, galactose, glucose, glycogen, inositol, lactose, maltose, mannitol, mannose, melezitose, melibiose, rhamnose, ribose, salicin, sorbitol, starch, sucrose, trehalose, and xylose are not utilized. No metabolic end product is detected in peptone-yeast extract medium supplemented with glucose. Maruo et al. (2008) reported that growth is stimulated by arginine but not Tween 80, yet this statement is not found in the original description by Nakazawa et al., and no amended description has been proposed. The G+C content of DNA is 50–51 mol%. The type strain is 12-3^T (= ATCC 700863^T = DSM 15641^T).

Denitrobacterium Anderson et al. (2000)

De.nit.ro.bac.te'ri.um. L. pref. *de* from; L. n. *nitro* nitro-compound; Gr. neut. dim.n. *bakterion* a small rod; M.L. neut. n. *Denitrobacterium* nitro-compound-reducing rod.

The genus is represented only by the type species *Denitrobacterium detoxificans* (de.tox.if'i.cans. L. pref. *de* from; L. n. *toxicum* poison; L. neut. n. *detoxificans* poison reducer). Cells are chemoorganotrophic and rod-shaped (0.5–1.0 × 1.0–1.5 μm); bulbous ends may be present. The species grows equally well at 32, 37, and 39 °C. Growth occurs in media containing clarified rumen fluid, peptone, and a suitable electron acceptor, including nitrate, 3-nitropropanol, 2-nitropropanol, 3-nitropropionate, nitroethanol, nitroethane, 1-nitropropane, 2-nitrobutane, DMSO, trimethylamine oxide, hydrogen, formate, or (DL)-lactate. H_2S is not produced, and gelatin is not hydrolyzed. Little if any acid is produced during growth in medium with hydrogen or formate as electron donor. Acetate is the major product after growth on lactate; D-lactate is used more readily than L-lactate. The G+C content of DNA ranges from 56 to 60 mol % (thermal denaturation method). A *c*-type cytochrome was found in the type strain NPOH1^T (= ATCC 700546^T = CCUG 56741^T), isolated from a population of ruminal microbes enriched for enhanced metabolism of 3-nitropropanol, the toxic aglycone of miserotoxin (3-nitro-1-propyl-b- d-glucopyranoside) (Anderson et al. 1996). Strain NPOH1^T differs from other strains of the species (NPOH2 = ATCC 700547; NPOH3 = ATCC 700548; and MAJ1 = ATCC 700549) in that it has the ability to reduce nitrate.

Eggerthella Wade et al. (1999), Emend. Maruo et al. (2008), Emend. Würdemann et al. (2009)

Eg.ger.thel'la. L. dim. ending *-ella*; M.L. fem. n. *Eggerthella* named after Arnold H. Eggerth, an American microbiologist who was the first person to report the isolation of [*Eubacterium lentum*] from human feces in 1935 (Eggerth 1935).

The genus *Eggerthella* comprises two species: *Eggerthella sinensis* (M.L. gen. n. *sinae* of China; N.L. fem. adj. *sinensis* pertaining to China, the country where the bacterium was discovered) (Lau et al. 2004b) and the type species *Eggerthella lenta* (len'ta. L. fem. adj. *lenta* slow). *Eggerthella lenta* was originally referred to as *Eubacterium lentum* (Moore et al. 1971; Holdeman et al. 1977). Other synonyms of this species include [*Bacteroides lentus*] and [*Pseudobacterium lentum*]. The proposal to create the name *Eggerthella lenta* was first published in 1999 by Wade et al. on the basis of 16S rRNA gene-based phylogenetic evidence, which showed that [*Eubacterium lentum*], [*Eubacterium exiguum*], and [*Peptostreptococcus heliotrinreducens*] formed a coherent cluster closely related to *Atopobium* spp. and *Coriobacterium glomerans* but only distantly related to *Eubacterium limosum*, the type species of the genus *Eubacterium* (Wade et al. 1999). Kageyama et al. also published a similar study in 1999 and proposed to create the name *Eggerthella* gen. nov. to accommodate [*Eubacterium lentum*] (Kageyama et al. 1999c). However, the work by Wade et al. has priority. Kageyama et al. reported as well that the cell wall of *Eggerthella lenta* contains type A3 peptidoglycan, yet this information cannot be found in the original work by Schleifer and Kandler to which Kageyama et al. referred (Schleifer and Kandler 1972). In their amended description of the genus *Eggerthella*, Maruo et al. stated that the cell wall contains A4*g*-type peptidoglycan with an (L-Ala)–D-Glu–m-Dpm–D-Glu peptide subunit and an inter-peptide bridge that consists only of D-Glu (Maruo et al. 2008). In 2009, Saunders et al. published the genome sequence of the type strain of *Eggerthella lenta* and stated that its cell wall contains A1*g*-type peptidoglycan (Saunders et al. 2009). The latest description with standing in nomenclature is the one by Maruo et al. 2008. The major respiratory quinones are MK-6 (dominant in *Eggerthella lenta*) and MMK-6 (dominant in *Eggerthela sinensis*). DMMK-6 is also detected in *Eggerthella sinensis*. Polar lipids consist of two phospholipids, phosphatidylglycerol and diphosphatidylglycerol, and four glycolipids. The main cellular fatty acid is $C_{16:0}$ DMA. The proportion of saturated cellular fatty acids is 61–76 %. Growth is stimulated by arginine (Sperry and Wilkins 1976a). Cells are usually arranged in chains. They are catalase- and arginine dihydrolase-positive. Colonies on blood agar are as follows: 0.25–1.0 mm, circular, entire, slightly raised, smooth, grey, and translucent to semiopaque (*Eggerthella lenta*) and greyish white, 0.5 mm in diameter after 48 h at 37 °C (*Eggerthella sinensis*). *Eggerthella lenta* reduces nitrate and has been found to produce ammonia from arginine and to contain cytochromes *a*, *b*, and *c* and a carbon monoxide-binding pigment (Sperry and Wilkins 1976b). The G+C content of DNA is 61–64 mol% (*Eggerthella lenta*) and 65–66 mol% (*Eggerthella sinensis*). The type strain of *Eggerthella lenta* is DSM 2243^T (= ATCC 25559^T = CCUG 17323A^T = CIP 106637^T = JCM 9979^T = NCAIM B.01418^T = NCTC 11813^T). The type strain of *Eggerthella sinensis* is HKU14^T (= DSM 16107^T = JCM 14551^T = LMG 22123^T). Discriminative features of *Eggerthella* spp. are shown in Table 11.8.

Enterorhabdus Clavel et al. (2009), Emend. Clavel et al. (2010)

En.te.ro.rhab'dus. Gr. n. *enteron* intestine; Gr. fem. n. *rhabdos* a rod; N.L. fem. n. *Enterorhabdus* a rod isolated from the intestine.

The genus *Enterorhabdus* comprises two species: *Enterorhabdus caecimuris* (ca.e.ci.mu'ris. L. n. *caecum* caecum; L. n. mus *muris* mouse; N.L. gen. n. *caecimuris* of the caecum of a mouse) and the type species *Enterorhabdus mucosicola* (mu.co.si'co.la. N.L. n. *mucosa* mucosa from L. adj. *mucosus -a -um* mucous; L. suff. *-cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *mucosicola* inhabitant of the intestinal mucosa). These species are mesophilic, aerotolerant anaerobes that grow as single short rods (0.5 × 2.0 μm) that do not produce glycosidases. Cultures in the stationary phase of growth in anoxic Wilkins-Chalgren-Anaerobe broth are characterized by stable pH (6.9–7.1) and a typically low turbidity (<0.5 McFarland standard). They grow well in the temperature range 30–40 °C. No growth occurs in the presence of 0.5 % (w/v) bile salts. *Enterorhabdus caecimuris* grows in the presence of 2 % (w/v) NaCl. Both species form pinpoint colonies on blood agar. The major cellular fatty acids are $C_{14:0}$, $C_{16:0}$, and $C_{16:0}$ DMA. Whole-cell sugars include galactose and ribose. The most dominant respiratory quinone is MMK-6. The G+C content is 64.2–64.5 mol%. The major polar lipids are diphosphatidylglycerol and two glycolipids. The type strain of *Enterorhabdus mucosicola* is Mt1B8^T(= DSM 19490^T = CCUG54980^T). The type strain of *Enterorhabdus caecimuris* is B7^T (= DSM 21839^T, =CCUG 56815^T). Discriminative features of *Enterorhabdus* spp. are shown in Table 11.9.

Gordonibacter Würdemann et al. (2009)

Gor.do'ni.bac'ter. N.L. masc. n. *Gordon* named after Jeffrey I. Gordon, MD, the Dr Robert J. Glaser Distinguished University Professor and Director of the Center for Genome Sciences at Washington University School of Medicine, St. Louis, MO, USA; N.L. masc. n. *bacter* a rod; N.L. masc.n. *Gordonibacter* a rod named after Jeffrey I. Gordon.

The genus is represented only by the type species *Gordonibacter pamelaeae* (pa.me'la.eae. N.L. fem. n. *pamelaeae* named after Dr Pamela Lee Oxley (née Fredericks), biochemist, environmentalist, teacher, mentor, and mother). Cells are catalase-positive coccobacilli (0.5–0.6 × 0.8–1.2 μm) with a conical cell apex. They are motile and characterized by the presence of a subpolarly inserted flagella when grown in BHI medium. Of note, one clinical isolate identified as *Gordonibacter pamelaeae* on the basis of 16S rRNA gene sequencing and phenotypic analysis was reported to be nonmotile (Woo et al. 2010). Growth is generally slow on BHI and Schaedler anaerobic media (Oxoid) supplemented with 5 % defibrinated horse blood, with pale-white, semitranslucent colonies forming after 48–72 h at 37 °C. Growth is enhanced by 1 % (w/v) arginine-HCl. Arabinose, glucose, mannose, raffinose, trehalose, xylose, L-methionine, L-phenylalanine, L-valine, L-valine plus L-aspartic acid, dextrin, and D-glucose 6-phosphate are not metabolized. Nitrate is not reduced. Only weak conversion of pyruvic acid and pyruvic acid methyl ester is observed. All other organic substrates included in the Biolog AN MicroPlate are not metabolized. Cellular fatty acids consist mainly (approximately 90 %) of saturated fatty acids (predominantly C_{15} and C_{16}). The major respiratory lipoquinone present is MK-6; MMK-6 is a minor component. The major polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and four glycolipids. The G+C content of DNA is 66 mol%. The type strain is 7–10-1-b^T(= DSM 19378^T = CCUG55131^T).

Olsenella Dewhirst et al. (2001)

Ol.sen.el'la. L. fem. dim. ending *-ella*, N.L. fem. n. *Olsenella* of Olsen, named to honor Ingar Olsen, a contemporary Norwegian microbiologist, who first described *Lactobacillus uli*.

The genus currently comprises three species: (a) *Olsenella profusa* (pro.fus'a. L. adj. *profusus* profuse, referring to the good growth of the organism), (b) *Olsenella umbonata* (um.bo.na'ta. N.L. fem. adj. *umbonata* bossed, umbonate (from L. masc. n.

Abbreviations: ai, anteiso, *CFA* cellular fatty acids

umbo, *umbonis* a shield boss), referring to the umbonate elevations of outgrown colonies on solid culture media) (Kraatz et al. 2011), and (c) the type species *Olsenella uli* (u'li.Gr. n. *oulon* the gum; N.L. gen. n. *uli* of the gum). Cells are microaerotolerantly (moderately obligately) anaerobic (less than 5 % O_2, v/v). They grow as small, elliptical rods that occur singly, in pairs, or short to very long serpentine chains. Convert a variety of sugars. Lactic acid is the major product from glucose. Minor products are formic and acetic acid. Able to grow on mucin from porcine stomach. All strains are negative for urease, *a*-galactosidase, *a*-arabinosidase, *b*-glucuronidase, *a*-mannosidase, *a*-fucosidase, raffinose fermentation, acidification of glycerol and melezitose, trypsin, *a*-chymotrypsin, reduction of nitrate, pyroglutamic acid arylamidase, glutamic acid decarboxylase, and glutamyl glutamic acid arylamidase. All strains are positive for mannose fermentation, acidification of glucose, and gelatin hydrolysis. Growth is stimulated by Tween 80 but not arginine. The cellular fatty acids consist mainly of saturated fatty acids. The G+C content of DNA is 63–64 mol%. Original values reported for [*Lactobacillus*] *uli* were $C_{18:1}$*cis*9 (major cellular fatty acid) and 53 mol% (G+C content of DNA) (Olsen et al. 1991). Göker et al. recently reported that *Olsenella uli* is characterized by the presence of a A4*b*-type peptidoglycan based on L-Orn-D-Asp (Goker et al. 2010). *Olsenella profusa* was previously designated *Eubacterium* group D52 (Holdeman et al. 1977). The description of *Olsenella umbonata* refers to the analysis of four strains (A2, lac 15, lac 16, and lac31^T). All lac strains were isolated from pig jejunal mucosa (Kraatz and Taras 2008), whereas strain A2 was isolated from sheep rumen as part of a study focusing on ammonia-producing bacteria (Eschenlauer et al. 2002). *Olsenella umbonata* was found to produce ammonium from peptone under anaerobic and unreduced microaerobic conditions (ca. 12 and 9 mmol/l, respectively). Growth of this species is positive in 20 % bile but absent in 6.5 % NaCl. Strain A2 (=CCUG 58212 = DSM 22619 = JCM 16157), which had been informally named [*Olsenella* (*Atopobium*) *oviles*] (Dewhirst et al. 2001; Eschenlauer et al. 2002), can be differentiated from the type strain lac31^T by a negative result for acidification of trehalose in the API 20 A strip. Discriminative features of *Olsenella* spp. are shown in *Table 11.10*.

Paraeggerthella Würdemann et al. (2009)

Pa'ra.eg.ger.thel'la. L. prep. *para* beside; N.L. fem. n. *Eggerthella* a bacterial genus name; N.L. fem. n. *Paraeggerthella* beside *Eggerthella*, named in recognition of the close relationship to the genus *Eggerthella*.

The genus is represented only by the type species *Paraeggerthella hongkongensis* (N.L. fem. adj. *hongkongensis*, pertaining to Hong Kong, the city where the bacterium was discovered). This species had been previously described as [*Eggerthella*] *hongkongensis* (Lau et al. 2004b), for which an emended description was published by Maruo et al. (2008). The type strain is HKU10^T (= DSM 16106^T = CCUG 49250^T), isolated in 1998 from the blood of a 30-year-old male patient suffering from alcoholic cirrhosis, portal hypertension, and epilepsy and diagnosed with perianal abscess (Lau et al. 2004a). Additional strains (HKU11, HKU12, HKU13) were isolated from blood cultures of a patient with an infected rectal tumor, a liver abscess, and acute appendicitis, respectively. These additional strains were not further studied in amended descriptions. The rationale for reclassifying [*Eggerthella*] *hongkongensis* into the novel genus *Paraeggerthella* was based on several major differences observed between strain HKU10^T and *Eggerthella* species: (a) 16S rRNA gene similarity values <95 %, (b) a lower amount of saturated cellular fatty acids (45 vs. 61–63 %), (c) the presence of $C_{18:1}$ w9c instead of $C_{16:0}$ DMA as major cellular fatty acid, (d) different polar lipid profiles (three instead of four glycolipids), and (e) the ability of *Paraeggerthella hongkongensis* to metabolize 3-methyl-D-glucose, palatinose, L-rhamnose, L-methionine, L-valine, L-valine plus L -aspartic acid, and uridine 5′-monophosphate. Physiological testing using Rapid ID32A and API 20A revealed just one positive reaction, for arginine dihydrolase. Lau et al. reported a positive reaction for *b*-glucosidase, which was not confirmed by Würdemann and colleagues. Results obtained with Biolog AN MicroPlates indicated that urocanic acid and L-threonine are metabolized. Weak conversion of rhamnose is observed. The other organic substrates included in the Biolog AN MicroPlate are not metabolized. No significant conversion of the flavonoids quercetin, rutin, genistein, and phloretin is observed. Cells are catalase-positive coccobacilli arranged in chains. They grow on blood agar as greyish white colonies of 0.5 mm in diameter after 48 h at 37 °C. The cell wall contains the A4*g*-type peptidoglycan. According to Würdemann et al., the major respiratory lipoquinone is MK-6 (68 %); MMK-6 is a minor component (32 %). Maruo et al. found that the principal respiratory quinone is MMK-6 and that minor menaquinones are MK-6 and DMMK-6. This discrepancy is likely due to growth conditions and technical issues, e.g., the fact that DMMK-6 can be difficult to detect using HPLC. Polar lipids consist of phosphatidylglycerol, diphosphatidylglycerol, and three glycolipids (GL1, GL2, andGL4). The G+C content of DNA of strain HKU10^T is 61–62 mol%.

Parvibacter Clavel et al. (2013)

Par.vi.bac'ter. L. adj. *parvus* small; N.L. masc. n. *bacter* rod; N.L. masc. n. *Parvibacter* small rod.

The genus is represented only by the type species *Parvibacter caecicola* (ca.e.ci'co.la. N.L. n. *caecum* blind pouch, caecum; L. suff. *-cola* (from L. n. *incola*), dweller, inhabitant; N.L. n. *caecicola* caecum dweller). Cells are aerotolerant small rods (0.5 × 1.5 μm) that grow only under strictly anoxic conditions in the temperature range from 25 to 37 °C. After 48 h at 37 °C on Wilkins-Chalgren-Anaerobe agar under anoxic conditions, colonies are circular, entire, pinpoint, and grey. Positive for proline, phenylalanine, leucine, tyrosine, alanine, glycine, and serine arylamidase. Negative for urease activity, arginine dihydrolase, *a*- and *b*-galactosidase, *a*- and *b*-glucosidase, *a*-arabinosidase, *b*-glucuronidase, *b*-*N*-acetylglucosamine, mannose and raffinose fermentation, glutamic acid decarboxylase, *a*-fucosidase, nitrate reduction, indole production, and alkaline phosphatase as well as arginine, leucyl glycine, pyroglutamic acid, histidine, and glutamyl glutamic acid arylamidase. The major cellular fatty acids are $C_{16:0}$ (26 %) and i-$C_{15:0}$ (11 %). Galactose, glucose, and ribose are detected as whole-cell sugars. The principal respiratory quinone is MMK-6. The diamino acid in the peptidoglycan is *meso*-diaminopimelic acid. The major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, three phospholipids, four glycolipids, and one unidentified lipid. The G+C content of DNA is 62.5 %. The type strain is NR06^T (= DSM 22242^T = CCUG 57646^T).

Slackia Wade et al. (1999), Emend. Nagai (2010)

Slack'ia. M.L. fem. n. named to honor Geoffrey Slack, distinguished British microbiologist and dental researcher.

The rationale for creating the genus name *Slackia* was to accommodate [*Eubacterium exiguum*] (Poco et al. 1996) and [*Peptococcus heliotrinreducans*] (Lanigan 1976) on the basis of 16S rRNA phylogenetic evidence showing that these two species formed a distinct cluster within the *Coriobacteriaceae*. The genus *Slackia* currently comprises six species: (a) *Slackia equolifaciens* (e.quo.li.fa'ci.ens. N.L. n. *equol-olis* equol; L. part. adj. *faciens* making; N.L. part. adj. *equolifaciens* equol-producing) (Jin et al. 2010), (b) *Slackia faecicanis* (fae.ci.ca'nis. L. n. *faex, faecis* feces; L. gen. n. *canis* dog; N.L. gen. n. *faecicanis* from dog feces) (Lawson et al. 2005), (c) *Slackia heliotrinireducens* (he.li.o.trin.i.re.duc. ens. M.L. n. *heliotrinum* derived from heliotrine, a pyrrolizidine alkaloid; L.adj. *reducans* reducing M.L. adj. *heliotrinireducens* referring to the ability to bring about oxidative cleavage of the heliotrine molecule), (d) *Slackia isoflavoniconvertens* (i.so.fla.vo.ni.con.ver'tens. N.L. neut. n. *isoflavonum* isoflavone; L. part. adj. *convertens* converting; *isoflavoniconvertens* isoflavone-converting) (Matthies et al. 2009), (e) *Slackia piriformis* (pi.ri.for'mis. L. n. *pirum* pear; L. adj.

Table 11.11

Abbreviations: *BHI* brain-heart infusion, *DMA* dimethyl acetal, *i* iso, *ND* not determined, *w* weak
[a]*w* weak, cells grew on medium containing 2 % oxgall, but the number of colonies was decreased compared with control medium without oxgall (5 % and 50 % cfu for *Slackia faecicanis* and *Slackia piriformis*, respectively)
[b]General anaerobic medium, Nissui Pharmaceutical, Tokyo, Japan

suffix-*formis*-like, in the shape of; N.L. fem. adj. *piriformis* pear-shaped, referring to the cell shape) (Nagai et al. 2010), and (f) the type species *Slackia exigua* (ex.i.gu'a. L. adj. *exigua* scanty, small, referring to the scanty or poor growth of this organism). Cells are cocci, coccobacilli, or short bacilli, the growth of which is stimulated by 0.5 % arginine. Sugars are not fermented. Positive for naphthol-AS-BI-phosphohydrolase but negative for alkaline phosphatase, *a*-arabinosidase, *N*-acetyl-*b*-glucosaminidase, chymotrypsin, *a*-fucosidase, *a*-galactosidase, *b*-galactosidase, *a*-glucosidase, *b*-glucosidase, *b*-glucuronidase, glutamic acid decarboxylase, glutamyl glutamic acid arylamidase, lipase (C14), *a*-mannosidase, 6-phospho-*b*-galactosidase, pyroglutamic acid arylamidase, trypsin, urease, and esculin hydrolysis. The main cellular fatty acids are $C_{18:1}$w9c and $C_{18:1}$w9c DMA. Respiratory quinones have not been detected in *Slackia piriformis*, *Slackia exigua*, *Slackia heliotrinireducens*, and *Slackia faecicanis* (*Slackia equolifaciens* and *Slackia isoflavoniconvertens* have not been analyzed). *Slackia heliotrinireducens* was isolated for its ability to reductively cleave hepatotoxic pyrrolizidines found in forages. It also contains a *c*-type cytochrome. This species was originally published as *Peptococcus heliotrinreducans* (Lanigan 1976), before its transfer to the genus *Peptostreptococcus* as *Peptostreptococcus heliotrinreducens* in 1986 on the basis of its high G+C content of DNA and the presence of various aminopeptidases (Ezaki and Yabuuchi 1986). Discriminative features of *Slackia* spp. are shown in *Table 11.11*.

Isolation, Enrichment, and Maintenance Procedures

It is striking that all members of the *Coriobacteriaceae* have been so far isolated only from body habitats of mammals and insects, which hints at evolutionary driving forces that made these bacteria best suited for efficient colonization and survival in such environments. The first cultivable representatives of the family, i.e., *Collinsella aerofaciens* and *Eggerthella lenta*, were recovered from human feces (Eggerth 1935). All strains of so far described species have been isolated by chance using either nonselective rich media or selective media and isolation procedures targeting specific metabolic functions or bacterial populations, e.g., conversion of isoflavones (*Asaccharobacter celatus*, *Slackia equolifaciens*, *Slackia isoflavoniconvertens*), mucosa-associated bacteria

(*Gordonibacter pamelaeae*, *Enterorhabdus mucosicola*, *Olsenella umbonata*), reduction of nitro-compounds (*Denitrobacterium detoxificans*), or ammonia production (*Olsenella umbonata*, *Slackia heliotrinireducens*). For this reason, and due as well to the metabolic versatility of the 30 species of the family, there is to date no selective medium available for exhaustive enrichment of *Coriobacteriaceae*. The efficacy of blood, arginine, or Tween 80 to stimulate growth as well as the resistance towards bile and antibiotics has hitherto not been tested for all species. Moreover, while strictly anoxic culture techniques are suited for cultivation of most species, *Olsenella* spp. grow under microaerophilic conditions and *Atopobium vaginae* is a facultative anaerobe. The isolation and maintenance conditions reported for the 30 species of the family are summarized in Table 11.12.

Ecology

The family *Coriobacteriaceae* includes a large majority of strictly anaerobic strains with fastidious growth requirements. They frequently coexist with a number of other microorganisms in complex ecosystems. As a result, the ecology of this family (as in the sense of the occurrence and functions of its members) was poorly studied until the emergence (and affordability) of culture-independent techniques such as polymerase chain reaction (PCR), sequencing of 16S rRNA genes as well as metabolomics and system biology approaches (Woo et al. 2008; Claus et al. 2011). It is now becoming clear that these previously understudied bacterial species carry out important physiological functions within their hosts.

Habitat and Occurrence

At the time of writing, the family accommodates 14 genera, 13 of which originate from the gastrointestinal tract of mammals (human, mouse, rat, dog, cow, and sheep). *Coriobacterium glomerans*, the type species of the family, has been so far retrieved only from the gut of insects (Haas and König 1988; Kaltenpoth et al. 2009). The diversity and composition of the human intestinal microbiota varies greatly between individuals (Qin et al. 2010). Nevertheless, *Coriobacteriaceae* can be considered as prevalent and dominant dwellers of the human intestine (and by extension of the mammalian intestine in general). Dominant means that certain species can be found at cell densities above 10^8 cells per gram intestinal content. Still, actinobacteria, and thus *Coriobacteriaceae*, represent usually a minor fraction of gut bacterial diversity (<2–5 % of total 16S rRNA gene sequences) when compared with members of the phyla Bacteroidetes and Firmicutes.

Culture-independent studies have demonstrated that the genus *Collinsella* is the most abundant human gut taxon of the family (Kageyama et al. 2000). The species *Collinsella aerofaciens* seems to be a member of the core human gut microbiome, i.e., "a set of bacterial molecular species that are altogether dominant and prevalent within the fecal microbiota of healthy humans" (Tap et al. 2009; Qin et al. 2010). Based on the use of specific 16S rRNA-targeted oligonucleotide probes for fluorescence in situ hybridization, Harmsen et al. found that the *Collinsella* and *Atopobium* phylogenetic groups were part of the dominant microbiota in 26 of 33 adult subjects, with cell counts $>10^9$ cell/g dry feces (Harmsen et al. 2000). In another similar study, mean proportions of the *Atopobium* group were >3 % of dominant bacteria in 39 postmenopausal women (Clavel et al. 2005). Thus, *Atopobium* spp. also seem to be predominant in human feces. However, it is important to note that the specificity of 16S probes warrants detection of relatively broad phylogenetic groups rather than specific species (e.g., the *Atopobium* probe S-*-Ato-0291-a-A-17 targets also other *Coriobacteriaceae*). In one study based on the use of quantitative PCR, *Slackia* spp. were detected in 16 of 40 fecal samples from healthy Japanese adults at a mean population density of $\log_{10}$ 6.4 ± 2.4 cell/g wet weight (Tsuji et al. 2010). PCR-based assays have been used as well to assess the occurrence of *Eggerthella lenta* in human feces, revealing that this species is detected in 30–40 % of tested samples (Schwiertz et al. 2000; Kageyama and Benno 2001). In fact, part of the aforementioned molecular data confirmed the pioneering culture-based work by W. E. C. Moore, S. M. Finegold, and L. V. Holdeman, who readily isolated a number of strains of [*Eubacterium*] *aerofaciens* and [*Eubacterium lentum*] from feces of healthy human adults. These isolates were usually recovered from 50 % of analyzed subjects at mean densities of $>10^9$ cfu/g dry weight (Moore and Holdeman 1974; Finegold et al. 1983). Some *Coriobacteriaceae* have also been detected in sewage samples using massively parallel pyrosequencing of hypervariable regions in microbial rRNA genes (McLellan et al. 2010). The genus *Collinsella* was detected at 0.27 % and 1.07 % total sequences in sewage and human fecal samples, respectively, but not in surface water. The presence of fecal microbial taxa in sewage water appears to be the consequence of human fecal pollution of the wastewater treatment plants rather than such environmental samples being the natural habitat of *Coriobacteriaceae*.

Regarding more recently described taxa within the family, *Enterorhabdus* spp. have been repeatedly found in high-throughput 16S rRNA gene sequence datasets from the mouse, human, and bovine intestinal tract (Benson et al. 2010; Werner et al. 2011; Hristov et al. 2012; Martinez et al. 2012). This speaks in favor of a widespread occurrence in various gut ecosystems, yet most likely at lower population densities. With respect to specific niches occupied by *Coriobacteriaceae* in the gut, it is worth noting that some members may be well suited for colonization of mucosal surfaces, as suggested by (a) the isolation of strains from mucosal samples or using selective culture media containing mucin (*Enterorhabdus mucosicola*, *Gordonibacter pamelaeae*, *Olsenella umbonata*), (b) the symbiotic relationship they may have with their hosts (*Coriobacterium glomerans*), and (c) their detection in mucosal samples using molecular-based techniques (*Atopobium* and *Collinsella* spp.) (Collado and Sanz 2007a, b; Nadal et al. 2007; Lyra et al. 2012).

[g]Details on gas phase were not provided

[f]Per L, 37 g brain-heart infusion, 5 g yeast extract, 5 mL 6 % (w/v) ammonium formate solution, 0.5 g cysteine-HCl, 5 mg hemin, 2.5 mg resazurin, 1 mg vitamin K_1, 4 % rabbit blood, pH 7.0

[h]Per L, 5 g NaCl, 15 g agar, 20 g tryptose, 2.5 g tryptone, 1 g yeast extract, 1 g of glucose, pH 7.4–7.6

[i]1.5 % agar, 1 % Parke Davis peptone, 0.4 % Na_2HPO_4. $12H_20$, 5 % blood, 0.15 % glucose, pH 7.6

[j]Per L: 3 g beef extract, 5 g yeast extract, 10 g peptone, 1.5 g glucose, 0.5 g L-cysteine. HCl, 0.2 g L-cystine, 4 g Na_2HPO_4, 0.5 g soluble starch, 0.5 g Tween 80, 0.5 g silicone, 15 g agar, 5 % horse blood, pH 7.7

[k]The National Animal Disease Center in Ames (IA, USA)

[l]Contained Na_2CO_3, resazurin, L-cysteine-HCl, and vitamins at concentrations that were the same as in the complete medium of Bryant and Robinson (Bryant and Robinson 1961). Also contained (in 1 L) 800 mg phytone peptone, 5 μg lipoic acid, 2 μg vitamin B_{12}, 40 % (v/v) clarified rumen fluid, and the same minerals as in the non-rumen fluid medium of Dawson et al. (Dawson et al. 1980). Supplemented for enrichment with milk vetch or alfafa forage + 4.2 mM nitropropanol

[m]Same as medium A with 8 and 0 % rumen fluid, respectively

[n]Treated with azathioprine, mutaflor and cortisone

[o]Per L, 5 g mucin (Sigma M1778), 0.5 % (v/v) ethanol, 500 mg L-cysteine, 1 mg yeast extract, 20 mg folic acid, 20 mg vitamin B_{12}, 50 mmol $NaHCO_3$, 10 mmol sodium acetate, 5 mmol Na_2HPO_4, 5 mmol NaCl, 3 mmol KH_2PO_4, 1 mmol $CaCl_2$, 1 mmol $MgCl_2$, 10 mmol $FeCl_3$, 1 % (w/v) agar, pH 7.7

[p]Suffered from alcoholic cirrhosis, portal hypertension, and epilepsy and diagnosed with perianal abscess

[q]Per L, 10.0 g mucin, 0.01 g peptone, 0.01 g yeast extract, 0.01 g glucose, 0.3 g NaCl, 0.1 g $CaCl_2$, 6.0 g KH_2PO_4, 5 mL Rogosa's salt solution, 1 mL modified (lacking elements already included in Rogosa's salt solution) Pfennig's SL8 trace element solution, 0.2 mL vitamin solution, 0.5 mg resazurin, 4–7.5 g agar, pH 5 (Kraatz and Taras 2008)

[r]Holdeman et al. (1977)

A number of species of the family have also been isolated from mammalian body habitats other than the gut. However, their prevalence in these other environments has not been investigated, apart from *Atopobium* spp. in the mouth and vagina (Zhou et al. 2004; Ravel et al. 2011; Belda-Ferre et al. 2012; Liu et al. 2012; Santiago et al. 2012). The other body origins of *Coriobacteriaceae* include:

(a) The blood: *Atopobium rimae* (Angelakis et al. 2009), *Eggerthella sinensis* and *Paraeggerthella hongkongensis* (Lau et al. 2004b), and *Gordonibacter pamelaeae* (Woo et al. 2010).
(b) The perineum region and vagina: *Atopobium minutum* (Hauduroy et al. 1937; Collins and Wallbanks 1992) and *Atopobium vaginae* (Rodriguez Jovita et al. 1999). The latter species is usually found in biofilms adherent to the vaginal mucosa rather than in the vaginal fluid (Verhelst et al. 2004; Swidsinski et al. 2005; Polatti 2012).
(c) The oral cavity and respiratory tract: *Atopobium fossor* (Bailey and Love 1986; Kageyama et al. 1999b), *Atopobium parvulum* and *Atopobium rimae* (Weinberg et al. 1937; Olsen et al. 1991; Collins and Wallbanks 1992), *Cryptobacterium curtum* (Nakazawa et al. 1999), *Olsenella profusa* and *Olsenella uli* (Dewhirst et al. 2001), and *Slackia exigua* (Poco et al. 1996; Wade et al. 1999). Using 16S rRNA gene sequencing, Dewhirst et al. identified *Olsenella uli* and *Olsenella profusa* from subgingival plaques in patients with severe periodontal disease, suggesting that, similarly to other *Coriobacteriaceae* in the gut and vaginal mucosa, *Olsenella uli* and *Olsenella profusa* favor an adherent mode of growth. However, in sheep rumen, *Olsenella umbonata* was isolated from ruminal fluid, indicating variability in the mode of growth of this genus (Kraatz et al. 2011).

Metabolic Activities

Conversion of Cholesterol-Derived Host Metabolites

The potential of *Coriobacteriaceae* to modulate host metabolism in vivo has been recently brought to light by reports of significant correlations between their occurrence and altered metabolic parameters, including (a) higher intestinal cholesterol absorption and higher levels of plasma non-high-density lipoprotein (non-HDL) cholesterol in hamsters (Martinez et al. 2009, 2012) and (b) energy metabolism via decreased glycogenesis and enhanced triglycerides synthesis as well as hepatic detoxification pathways (higher 2*b*- and 6*b*-hydroxylase activity) in mice (Claus et al. 2011). Moreover, a recent metagenomic analysis of fecal samples from approximately 350 human subjects indicated that the prevalence of *Eggerthella lenta* is linked to type-2 diabetes (Qin et al. 2012). However, these data are descriptive and there is yet no direct proof of molecular mechanisms underlying the impact of *Coriobacteriaceae* on host metabolism. In other words, research on bacteria/host interactions with respect to *Coriobacteriaceae* is in its infancy.

The best studied metabolic functions of *Coriobacteriaceae* are the dehydrogenation and dehydroxylation of cholesterol-derived host factors (Ridlon et al. 2006). The type and various strains of *Eggerthella lenta* and *Collinsella aerofaciens* possess hydroxysteroid dehydrogenases (HSDH), which are responsible for stereospecific oxidation and epimerization (change from *a* to *b* configuration or vice versa) of bile acids, thereby generating stable oxo-bile acid intermediates. Hitherto detected dehydrogenases include both 3*a*- and 12*a*-HSDH in *Eggerthella lenta* and 7*b*-HSDH in *Collinsella aerofaciens* (Eyssen and Verhulst 1984; Ridlon et al. 2006). This hints at metabolic chains between *Coriobacteriaceae* and other bacteria, since the combined activity of two position-specific, stereochemically distinct HSDH (e.g., 3*a* and 3*b*) is required for epimerization of bile salts (Ridlon et al. 2006).

Although early work reported that *Eubacterium* spp., especially strain VPI 12708, were also capable of dehydroxylating free primary bile acids (cholic and chenodeoxycholic acid) into secondary bile acids (deoxycholic and lithocholic acid) (White et al. 1988; Takamine and Imamura 1995), deeper taxonomic assignment revealed that these bacteria actually belong to the genus *Clostridium* (Kitahara et al. 2000). There is to date no report on bile acid dehydroxylase activity in *Eggerthella lenta* or other *Coriobacteriaceae*. One paper referred to 7*a*-dehydroxylation by one isolate related to [*Eubacterium lentum*] without standing in nomenclature (Hirano and Masuda 1982). Bacterial dehydroxylation renders bile acids more hydrophobic, thereby favoring passive reabsorption in the proximal colon (enterohepatic circulation). However, secondary bile salts may also contribute to the pathogenesis of cholesterol gallstones and colon cancer (Ridlon et al. 2006). Altered bile acid metabolism has also been associated with chronic intestinal inflammation (Gnewuch et al. 2009; Devkota et al. 2012; Duboc et al. 2012).

Transformation of bile salts by HSDH and dehydroxylases is believed to serve as an energy source for the bacteria and reduce the levels of bile acids with antimicrobial activities (Ridlon et al. 2006). Several *Coriobacteriaceae* are reported to be bile resistant, e.g., *Asaccharobacter celatus*, *Eggerthella lenta*, *Olsenella umbonata*, and *Slackia piriformis*. Additionally, the favorable generation of oxo-bile acids by *a*-HSDH at higher redox potentials such as those encountered at mucosal surfaces may be one additional reason for the colonization of these areas by some *Coriobacteriaceae* (Ridlon et al. 2006). Finally, *Eggerthella lenta* is also able to dehydroxylate corticoids such as deoxycorticosterone to form progesterone via 21-dehydroxylase activity (Bokkenheuser et al. 1977). This species also carries a corticoid-converting 16*a*-dehydroxylase (Bokkenheuser et al. 1980) and a 3*a*-HSDH (Bokkenheuser et al. 1979). Strikingly, despite the apparent implication for the host of this bacterial rearrangement of hormonal networks in the gut, related functional studies in experimental animal models have not yet been performed.

Polyphenol Metabolism

One of the most peculiar enzymatic properties of *Coriobacteriaceae* is the conversion of food polyphenols, especially the activation of the isoflavone daidzein to the bioactive metabolite equol (Clavel and Mapesa 2013). Isoflavones are dietary phytoestrogens that are abundant in soybean and soy-derived products. They share structural similarities with steroid hormones such as 17-*b*-estradiol and thus have low binding affinity to estrogen receptors (Kuiper et al. 1998; Kostelac et al. 2003). Equol is known to be the most potent isoflavone metabolite, e.g., it has stronger affinity to estrogen receptors than its substrate (Clavel and Mapesa 2013). The biological properties of equol have been given attention since the 1930s when reproductive failures started to affect sheep grazing on clover containing high amounts of isoflavones and later in the 1980s in captive cheetahs fed a soy-based diet (Setchell et al. 1987; Messina 2010). Since then, equol has been associated with protective effects against cardiovascular diseases, bone disorders, prostate and breast cancer, and other hormone-related conditions, even though gold-standard randomized control trials are urgently needed to substantiate results (Clavel and Mapesa 2013). In humans, only 30–50 % of individuals are able to produce equol from daidzein, possibly due to the absence of specific equol-producing bacteria in the rest of the population (Xu et al. 1995; Rowland et al. 2000).

Evidence of intestinal microbial equol production dates back from the early 1980s (Axelson and Setchell 1981). However, it was only in 2005 that the first equol-producing isolate, strain Julong 732, was cultured from human feces (Wang et al. 2005). To date, only ten bacterial strains capable of producing equol from daidzein have been isolated from intestinal samples of pigs, rodents, and humans. Nearly all of them ($n = 9$) fall into the family *Coriobacteriaceae* based on 16S rRNA gene sequence analysis. These strains include five type strains, which have been fully described and assigned valid names (human isolates are marked with stars in the following list): (1) *Adlercreutzia equolifaciens** FJC-B9^T (=DSM 19450^T) (GenBank accession AB306661) (Maruo et al. 2008), (2) *Asaccharobacter celatus* do03^T (=DSM 18785^T) (AB266102) (Minamida et al. 2006, 2008), (3) *Enterorhabdus mucosicola* Mt1B8^T (=DSM 19490^T) (AM747811) (Matthies et al. 2008; Clavel et al. 2009), (4) strain Julong 732* (AY310748) (Wang et al. 2005), (5) '*Eggerthella*' sp. YY7918* (AB379693) (Yokoyama and Suzuki 2008), (6) *Slackia equolifaciens** DZE^T (=CCUG 58231^T) (EU377663) (Jin et al. 2010), (7) *Slackia isoflavoniconvertens** HE8^T (=DSM 22006^T) (EU826403) (Matthies et al. 2009), (8) '*Slackia*' sp. NATTS* (AB505075) (Tsuji et al. 2010), and (9) strain D1 (DQ904563) (Yu et al. 2008). Of note, *Adlercreutzia equolifaciens*, *Asaccharobacter celatus*, and strain Julong 732 share >99 % similarity based on 16S rRNA-based phylogeny (Maruo et al. 2008). One additional equol-producing isolate, strain D2, seems not to belong to the *Coriobacteriaceae* based on 16S rRNA gene sequencing (DQ904564) (Yu et al. 2008). Interestingly, the production of equol from daidzein by '*Slackia*' sp. NATTS was found to be two to fourfold higher after addition of 1 g/L autoclaved adonitol, arabinose, galactose, lactitol, inositol, melezitose, ribose, sorbitol, sorbose, trehalose, or xylose to the culture medium(Tsuji et al. 2010). Conversely, the addition of fructooligosaccharides, galactooligosaccharides, inulin, lactose, raffinose, or sucrose inhibited equol production. This may fit with the observation that resistant polysaccharides do not enhance equol production in vivo (Larkin et al. 2007; Mathey et al. 2007).

In addition to isoflavones, dietary lignans are phytoestrogens that can also be activated by *Coriobacteriaceae*. Conversion of plant lignans (pinoresinol, lariciresinol, secoisolariciresinol, matairesinol, and corresponding glycosides) by gut bacteria involves two to five different reactions (deglycosylation, reduction, demethylation, dehydroxylation, and dehydrogenation) to form the enterolignans enterodiol and enterolactone (Clavel et al. 2006). Enterolignans were actually thought to be new steroid hormones after their first detection in urine samples from female primates and human adults (Setchell et al. 1980; Stitch et al. 1980). Their bacterial origin was highlighted shortly thereafter (Setchell et al. 1981; Borriello et al. 1985). Several strains of *Eggerthella lenta* were found to reduce and dehydroxylate plant lignans and intermediate metabolites thereof (Clavel 2006). Thus, beyond the metabolism of host-derived bile acids and steroid hormones, the species *Eggerthella lenta* is also involved in metabolic chains leading to the production of bioactive molecules from plant substrates in the gut. Recently, this species was also found to reductively cleave the heterocyclic C-ring of the flavanols epicatechin and catechin (Kutschera et al. 2011). Most importantly, the successful isolation and cultivation of phytoestrogen-converting strains open ways to assess the effects of bacterial metabolites on host health in detail using, for instance, gnotobiotic approaches (i.e., colonization of germfree animals with specific strains of interest) (Woting et al. 2010; Becker et al. 2011; Mabrok et al. 2012).

Pathogenicity, Clinical Relevance

As seen above, members of the *Coriobacteriaceae* carry out functions of importance for their hosts. However, several members of the genera *Atopobium*, *Eggerthella*, *Gordonibacter*, *Olsenella*, and *Paraeggerthella* have been also implicated in the development of various clinical pathologies including abscesses, intestinal diseases and tumors, periodontitis, vaginosis, and bacteremia. *Coriobacteriaceae* can thus be considered as pathobionts, i.e., potentially pathogenic commensal species of host body microbiota (Chow et al. 2011). However, one can say that nearly all published studies on *Coriobacteriaceae* refer to descriptive work, for instance, the enumeration of bacteria in diseased versus healthy tissues/subjects or the isolation of bacteria from clinical specimens. Hence, fundamental knowledge on how and when *Coriobacteriaceae* start to be detrimental to their hosts is lacking. The antimicrobial susceptibility profile of some family members has been well defined in various studies and is summarized in *Table 11.13*.

Table 11.13
Antimicrobial susceptibility profiles of *Coriobacteriaceae*

Bacteremia

Five of the 14 genera of the family include species which have been already isolated from blood samples of human patients: *Atopobium*, *Eggerthella*, *Gordonibacter*, *Olsenella*, and *Paraeggerthella*. There seems to be a consensus about the reservoir of infection as being the natural habitats of *Coriobacteriaceae*, i.e., the mouth and the gastrointestinal or genital tract, or acutely infected organs (Lau et al. 2004a; Salimnia et al. 2008; Angelakis et al. 2009; Woo et al. 2010; Thota et al. 2011).

The best documented cases of *Coriobacteriaceae*-driven bacteremia relate to *Eggerthella* spp. and closely related species. In Hong Kong, between 1998 and 2001, *Eggerthella lenta* was associated with five of 16 clinically relevant cases of bacteremia, whereas five additional cases were associated with the presence of its relatives *Eggerthella sinensis* and *Paraeggerthella hongkongensis* (Lau et al. 2004a, b). Lee et al. very recently published 10 additional cases of bacteremia due to *Eggerthella lenta* and *Paraeggerthella hongkongensis* in Taiwanese subjects hospitalized between 2001 and 2010 (Lee et al. 2012). Landais et al. also reported two cases of bacteremia in France that were associated with the presence of *Eggerthella lenta* based on 16S rRNA gene sequencing of isolates (the authors erroneously cited the genus name as '*Eggerthela*') (Landais et al. 2007). In this study, patient 1 was admitted to the hospital with fecal peritonitis related to intestinal perforation, whereas patient 2 had acute appendicitis. They received imipenem (1.5 g/day for 3 weeks) and amoxicillin/clavulanic acid (3 g/day), respectively, with favorable outcomes. Two additional clinically relevant strains of *Eggerthella lenta* have been reported, including one strain identified on the basis of the VITEK system after isolation from the blood of a 21-year-old African-American woman diagnosed with Crohn's disease who developed bacteremia after ileocaecal resection (Chan and Mercer 2008; Thota et al. 2011). This case of *Eggerthella lenta* bacteremia was successfully treated with a combination of meropenem, metronidazole, and vancomycin. Finally, one case of polymicrobial bloodstream infection with *Eggerthella lenta* and *Desulfovibrio desulfuricans* was reported in Sweden in one 86-year-old woman who was successfully treated with cefuroxime and amoxicillin (Liderot et al. 2010). Of note, a rather broad range of diseases may underlie translocation of *Eggerthella* spp. from the gut to the blood stream, since patients positive for these species in blood cultures were hospitalized for a variety of reasons (pelvic inflammatory disease, infected bed sore, perianal abscess, infected rectal tumor, liver abscess, acute appendicitis, and proctitis) and suffered from a variety of chronic diseases (lung, cervical and colon cancer, alcoholic cirrhosis, diabetes, cardiovascular disorders, recurrent pyogenic cholangitis) (Lau et al. 2004a; Landais et al. 2007). Finally, *Eggerthella lenta* was also isolated from (a) the pus of a hepatic abscess from a 42-year-old patient who was treated favorably with a course of metronidazole (1.5 g/day) (Landais et al. 2007) and (b) bone biopsy samples of the spine in one 82-year-old Chinese women with spondylodiscitis who was treated with trimethoprim/sulfamethoxazole and metronidazole (Bok and Ng 2009).

The genus *Atopobium* also gained attention following the isolation of strains from clinical samples (Olsen et al. 1991; Kumar et al. 2005). *Atopobium rimae*, together with *Streptococcus gordonii*, was recently associated with a case of septic shock in a 77-year-old woman in France, from whom two isolates were recovered from blood cultures on two separate occasions during hospitalization for pneumonia (Angelakis et al. 2009). Treatment of the patient with intravenous amoxicillin-clavulanate (2 g/200 mg) led to full recovery within 7 days. Beforehand, *Atopobium rimae* had been already identified in blood samples from a 47-year-old man with liver cirrhosis, who was treated with success using metronidazole and imipenem (Chung et al. 2007). Another *Atopobium* species phylogenetically closely related to *Atopobium rimae* (98 % 16S rRNA gene sequence identity) has also been associated with bacteremia (Salimnia et al. 2008). This species, provisionally named "*Atopobium detroiti*", was isolated from the blood of a 38-year-old paraplegic male patient hospitalized for presumed sepsis and characterized by a necrotic decubitus ulcer of the hip and poor oral hygiene after physical examination. Finally, the species *Atopobium vaginae* has also been identified in the context of intrauterine infection leading to fetal death and maternal bacteremia in a 40-year-old woman undergoing transcervical chorionic villus sampling (Knoester et al. 2011). Unlike *Eggerthella lenta*, *Atopobium vaginae* has been associated with metronidazole resistance (Ferris et al. 2004; De Backer et al. 2006; Knoester et al. 2011), and successful treatment of *Atopobium vaginae* bacteremia usually involves a course of *b*-lactam antibiotics alone or in combination with *b*-lactamase inhibitors or clindamycin (Knoester et al. 2011; Chan et al. 2012).

Less frequently reported cases of *Coriobacteriaceae*-driven bacteremia relate to bacteria other than *Eggerthella* and *Atopobium*. One isolate identified as *Gordonibacter pamelaeae* based on 16S rRNA gene sequencing and phenotypic description was recently recovered from the blood of an 82-year-old Chinese man diagnosed to have rectosigmoid carcinoma with lung metastasis (Woo et al. 2010). In contrast to the type strain of the species, this isolate was found to be nonmotile and positive for arginine arylamidase. The patient was successfully treated with a course of intravenous amoxicillin-clavulanate for 9 days. Finally, one case of bacteremia associated with a strain of *Olsenella uli* obtained from the blood of one 43-year-old male subject suffering from acute cholangitis has been reported (Lau et al. 2004a).

In summary, when compared with bacteremia due to usual suspects such as *Bacteroides fragilis*, enterobacteria, enterococci, or staphylococci, cases of *Coriobacteriaceae*-driven bacteremia seem to be relatively rare, but are very often clinically relevant. More research effort is needed to identify environmental factors and molecular mechanisms that favor initial colonization and survival of *Coriobacteriaceae* in the blood. Of note, only three genera within the family are positive for catalase activity: *Eggerthella*, *Gordonibacter*, and *Paraeggerthella*. All three have been associated with cases of bacteremia. The presence of catalase may help these organisms coping with oxidative stress during infection.

Gastrointestinal Pathologies

Although there are an increasing number of studies investigating the gut microbiota in colorectal cancer (CRC), the exact contribution of bacteria to molecular mechanisms underlying disease remains unclear. Intestinal bacteria are proposed to play a role in CRC via two main mechanisms: (1) the production of metabolites such as hydrogen sulfide or ammonia, which can have detrimental effects on host cell functions (Blaut and Clavel 2007), and (2) the alteration of innate immune mechanisms (Rakoff-Nahoum and Medzhitov 2007).

The role of a variety of bacteria such as enterotoxigenic *Bacteroides fragilis*, *Enterococcus faecalis*, *Fusobacterium* spp., *Prevotella* spp., and *Streptococcus bovis* in CRC has already been discussed (Wu et al. 2009; Al-Jashamy et al. 2010; Sobhani et al. 2011; Kostic et al. 2012). *Coriobacteriaceae* have gained attention in this field very recently. The occurrence of *Collinsella*, *Eggerthella*, *Olsenella*, and *Slackia* spp. was significantly higher on tumor site versus adjacent nonmalignant tissue in six Dutch patients who underwent resection for primary colon adenocarcinoma (Marchesi et al. 2011). Other recent studies on bacterial diversity in CRC patients found an increased prevalence of 16S rRNA gene sequences classified as *Actinobacteria*, including *Collinsella* spp., in feces from CRC versus healthy control subjects (Chen et al. 2012; Wang et al. 2012). In the study by Chen et al., the prevalence of sequences assigned to the *Coriobacteriaceae* was 1.19 % in CRC patients versus 0.74 % in healthy individuals. Still, these data refer only to the density of bacterial populations, and there is no indication that *Coriobacteriaceae* have overall positive or negative effects on tumorigenesis. *Coriobacteriaceae* have recently been referred to as "passenger" bacteria in CRC, in contrast to "driver" bacteria such as *Bacteroides fragilis* which seem to be involved in the initiation of disease (Tjalsma et al. 2012). Passenger bacteria are proposed to be best suited for colonization of disturbed microenvironments in the vicinity of tumors. In that context, the effect of local production of equol by *Slackia* spp. that colonize tumor sites in the gut may be worth investigating considering the biological properties of this bacterial product (Magee et al. 2006; Choi 2009). The effects of ammonia production by, for instance, *Olsenella* spp. or *Eggerthella lenta* may be worth investigating too (Eschenlauer et al. 2002; Kraatz et al. 2011).

Apart from cancer, the role of *Coriobacteriaceae* in other pathologies associated with gastrointestinal dysfunctions is ill defined. Isolates of *Eggerthella lenta* identified on the basis of fermentation and biochemical reactions were recovered in 44 % of 41 appendix tissue samples from children with suspected acute appendicitis (Rautio et al. 2000). Moreover, although clinical case reports and targeted isolation procedures hint at the relevance of *Coriobacteriaceae* in inflammatory bowel diseases, there is to date no corresponding quantitative or functional data available (Clavel et al. 2009, 2013; Würdemann et al. 2009; Joossens et al. 2011; Thota et al. 2011). Finally, there is an increasing body of evidence pointing at the involvement of gut bacteria in host energy balance and metabolic disorders (Backhed et al. 2004; Qin et al. 2012). *Coriobacteriaceae* have been detected in the feces of 14 overweight and obese human volunteers with no history of gastrointestinal disease (Walker et al. 2011). As previously reported in healthy individuals (Harmsen et al. 2000; Kageyama et al. 2000; Tap et al. 2009), *Collinsella aerofaciens* was amongst the most abundant taxonomic units (3.7 % of 16S rRNA clones) after *Faecalibacterium prausnitzii* (8.0 %), *Eubacterium rectale* (4.4 %), and *Clostridium clostridioforme* (3.8 %) in the fecal sample from six of the 14 volunteers. The proportion of *Collinsella aerofaciens* was significantly reduced to 0.6 % after consumption of a protein-rich, fat, and carbohydrate-reduced weight-loss diet. In another study, the number of 16S rRNA gene sequences assigned to *Coriobacteriaceae* in the feces of three obese subjects was found to be higher than in lean controls and in subjects after gastric bypass-induced weight loss (Zhang et al. 2009). Based on these descriptive findings on the dominance of *Coriobacteriaceae* in the gut and considering their metabolic potential with regard to hepatic functions and lipid homeostasis (see metabolic activities), their role in the regulation of host metabolic disorders is worth investigating in more details.

Allergy

Commensal gut microbial communities are known to influence host immune responses beyond the gut. For instance, they have been implicated in the regulation of molecular mechanisms underlying allergies (Hormannsperger et al. 2012). A molecular study comparing the fecal microbiota in <12-month-old infants with cow's milk protein allergy versus nonallergic infants ($n = 46$ each) found higher median counts of the *Atopobium* group in allergic infants (0.6 vs. 0.0 % of total bacteria) (Thompson-Chagoyan et al. 2011). Of note, in a former study, the *Atopobium* and *Collinsella* group represented a substantial proportion of the gut microbiota in the feces of formula-fed infants when compared with breast-fed infants (>17 vs. 0.5 % of total bacteria; $n = 6$ each) (Harmsen et al. 2000). Breast-feeding is proposed to have protective effects on the development of atopic disorders, although more data are needed to reach consensus in results (Mimouni Bloch et al. 2002; Batchelor et al. 2010; Brew et al. 2011).

Dental Caries and Abscess

In the human oral cavity, *Coriobacteriaceae*, including *Atopobium parvulum*, *Atopobium rimae*, and *Olsenella profusa*, have been detected during the final phase of caries extension in dental pulp with established and advanced infection (Nadkarni et al. 2010). The spatial distribution of these bacteria suggested an intricate association with members of the *Bacteroidetes* in tightly concentrated biomass, even though underlying reasons were unclear. Identification of bacterial pathogens by 16S rRNA gene-targeted PCR in the oral cavity of 21 patients suffering from primary or persistent endodontic infections revealed that some *Coriobacteriaceae* were amongst the most prevalent phylotypes: *Olsenella uli*,

Olsenella profusa, and *Atopobium parvulum* were identified in 33, 9.5, and 5 % of cases of infection, respectively (Siqueira and Rocas 2005). *Olsenella uli* was also identified in persistent endodontic infections in this study. This species was also found to be one of the most prevalent species in root canals from 139 teeth with apical periodontitis (Dewhirst et al. 2001; Chavez de Paz et al. 2004). A number of additional papers reported the detection of *Coriobacteriaceae*, especially *Atopobium* and *Olsenella* spp., in oral clinical samples (Kumar et al. 2003, 2005; Aas et al. 2008; Preza et al. 2008; Subramanian and Mickel 2009; Lima et al. 2011). In one additional study, high-throughput sequencing of 16S rRNA genes allowed the identification of *Coriobacteriaceae* in the oral cavity, infected root canal, and periapical abscess of eight patients (Hsiao et al. 2012). The genus *Atopobium* was mostly found in root canal samples, whereas the genus *Collinsella* was significantly overrepresented in abscess samples. Other *Coriobacteriaceae*, including *Olsenella*, *Slackia*, *Cryptobacterium*, and *Eggerthella* were seldom identified in oral cavity samples.

Bacterial Vaginosis

Bacterial vaginosis is a frequently reported polymicrobial infection in which the commensal microbiota usually dominated by lactobacilli is replaced by obligate anaerobes (Danielsson et al. 2011). The type strain of *Atopobium vaginae* was isolated from the vagina of a healthy woman (Rodriguez Jovita et al. 1999). The pathogenic potential of this species was highlighted in 2003 by a case of tubo-ovarian abscess following transvaginal oocyte recovery (Geissdorfer et al. 2003). Clinical isolates have also been recovered in the context of uterine endometritis (Yamagishi et al. 2011) and intrauterine infection (Knoester et al. 2011). Thanks to molecular techniques, this bacterium has been frequently detected in vaginal infections and is thought to be involved in 55–95 % of cases and responsible for therapeutic failures (Ferris et al. 2004; Verhelst et al. 2004; Polatti 2012). A recent evaluation of the microbiota in vaginal swabs from 220 women using pyrosequencing of 16S rRNA gene amplicons showed that women with vaginosis are characterized by diverse heterogeneous communities with a high prevalence of *Atopobium vaginae* and *Eggerthella* species (Srinivasan et al. 2012).

Atopobium vaginae is commonly identified alongside *Gardnerella vaginalis* in clinical samples, and their association appears to provide a reliable diagnosis (Lamont et al. 2011; Srinivasan et al. 2012). Fluorescence in situ hybridization analysis of vaginal biopsies provided further evidence of the strong co-occurrence of these species, which accounts for more than 90 % of the biofilm mass on vaginal epithelial surfaces (Swidsinski et al. 2005). The biofilm-forming properties of *Atopobium vaginae* and *Gardnerella vaginalis* contribute to the recalcitrance of infection by conferring a protective environment against both antibacterial therapies and immune responses. A 5-day treatment of polymicrobial *Gardnerella*, *Atopobium*, and *Lactobacillus* spp. biofilm using 400 mg/day moxifloxacin in women with bacterial vaginosis showed a significant decrease in *Atopobium* and *Gardnerella* coupled to an increase in lactobacilli in biofilms (Swidsinski et al. 2011). However, despite short-term clinical efficacy, moxifloxacin (similarly to metronidazole and clindamycin) fails to prevent the recurrence of vaginosis (Swidsinski et al. 2011; Bradshaw et al. 2012).

The antibiotic susceptibility profile of *Atopobium vaginae* reveals resistance to the antibiotics nalidixic acid and colistin with MIC values higher than 256 and 1,024 μg/mL, respectively, while metronidazole resistance was reported for a number of strains (Ferris et al. 2004; De Backer et al. 2006; Polatti 2012). Also, *Atopobium vaginae* was found to be susceptible to a range of antibiotics including clindamycin, the antibiotic of choice for bacterial vaginosis, as well as ampicillin, ampicillin-sulbactam, azithromycin, ceftriaxone, ciprofloxacin, imipenem, linezolid, meropenem, moxifloxacin, penicillin, rifampicin, and trovafloxacin (Ferris et al. 2004; De Backer et al. 2006). It was recently suggested that the nitrofuran derivative, nifuratel, provides an alternative therapy for bacterial vaginosis involving the common pathogens *Atopobium vaginae* and *Gardnerella vaginalis*, without affecting the commensal microbiota of the vagina (Togni et al. 2011; Polatti 2012).

Application

Due to the recent description of a substantial number of *Coriobacteriaceae* species and to the even more recent reports that highlight some of their physiologically and clinically relevant functions, the use of these bacteria for application purposes has been very limited so far, but is at favorable odds for the near future.

The ability of *Coriobacteriaceae* to convert dietary isoflavones into the bioactive product equol is of particular interest for potential nutraceutical or pharmaceutical applications. The observation that two thirds of the human population cannot produce equol has spurred considerable interest on applied microbiological approaches aimed at triggering equol production in non-equol producers, along with the hypothesis that people hosting equol-producing *Coriobacteriaceae* are more likely to benefit from potentially beneficial health effects of soyfood and isoflavone intake. However, most attempts fell short of their target. First, there is to date no official nutritional recommendation on the benefit of dietary soy isoflavones on human health and state-of-the-art intervention trials are needed (Clavel and Mapesa 2013). Second, a number of animal and human studies examined the use of probiotic strains to boost equol production but failed to establish clear evidence (Larkin et al. 2007; Clavel and Mapesa 2013). Finally, the intake of *Coriobacteriaceae* themselves as probiotic strains in human subjects is for obvious safety issues not sound. However, the use of already isolated and characterized *Coriobacteriaceae* can be of great value in several ways: (1) for gathering functional evidence that equol is indeed directly linked to beneficial health effects using gnotobiotic mouse models of diseases colonized with, for instance, equol-producing or steroid-dehydroxylating versus

non-active strains (Woting et al. 2010; Becker et al. 2011), (2) for studying the production and effects of so far unknown isoflavone products such as 5-hydroxy-equol (Matthies et al. 2008), and (3) for large-scale affordable production of equol, for instance, for the sake of intervention trials that require large quantity of pure material. With respect to the latter point, the enantiospecificity of equol production is noteworthy. Gut bacteria are known to produce exclusively the *S*-enantiomer of equol, which seems to be more biologically active than its counterpart *R*-equol (Setchell et al. 2005; Wang et al. 2005, 2007; Shinkaruk et al. 2010). Patents related to the bacterial or synthetic production of enantiomeric equol and to the isolation of involved bacterial enzymes have already been registered (Setchell et al., US2009/7528267, Shimada et al., US2010/0330627; Isono et al., US2011/0189134; Tsuji et al., US2011/0318309). *Coriobacteriaceae*-based applications for the sake of metabolite production are also valid with respect to secondary bile acids, as recently studied using a 7*b*-HSDH from *Collinsella aerofaciens* (Braun et al. 2012).

The aforementioned use of *Coriobacteriaceae* in gnotobiotic mouse models can actually be extended to the study of host metabolic functions. Such experiments would help deciphering, for instance, the health implication of *Eggerthella*-encoded bile acid and steroid dehydroxylases as well as the role of these bacteria on hepatic functions, e.g., lipid metabolism and detoxification pathways (Ridlon et al. 2006; Claus et al. 2011; Martinez et al. 2012). In addition, one member of the *Coriobacteriaceae* isolated from the bovine rumen, *Denitrobacterium detoxificans*, is capable of metabolizing the nitrotoxins 3-nitro-1-propanol and 3-nitro-1-propionate found in forages, thereby providing potential industrial application for clearance of nitrocompounds from environmental samples or enhancement of tolerance towards environmental toxins in cattle (Anderson et al. 2000, 2005). *Slackia heliotrinireducens* may also be of interest for the reduction of pyrrolizidine alkaloid poisoning in cattle (Hovermale and Craig 2002).

12 The Family *Corynebacteriaceae*

Andreas Tauch · Jasmin Sandbote
Institut für Genomforschung und Systembiologie, Centrum für Biotechnologie, Universität Bielefeld, Bielefeld, Germany

Abstract
The family *Corynebacteriaceae* is composed of the type genus *Corynebacterium* with almost 90 species and the monospecific genus *Turicella*. The status of *Turicella* as a genus is supported by phenotypic characteristics. Both taxa form a distinct clade in the order *Corynebacteriales* which is clearly separated from the related families *Dietziaceae* and *Tsukamurellaceae*. Most *Corynebacterium* species contain mycolic acids with 22–36 carbons, though few species and *Turicella otitidis* lack this component. The peptidoglycan is of the A1γ type with directly cross-linked *meso*-diaminopimelic acid. Arabinose and galactose are the major cell-wall sugars. Fatty acid profiles are rich in saturated and unsaturated components and may contain tuberculostearic acid. The quinone systems reported for *Corynebacterium* species consist exclusively of menaquinones, with major amounts of MK-8(H_2), MK-9(H_2), or a mixture of both. *Turicella otitidis* contains completely unsaturated menaquinones (MK-10, MK-11). A significant variability in the G+C content of genomic DNA of *Corynebacterium* species has been reported, ranging from ∼46 mol% (*Corynebacterium kutscheri*) to 74 mol% (*Corynebacterium auris*). Members of the family *Corynebacteriaceae* are found in diverse environments. Some species are used in industrial applications and food production, whereas other species are serious pathogens of humans or domestic animals. Many of the medically relevant species can be recovered as commensals or contaminants from a variety of clinical specimens. Some *Corynebacterium* species usually associated with animals have also been documented to cause human infections by zoonotic transmission. The closely related organisms *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, and *Corynebacterium pseudotuberculosis* are the only species which may produce potent exotoxins, i.e., diphtheria toxin and phospholipase D which both play a significant role in pathogenicity.

Taxonomy, Historical and Current

Short Description of the Family

Family *Corynebacteriaceae* Lehmann and Neumann 1907[AL] emend. Stackebrandt, Rainey and Ward-Rainey 1997, 485 emend. Zhi, Li and Stackebrandt 2009, 593

Co.ry.ne.bac.te.ri.a.ce'a.e. N.L. neut. n. *Corynebacterium* type genus of the family; suff. −*aceae* ending to denote a family; N.L. fem. pl. n. *Corynebacteriaceae* the *Corynebacterium* family.

The family *Corynebacteriaceae* (Lehmann and Neumann 1907; Stackebrandt et al. 1997; Zhi et al. 2009) belongs to the phylum Actinobacteria, class *Actinobacteria*, and order *Corynebacteriales* (Goodfellow 2012; Stackebrandt et al. 1997; Goodfellow and Jones 2012). The family encompasses the type genus *Corynebacterium* (Lehmann and Neumann 1896; Bernard et al. 2010) and the monospecific genus *Turicella* (Funke, et al. 1994). The cell-wall peptidoglycan is of type A1γ with directly cross-linked *meso*-diaminopimelic acid, and the major cell-wall sugars are arabinose and galactose (also referred to as wall chemotype IV). The glycan type of the cell walls

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_187,

contains acetyl residues. The major fatty acids are $C_{16:0}$ and $C_{18:1}$ ω9*c*; tuberculostearic acid (10-methyl $C_{18:0}$) may be present. Most *Corynebacterium* species contain major amounts of menaquinones with either eight or nine isoprenoic units in the side chain, one of which is saturated [MK-8(H_2), MK-9(H_2), or a mixture of both]. Completely unsaturated menaquinones (MK-10, MK-11) are found in *Turicella otitidis*. *Corynebacterium* species typically contain short-chain mycolic acids with a length of 22–36 carbon atoms (corynemycolic acids), but some species and *Turicella otitidis* lack mycolic acids entirely. The G+C content of the genomic DNA varies from ~46 to 74 (mol%). Specific 16S rRNA signature nucleotides for this family have been described (Zhi et al. 2009). The specific pattern of 16S rRNA signatures consists of nucleotides or nucleotide pairs at positions 250 (U), 316:337 (U–G), 418:425 (C–G), 586:755 (U–G), 599:639 (C–G), 662:743 (U–G), 987:1218 (G–C), and 1059:1198 (U–A).

Phylogenetic Structure of the Family and Its Genera

According to recent improvements in the taxonomy of actinomycetes, the family *Corynebacteriaceae* belongs to the phylum Actinobacteria, class *Actinobacteria*, and order *Corynebacteriales* (Goodfellow 2012; Stackebrandt et al. 1997; Goodfellow and Jones 2012). *The order Corynebacteriales includes* aerobic or facultatively anaerobic, Gram-stain-positive, catalase-positive actinomycetes. Arabinose and galactose are the major cell-wall sugars. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid and is of type A1γ (wall chemotype IV). Fatty acid profiles are rich in saturated and unsaturated components and usually contain tuberculostearic acid. Members of the order *Corynebacteriales* typically contain mycolic acids. Until recently, wall chemotype IV actinomycetes that contain mycolic acids were assigned to genera in the suborder *Corynebacterineae* (Stackebrandt et al. 1997; Zhi et al. 2009) which was recasted into the order *Corynebacteriales* in 2012 (Goodfellow and Jones 2012). In the revised taxonomy of the actinobacteria, the taxonomic ranks of subclasses and suborders are eliminated. The phylum Actinobacteria is now divided into six classes, and the class *Actinobacteria* now contains a total of 15 orders (Goodfellow and Jones 2012). Families and genera classified in the order *Corynebacteriales* can be distinguished from one another and from corresponding taxa in the phylum Actinobacteria by 16S rRNA similarity values and by taxon-specific 16S rRNA nucleotide sequences (Zhi et al. 2009). The pattern of 16S rRNA signatures for the order *Corynebacteriales* consists of nucleotides at positions 127:134 (G–Y), 564 (C), 672:734 (U–G), 833:835 (U–G), 952:1229 (U–A), and 986:1219 (U–A). Moreover, analyses of protein sequences from sequenced *Corynebacteriales* genomes have identified conserved signature proteins and conserved signature indels which are highly specific for this order (Gao and Gupta 2012). A two-amino-acid insert in a conserved region of a macrolide transporter ATP-binding protein is specifically present in all of the *Corynebacteriales* proteins, but not in the orthologous counterparts of other actinobacteria Likewise, a one-amino-acid deletion is uniquely present in a conserved region of the enzyme α-ketoglutarate decarboxylase in all *Corynebacteriales* protein sequences (Gao and Gupta 2012).

Members of the order *Corynebacteriales* are found in diverse environments, notably in the soil ecosystem, and some species are serious pathogens of humans and domestic animals (Goodfellow and Jones 2012). The order *Corynebacteriales* comprises the families *Corynebacteriaceae*, *Dietziaceae*, *Gordoniaceae*, *Mycobacteriaceae*, *Nocardiaceae*, *Segniliparaceae*, and *Tsukamurellaceae* and includes the recently described taxa *Millisia*, *Skermania*, *Smaragdicoccus*, *Tomitella*, and *Williamsia* (Goodfellow and Jones 2012). The genera classified in the families *Gordoniaceae*, *Mycobacteriaceae*, *Nocardiaceae*, and *Tsukamurellaceae* contain *N*-glycolated muramic acid and a phospholipid pattern which includes the taxonomically significant nitrogenous phospholipid phosphatidylethanolamine (phospholipid type II). They can be distinguished on the basis of the menaquinone composition and the overall chain length of their mycolic acids (Goodfellow and Jones 2012). Genera assigned to the families *Corynebacteriaceae* and *Dietziaceae* can be distinguished from the other mycolic acid-containing genera as they contain *N*-acetyl residues in the glycan moiety of the peptidoglycan. Recent analyses of genome sequences identified molecular signatures for the main clades of the phylum Actinobacteria (Gao and Gupta 2012). The detected conserved signature proteins and conserved signature indels provide useful markers for an understanding of the phylogeny of actinobacteria and the relationship of a number of clades in the order *Corynebacteriales*. A molecular signature based on the absence of 12 conserved signature proteins supports the deep branching of a clade of *Corynebacterium* species and *Dietzia* within the order *Corynebacteriales* (Gao and Gupta 2012).

The family *Corynebacteriaceae* is currently composed of the genus *Corynebacterium* with 89 species and the monospecific genus *Turicella* (Bernard and Funke 2012; Aravena-Román et al. 2012; Zhou et al. 2012; Frischmann et al. 2012; Wu et al. 2011; Shin et al. 2011a). Numerous phylogenetic studies based on 16S rRNA or *rpoB* gene sequences indicated that the genus *Turicella* forms a deeply branching lineage within the clade comprising the species of the genus *Corynebacterium* (Pascual et al. 1995; Ruimy et al. 1995; Riegel et al. 1995a, 1997a; Funke et al. 1995a, 1997a, 1998a; Collins et al. 1998; Fernández-Garayzábal et al. 1998; Wattiau et al. 2000; Brennan et al. 2001; Renaud et al. 2001; Goyache et al. 2003a; Khamis et al. 2004, 2005). This phylogenetic placement of the species *Turicella otitidis* among *Corynebacterium* species creates a non-monophyletic genus *Corynebacterium* (❯ *Fig. 12.1*), indicating that the current taxonomy needs to be revised (Pascual et al. 1995; Busse 2012). However, the status of *Turicella* as a genus was supported by the lack of mycolic acids and by the menaquinone pattern (MK-10, MK-11) (Funke et al. 1994). The latter feature excludes *Turicella otitidis* from the genus *Corynebacterium,* in which MK-9(H_2) or MK-8(H_2) or both are the major menaquinones (Collins et al. 1977; Funke et al. 1994), though significant

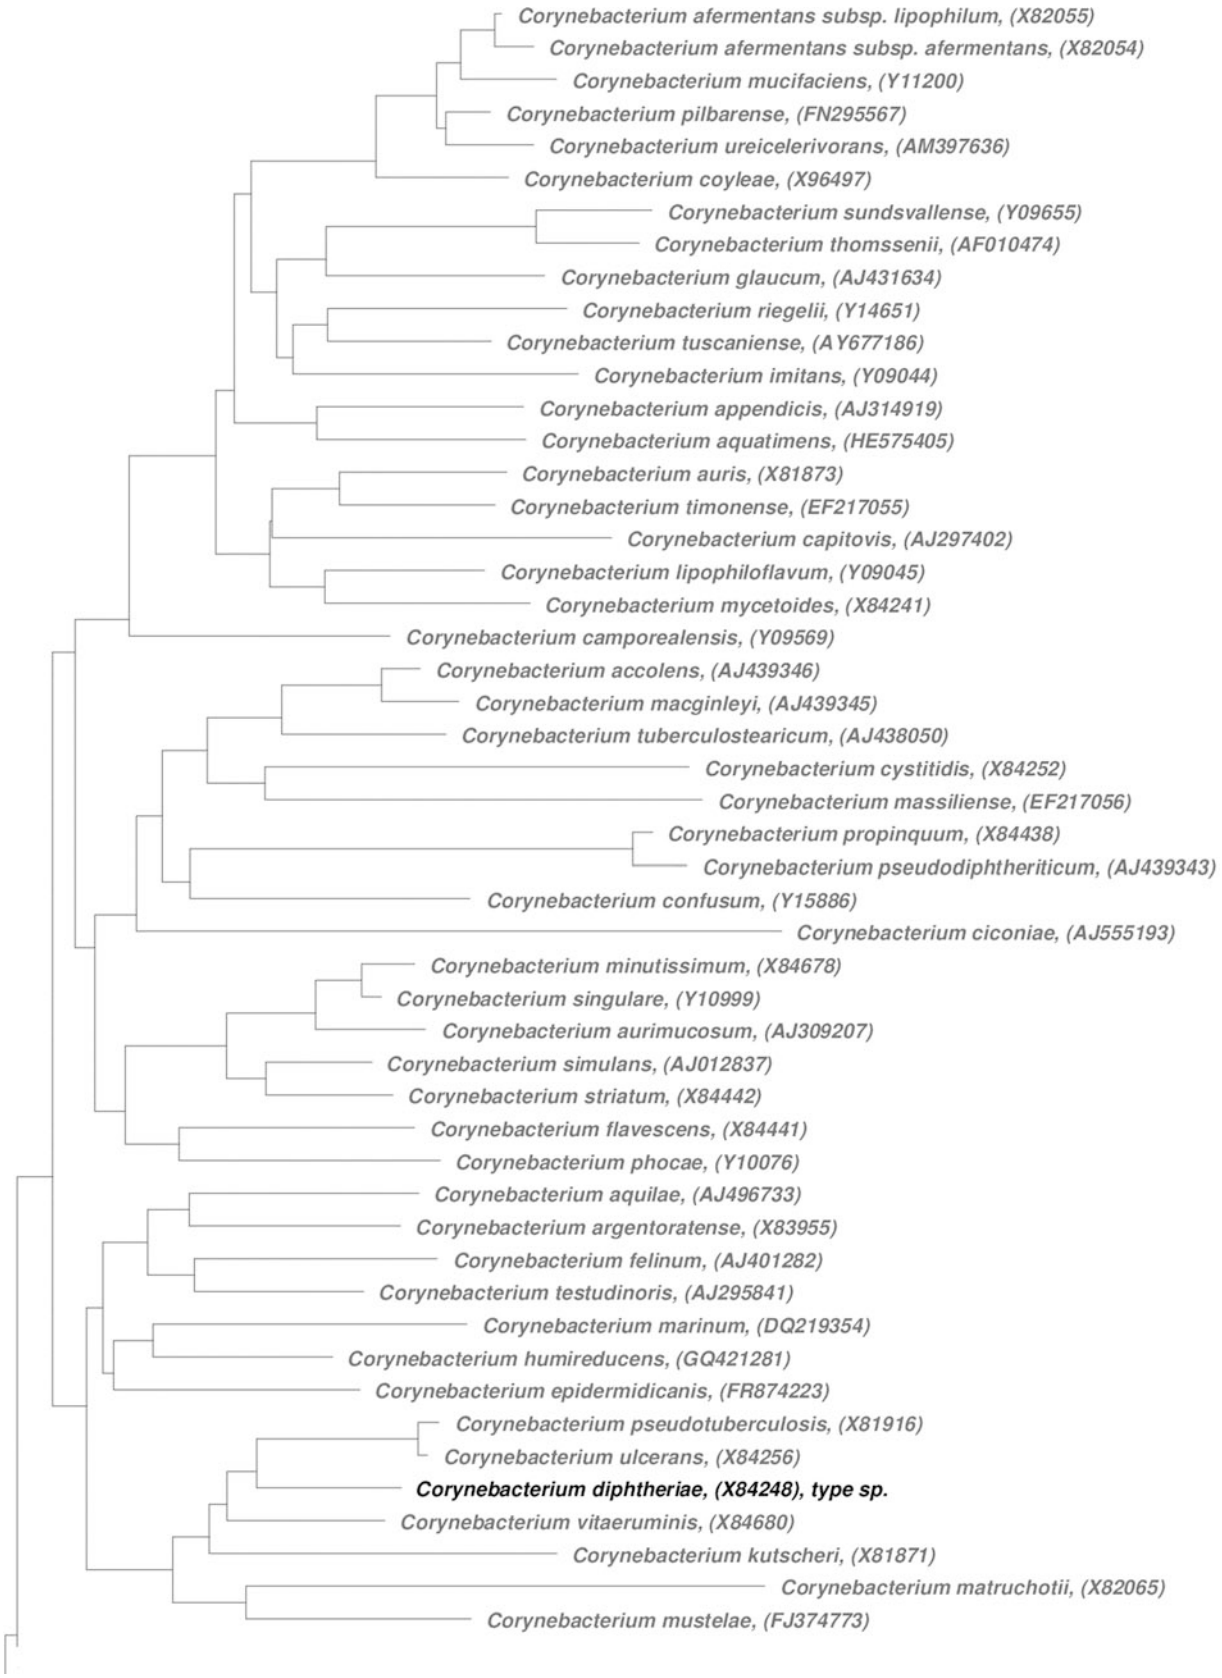

Fig. 12.1 (continued)

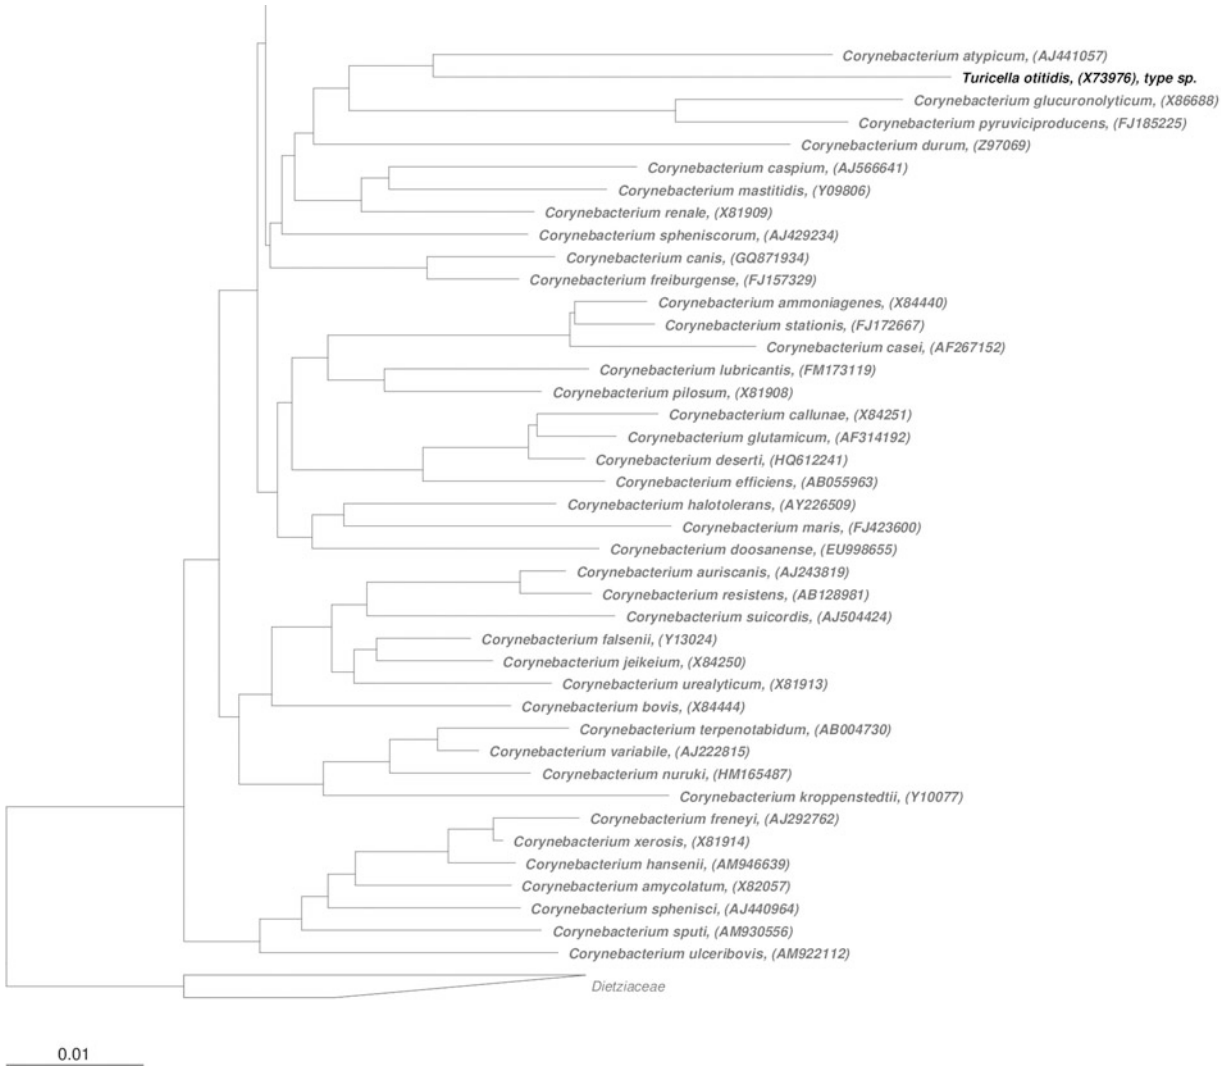

Fig. 12.1

Phylogenetic reconstruction of the family *Corynebacteriaceae* based on 16S rRNA gene sequences and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project database (Yarza et al. 2010). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Each branch of the tree contains species name and sequence accession number. Taxa of the family *Dietziaceae* were used as outliers. Scale bar indicates estimated sequence divergence

amounts of MK-7(H_2) may also be present (*Corynebacterium lubricantis*) (Kämpfer et al. 2009). *Corynebacterium glaucum* contains MK-7(H_2), MK-8(H_2), and MK-9(H_2) as respiratory menaquinones, with MK-8(H_2) as the major component (Yassin et al. 2003). Small amounts of MK-10(H_2) were found in *Corynebacterium bovis* (Collins et al. 1977) and *Corynebacterium thomssenii* (Zimmermann et al. 1998). Most *Corynebacterium* species contain mycolic acids as a component of the cell envelope, with the exception of a *Corynebacterium afermentans*-like organism isolated from middle ear fluid (Simonet et al. 1993), *Corynebacterium amycolatum* (Collins et al. 1988a), *Corynebacterium atypicum* (Hall et al. 2003), *Corynebacterium caspium* (Collins et al. 2004), *Corynebacterium ciconiae* (Fernández-Garayzábal et al. 2004), and *Corynebacterium kroppenstedtii* (Collins et al. 1998) (*Table 12.1*). These species form distinct phyletic lines within the phylogenetic tree of the family *Corynebacteriaceae* (*Fig. 12.1*). The lack of mycolic acids in *Corynebacterium kroppenstedtii* is obviously caused by gene loss, comprising at least a condensate gene cluster and a mycolate reductase gene which both contribute to the biosynthesis of mycolic acids in corynebacteria (Tauch et al. 2008a; Gande et al. 2004; Lea-Smith et al. 2007). The length of

Abbreviations: *F* fermentative, *O* oxidative, + feature present, − feature absent, *n.a.* data not available

[a]The G+C content of the genomic DNA is given in mol%. Data were generated with different methodologies. Data in parenthesis are from genome sequences

[b]Data in parenthesis indicate the number of carbons

[c]The presence of varying amounts (including trace amounts) of tuberculostearic acid is listed. Abbreviation: *TBSA* tuberculostearic acid

[d]Data in parenthesis indicate weak or delayed reaction. Abbreviation: *v* variable

mycolic acids found in *Corynebacterium* species mainly varies between 22 and 36 carbon atoms (Collins et al. 1982; Athalye et al. 1984) (Table 12.1), though ranges from 20 to 38 carbon atoms were also described (Butler et al. 1986; de Briel et al. 1992; Embley and Stackebrandt 1994). These so-called corynemycolic acids represent the simplest forms of the mycolate family, since they possess the shortest chain length (Daffé 2005). The composition of the corynemycolic acids from a *Corynebacterium* species might depend on the growth conditions, as fatty acids from lipid-rich media may be incorporated into both parts of the mycolic acid molecule (Daffé 2005). Lipophilic *Corynebacterium* species grown on Tween 80 exhibit a high content of unsaturated mycolic acids, presumably due to the incorporation of oleic acid from the detergent (Chevalier et al. 1988). Genome sequencing projects revealed that lipophilism of *Corynebacterium* species is also caused by gene loss, comprising the fatty acid synthase gene (Tauch et al. 2005, 2008a, b; Schröder et al. 2012a, b). The evolutionary event of gene loss occurred independently in distinct phyletic lines within the phylogenetic tree of the family *Corynebacteriaceae* (Fig. 12.1) and probably includes not only the hitherto examined species *Corynebacterium bovis* (Funke et al. 1997b), *Corynebacterium jeikeium* (Jackman et al. 1987), *Corynebacterium kroppenstedtii* (Collins et al. 1998), *Corynebacterium resistens* (Otsuka et al. 2005), and *Corynebacterium urealyticum* (Pitcher et al. 1992) but also the other known lipophilic species *Corynebacterium accolens* (Neubauer et al. 1991), *Corynebacterium afermentans* subsp. *lipophilum* (Riegel et al. 1993a), *Corynebacterium appendicis* (Yassin et al. 2002a), *Corynebacterium aquatimens* (Aravena-Román et al. 2012), *Corynebacterium lipophiloflavum* (Funke et al. 1997c), *Corynebacterium macginleyi* (Riegel et al. 1995b), *Corynebacterium mastitidis* (Fernández-Garayzábal et al. 1997), *Corynebacterium pyruviciproducens* (Tong et al. 2010), *Corynebacterium sputi* (Yassin and Siering 2008), *Corynebacterium tuberculostearicum* (Feurer et al. 2004), and *Corynebacterium ureicelerivorans* (Yassin 2007). *Corynebacterium diphtheriae* biotype *intermedius* is also regarded as a lipophilic bacterium (Funke et al. 1997b) (Table 12.1). *Corynebacterium lipophiloflavum* was described as slightly lipophilic (Funke et al. 1997c), although no fatty acid synthase gene is detectable in the draft genome sequence (Pagani et al. 2012). The family *Corynebacteriaceae* includes organisms that possess a cell-wall peptidoglycan of type A1γ with the characteristic *meso*-diaminopimelic acid. Major fatty acids are $C_{16:0}$ and $C_{18:1}$ ω9*c* (Bernard et al. 1991). Some species contain varying amounts of tuberculostearic acid (10-methyl $C_{18:0}$) (Table 12.1) which was detected in *Corynebacterium ammoniagenes* (Collins 1987a), *Corynebacterium appendicis* (Yassin et al. 2002a), *Corynebacterium aurimucosum* (Yassin et al. 2002b), *Corynebacterium bovis* (Funke et al. 1997b), *Corynebacterium confusum* (Funke et al. 1998a), *Corynebacterium deserti* (Zhou et al. 2012), *Corynebacterium jeikeium* (Jackman et al. 1987), *Corynebacterium kroppenstedtii* (Collins et al. 1998), *Corynebacterium lubricantis* (Kämpfer et al. 2009), *Corynebacterium maris* (Ben-Dov et al. 2009), *Corynebacterium massiliense* (Merhej et al. 2009), *Corynebacterium minutissimum* (Collins and Jones 1983a), *Corynebacterium mucifaciens* (Funke et al. 1997d), *Corynebacterium mycetoides* (Bernard et al. 1991), *Corynebacterium nuruki* (Shin et al. 2011a), *Corynebacterium pilosum* (Bernard et al. 1991), *Corynebacterium sputi* (Yassin and Siering 2008), *Corynebacterium stationis* (Bernard et al. 2010), *Corynebacterium terpenotabidum* (Takeuchi et al. 1999), *Corynebacterium tuberculostearicum* (Feurer et al. 2004), *Corynebacterium urealyticum* (Pitcher et al. 1992), *Corynebacterium ureicelerivorans* (Yassin 2007), *Corynebacterium variabile* (Collins 1987a), and *Turicella otitidis* (Funke et al. 1994). A remarkable variability in the G+C content of the genomic DNA of *Corynebacterium* species has been detected (Table 12.1), as the lowest value was reported for *Corynebacterium kutscheri* (~46 mol%) and the highest for *Corynebacterium auris* (74 mol%). Besides these two exceptions, the genomic G+C content of *Corynebacterium* species varies in principle between 51 and 68 mol% (Table 12.1). The genomic G+C content of *Corynebacterium accolens* isolates varies between 53.9 and 63.2 mol%, indicating that the characterized collection of strains contains various genomospecies (Neubauer et al. 1991).

The phylogenetic relatedness among *Corynebacterium* species is demonstrated by the 16S rRNA gene sequence-based tree of the family *Corynebacteriaceae* (Fig. 12.1). Molecular typing by 16S rRNA gene sequencing clearly distinguishes among most species of the genus *Corynebacterium,* as these can be separated by significant sequence variance. It is now recognized that a 16S rRNA gene sequence similarity range above 98.7–99 % should be mandatory for establishing the genomic uniqueness of a novel isolate (Stackebrandt and Ebers 2006). Several genomically distinct species within the genus *Corynebacterium* exhibit comparable or even higher levels of relatedness: *Corynebacterium aurimucosum* and *Corynebacterium minutissimum* (98.9 %) (Yassin et al. 2002b), *Corynebacterium coyleae* and *Corynebacterium afermentans* subsp. *afermentans* (98.2 %) (Funke et al. 1997a), *Corynebacterium deserti* and *Corynebacterium glutamicum* (98.4 %) (Zhou et al. 2012), *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* (98.5 %) and *Corynebacterium pseudotuberculosis* (98.5 %) (Pascual et al. 1995), *Corynebacterium hansenii* and both *Corynebacterium freneyi* (99.0 %) and *Corynebacterium xerosis* (98.5 %) (Renaud et al. 2007), *Corynebacterium macginleyi* and *Corynebacterium accolens* (98.7 %) (Riegel et al. 1995b), *Corynebacterium mucifaciens* and both subspecies of *Corynebacterium afermentans* (98.5 %) (Funke et al. 1997d), *Corynebacterium propinquum* and *Corynebacterium pseudodiphtheriticum* (99.2 %) (Pascual et al. 1995), *Corynebacterium singulare* and *Corynebacterium minutissimum* (99.1–99.6 %) (Riegel et al. 1997a), *Corynebacterium sundsvallense* and *Corynebacterium thomssenii* (98.8 %) (Bernard 2012), and *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis* (99.8 %) (Riegel et al. 1995c). Analysis of the levels of DNA relatedness revealed four genomospecies among *Corynebacterium jeikeium* isolates (Riegel et al. 1994). Although the respective *Corynebacterium jeikeium* strains showed genomic diversity at the species level, biochemical characteristics allowed their classification in this single taxon.

Molecular Analyses

16S rRNA Gene Sequence Analysis and Molecular Typing

Molecular typing by 16S rRNA gene sequencing is recommended as a starting point for characterization of *Corynebacterium* species and is in principle an efficient means to deduce phylogenetic relationships (Bernard 2012). However, the reliable identification of some *Corynebacterium* species from clinical specimens remains challenging (Coyle et al. 1993). Several strains of *Corynebacterium minutissimum*, *Corynebacterium striatum*, and *Corynebacterium xerosis* have been misidentified in the routine clinical laboratory and belong to the species *Corynebacterium amycolatum* (Funke et al. 1996; Wauters et al. 1996; Zinkernagel et al. 1996). A chemotaxonomic study on 25 clinical isolates originally identified as *Corynebacterium xerosis* revealed two different groups of strains, one of which unambiguously belonging to the species *Corynebacterium amycolatum* (Funke et al. 1996). Heterogeneity was also observed in a collection of 48 clinical strains that were tentatively identified as *Corynebacterium minutissimum* on the basis of standard biochemical reactions, and it was explained by misidentified *Corynebacterium amycolatum* strains (Zinkernagel et al. 1996). This observation indicates that the clinical microbiologist must be careful not to misidentify isolates of *Corynebacterium amycolatum* as *Corynebacterium minutissimum*. Detailed data on the biochemical and molecular identification of *Corynebacterium tuberculostearicum* isolated from clinical specimens from 18 hospitalized patients demonstrated that routine biochemical tests do not provide reliable identification of this species (Hinic et al. 2012). It was therefore proposed that *Corynebacterium tuberculostearicum* is often misidentified and its clinical relevance is underestimated. The use of matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometry was evaluated and shown to represent a helpful tool for the reliable identification of *Corynebacterium tuberculostearicum* isolates (Hinic et al. 2012). Analysis of the diversity within reference strains of *Corynebacterium matruchotii* by whole-cell fatty acid profiles, DNA-DNA dot blot hybridization, sequencing of two hypervariable regions of the 16S rRNA gene, and the pyrrolidonyl arylamidase test indicated that two reference strains, ATCC 33449 and ATCC 33822, are members of the species *Corynebacterium durum* (Rassoulian Barrett et al. 2001).

Four *Corynebacterium* species were reclassified within the genus and assigned to other species, including *Corynebacterium mooreparkense* (Brennan et al. 2001), *Corynebacterium nigricans* (Shukla et al. 2003a), *Corynebacterium seminale* (Riegel et al. 1995a), and *Corynebacterium lilium* (Liebl et al. 1991). According to additional data based on 16S rRNA gene sequencing and DNA-DNA hybridizations, *Corynebacterium mooreparkense* turned out to be a later heterotypic synonym of *Corynebacterium variabile* (Gelsomino et al. 2005). All *Corynebacterium mooreparkense* strains had a 16S rRNA gene sequence similarity of at least 99.5 % with *Corynebacterium variabile* and the DNA-DNA relatedness was 95 %. Likewise, the sequencing of the 16S rRNA gene and DNA-DNA hybridization analysis revealed that *Corynebacterium nigricans* can be reclassified as a charcoal-black-pigmented variant of *Corynebacterium aurimucosum* (Daneshvar et al. 2004). The type strains of *Corynebacterium seminale* (Riegel et al. 1995a) and *Corynebacterium glucuronolyticum* (Funke et al. 1995b) and other clinical isolates were shown by DNA-DNA hybridization and sequencing of the 16S rRNA gene to be related at the species level (Devriese et al. 2000). All strains were classified as *Corynebacterium glucuronolyticum*, because this species name has nomenclatural priority over *Corynebacterium seminale* (Devriese et al. 2000). *Corynebacterium lilium* and two glutamic acid-producing strains of *Corynebacterium ammoniagenes*, ATCC 13745 and ATCC 13746, were transferred to the species *Corynebacterium glutamicum* (Liebl et al. 1991; Oberreuter et al. 2002), whereas three environmental isolates that had tentatively been named *Corynebacterium thermoaminogenes* in a Japanese patent application were classified as the new species *Corynebacterium efficiens* (Fudou et al. 2002).

All *Corynebacterium* species previously associated with plants and attributed to diseases in plants have been reassigned. Therefore, the genus *Corynebacterium* is currently devoid of a species assigned as plant pathogenic. *Corynebacterium* species reclassified in other genera include the following: *Corynebacterium betae, Corynebacterium flaccumfaciens, Corynebacterium ilicis*, *Corynebacterium oortii*, and *Corynebacterium poinsettiae* in the genus *Curtobacterium*, as *Curtobacterium flaccumfaciens* (Collins and Jones 1983b; Young et al. 2004); *Corynebacterium beticola* in the genus *Erwinia*, as *Erwinia herbicola*, and later to *Pantoea agglomerans* (Collins and Jones 1982); *Corynebacterium equi* and *Corynebacterium hoagii* in the genus *Rhodococcus*, as *Rhodococcus equi* (Goodfellow and Alderson 1977); *Corynebacterium fascians* in the genus *Rhodococcus*, as *Rhodococcus fascians* (Goodfellow 1984); *Corynebacterium insidiosum*, *Corynebacterium michiganense*, *Corynebacterium nebraskense*, and *Corynebacterium sepedonicum* in the genus *Clavibacter*, as subspecies of *Clavibacter michiganensis* (Davis et al. 1984); *Corynebacterium iranicum*, *Corynebacterium rathayi*, and *Corynebacterium tritici* in the genus *Rathayibacter*, as *Rathayibacter iranicus*, *Rathayibacter rathayi*, and *Rathayibacter tritici*, respectively (Zgurskaya et al. 1993); *Corynebacterium paurometabolum* in the genus *Tsukamurella*, as *Tsukamurella paurometabola* (Collins et al. 1988b); and *Corynebacterium pyogenes* in the genus *Trueperella*, as *Trueperella pyogenes* (Ramos et al. 1997; Yassin et al. 2011).

Since the 16S rRNA gene sequences of *Corynebacterium* species show very little polymorphism, accurate molecular identification is only possible by sequencing the complete 16S rRNA gene (Khamis et al. 2004). *Corynebacterium* species which cannot be distinguished by 16S rRNA gene sequences can be further characterized by sequencing of other target genes, for instance the *rpoB* gene (Khamis et al. 2004). It was proposed that two *Corynebacterium* isolates belong to the same species if they show $\geq$95 % *rpoB* sequence similarity (Khamis et al. 2005). Higher proportions of corynebacterial isolates were

positively identified by partial *rpoB* gene sequence determination than by classification based on 16S rRNA gene sequences. However, in some ambiguous cases, *rpoB* gene sequencing should be used in conjunction with other tests for definitive species identification (Khamis et al. 2005). A number of other molecular techniques have been applied to separate closely related *Corynebacterium* species. Amplified rDNA restriction analysis (ARDRA) with the enzymes AluI, CfoI, and RsaI and the combination of the ARDRA patterns obtained after restriction with the three enzymes enabled the differentiation between the following species: *Corynebacterium accolens*, *Corynebacterium afermentans* subsp. *afermentans*, *Corynebacterium afermentans* subsp. *lipophilum*, *Corynebacterium amycolatum*, *Corynebacterium cystitidis*, *Corynebacterium diphtheriae*, *Corynebacterium jeikeium*, *Corynebacterium macginleyi*, *Corynebacterium minutissimum*, *Corynebacterium pilosum*, *Corynebacterium pseudotuberculosis*, *Corynebacterium renale*, *Corynebacterium striatum*, *Corynebacterium urealyticum*, and *Corynebacterium xerosis* (Vaneechoutte et al. 1995). Moreover, the value of rRNA gene RFLP analysis (ribotyping) as a molecular tool for the identification of *Corynebacterium* and *Turicella* species was evaluated, using the enzymes BstEII, SmaI, and SphI (Björkroth et al. 1999). BstEII clustering of many species followed known phylogenetic lineages, although the information provided by all three enzymes was considered essential for the reliable linking of strains of unknown identity with defined species (Björkroth et al. 1999). Ribotyping studies on a collection of *Corynebacterium urealyticum* isolates from humans and animals with HindIII revealed twelve different ribotypes. Most human isolates were found to be multidrug resistant and clustered into ribotypes named 8, 9, and 10, whereas strains from animals were significantly less antibiotic resistant and assigned to ribotypes 5 and 6 (Nieto et al. 2000). Ribotyping of *Corynebacterium pseudotuberculosis* with ApaI revealed differences between, but not within, the two biotypes *ovis* and *equi* derived from various types of lesions and different geographical locations (Sutherland et al. 1996; Costa et al. 1998). Ribotyping of *Corynebacterium ulcerans* from a female diphtheria patient and a chronic labial ulcer of her dog revealed that both isolates correspond to a single strain (Lartigue et al. 2005). Likewise, ribotyping of brown-pigmented *Corynebacterium striatum* strains provided evidence of person-to-person transmission in intensive care units (Leonard et al. 1994). The combination of ribotyping and pulsed-field gel electrophoresis (PFGE) demonstrated that *Corynebacterium imitans* strains from closely related persons were of clonal origin (Funke et al. 1997e). On the other hand, ribotyping was used to distinguish two toxigenic *Corynebacterium ulcerans* isolates from pharyngeal swabs of two patients from the same hospital which could not be distinguished by PFGE (Komiya et al. 2010). PFGE was used to characterize 48 *Corynebacterium striatum* isolates recovered from clinical specimens from long-term hospitalized patients with underlying diseases (Otsuka et al. 2006). The PFGE profiles revealed 14 distinct patterns with 20 subtypes, of which three types with four subtypes were related to a nosocomial outbreak of *Corynebacterium striatum*. Moreover, PFGE analysis confirmed that a single multidrug-resistant clone of *Corynebacterium striatum* is emerging as a pathogen in Italy (Campanile et al. 2009). Molecular genotyping of *Corynebacterium pseudotuberculosis* isolates from the United Kingdom by PFGE showed their epidemiological relatedness to an outbreak strain of caseous lymphadenitis in goats (Connor et al. 2000). Likewise, a clonally expanding epidemic of *Corynebacterium pseudotuberculosis* infections in horses was observed in Utah by molecular typing methods (Foley et al. 2004). Further genotyping studies of multinational ovine and caprine *Corynebacterium pseudotuberculosis* isolates using PFGE displayed a remarkable homogeneity among the investigated strains from Australia, Canada, Ireland, Northern Ireland, and The Netherlands (Connor et al. 2007). Based on these results, it would appear that the genome of *Corynebacterium pseudotuberculosis* is highly conserved, irrespective of the country of strain origin (Connor et al. 2007). Analysis of the length polymorphisms of the 16S–23S rDNA intergenic spacer by PCR-mediated amplification was used to reveal heterogeneity among strains of *Corynebacterium* species otherwise thought to be monophyletic (Aubel et al. 1997). Strains assigned to *Corynebacterium amycolatum*, *Corynebacterium jeikeium*, *Corynebacterium minutissimum*, and *Corynebacterium striatum* did not produce identical PCR profiles, suggesting that genomic heterogeneity occurs in these four species. RFLP analysis of the 16S–23S rRNA gene spacer using the enzyme CfoI allows differentiation between *Corynebacterium freneyi* and *Corynebacterium xerosis* (Funke and Frodl 2008). A randomly amplified polymorphic DNA (RAPD) method was applied to detect an association between *Corynebacterium striatum* from the bloodstream of a patient and that from the patient's central venous catheter (Chen et al. 2012). A molecular typing by RAPD analysis was also performed to demonstrate the patient-to-patient spread of a single strain of *Corynebacterium striatum* in a surgical intensive care unit. The same strain was isolated from surfaces and air sampled in the direct vicinity of infected patients and from the hands of personnel attending to infected patients (Brandenburg et al. 1996). RAPD and ribotyping were combined to prove that cutaneous sites and blood culture isolates of *Corynebacterium striatum* from the same patient were identical (Martín et al. 2003). RAPD was also combined with the amplification of DNA fragments surrounding rare restriction sites (ADSRRS fingerprinting) to distinguish *Corynebacterium pseudotuberculosis* strains isolated from goats (Stefańska et al. 2008). The value of discrimination was higher for ADSRRS fingerprinting, indicating that this rapid technique may be applied for epidemiological studies of intraspecific relatedness of *Corynebacterium pseudotuberculosis* isolates. Ophthalmic clinical isolates of the species *Corynebacterium macginleyi* were characterized by multilocus sequence typing (MLST) analysis of seven housekeeping genes: *adk*, *dnaA*, *fumC*, *gltA*, *gyrB*, *icd*, and *purA*. The MLST analysis grouped the majority of *Corynebacterium macginleyi* isolates into a single lineage. RAPD analysis supported this finding and indicated that a particular lineage of *Corynebacterium macginleyi* was dominant on the human ocular surface (Eguchi et al. 2008). A molecular method based

on the use of different primers for amplification of the cell division gene *divIVA* by conventional or real-time PCR was developed to identify *Corynebacterium amycolatum* (Letek et al. 2006). This technique allows to distinguish *Corynebacterium amycolatum* from the closely related *Corynebacterium minutissimum*, *Corynebacterium striatum*, and *Corynebacterium xerosis*, without the requirement of further molecular analysis (Letek et al. 2006). The differentiation of *Corynebacterium amycolatum*, *Corynebacterium minutissimum*, *Corynebacterium striatum,* and related species was also evaluated by pyrolysis-gas–liquid chromatography with atomic emission detection. This phenotypic method, which analyzes the whole chemical composition of bacteria, clearly separates *Corynebacterium amycolatum* from other species (Voisin et al. 2002). Real-time PCR is a rapid tool to confirm the presence of the diphtheria toxin gene *tox* in an isolate or specimen, although some toxigenic *Corynebacterium ulcerans* strains show atypical results in a real-time PCR for *tox*, revealing potential for false-negative real-time PCR results (Cassiday et al. 2008). The rapid detection and molecular differentiation of toxigenic *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* strains is possible by LightCycler PCR. Since the *tox* genes of these species differ from each other in DNA and amino acid sequences, both *tox* genes can be covered by real-time PCR methods. A LightCycler PCR assay reliably recognized *tox* genes from *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* and differentiated these target genes by fluorescence resonance energy transfer (FRET) hybridization probe melting curve analysis (Sing et al. 2011). A combined PCR assay for the *tox* and *rpoB* genes was established for the direct identification of the diphtheria toxin gene of *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* and the molecular discrimination of both species, irrespective of their toxigenic status (Mancini et al. 2012). A PCR-based assay to detect the *dtxR* gene associated with *Corynebacterium diphtheriae* strains has been used as a method to screen for this organism (Pimenta et al. 2008).

Identification of *Corynebacterium* species was also evaluated by matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometry. The identification of 92 clinical isolates was compared with the classification using *rpoB* or 16S rRNA gene sequencing. Eighty isolates were correctly identified to the species level, with the exception of *Corynebacterium aurimucosum* being misidentified as the closely related *Corynebacterium minutissimum* (Alatoom et al. 2012). Another study used a bacterial collection including 40 *Corynebacterium diphtheriae,* 13 *Corynebacterium pseudotuberculosis,* 19 *Corynebacterium ulcerans,* and 270 other *Corynebacterium* isolates for evaluating the identification of *Corynebacterium* species by MALDI-TOF mass spectrometry (Farfour et al. 2012). This new method provides also a helpful tool for the reliable identification of *Corynebacterium tuberculostearicum* that is often misidentified in clinical samples (Hinic et al. 2012). Moreover, 52 multiresistant *Corynebacterium striatum* strains from different Spanish hospitals were characterized by MALDI-TOF mass spectrometry, revealing different clonal populations within the clinical samples (Gomila et al. 2012). The identification of the potentially toxigenic species *Corynebacterium diphtheriae, Corynebacterium ulcerans,* and *Corynebacterium pseudotuberculosis* is essential for rapid diagnosis and treatment of diphtheria and diphtheria-like diseases. MALDI-TOF mass spectrometry was performed in comparison with classical microbiological and molecular methods on 116 *Corynebacterium* strains. All 90 potentially toxigenic *Corynebacterium* strains collected by the German National Consiliary Laboratory on Diphtheria were correctly identified by MALDI-TOF mass spectrometry (Konrad et al. 2010).

A broad spectrum of molecular typing schemes was applied to *Corynebacterium diphtheriae* isolates, in order to establish their epidemiological relatedness and genetic divergence and to analyze their circulation in the human population (De Zoysa et al. 1995; Popovic et al. 1996; Marston et al. 2001; Damian et al. 2002; Zasada et al. 2010). Four typing methods, including ribotyping, pulsed-field gel electrophoresis (PFGE), random amplification of polymorphic DNA (RAPD), and amplified fragment length polymorphism (AFLP) were compared for their use in the characterization of *Corynebacterium diphtheriae* strains (De Zoysa et al. 2008). This study revealed that ribotyping is highly discriminatory and reproducible and is probably the method of choice for typing *Corynebacterium diphtheriae*. PFGE and AFLP were less discriminatory than ribotyping and RAPD. An assessment of the transcontinental spread of the organism showed that several genotypes of *Corynebacterium diphtheriae* circulated on different continents and that each outbreak was caused by a distinct clone. The ribotypes seen in Europe appeared to be distinct from those seen elsewhere, and certain ribotypes appeared to be unique to particular countries (De Zoysa et al. 2008). A multilocus sequence typing (MLST) scheme has been developed for *Corynebacterium diphtheriae* surveillance and is based on data derived from sequencing of seven housekeeping genes: *atpA*, *dnaE*, *dnaK*, *fusA*, *leuA*, *odhA*, and *rpoB* (Bolt et al. 2010). The sequence data are stored and curated in databases and used to assign allelic numbers to a sequence type (Jolley et al. 2004; Dallman et al. 2008). MLST was applied to analyze 150 *Corynebacterium diphtheriae* isolates from 18 countries and encompassing a period of 50 years. Strain discrimination was in accordance with ribotyping data, and clonal complexes associated with disease outbreaks were clearly identified by MLST. Therefore, the MLST scheme provides a valuable tool for monitoring and characterizing *Corynebacterium diphtheriae* strains (Bolt et al. 2010). Moreover, a macroarray-based spoligotyping method was evaluated for *Corynebacterium diphtheriae* strain typing (Mokrousov et al. 2005, 2007, 2009). The spoligotyping method is based on simultaneous reverse-hybridization analysis of two clustered regularly interspaced short palindromic repeats (CRISPR) loci present in the genome of *Corynebacterium diphtheriae*. The method was evaluated with 154 clinical strains of *Corynebacterium diphtheriae* previously identified as belonging to the ribotypes Sankt-Peterburg and Rossija. The 154 strains were subdivided into 34 spoligotypes, comprising 14 unique strains and 20 types shared by 2–46 strains (Mokrousov et al. 2005). Therefore, spoligotyping allows efficient discrimination

within an epidemic clonal group of *Corynebacterium diphtheriae* and is applicable to phylogenetic reconstruction and epidemiological investigations (Mokrousov et al. 2005, 2009; Trost et al. 2012). Another genome-based method is comparative genomic hybridization, thereby detecting the heterogeneity in the distribution of pathogenicity islands in the genomes of *Corynebacterium diphtheriae* isolates (Iwaki et al. 2010). The future use of multiple genome sequences can give a phylogenomic overview of the genus *Corynebacterium* by using a core gene set as the basis of multilocus sequence typing (Adékambi et al. 2011) or by generating alignments for genomic regions that are characteristic or unique for a specified subgroup of species (Ågren et al. 2012).

Genome Analysis

A new generation of DNA sequencing approaches, collectively called next-generation DNA sequencing technologies, has provided unprecedented opportunities for high-throughput genome research (Mardis 2008; Shendure and Ji 2008). The application of these DNA sequencing technologies has provided detailed insights into the genome architecture and gene content of *Corynebacterium* species. The first next-generation DNA sequencing studies have focused on the genomes of corynebacterial pathogens because of their importance in human and animal disease. Complete genome sequences are meanwhile available for a black-pigmented *Corynebacterium aurimucosum* isolate (Trost et al. 2010a), multiple toxigenic and non-toxigenic strains of *Corynebacterium diphtheriae* (Cerdeño-Tarrága et al. 2003; Trost et al. 2012), *Corynebacterium jeikeium* (Tauch et al. 2005), *Corynebacterium kroppenstedtii* (Tauch et al. 2008a), multiple strains of the *Corynebacterium pseudotuberculosis* biovars *ovis* and *equi* (Trost et al. 2010b; Cerdeira et al. 2011a, b; Ruiz et al. 2011; Silva et al. 2011, 2012; Hassan et al. 2012; Lopes et al. 2012; Pethick et al. 2012a, b; Ramos et al. 2012), *Corynebacterium resistens* (Schröder et al. 2012a), *Corynebacterium ulcerans* from human and animal sources (Trost et al. 2011; Sekizuka et al. 2012), and *Corynebacterium urealyticum* (Tauch et al. 2008b). Complete genome sequences from environmental corynebacteria include *Corynebacterium efficiens* (Nishio, et al. 2003), *Corynebacterium glutamicum* (Kalinowski et al. 2003; Ikeda and Nakagawa 2003; Yukawa et al. 2007), and *Corynebacterium variabile* (Schröder et al. 2011). The genome of *Turicella otitidis* was sequenced to a high-quality draft status (Brinkrolf et al. 2012). The Genomes OnLine Database GOLD lists additional corynebacterial species that are targeted for genome sequencing or whose genomes have already been sequenced and annotated to a permanent high-quality draft status (Pagani et al. 2012). The latter section includes the additional species: *Corynebacterium accolens*, *Corynebacterium ammoniagenes*, *Corynebacterium amycolatum*, *Corynebacterium glucuronolyticum*, *Corynebacterium lipophiloflavum*, *Corynebacterium matruchotii*, *Corynebacterium striatum*, and *Corynebacterium tuberculostearicum*. The draft genome sequencing projects of *Corynebacterium bovis* (Schröder et al. 2012b), *Corynebacterium casei* (Monnet et al. 2012), *Corynebacterium nuruki* (Shin et al. 2011b), and *Turicella otitidis* (Brinkrolf et al. 2012) were published briefly as genome announcements.

The corynebacterial genome consists in principle of a single, circular chromosome within a size range from 2.28 Mb (*Corynebacterium pseudotuberculosis*) to 3.43 Mb (*Corynebacterium variabile*), although plasmids were described in several species. The chromosomes of corynebacteria from human and animal sources are generally smaller (2.28–2.96 Mb) than those from environmental species (3.11–3.43 Mb), and approximately 2,000–3,000 protein-coding genes were predicted by bioinformatic methods (Pagani et al. 2012). The number of *rrn* operons varies from three copies (e.g., *Corynebacterium jeikeium*) to six copies (e.g., *Corynebacterium variabile*) per chromosome. The G+C content of the genomic DNA varies in a wide range between the species (*Table 12.1*), as it can been expected when considering the taxonomic description of *Corynebacterium* species (Funke et al. 1997b). However, some genome sequences of type strains revealed a significantly lower or higher G+C content of the genomic DNA than that deduced earlier from experimental taxonomic studies, for instance *Corynebacterium kroppenstedtii* (Tauch et al. 2008a), *Corynebacterium nuruki* (Shin et al. 2011b), and *Corynebacterium resistens* (Schröder et al. 2012a) (*Table 12.1*). The G+C content of the genomic DNA of *Turicella otitidis* is 71.35 mol% (Brinkrolf et al. 2012) which is in the range of 65–72 mol% published previously (Funke et al. 1994). The draft genome sequence of *Turicella otitidis* has a size of 2.08 Mb (Brinkrolf et al. 2012). The sequenced corynebacteria revealed a high degree of synteny of orthologous genes over the entire length of the chromosomes. A remarkable difference in the overall synteny of genes was only observed in the chromosomes of *Corynebacterium jeikeium* (Tauch et al. 2005), *Corynebacterium resistens* (Schröder et al. 2012a), *Corynebacterium urealyticum* (Tauch et al. 2008b), and *Corynebacterium variabile* (Schröder et al. 2011). These genomes are characterized by three similar inversions which provided evidence for a common evolutionary scenario for these species. A new order of orthologous coding regions was also detected in the chromosome of *Corynebacterium kroppenstedtii* indicating the occurrence of genomic inversions during the evolution of this mycolic acid-free species (Tauch et al. 2008a). In principle, corynebacteria have an exceptionally stable genome structure with respect to the order of orthologous genes and have apparently maintained an ancestral genome organization (Ventura et al. 2007; Tauch 2008). A survey for recombinational repair systems among corynebacterial genomes suggested that the absence of the *recBCD* genes is responsible for the suppression of genome shuffling in these species (Nakamura et al. 2003). Nevertheless, mechanisms of horizontal gene transfer played an important role in the evolution of corynebacterial genomes and in intra-species genome plasticity, as it is exemplified by the presence of genomic islands that can cause the acquisition of blocks of genes, thereby producing evolution in quantum leaps (Schmidt and Hensel 2004). During a pan-genomic study of the

species *Corynebacterium diphtheriae*, 57 genomic islands were detected among the 13 sequenced strains (Trost et al. 2012). Comparative content analysis of the detected genomic islands revealed that some genomic regions are strain specific, whereas others are completely or partially conserved in more than one strain. The detected genomic islands were classified as pathogenicity islands, resistance islands, phage islands, or metabolic islands according to their predicted gene content (Trost et al. 2012). The gene content of genomic islands was also deduced from the genome sequences of *Corynebacterium efficiens* and *Corynebacterium glutamicum*, revealing the presence of metabolic islands and phage islands in these environmental species (Zhang and Zhang 2005; Tauch 2008).

Prophages

Prophages harboring the *tox* gene for diphtheria toxin were identified in the genome sequence of five *Corynebacterium diphtheriae* strains (Cerdeño-Tarrága et al. 2003; Trost et al. 2012). Two almost identical copies of corynephage ω^{tox+} were detected in the chromosome of *Corynebacterium diphtheriae* PW8 (Trost et al. 2012), as deduced previously from restriction endonuclease maps of phage DNA (Rappuoli et al. 1983a). The non-tandem copies of the prophage are separated by a 2-kb gene region that is flanked by two copies of a $tRNA^{Arg}$ gene in all *Corynebacterium diphtheriae* genomes (Trost et al. 2012). Nucleotide sequence comparisons revealed that the ω^{tox+} phage of *Corynebacterium diphtheriae* PW8 is homologous to corynephage β^{tox+} which has been integrated into the chromosome of the avirulent strain *Corynebacterium diphtheriae* C7 (Freeman 1951). This observation confirms an early study demonstrating by restriction mapping that the two phages differ in only three genomic regions (Rappuoli et al. 1983a). A different tox^+ phage was detected in the genome of *Coynebacterium diphtheriae* 31A, although all *tox* genes sequenced during the pan-genomic study showed a perfect nucleotide sequence identity (Trost et al. 2012). It has been proposed that the diphtheria toxin gene was acquired by corynephage β due to the terminal location of *tox* in the genome of the prophage and the significantly decreased G+C content of this gene region (Cerdeño-Tarrága et al. 2003). The detection of an identical *tox* gene in the prophage of *Corynebacterium diphtheriae* 31A indicates that the acquisition of *tox* had occurred independently in different corynephages or that gene shuffling is a common mechanism in corynephages. Interestingly, another type of tox^+ corynephage was recently identified in the chromosome of *Corynebacterium ulcerans* 0102 (Sekizuka et al. 2012). This observation suggests that tox^+ corynephages can have different genome architectures and that different phages contribute to the spread of the *tox* gene in the human population.

Prophages or phage islands were also identified in other corynebacterial genomes due to the lack of homology of the respective chromosomal region to the genomes of other *Corynebacterium* species and variations of the local G+C content of the genomic DNA. Five putative prophages were detected in *Corynebacterium ulcerans* (Trost et al. 2011). The prophage-like regions ΦCULC22I and ΦCULC809I have a size of about 42 kb and are characterized by highly similar genetic maps. The annotation of the *Corynebacterium aurimucosum* chromosome revealed the presence of two putative prophages, ΦCauriI and ΦCauriII (Trost et al. 2010a). Both prophage regions contain at their 3′ ends genes encoding λ repressor-like transcription regulators and phage-related integrases. Almost all genes of the prophage regions are encoded on the leading strand of the left replichore of the *Corynebacterium aurimucosum* chromosome. The size difference between both prophage genomes suggests that at least ΦCauriI is incomplete and a defective remnant of a formerly active corynephage. Two breakpoints of synteny between the chromosomes of *Corynebacterium resistens* and *Corynebacterium jeikeium* are caused by the presence of genes related to two prophages, named ΦCRES I and ΦCRES II (Schröder et al. 2012a). The genomic segment assigned to ΦCRES I has a size of about 58.7 kb and comprises 51 genes, whereas the ΦCRES II region has a size of about 40.2 kb and comprises 44 genes. Both putative prophage genomes share not only a very similar set of protein-coding regions but also a highly similar order of these genes, suggesting that the respective phages are genetically related. A phage island present in the *Corynebacterium variabile* chromosome has a size of about 48.3 kb and comprises 60 genes (Schröder et al. 2011). Most genes (39 out of 60) identified in the phage island encode hypothetical proteins of unknown function, whereas others encode enzymes involved in phage DNA replication, recombination, and repair. The structural proteins encoded by the phage island revealed similarities to the tail proteins of *Rhodococcus* phage ReqiPine5 and to the capsid structure of *Listeria* phage A006 (Schröder et al. 2011).

Another structural feature of some corynebacterial genomes is arrays of so-called clustered regularly interspaced short palindromic repeats (CRISPRs) (Mokrousov et al. 2007; Trost et al. 2010a, 2012; Schröder et al. 2012a). These arrays are composed of direct repeats that are separated by non-repetitive, similar-sized spacers. Together with a repertoire of associated *cas* genes, CRISPR arrays have been suggested to confer resistance to bacteriophages by RNA interference-like mechanisms, with a specificity that is determined by sequence similarities between the spacers and foreign DNA sequences (Barrangou et al. 2007; Terns and Terns 2011). Three different types of CRISPR arrays were detected in the genomes of sequenced *Corynebacterium diphtheriae* strains (Trost et al. 2012). These CRISPR arrays vary by the nucleotide sequence of the direct repeats, the number of spacer sequences, and the set of associated *cas* genes. *Corynebacterium diphtheriae* CRISPR type I is composed of three associated *cas* genes, and the number of spacers ranged from 1 to 28. CRISPR type II contains eight *cas* genes, and the number of repeats in these arrays ranged from 4 to 26, whereas the number of repeats in CRISPR type III ranged from 12 to 42, with eight flanking *cas* genes. Combinations of CRISPR type I and CRISPR type II were detected in three *Corynebacterium diphtheriae* genomes. The comparison of the spacer sequences revealed

that only 48 out of the 219 spacers are shared by two or three *Corynebacterium diphtheriae* strains, demonstrating that CRISPR arrays provide a solid basis to discriminate between different isolates (Trost et al. 2012). A CRISPR-based method to determine the phylogenetic relationship of *Corynebacterium diphtheriae* isolates is spoligotyping (Mokrousov et al. 2007, 2009). Targets for spoligotyping are the variable spacer regions between the conserved direct repeats of CRISPR arrays, as variations in the number or nucleotide sequence of spacers may provide patterns for the differentiation between subtypes of bacterial isolates (Grissa et al. 2008). An array of 98 CRISPRs and seven *cas* genes was found in the *Corynebacterium aurimucosum* chromosome (Trost et al. 2010a), and a DNA region with 73 CRISPRs and eight *cas* genes was annotated in the chromosome of *Corynebacterium resistens* (Schröder et al. 2012a). CRISPR arrays might be present also in other corynebacterial genome sequences. They can be identified in silico by means of the CRISPR Finder tool (Grissa et al. 2007).

Plasmids

Several plasmids were detected in *Corynebacterium* species and completely sequenced. Plasmid pNG2 (15.1 kb) from *Corynebacterium diphtheriae* is a prototype of a new plasmid family which is widely distributed in corynebacteria (Tauch et al. 2003a). This plasmid is characterized by a novel type of replication initiator protein and an associated 22-bp box element. Plasmid pNG2 and derivatives were initially detected in *Corynebacterium diphtheriae* strains and mediated erythromycin resistance (Schiller et al. 1980). R-plasmids were also found in *Corynebacterium xerosis* strains (Kono et al. 1983), although at least one host strain (M82B) was later reclassified as *Corynebacterium striatum* (Tauch et al. 2000a). The R-plasmid of M82B, pTP10 (51.4 kb), represents a mosaic structure of DNA elements associated with plasmid maintenance functions or multidrug resistance. The complete DNA sequence of pTP10 provides genetic information regarding the mechanisms of resistance against 16 antimicrobial agents that belong to six structural classes (Tauch et al. 2000a). A screening of 62 clinical isolates of *Corynebacterium jeikeium* revealed that 17 strains possessed small plasmids ranging in size from 7.6 to 14.9 kb. The plasmids formed four genetic groups according to DNA restriction analysis, and the complete DNA sequence of a representative from each group (pK43, pK64, pCJ84, and pB85766) was determined (Tauch et al. 2004). Plasmid pK64 contains the *ypkK* gene which encodes corynicin JK, a member of a new family of antimicrobial proteins (bacteriocins) with modular structure in Gram-positive bacteria (Swe et al. 2007). Corynicin JK is active against *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* (Swe et al. 2007). Plasmid pKW4 (14.3 kb) from *Corynebacterium jeikeium* was also associated with the production of a bacteriocin-like substance with a narrow killing spectrum, although the genetic determinant of this feature remained unknown (Kerry-Williams and Noble 1984; Tauch et al. 2005). The multidrug resistance of *Corynebacterium resistens* was mainly attributed to the presence of plasmid pJA144188 (28.3 kb) which harbors several antibiotic resistance genes, including a *tet*(W) tetracycline-minocycline resistance region which was detected for the first time in corynebacteria (Schröder et al. 2012a). Likewise, the presence of plasmid pET44827 (29 kb) in *Corynebacterium aurimucosum* explained the black pigmentation of the host strain, as it harbors five genes that might be responsible for the synthesis of a 3,3′-bipyridyl-like pigment. According to the annotation of pET44827 genes, it is most likely that the black pigment of *Corynebacterium aurimucosum* ATCC 700975 is synthesized by the concerted action of a non-ribosomal peptide synthetase and an unknown condensase function (Trost et al. 2010a). The small cryptic plasmid p1B146 (4,2 kb) was identified in a *Corynebacterium tuberculostearicum* strain derived from healthy human skin (Wieteska et al. 2011), whereas the cryptic plasmids pCR1−pCR4 (1.4–5.7 kb) were found in a single strain of *Corynebacterium renale* (Nath and Deb 1995; Srivastava et al. 2010).

Plasmids were also detected during a systematic survey of *Corynebacterium glutamicum* strains (Tauch et al. 2003b; Tauch 2005). They range in size from 2.4 kb (pXZ10142) to 95 kb (pGX1906). Sequenced plasmids were classified into four plasmid families according to the type of replication and the amino acid sequence similarities of the replication initiator proteins. The cryptic plasmids pEC2 (23.7 kb) and pEC3 (48.7 kb) are part of the *Corynebacterium efficiens* genome (Nishio et al. 2003). The small cryptic plasmid pCC1 (4.1 kb) was isolated from *Corynebacterium callunae* (Venkova-Canova et al. 2004), and plasmid pBY503 (15 kb) was detected in *Corynebacterium stationis* (Kurusu et al. 1991). Most *Corynebacterium glutamicum* plasmids are also cryptic, but pAG1, pCG4, pTET, and pXZ10145 were associated with antibiotic resistances (Tauch et al. 2003b; Tauch 2005).

Class 1 integrons were detected on plasmids pCG4 (*aadA2* gene cassette) and pTET3 (*aadA9* gene cassette) from *Corynebacterium glutamicum* (Nešvera et al. 1998; Tauch et al. 2002, 2003b) and on plasmid pJA144188 from *Corynebacterium resistens* (Schröder et al. 2012a). The class 1 integron of pJA144188 is characterized by small deletions in the 5′ and 3′ conserved segments and by a gene cassette array that comprises the rare *aacA1*:*gcuG* tandem gene cassette and the *aadA1a* gene cassette (Schröder et al. 2012a). Another class 1 integron with *dfrA16* and *qacH* gene cassettes is present in the genome of a *Corynebacterium diphtheriae* biovar *mitis* strain (Barraud et al. 2011).

Proteome Analysis

Comprehensive proteome maps are available for *Corynebacterium glutamicum* (Hermann et al. 2001; Hansmeier et al. 2006a), *Corynebacterium efficiens* (Hansmeier et al. 2006a), and *Corynebacterium jeikeium* (Hansmeier et al. 2007), including the cytosolic, cell surface, and extracellular proteome fractions. The extracellular and cell surface proteome of *Corynebacterium diphtheriae* was also mapped (Hansmeier et al. 2006b).

Phenotypic Analyses

Genus I. *Corynebacterium* Lehmann and Neumann 1896, 350[AL] emend. Bernard, Wiebe, Burdz, Reimer, Ng, Singh, Schindle and Pacheco 2010, 877

Co.ry.ne.bac.te'ri.um. Gr. n. *coryne* a club; L. neut. n. *bacterium* a rod, and in biology a bacterium (so called because the first ones observed were rod-shaped); N.L. neut. n. *Corynebacterium* a club bacterium.

Cells are Gram-positive, nonmotile, nonspore-forming, straight to slightly curved rods with tapered ends. Rods are usually short or of medium length. Club-shaped forms may be observed; sometimes ellipsoidal, ovoid, or rarely "whip handles" (*Corynebacterium matruchotii*) or thinner rods with bulges (*Corynebacterium sundsvallense*) are observed. Some cells stain unevenly. No species has aerial mycelium. Snapping division produces angular and palisade arrangements of cells. Metachromatic (polyphosphate) granules may be observed for some species. All species are catalase positive. All species are oxidase negative, with few exceptions (Table 12.1). Many species are facultatively anaerobic and some are (strictly) aerobic. Chemoorganotrophs. Some species are lipophilic or lipid auxotroph (Table 12.1). Many species produce acid from glucose and some other sugars (Table 12.1). Several species alkalinize citrate as the sole carbon source. The cell-wall peptidoglycan is based on *meso*-diaminopimelic acid (A1γ type). The glycan type of the cell walls contains acetyl residues. Major cell-wall sugars are arabinose and galactose (arabinogalactan). Short-chain mycolic acids with 22–36 carbon atoms in length may be present, but some species lack corynemycolates entirely (Table 12.1). Long-chained cellular fatty acids are of the straight-chain saturated and monounsaturated types, with significant amounts of palmitic acid ($C_{16:0}$), stearic acid ($C_{18:0}$), and oleic acid ($C_{18:1}$ w9*c*) as major components. Small or moderate amounts of tuberculostearic acid (10-methyl $C_{18:0}$) and other cellular fatty acids may also be present (Bernard et al. 1991). Branched-chain or hydroxylated fatty acids are absent or found only in trace amounts. Fermentation products may include small volumes of acetic, succinic, and lactic acids, but production of propionic acid is species specific (Bernard et al. 2002). The major respiratory menaquinones are MK-8(H_2) and/or MK-9(H_2). MK-7(H_2) has been detected in *Corynebacterium glaucum* and *Corynebacterium lubricantis*, and small amounts of MK-10(H_2) have been found in *Corynebacterium thomssenii*. Phospholipids include phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol dimannosides, and other glycolipids (Yagüe et al. 2003). Phosphatidylethanolamine is absent, with the exception of *Corynebacterium bovis* and *Corynebacterium urealyticum*. The DNA G+C content varies between ~46 and 74 mol%. Type species is *Corynebacterium diphtheriae* (Kruse 1886) Lehmann and Neumann 1896, 350[AL].

Genus II. *Turicella* Funke, Stubbs, Altwegg, Carlotti, and Collins 1994, 272[VP]

Tu.ri.cel'la. *Turicum* proper name Turicum; L. fem. dim. suff. *−ella*; N.L. fem. dim. n. *Turicella* pertaining to Turicum, the Latin name of Zurich, Switzerland, where the first isolates were collected.

Cells are Gram-positive, nonmotile, nonspore-forming diphtheroids that occur as single cells or are arranged in V-shaped forms or palisades. Colonies are circular, convex, and creamy in color and range from 1.0 to 2.0 mm in diameter after 48 h of incubation at 37 °C on sheep blood agar. Catalase positive and oxidase negative. Metabolism is respiratory. The cell wall contains *meso*-diaminopimelic acid, arabinose, and galactose. Mycolic acids are not present. The principal menaquinones are MK-10 and MK-11. The straight-chain saturated fatty acids are mainly palmitic ($C_{16:0}$) and stearic ($C_{18:0}$) acids. Oleic acid ($C_{18:1}$ w9*c*) is the predominant unsaturated fatty acid. Tuberculostearic acid (10-methyl $C_{18:0}$) is produced. The DNA G+C content varies between 65 and 72 mol%. Type species is *Turicella otitidis* Funke, Stubbs, Altwegg, Carlotti, and Collins 1994, 272[VP].

Turicella otitidis can be cultivated on Columbia agar base supplemented with 5 % sheep blood in a 5 % CO_2 atm, trypticase soy agar with 5 % sheep blood, chocolate agar supplemented with pyridoxal in a 5 % CO_2 atm, cooked-meat broth, and brain-heart infusion broth supplemented with 2 % yeast extract (Bernard and Funke 2012). Acid is not produced from D-glucose, glycogen, lactose, maltose, D-mannitol, ribose, sucrose, and D-xylose, or on triple sugar iron agar. Nitrate is not reduced. Indole is not produced. Urea and esculin are not hydrolyzed. Growth is visible in the presence of 6.5 % NaCl. Acid phosphatase, alkaline phosphatase, and leucine arylamidase are produced (Funke et al. 1994). The detection of completely unsaturated menaquinones (MK-10, MK-11) and the lack of mycolic acids distinguishes *Turicella otitidis* from *Corynebacterium* species. The non-fermentative metabolism is another characteristic distinguishing *Turicella otitidis* from the majority of *Corynebacterium* species (Table 12.1). The lipoarabinomannan of *Turicella otitidis* has a novel truncated structure which has been determined to consist of a mannosyl phosphatidylinositol anchor unit carrying an (α 1→6)-linked mannan core and substituted with terminal-arabinosyl branches (Gilleron et al. 2005).

Metabolic Pathways and Metabolism

The knowledge of metabolic pathways and the metabolism of *Corynebacterium* species and *Turicella otitidis* is very limited. Standard biochemical testing can be performed using commercially available manual identification test strips (Bernard 2012). *Corynebacterium* species and coryneforms exhibit a variety of metabolic processes, i.e., they can be fermentative, oxidative, assimulative, or nonreactive to most or all substrates on a species-specific basis (Bernard 2012). The metabolism of

Corynebacterium glutamicum has been extensively studied because of its relevance in engineering high-performance strains for the production of amino acids and other valuable products (Eggeling and Bott 2005; Yukawa and Inui 2013). These metabolic analyses were based on the annotated genome sequence and were additionally facilitated by the availability of transcriptomic and proteomic techniques. In the view of systems biology (Vertès et al. 2012), comprehensive genome-scale metabolic networks of *Corynebacterium glutamicum* were reconstructed in silico (Kjeldsen and Nielsen 2009; Shinfuku et al. 2009). The transcriptional regulatory repertoire of *Corynebacterium glutamicum* was also used for the in silico reconstruction of a gene-regulatory network (Schröder and Tauch 2010), and both networks were combined in an integrated version containing genes of pathways involved in lysine and glutamate production (Brinkrolf et al. 2010). A genome-scale cellular network of *Corynebacterium glutamicum* was also reconstructed by integrating data of the genome-wide metabolic and gene-regulatory subnetworks. This integrated cellular network is composed of 1,384 reactions, 1,276 metabolites, 88 transcriptional regulators, and 999 pairs of regulatory relationships. The transcriptional regulatory subnetwork was arranged into five hierarchical layers (Schröder and Tauch 2010), and the metabolic subnetwork presented a clear bow-tie structure (Jiang et al. 2012). In silico reconstructions of metabolic networks in *Corynebacterium* species can be performed almost automatically with the software tool CARMEN (Schneider et al. 2010). This tool supports the visualization of metabolic networks based on pathway information from the KEGG database or from user-defined templates and supports the interpretation of genome data in a functional context. The in silico reconstruction of pathways involved in the central metabolism of *Corynebacterium aurimucosum* (Trost et al. 2010a) and in the central carbohydrate and amino acid metabolism of *Corynebacterium resistens* (Schröder et al. 2012a) helped to deduce the lifestyle of both bacteria from their genome sequences. Metabolic features of *Corynebacterium variabile* relevant for the lifestyle on the surface of smear-ripened cheeses and during cheese ripening were deduced from the reconstruction of pathways involved in the central carbohydrate metabolism, in the biosynthesis of vitamins and cofactors, and in amino acid metabolism (Schröder et al. 2011). This analysis provided insights into the iron metabolism and the capacity of *Corynebacterium variabile* to perform lipolysis and proteolysis, thereby revealing a strong adaption of this bacterium to the iron-depleted and lipid-rich cheese surface habitat (Schröder et al. 2011).

Isolation, Enrichment and Maintenance Procedures

No selective media or enrichment procedures are known that are specifically suited for this group of organisms (Liebl 2005). However, special selective agars exist for *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* from respiratory specimens (Efstratiou and George 1999). Growth of *Corynebacterium* species and *Turicella otitidis* is generally achieved using a temperature range from 30 °C to 37 °C, particularly in air plus 5 % CO_2. Most species originally obtained from clinical specimens are routinely cultured on complex media, such as Columbia agar, brain-heart infusion agar, trypticase soy agar, or chocolate agar (*Corynebacterium aquatimens*), supplemented with 5 % horse or sheep blood where appropriate. Fastidious *Corynebacterium* species can be missed by routine culturing, because the organism does not grow after standard overnight incubation. Therefore, incubation may last longer than 24 h, at least in the case of *Corynebacterium urealyticum* (Soriano and Tauch 2008). A selective medium for the isolation of *Corynebacterium urealyticum* from urine and skin samples of hospitalized patients has been described (Zapardiel et al. 1998). Specific media have been designed and applied for the isolation of environmental corynebacteria from activated sludge (*Corynebacterium doosanense*) (Lee et al. 2009), the anode of a wastewater-fed microbial fuel cell (*Corynebacterium humireducens*) (Wu et al. 2011), saline soil (*Corynebacterium halotolerans*) (Chen et al. 2004), and coastal sediment (*Corynebacterium marinum*) (Du et al. 2010).

Growth of some *Corynebacterium* species is enhanced by the addition of 5 % horse or sheep blood to the synthetic medium or by using mixtures of lipids (e.g., 1 % Tween 80) as media supplements (Funke et al. 1997b). These species are generally referred to as lipophilic or lipid-requiring corynebacteria, since they grow poorly on standard laboratory media but show enhanced growth on sheep blood or brain-heart infusion broth supplemented with 0.1–1 % Tween 80 (Riegel et al. 1995b; Funke et al. 1997b). Recent genome sequencing projects revealed that the absence of fatty acid synthase genes apparently results in a strict nutritional requirement for exogenous fatty acids in the lipophilic species *Corynebacterium bovis* (Schröder et al. 2012b), *Corynebacterium jeikeium* (Tauch et al. 2005), *Corynebacterium kroppenstedtii* (Tauch et al. 2008a), *Corynebacterium resistens* (Schröder et al. 2012a), and *Corynebacterium urealyticum* (Tauch et al. 2008b). *Corynebacterium jeikeium* has a cellular fatty acid composition with the majority of these compounds being of the straight-chain, monounsaturated types (Yagüe et al. 2003), and it is worth mentioning that the chemical composition of Tween 80 almost exactly meets this requirement of *C. jeikeium*. Therefore, the term lipid auxotroph is also appropriate for the description of lipophilic corynebacteria lacking a fatty acid synthase gene (Tauch et al. 2005). However, it remains to be elucidated whether this genetic explanation is also applicable for the phenotypic description of other lipophilic *Corynebacterium* species (*Table 12.1*).

Members of the genus *Corynebacterium* may require additional supplements (amino acids, vitamins, purins, or pyrimidines) in synthetic culture media to grow, in particular when cultivated in minimal media. The knowledge of metabolic pathways deduced from complete genome sequences may help

to design minimal media for a species of interest (Brune et al. 2011). However, systematic growth assays with *Corynebacterium resistens* revealed a cysteine auxotrophy (Schröder et al. 2012c), despite the presence of all genes of the cysteine biosynthesis pathway (Schröder et al. 2012a). Most, if not all, *Corynebacterium* species are auxotrophic for the vitamin biotin due to the lack of a varying number of genes involved in the biotin biosynthesis pathway (Brune et al. 2012).

Cells of *Corynebacterium* species and *Turicella otitidis* do not require special protocols and procedures for storage. Short-term storage can be performed at 4 °C or room temperature on enriched media such as Columbia agar or brain-heart agar supplemented with 5 % horse or sheep blood where appropriate. Medium-term storage of *Corynebacterium* cells and *Turicella otitidis* can be done by using commercially available cryosystems to prepare cells for storage at −80 °C. Long-term preservation may be performed by standard lyophilization procedures.

Ecology

Currently, about 50 *Corynebacterium* species have been described that were initially isolated from humans or human clinical samples. Only *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, and *Corynebacterium pseudotuberculosis* can be regarded as toxigenic species, as they may produce potent exotoxins, i.e., diphtheria toxin or phospholipase D (Barksdale et al. 1981; Groman et al. 1984; Wong and Groman 1984; Holmes 2000). Other species of medical origin may be assigned opportunistic pathogens, as they rarely cause human infections and are in principle part of the human microbiome (Lewis et al. 2012; The Human Microbiome Project Consortium 2012a). However, there have been numerous case reports claiming an association of *Corynebacterium* species with disease. This increased detection of *Corynebacterium* species is amongst others caused by the growing number of immunocompromised patients whose diagnosis and treatment have become ever more intensive and invasive, resulting in better growth conditions for microbes (Funke et al. 1997b). Many of the medically relevant *Corynebacterium* species can also be recovered as commensals or contaminants from a variety of clinical specimens (Bernard 2012). Species associated with humans in addition to *Corynebacterium diphtheriae* include the following: *Corynebacterium accolens* from various clinical materials isolated from both patients and healthy individuals, a breast abscess, a case of endocarditis of native aortic and mitral valves, and the anterior nares (Neubauer et al. 1991; Claeys et al. 1996; Ang and Brown 2007; The Human Microbiome Project Consortium 2012b); *Corynebacterium afermentans* from blood cultures and multiple abscesses in brain, lung, and liver (Riegel et al. 1993a; Dykhuizen et al. 1995; Minkin and Shapiro 2004); *Corynebacterium ammoniagenes* from infant feces and floor dust samples (Collins 1987b; Täubel et al. 2009); *Corynebacterium amycolatum* from human skin, clinical specimens, and female patients with mastitis (Collins et al. 1988a; Lagrou et al. 1998; Paviour et al. 2002); *Corynebacterium appendicis* from an abdominal swab of a patient with appendicitis accompanied with abscess formation (Yassin et al. 2002a); *Corynebacterium aquatimens* from blood cultures of a patient with bacteremia (Aravena-Román et al. 2012); *Corynebacterium argentoratense* from human throat specimens (Riegel et al. 1995d); *Corynebacterium atypicum* from an unknown human clinical source (Hall et al. 2003); *Corynebacterium aurimucosum* from various clinical sources and in samples from the female urogenital tract (Yassin et al. 2002b; Daneshvar et al. 2004); *Corynebacterium auris* from patients with ear infections (Funke et al. 1995a); *Corynebacterium confusum* from a blood culture, patients with foot infections, and a breast abscess (Funke et al. 1998a; Bernard et al. 2002); *Corynebacterium coyleae* from blood cultures of patients with previous surgical intervention and a pancreatic abscess (Funke et al. 1997a; Taguchi et al. 2006); *Corynebacterium durum* from respiratory tract specimens, sputum, and a neck abscess (Riegel et al. 1997b; von Graevenitz et al. 1998; Bernard et al. 2002); *Corynebacterium falsenii* from blood cultures and a clinically significant bacteremia occurring in an infant while on vancomycin therapy (Sjödén et al. 1998; Tam et al. 2010); *Corynebacterium freneyi* from various clinical sources and a case of bacteremia following vascular surgery (Renaud et al. 2001; Auzias et al. 2003); *Corynebacterium glucuronolyticum* from the urogenital tract of male patients, peritoneal fluid, and prostate fluid (Funke et al. 1995b; Riegel et al. 1995a; Bernard et al. 2002); *Corynebacterium hansenii* from a pus swab of a patient with liposarcoma (Renaud et al. 2007); *Corynebacterium imitans* from nasopharyngeal specimens of patients with suspected diphtheria (Funke et al. 1997e); *Corynebacterium jeikeium* from various clinical sources and the human skin, including the axilla (Jackman et al. 1987; Tauch et al. 2004; Mookadam et al. 2006; Barzantny et al. 2012); *Corynebacterium kroppenstedtii* from a lung biopsy, the sputum of a patient with pulmonary disease, patients with granulomatous mastitis, and the retroauricular crease (Collins et al. 1998; Paviour et al. 2002; Taylor et al. 2003a; Riegel et al. 2004; Bernard et al. 2002; The Human Microbiome Project Consortium 2012b); *Corynebacterium lipophiloflavum* from a vaginal swab from a patient with the clinical diagnosis of bacterial vaginosis (Funke et al. 1997c); *Corynebacterium macginleyi* from conjunctival swabs, from the urine of a patient with a permanent bladder catheter, and from a central venous catheter in a case of sepsis (Riegel et al. 1995b; Funke et al. 1998b; Joussen et al. 2000; Villanueva et al. 2002; Mosele et al. 2012); *Corynebacterium massiliense* from blood and articular hip fluid (Merhej et al. 2009); *Corynebacterium matruchotii* from the oral cavity, cases of severe caries in young permanent teeth, the reproductive tract of women, and a mattress dust sample (Collins 1982a; Gross et al. 2010; Cherkasov and Gladysheva 2010; Täubel et al. 2009); *Corynebacterium minutissimum* as the causative agent of erythrasma in humans and from the axilla (Collins and Jones 1983a; Holdiness 2002; Troccaz et al. 2004); *Corynebacterium mucifaciens* from blood cultures, a wound swab, joint fluid, ear and nasal specimens, and the axillary microflora (Funke et al. 1997d; Morinaka et al. 2006; Taylor et al. 2003b); *Corynebacterium mycetoides* as the etiologic agent of a tropical ulcer

(Mungelluzzi and Caprilli 1965; Collins 1982b); *Corynebacterium pilbarense* from an ankle aspirate (Aravena-Roman et al. 2010); *Corynebacterium propinquum* from blood cultures and respiratory tract specimens (Riegel et al. 1993b; Motomura et al. 2004); *Corynebacterium pseudodiphtheriticum* from urine, respiratory specimens, blood, catheter tips, peritoneal fluid, and surgical wounds (Camello et al. 2009); *Corynebacterium pyruviciproducens* from a groin abscess (Tong et al. 2010); *Corynebacterium resistens* from blood cultures and samples taken from patients with acute myelocytic leukemia and myelodysplastic syndrome (Otsuka et al. 2005); *Corynebacterium riegelii* from female patients with urinary tract infections (Funke et al. 1998c); *Corynebacterium simulans* from a foot abscess, a boil, a biopsy sample of an axillar lymph node, and a mattress dust sample (Wattiau et al. 2000; Täubel et al. 2009); *Corynebacterium singulare* from semen and blood specimens (Riegel et al. 1997a); *Corynebacterium sputi* from the sputum of a patient with pneumonia (Yassin and Siering 2008); *Corynebacterium stationis* from blood cultures (Bernard et al. 2010); *Corynebacterium striatum* from a variety of human material (Eberson 1918; Martínez-Martínez et al. 1997); *Corynebacterium sundsvallense* from an intrauterine device in a woman with suspected endometritis or pyosalpingitis and from a sinus drainage from the left groin of a male patient (Collins et al. 1999a); *Corynebacterium thomssenii* from the pleural fluid of a patient with chronic renal failure (Zimmermann et al. 1998); *Corynebacterium timonense* from blood and articular hip fluid (Merhej et al. 2009); *Corynebacterium tuberculostearicum* from various clinical specimens, human axilla, tuna, and industrial environment (Brown et al. 1984; Feurer et al. 2004; Troccaz et al. 2004); *Corynebacterium tuscaniense* from blood cultures of a patient with endocarditis (Riegel et al. 2006); *Corynebacterium urealyticum* from human skin and the urinary tract of patients with underlying urological diseases (Pitcher et al. 1992; Soriano and Tauch 2008); *Corynebacterium ureicelerivorans* from blood cultures and other normally sterile sites in humans and from mattress dust samples (Yassin 2007; Fernández-Natal et al. 2009; Täubel et al. 2009); and *Corynebacterium xerosis* from various clinical samples and a brain abscess (Wooster et al. 1999). In the case of the latter species, it has to be considered that strains reported in the literature as *Corynebacterium xerosis* are probably misidentified and correspond to the species *Corynebacterium amycolatum* (Funke et al. 1996). *Turicella otitidis* was isolated from patients with otitis media, a cervical abscess, and a composted pine bark biofilter (Funke et al. 1994; Fernández-Pérez et al. 1999; Strauss et al. 2000).

Most strains of *Corynebacterium* species associated with humans were initially recovered from a variety of clinical specimens or sterile body sites. Therefore, the isolation procedure did not reveal information about the natural habitats of *Corynebacterium* species on the human body. This lack of knowledge was recently covered by meta-analyses in the course of the human microbiome project (Turnbaugh et al. 2007; Grice et al. 2009; Costello et al. 2009). To obtain an integrated view on the temporal and spatial distribution of the human microbiota, bacteria were surveyed from up to 27 body sites in healthy adults (Costello et al. 2009). The composition of the bacterial community was determined primarily by the body habitat, with high interpersonal variability and variations in time of the personalized microbiota. The colonization of the human skin is most probably driven by the highly variable ecology on the skin surface (Grice and Segre 2011). The complexity and stability of the microbial community are dependent on the specific characteristics of the skin site (Grice et al. 2009). Metagenomic analysis revealed that *Staphylococcus* and *Corynebacterium* species are the most abundant organisms colonizing moist areas of the human skin (Costello et al. 2009; Grice et al. 2009). The diversity of the microbiota of the human axilla was investigated in more detail by the cosmetic industry, as axillary malodor is attributable to the microbial biotransformation of odorless, natural secretions (James et al. 2004; Egert et al. 2011; Barzantny et al. 2012). A range of *Corynebacterium* species was detected on the axillary skin, as so-called operational taxonomic units based on amplified 16S rRNA gene sequences revealed similarities to sequences from *Corynebacterium afermentans*, *Corynebacterium amycolatum*, *Corynebacterium appendicis*, *Corynebacterium kroppenstedtii*, *Corynebacterium mucifaciens*, *Corynebacterium riegelii*, *Corynebacterium striatum*, and *Corynebacterium tuberculostearicum* (Taylor et al. 2003b; Egert et al. 2011). *Corynebacterium minutissimum* and *Corynebacterium tuberculostearicum* were isolated from the axilla and shown to produce an authentic axillary odor from collected sweat material (Troccaz et al. 2004). A probable route of human body odor formation proposed in the literature is the conversion of long-chain fatty acids into volatile short-chain fatty acids, probably by lipophilic corynebacteria which exhibit strong external lipase activities (James et al. 2004; Barzantny et al. 2012). The volatile branched-chain fatty acid (*E*)-3-methyl-2-hexenoic acid, for instance, is released from an odorless precursor by the action of a N^{α}-acylglutamine aminoacylase expressed in *Corynebacterium striatum* (Natsch et al. 2005). Moreover, the release of the malodor component 3-methyl-3-sulphanylhexan-1-ol from its odorless Gly-Cys-(S)-precursor was demonstrated in vitro by combining two enzymes (TpdA and AecD) which were cloned from axilla isolates of the species *Corynebacterium striatum* or *Corynebacterium jeikeium* (Emter and Natsch 2008). Knowledge of the putative habitat of a *Corynebacterium* species can be deduced also from metabolic analyses of the genome sequence, as demonstrated in the cases of *Corynebacterium aurimucosum* (Trost et al. 2010a), *Corynebacterium resistens* (Schröder et al. 2012a), and *Turicella otitidis* (Brinkrolf et al. 2012).

Corynebacterium species also appear to be commensals in animals or birds, and some species can cause significant infections. Others have been implicated in the transmission from animals to humans probably causing zoonotic infections. *Corynebacterium* species associated with animals or birds include the following: *Corynebacterium amycolatum* from dairy cows with mastitis (Hommez et al. 1999); *Corynebacterium aquilae* from the mouth of a Spanish Imperial eagle (*Aquila adalberti*) and the choanae of the Golden eagle (*Aquila chrysaëtos*)

(Fernández-Garayzábal et al. 2003); *Corynebacterium auriscanis* isolated from dogs with ear infections and associated with canine otitis externa (Collins et al. 1999b; Aalbæk et al. 2010); *Corynebacterium bovis* from milk samples of infected mammary glands of dairy cows (Watts et al. 2000); *Corynebacterium camporealensis* from the milk of sheep suffering from subclinical mastitis (Fernández-Garayzábal et al. 1998); *Corynebacterium canis* from a wound infection caused by a dog bite (Funke et al. 2010a); *Corynebacterium capitovis* from skin scrapings from the infected head of a sheep (Collins et al. 2001a); *Corynebacterium caspium* from the penis of a Caspian seal (*Phoca caspica*) (Collins et al. 2004; Kuiken et al. 2006); *Corynebacterium ciconiae* from the tracheas of healthy black storks (*Ciconia nigra*) (Fernández-Garayzábal et al. 2004); *Corynebacterium cystitidis* from cows with cystitis and pyelonephritis (Yanagawa and Honda 1978; Rosenbaum et al. 2005); *Corynebacterium epidermidicanis* from the skin of a dog with pruritus (Frischmann et al. 2012); *Corynebacterium falsenii* from the mouth of a Spanish Imperial eagle (*Aquila adalberti*), the trachea of the Golden eagle (*Aquila chrysaëtos*), and bioaerosols from duck houses (Fernández-Garayzábal et al. 2003; Martin et al. 2010); *Corynebacterium felinum* from a Scottish wild cat (*Felis sylvestris*) that had died from feline influenza (Collins et al. 2001b); *Corynebacterium freiburgense* from a patient's wound obtained from a dog bite (Funke et al. 2009); *Corynebacterium glucuronolyticum* from the urogenital tract of pigs (Devriese et al. 2000); *Corynebacterium kutscheri* from mice, rats, and probably hamsters (Bernard and Funke 2012; Amano et al. 1991); *Corynebacterium mastitidis* from the milk of sheep with subclinical mastitis and from preputial gland abscesses in mice (Fernández-Garayzábal et al. 1997; Radaelli et al. 2010); *Corynebacterium minutissimum* from dairy cows with mastitis (Hommez et al. 1999); *Corynebacterium mustelae* from lung tissue, the liver, and kidneys of a male ferret with lethal sepsis (Funke et al. 2010b); *Corynebacterium phocae* from the nasal cavities of common seals (*Phoca vitulina*) (Pascual et al. 1998); *Corynebacterium pilosum* from horse, dog, and cows, in the latter host associated with urinary tract infections (Yanagawa and Honda 1978; Thomas and Gibson 1981; Higgins and Messier 1997; Yeruham et al. 2006); *Corynebacterium pseudotuberculosis* predominantly from sheep, goats, horses, and cattle and associated with caseous lymphadenitis or ulcerative lymphangitis (Eberson 1918; Baird and Fontaine 2007); *Corynebacterium renale* from cattle, goats, macaques, and cows, in the latter associated with pyelonephritis (Ernst 1906; Fatihu and Addo 1991; Altmaier et al. 1994; Rosenbaum et al. 2005; Venezia et al. 2012); *Corynebacterium sphenisci* and *Corynebacterium spheniscorum* from the cloacae of healthy wild penguins (*Spheniscus magellanicus*) (Goyache et al. 2003a; Goyache et al. 2003b); *Corynebacterium suicordis* from pigs with pericarditis, pleuritis, pneumonia, and enlarged lymph nodes (Vela et al. 2003): *Corynebacterium testudinoris* from necrotic lesions in the mouth of a tortoise (Collins et al. 2001b); *Corynebacterium ulcerans* from dairy cows, dromedary camels, cats, dogs, goats, pigs, squirrels, free-living otters, macaques, and roe deer (Tiwari et al. 2008; Schuhegger et al. 2009; Bonmarin et al. 2009; Rau et al. 2012; Trost et al. 2011); *Corynebacterium ulceribovis* from the udder of a cow with a profound ulceration (Yassin 2009); *Corynebacterium urealyticum* from urinary tract infections in dogs and cats (Gomez et al. 1995; Suarez et al. 2002; Bailiff et al. 2005; Cavana et al. 2008); *Corynebacterium vitaeruminis* from the rumen of a cow and from the reproductive tract of women (Bechdel et al. 1928; Cherkasov and Gladysheva 2010); and *Corynebacterium xerosis* from clinical specimens of cows, pigs, goats, and sheep and probably in bioaerosols from duck houses (Palacios et al. 2010; Martin et al. 2010).

Some *Corynebacterium* species which have been detected in animals have also been documented to be the cause of infections in humans, probably by zoonotic transmission. These infections usually occurred in patients who had close contact with domestic or wild animals, i.e., during the occupational handling of animals, by animal bites, or by other means. *Corynebacterium amycolatum*, *Corynebacterium falsenii*, *Corynebacterium glucuronolyticum*, *Corynebacterium minutissimum*, *Corynebacterium urealyticum*, and *Corynebacterium xerosis* are usually associated with human disease, and zoonotic transmission has not been described. A case of zoonotic transmission of *Corynebacterium auriscanis* to humans has been reported, describing a leg wound infection following a dog bite in a previously healthy human patient (Bygott et al. 2008). *Corynebacterium freiburgense* was probably transmitted from the mouth of a dog to a female who had been bitten by her dog on her forearm, and *Corynebacterium canis* was also isolated from a wound infection caused by a dog bite (Funke et al. 2009, 2010a). Moreover, an infection with *Corynebacterium kutscheri* in a human has been reported after the patient had been bitten by a rat (Holmes and Korman 2007). Human infections of unknown means include a fatal case of prosthetic valve endocarditis caused by *Corynebacterium pilosum* (Sobrino et al. 1991), a fatal case of endocarditis caused by *Corynebacterium bovis* (Vale and Scott 1977), and a case of *Corynebacterium bovis* shoulder prosthetic joint infection (Achermann et al. 2009). The latter species was also isolated from a persistent leg ulcer, a human blood culture, and other clinical samples (Vale and Scott 1977; Bernard et al. 2002), whereas *Corynebacterium mastitidis* was detected in human ophthalmic samples (Eguchi et al. 2008). Human infections with *Corynebacterium pseudotuberculosis* can occasionally occur in adults who have close contact with animals (Peel et al. 1997), although a rare case of necrotizing lymphadenitis was described in a 12-year-old French girl (Join-Lambert et al. 2006). *Corynebacterium ulcerans* has been detected as a commensal in domestic and wild animals, and both groups may serve as reservoirs for the zoonotic transmission of this pathogen (Hogg et al. 2009; Wagner et al. 2010). Pet animals can also be included as carriers and potential infectious sources of *Corynebacterium ulcerans*, as a non-diphtheria toxin-producing strain caused a rare skin infection after transmission from a pet cat. The presence of *Corynebacterium ulcerans* in the mouth of the cat was confirmed by 16S rRNA gene analysis (Corti et al. 2012). Likewise, a single strain of *Corynebacterium ulcerans* was isolated from a female diphtheria patient and a chronic labial ulcer of her dog (Lartigue et al. 2005). The possible zoonotic transmission of

toxigenic *Corynebacterium ulcerans* from companion animals was also observed in a case of fatal diphtheria (Hogg et al. 2009). This observation is of particular interest, as toxigenic strains of *Corynebacterium ulcerans* can be regarded as an emerging zoonotic agent causing diphtheria-like illness in humans (Bonmarin et al. 2009; De Zoysa et al. 2005; Zakikhany and Efstratiou 2012). A case of toxigenic *Corynebacterium ulcerans* infection in a fully immunized veterinary student was reported from London, United Kingdom (Taylor et al. 2010). The case had been in close contact with a number of domestic animals. However, none of these were reported to have exhibited any clinical signs suggestive of *Corynebacterium ulcerans* infection. Moreover, toxigenic *Corynebacterium ulcerans* strains were isolated from domestic dogs in Japan. Comparative analysis of the isolates using PFGE and toxin gene typing suggests that transmission between asymptomatic dogs might have occurred (Katsukawa et al. 2009, 2012). On the other hand, *Corynebacterium diphtheriae* has been isolated from dairy cattle (Greathead and Bisschop 1963), a cow with chronic active dermatitis (Corboz et al. 1996), and domestic cats with severe otitis (Hall et al. 2010). The feline strains differed phenotypically from previously described biotypes but were regarded as typical *Corynebacterium diphtheriae* (Hall et al. 2010). Toxigenic *Corynebacterium diphtheriae* strains have been associated with wound infection in horses (Henricson et al. 2000; Leggett et al. 2010) which may act as reservoirs for toxigenic *Corynebacterium diphtheriae* strains and may facilitate the potential transmission of the pathogen to humans.

Corynebacterium ilicis was reported to be a plant-pathogenic member of the genus *Corynebacterium*, but the taxonomic position of this species has been a matter of debate (Judicial Commission of the International Committee on Systematics of Prokaryotes 2008). The Judicial Commission ruled that the features associated with *Corynebacterium ilicis* are represented by the type strain ICMP 2608 (ICPB CI144) and that *Arthrobacter ilicis* is not a homotypic synonym of *Corynebacterium ilicis*. However, *Corynebacterium ilicis* was later reassigned to *Curtobacterium flaccumfaciens* (Young et al. 2004; Bernard and Funke 2012). Therefore, the genus *Corynebacterium* is currently devoid of plant-pathogenic species.

Other *Corynebacterium* species have been described as being recovered from food products or from the environment, such as soil, water, marine ecosystems, or plant surfaces: *Corynebacterium callunae* from heather (Yamada and Komagata 1972; Bernard and Funke 2012); *Corynebacterium casei* from the surface of smear-ripened cheeses (Brennan et al. 2001; Mounier et al. 2005); *Corynebacterium deserti* from a mixed sand sample collected in a desert in the west of China (Zhou et al. 2012); *Corynebacterium doosanense* from activated sludge taken from a wastewater treatment plant in Yeongdeuk-gun, Republic of Korea (Lee et al. 2009); *Corynebacterium efficiens* from soil, vegetables, and onion bulbs (Fudou et al. 2002); *Corynebacterium flavescens* from dairy products (Bernard and Funke 2012); *Corynebacterium glaucum* from a cosmetic dye (Yassin et al. 2003); *Corynebacterium glutamicum* from soil contaminated with bird feces, sewage, manure, vegetables, and fruits (Abe et al. 1967; Liebl 2005); *Corynebacterium halotolerans* from a saline soil sample that was collected in Xinjiang Province, China (Chen et al. 2004); *Corynebacterium humireducens* from the anode of a microbial fuel cell fed with artificial wastewater (Wu et al. 2011); *Corynebacterium lubricantis* from a coolant lubricant (Kämpfer et al. 2009); *Corynebacterium marinum* from coastal sediment close to a coal-fired power station in Qingdao, China (Du et al. 2010); *Corynebacterium maris* from the mucus of the coral *Fungia granulosa* from northern Red Sea, Gulf of Eilat, Israel (Ben-Dov et al. 2009); *Corynebacterium nuruki* from *nuruk* which is a Korean alcohol fermentation starter (Shin et al. 2011a); *Corynebacterium terpenotabidum* from soil (Takeuchi et al. 1999); and *Corynebacterium variabile* from the surface of smear-ripened cheeses (Brennan et al. 2001; Mounier et al. 2005).

The detection of *Corynebacterium* species in various habitats has been broaded by recent scientific discoveries based on culture-independent studies and the systematic application of next-generation DNA sequencing technologies, for instance, in the course of the human microbiome project (Turnbaugh et al. 2007; Lewis et al. 2012). These metagenomic approaches provide huge sets of DNA sequences assigned to the bacterial 16S rDNA (Handelsman 2004) and provide new insights into the ecology of *Corynebacterium* species. Metagenome projects have been performed with various environmental samples (Pagani et al. 2012), and it is therefore helpful to screen the NCBI database for the presence of operational taxonomic units with significant similarity to the species under investigation. For instance, *Corynebacterium aurimucosum* 16S rDNA was detected in a bacterial population collected in the entrance area of a clean room environment in the Johnson Space Center (La Duc et al. 2007; Moissl et al. 2007) and in dust samples taken from office rooms in buildings located in central Finland (Rintala et al. 2008). This species was detected previously only in clinical specimens from patients with acute or chronic joint or bone infections, in infected diabetic foot wounds, in a biopsy sample from a patient with rheumatoid arthritis, and in samples from female urogenital sources (Trost et al. 2010a). *Turicella otitidis* was almost exclusively isolated from the human ear (Jeziorski et al. 2009), but 16S rDNA of this species was detected in the microbial community of the human ileum (Li et al. 2012), in floor dust, and in mattress dust (Täubel et al. 2009). The latter study indicates that human-derived bacteria account for a large part of the Gram-positive bacterial content in house dust.

Pathogenicity, Clinical Relevance

Corynebacterium diphtheriae, *Corynebacterium ulcerans*, and *Corynebacterium pseudotuberculosis* are the only species of the genus *Corynebacterium* which may produce potent exotoxins, diphtheria toxin and phospholipase D, both playing significant roles in pathogenicity (Barksdale et al. 1981; Groman et al. 1984; Wong and Groman 1984; Holmes 2000; Dorella et al. 2006). Due to their importance in human and veterinary medicine, the pathogenicity and virulence factors of these related species

have been studied intensively. Potential virulence factors of other species from human clinical sources, including *Corynebacterium jeikeium* (Tauch et al. 2005), *Corynebacterium urealyticum* (Tauch et al. 2008b), *Corynebacterium aurimucosum* (Trost et al. 2010a), and *Corynebacterium resistens* (Schröder et al. 2012a), were deduced from their annotated genome sequences, although the physiological importance of these factors remains largely unknown. The annotated genome sequences of *Corynebacterium kroppenstedtii* (Tauch et al. 2008a) and *Turicella otitidis* (Brinkrolf et al. 2012) did not reveal any apparent virulence factors. The evaluation of the genomic data indicated that lipophilism as a metabolic feature is probably involved in the pathogenicity of *Corynebacterium kroppenstedtii* and associated with granulomatous mastitis (Paviour et al. 2002; Taylor et al. 2003a). The organisms were detected in lipid-rich spaces surrounded by neutrophils and histiocytes in a histological specimen from the left breast of a Samoan woman (Taylor et al. 2003a). The lack of apparent virulence factors in *Turicella otitidis* is consistent with the low pathogenic potential of this species (Holzmann et al. 2002). Virulence factors and mechanisms of pathogenicity of other *Corynebacterium* species of medical origin are largely unknown.

Corynebacterium diphtheriae is the primary cause of the communicable disease diphtheria which is an upper respiratory tract illness initially characterized by sore throat, low-grade fever, and an adherent membrane (pseudomembrane) on the tonsils, the pharynx, or the nasal cavity (Hadfield et al. 2000). The major virulence factor of toxigenic *Corynebacterium diphtheriae* strains is diphtheria toxin, a potent A-B exotoxin that inhibits protein biosynthesis by ADP-ribosylation of the elongation factor EF-2 and kills susceptible host cells (Holmes 2000; Yates et al. 2006). As the diphtheria toxin is encoded by the *tox* gene present in the genome of a family of genetically similar corynephages, the toxigenicity of *Corynebacterium diphtheriae* is dependent on the lysogenization by a tox^+ corynephage (Holmes 2000). The regulation of diphtheria toxin expression is under bacterial control, as the corresponding iron-sensing regulator DtxR is encoded in the chromosome of *Corynebacterium diphtheriae*. Transcription of the *tox* gene is directly linked to bacterial iron homeostasis, as low iron concentrations induce the expression of diphtheria toxin (Tao et al. 1994). The enhanced synthesis of diphtheria toxin in *Corynebacterium diphtheriae* PW8 is most likely caused by a gene-dosage effect, as two ω^{tox+} phages are integrated into two non-tandem attachment sites of the chromosome (Rappuoli et al. 1983b; Trost et al. 2012). Since 1923, a diphtheria toxoid vaccine is produced from purified diphtheria toxin treated with formalin to inactivate the toxicity of the protein and to maintain its immunogenicity (Kitchin 2011). *Corynebacterium diphtheriae* PW8 and derivatives are widely used for the production of diphtheria toxin by submerged fermentation due to their ability to secrete high amounts of the toxin into the culture supernatant. Diphtheria is very effectively controlled in developed countries by an efficient immunization program (Vitek 2006), and only sporadic cases are observed in Europe (Zakikhany and Efstratiou 2012). The largest outbreak since the advent of mass immunization took place in Russia and the newly independent states of the former Soviet Union in the 1990s (Dittmann et al. 2000). The complete genome sequence of a clinical isolate related to this outbreak (*Corynebacterium diphtheriae* NCTC 13129) provided genetic information about potential virulence factors besides the diphtheria toxin, like iron transport systems and subunits of adhesive pili (Cerdeño-Tarrága et al. 2003). A genome comparison based on genomic hybridization showed remarkable differences in the distribution of putative pathogenicity islands of *Corynebacterium diphtheriae* PW8 and *Corynebacterium diphtheriae* C7(−) and provided first insights into the plasticity of the genome and the diversity of clinical isolates (Iwaki et al. 2010). This view was broadened by a comprehensive comparative genome analysis of toxigenic and non-toxigenic strains and the characterization of the pan-genome of *Corynebacterium diphtheriae* (Trost et al. 2012). This study revealed a diverse genome architecture of tox^+ corynephages and indicated that different phages can contribute to the spread of the *tox* gene in humans. Most pathogenicity islands revealed typical characteristics of horizontal gene transfer, and the majority of these islands encode subunits of a diverse set of adhesive pili which can probably play prominent roles in adhesion of *Corynebacterium diphtheriae* to different host tissues. This result implies that important variations exist on the cell surface of toxigenic and non-toxigenic *Corynebacterium diphtheriae* strains which are relevant for the initial step of an infection. Therefore, variation in the distributed gene content of individual strains is a common strategy of *Corynebacterium diphtheriae* to establish differences in host-pathogen interactions (Trost et al. 2012). However, virulence factors other than adhesive pili can contribute to the adhesion of *Corynebacterium diphtheriae* to host cells, including proteins of the resuscitation-promoting factor-interacting protein family and the cell-wall-associated hydrolase family (Ott et al. 2010; Kolodkina et al. 2011). Moreover, experimental data points to the unusual lipoarabinomannan of *Corynebacterium diphtheriae* as an adhesin to human respiratory epithelial cells, thereby contributing to the pathogenicity of this bacterium (Moreira et al. 2008). In contrast to the lipoarabinomannans of other corynebacterial species, the lipoglycan of *Corynebacterium diphtheriae* presents an unusual substitution of the α-1→6-mannan backbone by α-*D*-Ara*f*.

Toxigenic *Corynebacterium ulcerans* was first isolated from a throat lesion of a patient with respiratory diphtheria-like illness (Gilbert and Stewart 1926). Respiratory diphtheria-like illness caused by toxigenic strains of *Corynebacterium ulcerans* is now being described as an emerging, possibly zoonotic disease (Hogg et al. 2009; Dias et al. 2011; Zakikhany and Efstratiou 2012). It is increasingly reported from various industrialized countries and recently became more common than *Corynebacterium diphtheriae* infections in the United Kingdom (Tiwari et al. 2008; Wagner et al. 2010). *Corynebacterium ulcerans* strains that produce diphtheria toxin can cause infections of the human skin that completely mimic typical cutaneous diphtheria (Wagner et al. 2001). Toxigenic *Corynebacterium ulcerans* isolates produce diphtheria toxins with variations in the amino acid sequence when compared with that encoded by

Corynebacterium diphtheriae (Sing et al. 2003, 2005). Both species can harbor different corynephages carrying the *tox* gene for the diphtheria toxin (Trost et al. 2012; Sekizuka et al. 2012). Infections with toxigenic *Corynebacterium ulcerans* usually occur in adults, who consumed raw milk (Bostock et al. 1984) or had close contact with domestic animals (Wagner et al. 2010). *Corynebacterium ulcerans* has been detected also in wild animals, implying that both groups of animals may serve as reservoirs for zoonotic transmissions (Hogg et al. 2009). Ribotyping of *Corynebacterium ulcerans* strains isolated from a female diphtheria patient and from an ulcer of her dog revealed that both isolates correspond to a single clone (Lartigue et al. 2005). This example demonstrated that a distinct *Corynebacterium ulcerans* strain can infect different hosts. Besides diphtheria toxin, phospholipase D can be produced by *Corynebacterium ulcerans* (Barksdale et al. 1981). This toxin might play a role in pathogenicity of so-called non-toxigenic strains which were isolated from human clinical specimens not fitting reporting criteria for cases of diphtheria (Dewinter et al. 2005). The knowledge of virulence factors in non-toxigenic strains was recently extended by sequencing the genomes of two *Corynebacterium ulcerans* isolates from human and animal specimens, respectively (Trost et al. 2011). A bioinformatic screening for candidate virulence factors revealed the presence of genes coding for phospholipase D, neuraminidase H, endoglycosidase E, and subunits of adhesive pili in both *Corynebacterium ulcerans* genomes. The *rbp* gene encoding a putative ribosome-binding protein with striking structural similarity to Shiga-like toxins was detected only in the genome of the human isolate. The enzymatic activity of the ribosome-binding protein Rbp can probably lead to inhibition of protein biosynthesis, as is the case with diphtheria toxin (O'Loughlin and Robins-Browne 2001).

Corynebacterium pseudotuberculosis is a facultative intracellular pathogen (Dorella et al. 2006) that can be distinguished into the biovar *ovis* (from sheep and goats; negative nitrate reduction) and the biovar *equi* (from horses and bovines; positive nitrate reduction) according to the results of a nitrate reduction test (Biberstein et al. 1971). In sheep and goats, *Corynebacterium pseudotuberculosis* biovar *ovis* strains are responsible for causing the infectious, contagious, chronic disease caseous lymphadenitis which is mainly characterized by the presence of caseous necrosis on the lymphatic glands or abscess formation in superficial lymph nodes and subcutaneous tissues (Baird and Fontaine 2007). The disease is generally transmitted through direct contact with superficial wounds. The visceral form of caseous lymphadenitis can affect internal organs, resulting in weight loss and death of the infected animals (Hodgson et al. 1999). *Corynebacterium pseudotuberculosis* can be rapidly detected among diseased animals by the use of a multiplex PCR assay directed to the 16S rDNA and the *rpoB* and *pld* genes of this bacterium (Pacheco et al. 2007). Licensed vaccines intended for the use in sheep herds showed a variable efficiency in goat immunization (Williamson 2001; Dorella et al. 2009). Infections in horses by *Corynebacterium pseudotuberculosis* biovar *equi* display different disease patterns: external abscesses, ulcerative lymphangitis of the limbs, and a visceral form that affects the internal organs (Pratt et al. 2005). Regarding at least bulls and buffalo, there is evidence of the mechanical transmission of *Corynebacterium pseudotuberculosis* by houseflies, in addition to the transmission via skin contact between animals (Addo 1983; Yeruham et al. 2003). Phospholipase D is the primary virulence factor of *Corynebacterium pseudotuberculosis* (Dorella et al. 2006). It promotes the hydrolysis and degradation of sphingomyelin in endothelial cell membranes which increases vascular permeability and contributes to the spread and persistence of the bacterium in the host (Williamson 2001). The expression of phospholipase D is regulated by multiple environmental stimuli, including heat, and plays a role in the reduction of macrophage viability following infection (McKean et al. 2007a, b). Moreover, some strains of *Corynebacterium pseudotuberculosis* can express the diphtheria toxin (Funke et al. 1997b). The *fagABC* operon and the *fagD* gene are involved in iron acquisition and play a supportive role in virulence of *Corynebacterium pseudotuberculosis* (Billington et al. 2002). The *fag* genes are found on a pathogenicity island along with the *pld* gene which encodes phospholipase D (Ruiz et al. 2011). More recently, the presence of two pilus gene clusters has been reported in the genome of *Corynebacterium pseudotuberculosis* FRC41 (Trost et al. 2010b). Adhesive pili play an important role in bacterial virulence as they enable pathogens to bind to molecules on various host tissues (Ton-That and Schneewind 2003). After attaching to the host cell surface, the pathogen is able to initiate specific biochemical processes, such as extracellular and intracellular invasion, that will result in its proliferation in and dissemination among the host tissues (Wilson et al. 2002). Strain FRC41 from a human clinical specimen also encodes the virulence factors endoglycosidase E, neuraminidase H, nitric oxide reductase, an invasion-associated protein, and secreted serine proteases (Trost et al. 2010b). The cAMP-sensing transcription regulator GlxR plays a key role in controlling the expression of several genes contributing to virulence (Trost et al. 2010b).

Corynebacterium jeikeium is an opportunistic human pathogen and usually multidrug resistant (Funke et al. 1997b). It is considered part of the normal human skin flora, and colonization is predominantly found in the axillary, inguinal, and perineal areas (Coyle and Lipsky 1990). *Corynebacterium jeikeium* has been recognized as the causative agent of a variety of severe nosocomial infections (Funke et al. 1997b; Belmares et al. 2007; Schoen et al. 2009), most frequently associated with immunocompromised patients with malignancies, in-place medical devices, breaks in the skin barrier, and therapy with broad-spectrum antibiotics (Funke et al. 1997b). Antimicrobial susceptibility studies revealed that *Corynebacterium jeikeium* isolates are substantially resistant against clinically relevant antibiotics and that the glycopeptides vancomycin and teicoplanin remain universally active against this species (Lagrou et al. 1998; Traub et al. 1998). Metabolic analyses of the complete genome sequence indicated that *Corynebacterium jeikeium* is strictly dependent on the presence of exogenous fatty acids for growth which is consistent with the lipophilic phenotype of this species (Tauch et al. 2005). Potential virulence factors of *Corynebacterium jeikeium*, i.e., neuraminidase, alkaline ceramidase,

cholesterol esterase, cholesterol oxidase, and acid phosphatase, are apparently involved in ensuring the availability of fatty acids by damaging host tissue (Tauch et al. 2005). Bacteriocin-producing plasmids have been detected in *Corynebacterium jeikeium* which may facilitate the colonization of the human skin and prohibit the invasion of other corynebacterial species into the same habitat (Tauch et al. 2005; Swe et al. 2007). Multidrug resistance of *Corynebacterium jeikeium* strains is mediated by transposable elements, defective derivatives thereof, drug: H^+ antiporters, and Na^+-driven multidrug efflux pumps encoded in the chromosome and conferring resistances to macrolides, lincosamides, aminoglycosides, chloramphenicol, tetracycline, and fluoroquinolones (Tauch et al. 2005).

Corynebacterium urealyticum is a multidrug-resistant organism with a potent urease activity (Pitcher et al. 1992; Soriano and Tauch 2008) which is the major virulence factor of this pathogen. The bacterium is a common skin colonizer of hospitalized individuals who are receiving broad-spectrum antibiotics and also an opportunistic pathogen causing acute cystitis, pyelonephritis, encrusted cystitis, and encrusted pyelitis (Soriano and Tauch 2008; Famularo et al. 2008). *Corynebacterium urealyticum* is frequently isolated from the groin of elderly inpatients (Soriano et al. 1988) which favors the colonization of urinary catheters. It has been demonstrated experimentally that *Corynebacterium urealyticum* adheres efficiently to urinary catheters, thereby providing access to the human urinary tract (Soriano et al. 1993). Once the bacterium adheres to the epithelium of the urinary tract, it can grow under the stimulation of the urea present in the urine. The enzymatic activity of urease leads to hyperammoniuria and alkalinization of the urine which in turn causes hypersaturation with struvite and calcium phosphate with the consequent crystallization of struvite and apatite (Soriano and Tauch 2008). Both types of urinary stone have been reproduced by in vitro and in vivo experiments (Soriano et al. 1986, 1987). In addition to stone formation and associated obstructive complications, the potent urease activity of *Corynebacterium urealyticum* is also considered to be responsible for an ammonia-induced cytotoxicity for the renal epithelium. Options to neutralize such effect with acetohydroxamic acid were investigated, showing that this drug is able to neutralize the urease of *Corynebacterium urealyticum*, thereby also preventing the formation of struvite stones (Soriano et al. 1987). Multidrug resistance of *Corynebacterium urealyticum* is mediated by transposable elements present in the chromosome, conferring resistances to macrolides, lincosamides, aminoglycosides, chloramphenicol, and tetracycline (Tauch et al. 2008b).

Corynebacterium aurimucosum is detected rarely in human clinical specimens and has been recovered from blood cultures of a patient with bronchitis (Yassin et al. 2002b), from patients with acute or chronic joint or bone infections, from infected diabetic foot wounds, and from a biopsy sample from a patient with rheumatoid arthritis (Trost et al. 2010a). Unusual black-pigmented variants of *Corynebacterium aurimucosum* were isolated in Canada and the United States from female urogenital sources, mostly from vaginal and cervical swabs (Shukla et al. 2001; Bernard et al. 2002), and from the genital tract of women who had complications during pregnancy (Shukla et al. 2003b). According to their pigmentation, the name *Corynebacterium nigricans* was proposed for these isolates (Shukla et al. 2003a). However, biochemical analyses and sequencing of the 16S rRNA gene suggested that *Corynebacterium nigricans* is a later synonym for *Corynebacterium aurimucosum* (Daneshvar et al. 2004). The genome sequence of a black-pigmented strain (*Corynebacterium nigricans* CN-1) provided insights into the physiology and lifestyle of this potential pathogen in pregnant women (Trost et al. 2010a). The data obtained by the genome project suggest that *Corynebacterium aurimucosum* could be both a resident of the human gut and a pathogen in the female genital tract causing complications during pregnancy. Biosynthesis of the black pigment is probably required for colonization of the female genital tract by protecting the bacterial cells against the high hydrogen peroxide concentration in the vaginal environment. The 29,037-bp plasmid pET44827 was found to code for a putative non-ribosomal peptide synthetase which appeared to play a key role in the synthesis of the black pigment. Another possibility is that black-pigmented strains are sexually transmitted from infected men to some women who engage in sex during pregnancy (Trost et al. 2010a).

Corynebacterium resistens, a highly multidrug-resistant bacterium, was recovered from blood samples, bronchial aspirates, and abscess specimens in a Japanese hospital (Otsuka et al. 2005). Bacteremia associated with this organism in immunocompromised patients was rapidly fatal as therapies with the antibiotic minocycline failed (Otsuka et al. 2005). Strains obtained from inpatients revealed high levels of resistance to macrolides, aminoglycosides, tetracyclines, quinolones, and β-lactams, whereas a single isolate from an outpatient was susceptible to imipenem and minocycline. Susceptibility assays showed that the glycopeptides vancomycin and teicoplanin remain universally active against all isolates (Otsuka et al. 2005). The complete genome sequence of *Corynebacterium resistens* helped to identify genes contributing to virulence and multidrug resistance of this bacterium (Schröder et al. 2012a). Metabolic features probably related to the natural habitat indicate that *Corynebacterium resistens* might colonize the inguinal or perineal regions of the human body. The lipophilic lifestyle is linked with the enzymatic functions of several predicted virulence factors which probably ensure the availability of external fatty acids for growth by causing damage to membranes of host cells. Plasmid pJA144188 harbors several genes contributing to a broad spectrum of antibiotic resistance of *Corynebacterium resistens*, including a tetracycline-minocycline resistance region of the Tet W type known from *Lactobacillus reuteri* and *Streptococcus suis* (Schröder et al. 2012a).

Antibiotic Susceptibility and Mechanisms of Antibiotic Resistance

Antibiotic resistance of *Corynebacterium* species and *Turicella otitidis* may hamper patient management and the efficient medical treatment of infectious diseases. This has been documented

with the detection of highly resistant *Corynebacterium resistens* strains and the apparent failure of minocycline therapy which probably contributed to the subsequent death of a patient from sepsis (Otsuka et al. 2005). A life-threatening infection with daptomycin-resistant *Corynebacterium jeikeium* has been documented in a neutropenic patient (Schoen et al. 2009), and a multidrug-resistant *Corynebacterium striatum* strain was associated with bilateral pneumonia and pulmonary embolism in a heart transplant patient (Tarr et al. 2003). An earlier example is an outbreak of diphtheria in Seattle between 1972 and 1982 involving 1,100 cases, primarily adults with cutaneous lesions (Coyle et al. 1989). Erythromycin- and clindamycin-resistant *Corynebacterium diphtheriae* isolates were recovered from skin lesions, and erythromycin-inducible cross-resistance to vernamycin B_{α} was demonstrated (Coyle et al. 1979). This is remarkable as erythromycin had been considered the drug of choice for diphtheria patients in Seattle since the epidemic began in 1972 (Coyle et al. 1979). Multidrug resistance of *Corynebacterium diphtheriae* has been reported recently in a biovar *mitis* strain isolated from a skin abscess of an unvaccinated patient (Mina et al. 2011). *Corynebacterium amycolatum*, *Corynebacterium jeikeium*, and *Corynebacterium urealyticum* are generally regarded as multidrug resistant (Philippon and Bimet 1990; de Miguel-Martinez et al. 1996; Funke et al. 1997b; Soriano and Tauch 2008; Fernandez-Roblas et al. 2009). Multidrug resistance was also observed in *Corynebacterium xerosis* (Lortholary et al. 1993; Wallet et al. 1994) and *Corynebacterium striatum* (Dobler and Braveny 2003; Tarr et al. 2003; Otsuka et al. 2006; Iaria et al. 2007; Campanile et al. 2009).

The in vitro activity of various commonly used antibiotics against multidrug-resistant *Corynebacterium* species was evaluated by detecting minimum inhibitory concentrations (MICs) and time-death curves according to the recommendations of the Clinical and Laboratory Standards Institute. *Corynebacterium resistens* was described as being susceptible to the glycopeptides vancomycin and teicoplanin (Otsuka et al. 2005), as it is universally the case with *Corynebacterium amycolatum*, *Corynebacterium jeikeium*, *Corynebacterium striatum*, and *Corynebacterium urealyticum* (Lagrou et al. 1998; Traub et al. 1998; Gómez-Garcés et al. 2007). The semisynthetic glycopeptide telavancin (TD-6424) was shown to be active against *Corynebacterium amycolatum* and *Corynebacterium jeikeium* (Goldstein et al. 2004). High in vitro activity against clinical *Corynebacterium* isolates was observed with quinupristin/dalfopristin, tigecycline, linezolid, and daptomycin (Goldstein et al. 2003; Fernandez-Roblas et al. 2009). Tigecycline was very effective against multidrug-resistant species, indicating that this antibiotic is a good alternative for the therapy of corynebacterial infections (Salas et al. 2008; Fernandez-Roblas et al. 2009; Dinleyici et al. 2010). The two fluorinated oxazolidinones, U-100592 and U-100766, were positively evaluated against *Corynebacterium jeikeium* (Jones et al. 1996). Likewise, the oxazolidinone linezolid was very active against multidrug-resistant *Corynebacterium* species and *Turicella otitidis* (Jones et al. 2002; Gómez-Garcés et al. 2007). Time-death curves revealed that this antibiotic is effective as bacteriostatic agent. In contrast, β-lactams, macrolides, lincosamides, aminoglycosides, and fluoroquinolones showed generally high MICs (Gómez-Garcés et al. 2007). The cyclic lipopeptide antibiotic daptomycin was used as antibiotic therapy for the treatment of *Corynebacterium striatum* endocarditis (Shah and Murillo 2005; Fernández-Guerrero et al. 2012) and *Corynebacterium jeikeium* prosthetic valve endocarditis (Lappa et al. 2012), although daptomycin resistance has been observed in both species (Tran et al. 2012; Schoen et al. 2009).

Resistance to erythromycin and other macrolide-lincosamide-streptogramin B (MLS) antibiotics was associated with the presence of the *erm*(X) gene in *Corynebacterium afermentans* subsp. *afermentans* (Ortiz-Pérez et al. 2010), *Corynebacterium amycolatum* (Yagüe Guirao et al. 2005; Ortiz-Pérez et al. 2010), *Corynebacterium aurimucosum* (Ortiz-Pérez et al. 2010), *Corynebacterium coyleae* (Ortiz-Pérez et al. 2010), *Corynebacterium diphtheriae* (Schiller et al. 1980; Tauch et al. 2003a), *Corynebacterium jeikeium* (Rosato et al. 2001; Tauch et al. 2005; Yagüe Guirao et al. 2005; Ortiz-Pérez et al. 2010), *Corynebacterium pseudodiphtheriticum* (Olender and Niemcewicz 2010), *Corynebacterium resistens* (Schröder et al. 2012a), *Corynebacterium striatum* (Tauch et al. 2000a; Campanile et al. 2009; Ortiz-Pérez et al. 2010), and *Corynebacterium urealyticum* (Tauch et al. 2008b; Ortiz-Pérez et al. 2010). This gene encodes a 23S rRNA methyltransferase and can be associated with plasmids and mobile DNA elements, for instance, with the widely distributed transposon Tn*5432* (Tauch et al. 2000a). The related *erm*(B) determinant was detected in an unclassified *Corynebacterium* species (Luna et al. 1999) and in two *Corynebacterium urealyticum* strains (Ortiz-Pérez et al. 2010), as was the *mef* resistance gene in *Corynebacterium jeikeium* which encodes a macrolide efflux pump (Luna et al. 1999). However, resistance to MLS antibiotics is mainly due to the presence of the Erm(X) methylase in *Corynebacterium* species (Ortiz-Pérez et al. 2010).

Resistance to tetracycline and minocycline in *Corynebacterium resistens* is encoded by the *tet*(W) gene encoding a ribosomal protection protein (Schröder et al. 2012a). The ribosomal protection determinant *tet*(M) was detected by DNA-DNA hybridization in *Corynebacterium striatum* (Roberts et al. 1992). The unusual resistance gene pair *tetAB* encoding a tetracycline efflux system was also detected in this species (Tauch et al. 2000a; Campanile et al. 2009). Chloramphenicol resistance is mediated by the *cmx* gene encoding a specific antibiotic efflux system in *Corynebacterium jeikeium* (Tauch et al. 2005), *Corynebacterium resistens* (Schröder et al. 2012a), *Corynebacterium striatum* (Tauch et al. 2000a; Campanile et al. 2009), and *Corynebacterium urealyticum* (Tauch et al. 2008b). Resistances to a broad spectrum of aminoglycosides is conferred by a variety of genes encoding different enzymatic functions or at least different substrate specificities (Shaw et al. 1993; Vakulenko and Mobashery 2003). The *aphA1-IAB* gene encodes an enzyme of the aminoglycoside 3′-phosphotransferase protein family, APH (3′)-Ic. It is active against kanamycin, neomycin, lividomycin, paromomycin, and ribostamycin, and was found in *Corynebacterium striatum* (Tauch et al. 2000a; Campanile et al. 2009) and *Corynebacterium urealyticum* (Tauch et al. 2008b).

The resistance gene *aadA1a* encodes the aminoglycoside 3″-adenyltransferase ANT(3″)-Ia with a specific substrate profile comprising only streptomycin and spectinomycin, whereas the *aacA1* gene encodes the aminoglycoside 6′-acetyltransferase AAC(6′)-Ia that can confer cross-resistance against kanamycin, amikacin, dibekacin, netilmicin, sisomicin, and tobramycin. Both resistance genes were detected in *Corynebacterium resistens* (Schröder et al. 2012a). The *strA-strB* genes occur as a tandem pair in *Corynebacterium* species (Tauch et al. 2005, 2008b; Schröder et al. 2012a) and encode the aminoglycoside 3″-phosphotransferase APH(3″)-Ib and the aminoglycoside 6-phosphotransferase APH(6)-Id, respectively. Both enzymes can specifically confer streptomycin resistance (Chiou and Jones 1995). The sulfonamide resistance gene *sul1*, encoding a sulfonamide-insensitive dihydropteroate synthase, was detected in *Corynebacterium resistens* (Schröder et al. 2012a), and both the trimethoprim resistance gene *dfrA16* and the quaternary ammonium compound resistance gene *qacH* were found in a *Corynebacterium diphtheriae* biovar *mitis* strain (Barraud et al. 2011).

Resistances against quinolones and fluoroquinolones are often caused by mutations in the so-called quinolone resistance-determining region (QRDR) of the gyrase gene *gyrA* (Hooper 1999). Single amino acid substitutions in the GyrA protein are sufficient to generate quinolone resistance in corynebacteria, but double mutations in the *gyrA* gene are necessary for high-level resistances (Sierra et al. 2005; Eguchi et al. 2008). The amino acid sequence motif LAIYG of the GyrA protein from *Corynebacterium resistens*, for instance, contains the distinct leucine and glycine residues which were associated with high-level resistances to ciprofloxacin, levofloxacin, and norfloxacin in clinical isolates of *Corynebacterium macginleyi* (Eguchi et al. 2008; Schröder et al. 2012a). Likewise, specific double mutations in the QRDR of the *gyrA* genes from *Corynebacterium striatum* and *Corynebacterium amycolatum* resulted in amino acid changes of the GyrA proteins and in high levels of fluoroquinolone resistance (Sierra et al. 2005). The resistance of corynebacteria against β-lactams might be associated with the presence of antibiotic-insensitive types of penicillin-binding proteins. The high-molecular weight penicillin-binding protein PBP2C and the L,D-transpeptidase Ldt1 of *Corynebacterium jeikeium* are two examples of ampicillin-insensitive cross-linking enzymes involved in peptidoglycan biosynthesis (Lavollay et al. 2009).

Antibiotic resistances were detected also in environmental *Corynebacterium glutamicum* isolates during a systematic survey for the presence of plasmids, revealing that the R-plasmids pAG1, pCG4, pTET3, and pXZ10145 harbor antibiotic resistance determinants against tetracycline, streptomycin, spectinomycin, chloramphenicol, and sulfonamides (Tauch et al. 2003b; Tauch 2005). Tetracycline resistance in *Corynebacterium glutamicum* is due to the presence of the *tet*(Z) and *tet*(33) genes encoding efflux proteins (Tauch et al. 2000b, 2002), whereas aminoglycoside resistance is mediated by the *aadA2* and *aadA9* genes encoding aminoglycoside 3″-adenyltransferases of the ANT(3″)-I protein family (Nešvera et al. 1998; Tauch et al. 2002, 2003b). Plasmid pAG1 possesses its own tylosin resistance determinant *rlmAII*, but its host strain showed resistance against this macrolide antibiotic only in conjunction with the *tlrD* gene from *Streptomyces fradiae*, although *tlrD* alone is generally insufficient to confer tylosin resistance (Liu and Douthwaite 2002).

Application

Several *Corynebacterium* species recovered from food products or from the environment have been used in industrial applications. The most prominent example is *Corynebacterium glutamicum* that is widely used in the industrial production of amino acids, especially L-glutamic acid and L-lysine, which are important in human and animal nutrition, respectively (Kimura 2005; Kelle et al. 2005). Both L-glutamic acid and L-lysine are produced on a large industrial scale by genetically modified high-performance strains of this species (Leuchtenberger et al. 2005; Becker et al. 2011; Hirasawa et al. 2012; Ikeda and Takeno 2013). Besides these traditional products, considerable progress has been made in recent years in the fermentative production of other amino acids by metabolically engineered *Corynebacterium glutamicum* strains, including alanine, arginine and citrulline, cysteine, methionine, serine, and branched-chain amino acids (Ikeda and Takeno 2013). The biotechnological potential of *Corynebacterium glutamicum* goes beyond amino acid synthesis and includes the targeted production of organic acids (lactate and succinate), alcohols and fuels (ethanol, butanol, isobutanol, and xylitol), aromatic compounds (phenol and terephthalate), biopolymers (polylactate, polysuccinate, and poly-(3-hydroxybutyrate)), polyamines (cadaverine and putrescine), industrial enzymes, and therapeutic proteins (Vertès et al. 2013; Jojima et al. 2013). *Corynebacterium glutamicum* has been studied also for a variety of bioremediation uses, mining purposes, and the biosorption of toxic heavy metals (Vertès et al. 2013).

Corynebacterium efficiens was originally detected during a systematic search for new glutamic acid-producing bacteria that can grow at higher temperatures than *Corynebacterium glutamicum* (Fudou et al. 2002). Production strains derived from a wild-type strain of *Corynebacterium efficiens* by genetic engineering might reduce the need for cooling during fermentation (Fudou et al. 2002). A comparison between orthologous proteins of *Corynebacterium glutamicum* and *Corynebacterium efficiens* revealed a tremendous bias in amino acid substitutions in the latter species, particularly towards arginine and glycine (Nishio et al. 2003). The analysis of amino acid substitutions in 13 pairs of orthologous enzymes relevant for the production of L-glutamic acid or L-lysine in both *Corynebacterium* species revealed that three substitutions, lysine to arginine, serine to alanine, and serine to threonine, are important for thermostability. Therefore, *Corynebacterium efficiens* seems to have acquired thermostability through the accumulation of specific amino acid substitutions which, in part, correlate with the increased G+C content of the genomic DNA (Nishio et al. 2004).

Corynebacterium terpenotabidum Y-11 is capable of degrading squalene which is a naturally abundant linear triterpene (C_{30}) and an important biosynthetic precursor of steroids and triterpenes in many living organisms (Yamada et al. 1975; Takeuchi et al. 1999). The *Corynebacterium terpenotabidum* Y-11 strain cannot grow on glucose as a sole carbon source, but is able to grow in synthetic media containing squalene or fatty acids or their esters and triglycerides (Yamada et al. 1977). Microbial degradation of squalene can provide optically active precursors for the industrial production of physiologically active compounds. Metabolically engineered strains of *Corynebacterium ammoniagenes* were shown to be useful for the overproduction of deoxycytidine (Lee et al. 2011), uridine 5′-monophosphate (Wang et al. 2007), and 5′-inosine monophosphate (Abbouni et al. 2004). A large-scale production system of *N*-acetyllactosamine, a core structure of various oligosaccharides, was established by a whole-cell reaction through the combination of recombinant *Escherichia coli* strains and *Corynebacterium ammoniagenes* (Endo et al. 1999). Likewise, UDP-galactose and globotriose can be produced on a large scale by coupling *Corynebacterium ammoniagenes* and metabolically engineered *Escherichia coli* strains (Koizumi et al. 1998). Another example is the production of riboflavin by *Corynebacterium ammoniagenes* (Koizumi et al. 2000)

Corynebacterium ammoniagenes was found in significant numbers in ripening cultures on the surface of German brick cheeses and might contribute to the ripening process (Valdés-Stauber et al. 1997). It is therefore a potential candidate for designing a defined ripening culture for rennet red-smear cheese. *Corynebacterium casei* and *Corynebacterium variabile* are part of the complex microflora on the surface of smear-ripened cheeses and contribute to the development of flavor and textural properties during cheese ripening (Beresford et al. 2001). *Corynebacterium variabile* can produce acetoin, butanediol, and methanethiol which are important flavor compounds in smear-ripened cheeses (Schröder et al. 2011). Analyses of the biodiversity of the microflora on the surface of a farmhouse smear-ripened cheese at four stages of ripening showed that the bacterial flora of inoculated and non-inoculated cheeses was dominated by *Corynebacterium casei* and *Corynebacterium* variable (*Corynebacterium mooreparkense*). In addition, *Corynebacterium flavescens* was detected on the surface of the inoculated cheeses (Brennan et al. 2002). *Corynebacterium casei* and *Corynebacterium variabile* are present not only on the surface of various types of Irish farmhouse smear-ripened cheeses but also in the dairy environment and on the skin of the cheese personnel, indicating that a distinct "in-house" microflora exists in cheese plants (Mounier et al. 2005, 2006). Both species have also been detected on the surface of Gubbeen, a red-smear cheese (Rea et al. 2007).

Corynebacterium nuruki was isolated from food-related material, i.e., the Korean alcohol fermentation starter nuruk (Shin et al. 2011a). *Nuruk* is used as an amylolytic substance in the manufacture of traditional Korean rice wine and is a mixture of grains and various microorganisms including mold, yeast, and bacteria. These components execute fermentation of rice and make an alcoholic beverage named *makgeolli* (Aidoo et al. 2006). *Corynebacterium vitaeruminis*, *Corynebacterium xerosis*, and *Corynebacterium amycolatum* were found in varying amounts in the microbial population present in the fermented beverage *cauim* produced by Brazilian Amerindians (Almeida et al. 2007). This beverage is produced with the substrates cassava, rice, corn, maize, and peanuts, and it is the main staple food for infants until the age of 2.

13 The Family *Cryptosporangiaceae*

Tomohiko Tamura
Biological Resource Center (NBRC), National Institute of Technology and Evaluation (NITE), Kisarazu-shi, Chiba, Japan

Abstract

Cryptosporangiaceae is a family within the order "*Frankiales*," which includes the genera *Cryptosporangium* and *Fodinicola*. Members of this family are characterized by formation of aerial and substrate hyphae, *meso*-A_2pm as a cell-wall diamino acid, iso-$C_{16:0}$ as the major cellular fatty acid, phosphatidylethanolamine as a diagnostic polar lipid, and MK-9(H_4), MK-9(H_6), and MK-9(H_8) as major isoprenoid quinones. However, regardless of the reliability of algorithms used to analyze 16S rRNA gene sequences for type strains of *Cryptosporangium* and *Fodinicola*, the position of the genus *Fodinicola* must be considered tentative. Members of this family are found in soil, on rocks, and in leaf litter.

Taxonomy: Historical and Current

Short Description of the Families

The family description is based mainly on phylogenetic positions and patterns of 16S rRNA gene sequence signatures. However, the family *Cryptosporangiaceae* exhibits some diagnostic phenotypic characteristics differing from each other and from four neighboring families of the order "*Frankiales*" (◉ *Table 13.1*).

Cryptosporangiaceae Zhi, Li, and Stackebrandt 2009 596^{VP}

Cryp′to.spo.ran.gi.a′ce.ae. N.L. neut. n. *Cryptosporangium*, type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Cryptosporangiaceae*, the *Cryptosporangium* family (Zhi et al. 2009).

Phylogenetically, a member of the order "*Frankiales*" (Ludwig et al. 2012), phylum Actinobacteria.

The family contains the genera *Cryptosporangium* (Tamura et al. 1998) and *Fodinicola* (Carlsohn et al. 2008). Although most members of the order "*Frankiales*" do not form both substrate and aerial mycelium, members of this family can form both these structures.

Sporangiospores may occur. Motile or nonmotile. Cross-linkage of peptidoglycan is by the A type; diagnostic diamino acids include *meso*-diaminopimelic acid. Each peptidoglycan is directly linked without interpeptide bridges, and the muramic acid in peptidoglycan is N-acetylated. While methyl 14-methylpentadecanoate (iso-$C_{16:0}$) is the prominent fatty acid, $C_{17:1}$, 10-methyl $C_{17:0}$, and $C_{18:1}$ may also be present. Menaquinones MK-9(H_6), MK-9(H_4), and MK-9(H_8) are the predominant isoprenoid quinones, and MK-9(H_2) may also be present. The pattern of 16S rRNA signatures consists of nucleotides at positions 66:104 (G-C), 158:163 (G-C), 186:191 (G-C), 195 (U), 196 (C), 293:304 (G-C), 600:638 (G-C), 601:637 (A-U), 841 (U), 952:1229 (C-G), 986:1219 (A-U), 1042 (U), 1251 (G), and 1003:1037 (A-C). Predominant polar lipids include phosphatidylethanolamine, phosphatidylglycerol, phosphatidylserine, phosphatidylinositol, and several phospholipids and glycolipids. Mycolic acids and teichoic acids are absent. Xylose, as a diagnostic whole-cell sugar, is present, and acofriose (3-*O* methyl rhamnose), as a whole-cell sugar, may also be present. G+C values are in the DNA range between 65 and 76 mol%. Members of the genus *Cryptosporangium* have been isolated from soil and cultivated soil, and members of the genus *Fodinicola* have been isolated from rocks from a medieval alum slate mine. Both the genera *Cryptosporangium* and *Fodinicola* are affiliated with the suborder *Frankineae*, but not affiliated with any family according to the original report (Tamura et al. 1998; Carlsohn et al. 2008). The family *Cryptosporangiaceae* was proposed by Zhi et al. (2009);

the genera *Cryptosporangium* and *Fodinicola* are assigned to this family. Diagnostic properties of the genera *Cryptosporangium* and *Fodinicola* are shown in *Table 13.2*.

Phylogenetic Structure of the Family and Its Genera

The family *Cryptosporangiaceae* currently includes two genera, *Cryptosporangium* and *Fodinicola*. Phylogenetic trees constructed using both neighbor-joining and maximum-likelihood methods indicate that members of the genus *Cryptosporangium* form a coherent clade, but that the genera *Cryptosporangium* and *Fodinicola* do not form a coherent clade (*Fig. 13.1a, b*). Carlsohn et al. (2008) reported *Fodinicola* has a phylogenetically deep branching point within the family of the suborder *Frankineae*, similar values were observed with respect to type strains of both *Cryptosporangium* and *Sporichthya* (92.9–94.8 % and 93.9–94.5 %, respectively), and members of the genera *Frankia* and *Acidothermus* are slightly less closely related to *Fodinicola feengrottensis* (92.5–93.0 %) than members of the genus *Cryptosporangium*. The genus *Fodinicola* was not proposed to be affiliated with any families in the original paper. However, Zhi et al. (2009) updated the 16S rRNA gene sequence-based definition for higher ranks of the class *Actinobacteria* and proposed the novel family *Cryptosporangiaceae*. The genus *Fodinicola* was not assigned to any families in this paper. Ludwig et al. (2012) proposed that the monospecific genus *Fodinicola* (type species *Fodinicola feengrottensis*) is tentatively classified in the family *Cryptosporangiaceae* as a genus incertae sedis based upon similarities in 16S rRNA gene sequence. Depending on the algorithm used to construct the phylogenetic tree, the relationship between the genera *Cryptosporangium* and *Fodinicola* may change. A number of *Fodinicola* strains should be analyzed to determine phylogenetic position.

Molecular Analyses

DNA-DNA Hybridization Studies

DNA-DNA hybridization (DDH) studies have been performed on all *Cryptosporangium* type strains. DDH relatedness has been reported between the type strains of *Cryptosporangium mongoliense* and the other four type strains of the genus (5–20 %; Ara et al. 2012); between *Cryptosporangium minutisporangium* and the other three type strains without *Cryptosporangium mongoliense* (14–22 %; Tamura and Hatano 2001); between *C. aurantiacum* and the other three type strains without *Cryptosporangium mongoliense* (15–21 %; Tamura and Hatano 2001); and between *Cryptosporangium arvum* and *Cryptosporangium japonicum* (38–44 %; Tamura et al. 1998). Although *Cryptosporangium* sp. YU655-31 and *Cryptosporangium* sp. YU656-31 showed 40–57 % DDH relatedness to *Cryptosporangium arvum* and *Cryptosporangium japonicum*, strains YU655-31 and YU656-31 showed diagnostic differences in phenotypic characteristics from the type species of *Cryptosporangium arvum* and *Cryptosporangium japonicum*. Therefore, the strains YU655-31 and YU656-31 are not assigned as species.

Genome Analyses

The incomplete genome sequence of the type strain of *Cryptosporangium arvum* DSM 44712^T = YU 629-21^T (GOLD ID Gi02260) has been released and the genome sequencing of the type strain of *Cryptosporangium japonicum* DSM 44713^T (GOLD ID Gi11347) is underway. The genome of the type strain of *Cryptosporangium arvum* contains 9,195,993 bp, 8,650 open reading frames (orfs), and a mol% G+C content of 72 %.

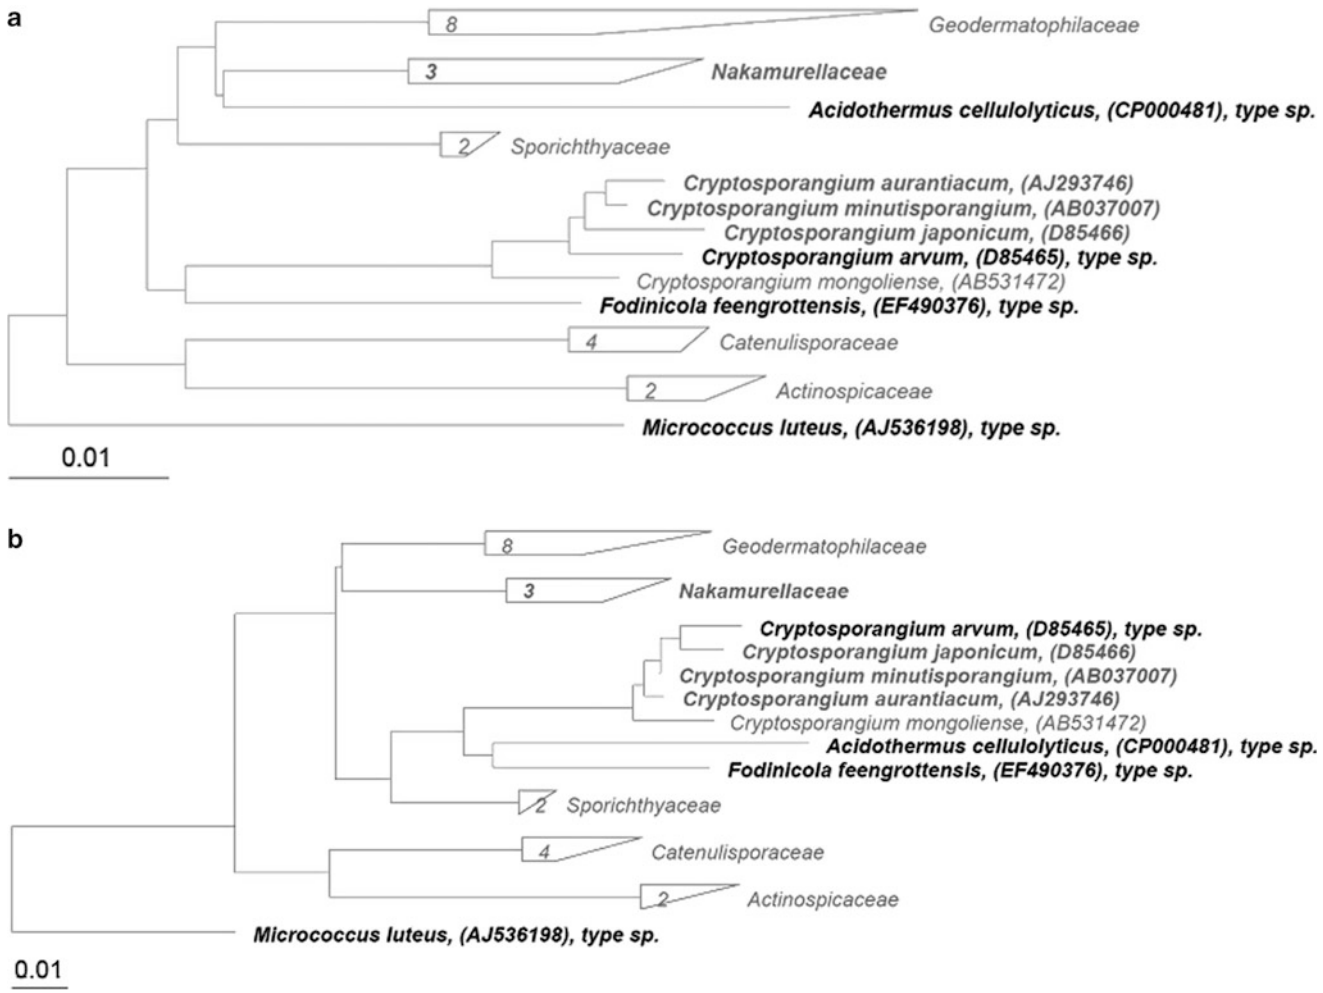

Fig. 13.1

Phylogenetic reconstruction of the family *Cryptosporangiaceae* based on 16S rRNA. Tree (a) created using the neighbor-joining algorithm with the Jukes-Cantor correction, the tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. Tree (b) created using the maximum-likelihood algorithm RaxML (Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as outgroups. In addition, on both trees, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Phages

No phages have been observed to lyze strains of *Cryptosporangium* and *Fodinicola*.

Phenotypic Analyses

Cryptosporangium Tamura Hayakawa and Hatano 1998, 1003[VP]

Cryp'to. spo .ran'gi.um. Gr. adj. *kruptos*, hidden; N.L. n. *sporangium* [from Gr. n. *spora*, a seed (and in biology a spore), and Gr. n. *angeion* (Latin transliteration *angium*), vessel], sporangium; N.L. neut. n. *Cryptosporangium*, an organism with sporangia (spore containing vessels) covered or hidden by mycelium.

Cryptosporangium strains form branching hyphae. Non-fragmentary substrate mycelia and aerial mycelia are present. These organisms develop round or irregularly shaped sporangia that are 3–10 μm in diameter. Light microscopy has shown that their features resemble those of *Actinoplanes* strains. *Cryptosporangium aurantiacum* and *Cryptosporangium minutisporangium* were originally reported as "*Actinoplanes aurantiacus*" (Ruan et al. 1976) and *Actinoplanes minutisporangius* (Ruan et al. 1986), respectively. The muramic acid in peptidoglycan allows differentiation between the genera *Cryptosporangium* (acetyl) and *Actinoplanes* (glycolyl).

[a]Data from Ara et al. (2012), Tamura et al. (1998), Tamura and Hatano (2001)
+ present, − absent, *ND* no data available

Some sporangia, particularly on the central region of the colony, are submerged under thick mycelia. Sporangiospores are motile when they are suspended in water.

Good growth occurs at 20–25 °C. The organism shows good growth on yeast extract-malt extract agar, Bennett's agar, and yeast extract-starch agar. Generally, the vegetative mycelia are yellow to orange and the aerial mycelia are white. Different cultural features and physiological characteristics between type strains of the genus *Cryptosporangium* are shown in *Tables 13.3* and *13.4*, respectively.

The cell walls contain glutamic acid, glycine, alanine, and *meso*-diaminopimelic acid. Wall chemotype is II according to

Data from Ara et al. (2012), Tamura et al. (1998), Tamura and Hatano (2001)

+ present. – absent, *w* weakly positive, *ND* no data available

Lechevalier and Lechevalier (1970), and the peptidoglycan type is thought to be A1γ according to Schleifer and Kandler (1972). Glucose and acofriose are detected as whole-cell sugars. The major fatty acids $C_{17:1}$, $C_{18:1}$, and iso-$C_{16:0}$ are present. The major menaquinones include MK-9(H_6), MK-9(H_4), and 9(H_8). Phosphatidylethanolamine is present as the diagnostic phospholipids (phospholipid pattern type PII).

The mol% G + C content is 56–58 %.

The type species is *Cryptosporangium arvum* (Tamura et al. 1998). The type strain is YU629-21 = DSM 44712 = HUT 6619 = JCM 10424 = NBRC 15965 = NCIMB 13630.

Actinoplanes minutisporangius (Ruan et al. 1986) is a synonym of *Cryptosporangium minutisporangium* (Tamura and Hatano 2001). "*Actinoplanes aurantiacus*" (Ruan et al. 1976) is a synonym of *Cryptosporangium aurantiacum* (Tamura and Hatano 2001).

Fodinicola Carlsohn Groth Saluz Schumann and Stackebrandt 2008, 1534[VP]

Fo.di.ni'co.la. L. n. *fodina*, a pit, mine; L. suff. *-cola* (from L. n. *incola*), dweller; N.L. masc. n. *Fodinicola*, a mine dweller.

Fodinicola strains form branched substrate mycelium and have sparse to abundant white aerial mycelium. Aerial hyphae break up into irregular rod-like elements. Phenotypic characteristics of the genus *Fodinicola* are shown in Table 13.5. Cell-wall sugars include xylose and minor amounts of an unknown compound. The predominant menaquinones include MK-9(H_4), MK-9(H_6), and MK-9(H_8). Polar lipids comprise diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, and several unknown phospholipids and glycolipids, together with unknown ninhydrin-positive compounds. The cellular fatty acid profile is characterized by the predominance of iso-$C_{16:0}$, 10-methyl $C_{17:0}$, $C_{17:1}$ cis9, 10-methyl iso-$C_{18:0}$, and $C_{17:0}$.

The mol% G + C content of the type strain of the type species is 65 %.

The type species is *Fodinicola feengrottensis* Carlsohn et al. 2008. Type strain is HKI 0501 = DSM 19247 = JCM 14718.

"*Speleomyces feengrottensis*" is a synonym of *Fodinicola feengrottensis*.

Isolation, Enrichment, and Maintenance Procedures

Cryptosporangium arvum and *Cryptosporangium japonicum* were isolated from soil samples collected from a vegetable field in Kofu, Yamanashi Prefecture, Japan, and from a sugar cane field on Miyako Island, Okinawa Prefecture, Japan, respectively (Tamura et al. 1998). The capillary method (Hayakawa et al. 1991) was used to isolate both strains. An air-dried soil sample (0.5 g) was placed in each of the cylindrical wells of a Lucite plate and sterile distilled water was then carefully added to the wells and connecting channel until they were full. After incubating the plate for 1 h at 30 °C, a 1-μL capillary filled with chemotaxis buffer containing vanillin as attractant was set in the Lucite plate. After incubating the plate for 1 h at 30 °C, solution in the capillary was serially diluted and spread onto humic acid/vitamin (HV) agar (Hayakawa and Nonomura 1987) containing 1.0 g/L humic acid, 0.02 g/L $CaCO_3$, 0.01 g/L $FeSO_4.7H_2O$, 1.71 g/L KCl, 0.05 g/L $MgSO_4.7H_2O$, 0.5 g/L Na_2HPO_4, 5 ml/L B-vitamin solution, 50 mg/L cycloheximide, and 18.0 g/L agar (pH 7.2). The B-vitamin solution contained 0.1 mg/mL each of thiamin-HCl, riboflavin, niacin, pyridoxin-HCl, inositol, Ca-pantothenate and *ρ*-aminobenzoic acid, and 0.05 mg/mL biotin. Agar plates were incubated at 28 °C for approximately 3 weeks. Subcultivation of the isolate was conducted in yeast extract-malt

extract agar (ISP 2 medium: Shirling and Gottlieb 1966) containing 4 g/L yeast extract, 10 g/L malt extract, 4 g/L glucose, and 20 g/l agar (pH 7.3), and yeast extract-soluble starch (YS) agar containing 2 g/L yeast extract, 10 g/L soluble starch, and 15 g agar (pH 7.3).

Cryptosporangium minutisporangium (Ruan et al. 1986; Tamura and Hatano 2001), the original name of which was *Actinoplanes minutisporangius*, was isolated from a soil sample from China (Ruan et al. 1986).

Cryptosporangium aurantiacum (Tamura and Hatano 2001), the original name of which was "*Actinoplanes aurantiacus*," was isolated from a soil sample and lake mud, collected near Bi Yun-Shi, Beijing, China (Ruan et al. 1976).

Cryptosporangium mongoliense (Ara et al. 2012) was isolated from a soil sample, collected from close to Khuvsgul Lake, Khuvsgul Province, Mongolia, using the rehydration and centrifugation (RC) method (Hayakawa et al. 2000) using HV agar supplemented with 20 mg/L trimethoprim and 10 mg/L nalidixic acid at 28 °C. Subcultivation was conducted on YS agar and maltose-Bennett's agar containing 1 g/L yeast extract, 1 g/L beef extract, 2 g/L NZ amine type A, 10 g/L maltose monohydrate, and 15 g/L agar (pH 7.3) at 28 °C for 3 weeks.

Hayakawa et al. (2010) reported that *Cryptosporangium* strains were isolated from soil samples collected from Iriomote Island, Okinawa, Japan. Additionally, Hop et al. (2011) reported that actinomycetes belonging to the genus *Cryptosporangium* were frequently isolated from leaf-litter samples collected from various locations in Vietnam, using the RC method and HV agar supplemented with nalidixic acid (20 mg/L), cycloheximide (50 mg/L), and kabicidin (20 mg/L).

Fodinicola feengrottensis (Carlsohn et al. 2008) was isolated from acidic and heavy metal-containing rocks collected in the "Barbara Grotto" of the Feengrotten medieval alum slate mine in Saalfeld, Thuringia, Germany. Material from the rock surface was scraped off using a sterile cotton swab and the adhering bacteria were dispersed in approximately 1-mL sterile distilled water. Aliquots of the resultant suspension were spread over starch-casein agar plates (Küster and Williams 1964) supplemented with cycloheximide (50 μg/mL). Agar plates were incubated at 28 °C for approximately 4 weeks. Subcultivation of the isolate was conducted on solidified organic medium 79 (Prauser and Falta 1968) containing 10.0 g/L dextrose, 10.0 g/L peptone, 2.0 g/L casein peptone, 2.0 g/L yeast extract, 6.0 g/L NaCl, 15.0 g/L agar (pH 7.8), and ISP 2 medium.

Members of the family *Cryptosporangiaceae* grow in complex liquid or on solidified media, such as ISP-2 medium, Bennett's agar containing 1 g/L yeast extract, 1 g/L beef extract, 2 g/L NZ amine, 10 g/L glucose, and 20 g/L agar (pH 7.3), YS agar and yeast extract-glucose broth containing 10 g/L yeast extract, and 10 g/L glucose. Members of these families do not require special procedures for maintenance or preservation. Cultures can be maintained by serial transfers onto the appropriate solid media. Growth on agar slants can be maintained at 4 °C for over 1 month. Medium-term preservation is in 12–15 % (v/v) glycerol suspensions at −80 °C. Long-term preservation of liquid cultures supplemented with 12–15 % (v/v) glycerol or 7 % (v/v) dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−150 °C). Freeze drying and L-drying methods can be also applied for long-term storage.

Ecology

Members of the family *Cryptosporangiaceae* were isolated from soils of vegetable fields, lake muds, acidic and heavy metal-containing rocks, and leaf litter. However, ecological information is insufficient since most known species are type strains. The following strains have been registered the 16S rRNA gene sequence to GenBank as *Cryptosporangium* strains: *Cryptosporangium* sp. LW-09 (AB607852) was isolated from Vietnam (Hop et al. 2011); *Cryptosporangium* sp. HBUM171259 (EU119260) and HBUM83975 (EU119259) were isolated from soil at China; *Cryptosporangium* sp. YIM 75710 (FJ911536) was isolated from Whitestone Quarry at Betamcherla, Kurnool, Andhra Pradesh, India; and *Cryptosporangium* sp. RS-53 (FM998040) was isolated from a rhizosphere soil of a plant *Peucedanum japonicum* Thunb. In addition, uncultured bacterium clone ncd393a10c1 (HM322140) having 98–99 % of similarities to validly published *Cryptosporangium* species by BLAST search was collected by swab from skin on antecubital fossa (Kong et al. 2012). *Fodinicola* sp. HKI 0511 (EU232177) having 99 % of similarity to *Fodinicola feengrottensis* was isolated from a medieval mine. Further studies are required to elucidate the ecological niche and function of members of the family.

Pathogenicity and Clinical Relevance

Pathogenicity has not been reported for any members of the family *Cryptosporangiaceae*.

Fodinicola feengrottensis cells are susceptible to chloramphenicol (30), ciprofloxacin (5), imipenem (10), kanamycin sulfate (30), norfloxacin (10), novobiocin (5), oxytetracycline hydrochloride (30), streptomycin sulfate (10), sulfonamide (200), and vancomycin hydrochloride (30). They are not susceptible to ampicillin (10), lincomycin hydrochloride (2), meticillin (5), nalidixic acid (30), penicillin G (10 IU), polymyxin B (300 IU), and rifampicin (30).

No information regarding antibiotic sensitivity and resistance is available for members of the genus *Cryptosporangium*.

Application

There have been several reports regarding the special use of members of the family *Cryptosporangiaceae*.

14 The Family *Dermabacteraceae*

Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The family *Dermabacteraceae* is a phylogenetically and chemotaxonomically well defined taxon within the order *Micrococcales*, consisting at present of 4 genera and 17 species, with the majority of species described in *Brachybacterium*. *Dermabacter*, *Helcobacillus*, and *Devriesea* are monospecific. Cell morphology is rod shaped in young growth stage, forming coccoid to ovoid cells in older growth phases. Cells are nonmotile, lack mycolic acid, and do not form endospores. Strains are aerobic to facultative anaerobic. Members have a peptidoglycan type A4γ, major fatty acids are ai-$C_{17:0}$ and ai-$C_{15:0}$, predominant menaquinones (except for *Helcobacillus massiliensis*) are MK 7, MK8, or MK9 and major phospholipids are phosphatidylglycerol and diphosphatidylglycerol. The range of habitats from which the type strains were isolated is broad. Species include commensals of human and lizard's skin with the potential to be opportunistic pathogens, marine strains associated to invertebrates, strains isolated from milk and milk products, and soil organisms that are able to thrive in various conditions. One strain is able to fix nitrogen non-symbiotically. DNA-based studies reveal that, except for brachybacteria, members of the family are rare in actinomycetes 16S rRNA clone libraries.

Taxonomy: Historical and Current

The origin of the type genus of the family, *Dermabacter*, goes back to the Jones and Collins (1988) who investigated Gram-positive, asporogenous, and rod-shaped bacteria isolated from human skin. With the advent of chemotaxonomic methods the status of these "coryneform" organisms were elucidated, resulting in the delineation of the genus *Dermabacter* from other meso-diaminopimelic acid (A_2pm) containing taxa, such as *Corynebacterium*, *Caseobacter*, and *Brevibacterium*. In the same year, Collins et al (1988) described Schefferle strain 6-10^T (Schefferle 1966) from poultry deep litter as *Brachybacterium faecium* with similar chemotaxonomic properties than *Dermabacter* but without giving reference to this taxon. The first fragmentary 16S rRNA gene sequences of *Brachybacterium faecium* strains from clinical origin (CDC group 3 and 5) were published by Funke et al. (1994) and by Cai and Collins (1994) for a comparative analysis between *Dermabacter* and *Brevibacterium*. The first indication that *Dermabacter* and *Brachybacterium* are actually phylogenetic neighbors was published by Schubert et al. (1996) in their description of two novel *Brachybacterium* species from cheese surfaces.

Phylogenetic Structure of the Family and Its Genera

Dermabacteraceae Stackebrandt, Rainey, and Ward-Rainey 1997, 485^{VP}, emend Zhi et al. 2009.

Der.ma.bac.te.ra'ce.ae. M.L. masc. n. *Dermabacter*, type genus of the family; *-aceae*, ending to denote a family; M.L. fern. pl. n. *Dermabacteraceae*, the *Dermabacter* family.

The family *Dermabacteraceae* was described by Stackebrandt et al. (1997) on the basis of the isolated position of the16S rRNA gene sequences of type strains in the phylogenetic dendrogram of actinobacteria available at that time and by a set of signature nucleotides which was revised by Zhi et al. (2009). This set of signatures are (position : composition) 120 : A; 131-231 : C-G; 196 : U; 342-347 : C-G; 444-490 : A-U; 580-761 : U-A; 602-636 : C-G; 670-736 : A-U; 822-878 : G-C; 823-877 : G-C; 826-874 : C-G; 827: U; 843 : C; 950-1231 : U-G; 1047-1210 : G-C; 1109 : C; 1145 : G; 1309-1328 : G-U; 1361 ; G; 1383 : C. The signature information was not used to affiliate newly described genera to the family, i.e., *Devriesea* (Martel et al. 2008) and *Helcobacillus* (Renvoise et al. 2009), and deviations from the published set may have occurred.

The family presently comprises three monospecific genera and *Brachybacterium* with presently 14 species and the family

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_170,

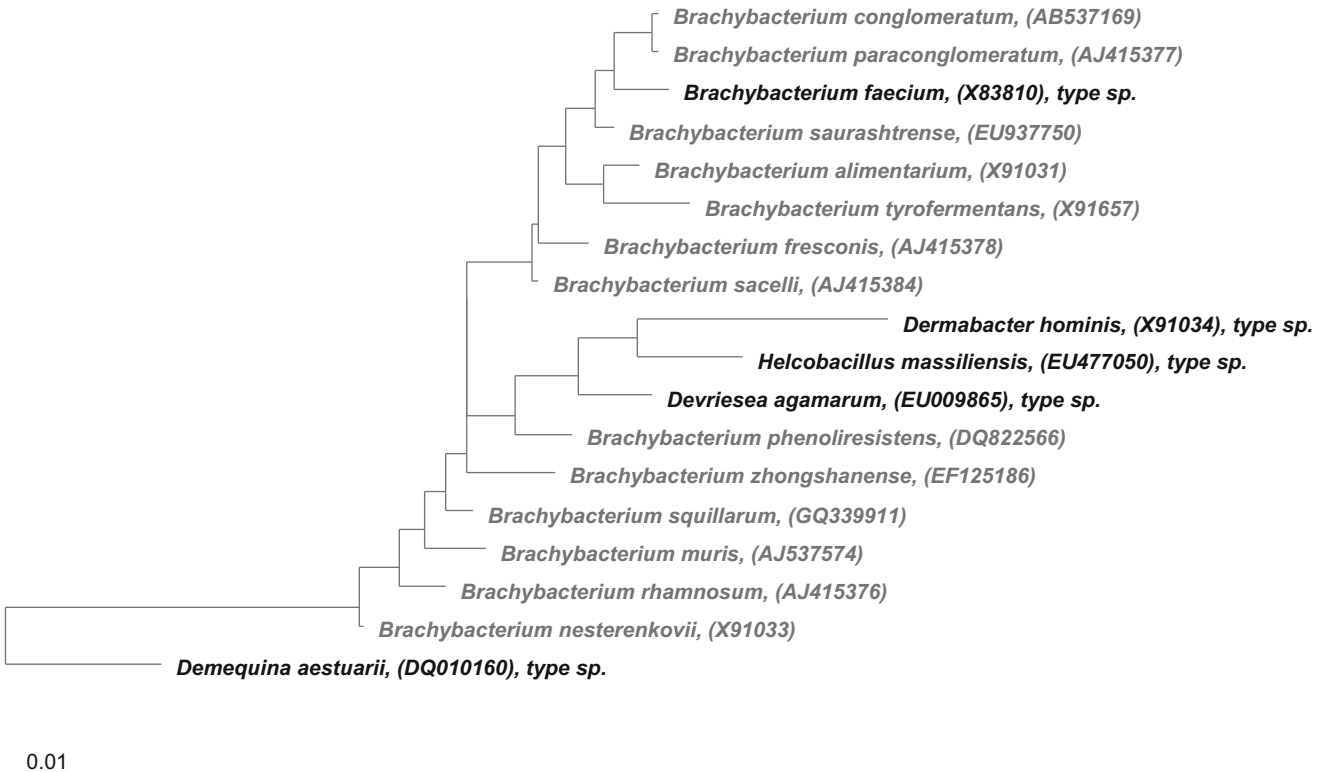

Fig. 14.1
Maximum-likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the family *Dermabacteraceae* present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences. The type strains of *Brachybacterium* used for dendrogram construction are indicated in the heading of *Table 14.2*. Those for the other type strains are: *Devriesea agamarum* IMP2^T, *Dermabacter hominis* DSM 7083^T, *Helcobacillus massiliensis* strain 6401990^T. The *bar* indicates 1 % sequence divergence

appears to be a sister clade of the family of *Jonesiaceae* (Ludwig et al. 2012) within the order *Micrococcales*.

The family *Dermabacteraceae* is well defined by molecular criteria: All genera form a phylogenetic tight cluster irrespective of the algorithms used for treeing calculation (*Fig. 14.1*), with lower 16S rRNA gene similarity values around 95–96 %. The species-rich genus *Brachybacterium* sees several smaller subbranches, but only a few of these clusters are supported by higher than 70 % bootstrap values. The largest of these is defined by *B. faecium*, *B. conglomeratum*, *B. paraconglomeratum*, and the recently described *B. saurashtrense* (Gontia et al. 2011), another one by *B. nesterenkovii*, *B. muris*, *B. squillarum*, and *B. rhamnosum* (although with low bootstrap values; Park et al. 2011a), while the other type strain sequences change their position within the genus limits. While the neighbor-joining tree (not shown), groups all species of *Brachybacterium* in a coherent cluster, the maximum-likelihood tree separates this genus by the lineage containing *Devriesea*, *Helcobacillus* and *Dermabacter* (*Fig. 14.1*).

Morphologically and chemotaxonomically, the genus is also well defined (*Table 14.1*). Cell morphology is often rod shaped in young growth stage, forming coccoid to ovoid cells in older growth phases. V-form arrangement of cells may occur. Cells are nonmotile, lack mycolic acid, and do not form endospores. Strains are aerobic to facultative anaerobic. If investigated, members have a peptidoglycan type (A4γ, according to Schleifer and Kandler 1972), defined by meso-A_2pm in position 3 of the peptide subunit and either glutamic acid (often substituted by glycine) or aspartic acid (see *Table 14.2* for a more revised typing system of Schumann (2011)). Major fatty acids are ai-$C_{17:0}$ and ai-$C_{15:0}$ (ai, anteiso) with variations in some iso-branched and straight chain fatty acids. Except for *Helcobacillus massiliensis*, in which menaquinones could not be detected, the predominant menaquinones are full unsaturated, mainly MK 7, MK8, or MK9. Major phospholipids are phosphatidylglycerol and diphosphatidylglycerol (phosphoethanolamine may occur) as well as unidentified other components (e.g., glycolipids, phospholipids, and other rare lipids). *Dermabacter* and *Devriesea* have a lower DNA G+C content of about 61–63 mol% than *Helcobacillus* and *Brachybacterium* (68–73 mol%). In contrast to the coherent chemotaxonomic properties, the habitat of the organisms enclosed in the family varies widely (see below and *Table 14.2*)

Table 14.1

Molecular Analyses

DNA-DNA Hybridization Studies

Extensive DNA-DNA hybridization studies (DDH) have been performed on strains of individual species as well as among species as the phylogenetic relationships are often around 98 % (*Table 14.2*). A large variety of different hybridization formats were used and data are not always comparable. Nevertheless, the genospecies circumscription definition of Wayne et al. (1987) of about 70 % DDH similarity and the recommendation of Stackebrandt and Goebel (1994) to perform DDH analysis at 16S rRNA gene similarities above 97 % were followed.

The membership of several CDC groups 3 and 5 strains, many of which originated from blood samples, to the species *Dermabacter hominis* (Gruner et al. 1994), was evaluated by the hydroxyapatite method (Brenner et al. 1982) and the affiliation was supported by chemotaxonomic evidence (Funke et al. 1994). For the affiliation of milk strains to the species *B. nesterenkovii* (Gvozdyak et al. 1992), the membrane-filter method was used (Meyer and Schleifer 1978), Schubert et al. (1996) used the nick-translation method (Kelly et al. 1970) to compare novel *Brachybacterium* type strains from cheese surface with other type strains of the genus, the renaturation method of De Ley et al. (1970) was used to differentiate *B. zhongshanense* (Zhang et al. 2007) and *B. saurashtrense* (Gontia et al. 2011) from other *Brachybacterium* type strains, while Park et al. (2011a) used Cy5-labeled DNA probes in a genome-spotted microarray format (Bae et al. 2005) for defining *B. squillarum*. The fluorimetric method of Ezaki et al. (1989) was used in a number of investigations, e.g., *B. conglomeratum, B. paraconglomeratum* and *B. rhamnosum* (Takeuchi et al. 1995), *Brachybacterium* strains from medieval wall paintings (Heyrman et al. 2002), and *B. phenoliresistens* (Chou et al. 2007).

Other Methods

In addition to biochemical profiling (all studies), DDH, and serological investigation (Gvozdyak et al. 1992), a few studies included other molecular methods to display the degree of variations among strains. REP PCR fingerprinting was used to demonstrate the genomic homogeneity among isolates from wall paintings (Heyrman et al. 2002) and despite small differences in these patterns, the authors decided on the basis of highly similar 16S rRNA sequences and high DDH similarities to combine strains with different REP-PCR patterns into the same species. The same method, as well as SDS page electrophoresis, was used by Buczolits et al. (2003) to show the distinctness of *B. muris* DSM 15640^T versus *B. sacelli* DSM 14566^T; *B. nesterenkovii* CCM 2432; *B. rhamnosum* DSM 10240^T; *B. alimentarium* CCM 4520^T; and *B. fresconis* DSM 14564^T. Insertion-sequence PCR fingerprint patterns were generated to discriminate *B. zhongshanense* JB^T, *B. muris* DSM 15640T, and *B. nesterenkovii* LMG 19549^T (Zhang et al. 2007).

Genome Comparison

Two genome sequences of the family have been published recently: one complete sequence of *Brachybacterium faecium* DSM 4810^T (Lapidus et al. 2009, accession number CP001643), a draft genome sequence of *B. squillarum* M-6-3^T (Park et al. 2011b, and shotgun fragments AGBX01000001-AGBX01000008). The genomes differ in several aspects, especially *B. squillarum* lacks annotated genes for defense mechanisms (*B. faecium*: 53), intracellular trafficking and secretion (*B. faecium*: 25), and RNA processing and modification (*B. faecium*: 1). *Table 14.3* gives a comparison of features of the two sequences available, a more complete analysis for *B. faecium* DSM 4810^T has been published (Lapidus et al. 2009).

Table 14.3
Comparison of some features of the genomes of the type strains of *Brachybacterium faecium* and *B. squillarum*

Properties	*B. faecium* DSM 4810^T closed	*B. squillarum* M-6-3^T draft genome

[b]Park et al. (2011a), real-time PCR method

Phenotypic Analyses

Table 14.1 lists the main features of family specific features. The differentiating properties of the species are listed in *Tables 14.1* and *14.4* and only additional salient characteristics will be indicated in the text below. A comparative study suffers from the lack of a coherent set of data evaluated for all type strains. Morphological and cultural properties, as well as other results of commercial test system characterization, are listed in the original species descriptions. Most strains are catalase-positive and all strains are oxidase-negative. If investigated, acid is produced from glucose, maltose, and sucrose (not the type strain of *B. faecium* NCIB 9860^T) but not from adonitol, dulcitol, gluconate, glycogen, inulin, L-arabitol, rhamnose, sorbitol, tatgatose, and xylitol, though some strains can oxidize these compounds. Some diverging properties are recorded in the literature when reactions of previously described type strains were repeated in the characterization of novel type strains.

Brachybacterium Collins et al. 1988, 46^{VP}

Bra.chy.bac.te'ri.um. Gr. adj. *brachy* short; L. neut. dim. n. *bacterium* rod; M.L. neut. n. *Brachybacterium* a small rodlet.

Strains of the type species *Brachybacterium faecium* were originally labeled *Corynebacterium* ssp. and *Arthrobacter* spp, but when included in a numerical taxonomic study (Jones 1975) they grouped with *Listeria monocytogenes*. It was not until a comparative chemotaxonomic study (Collins et al. 1988), including a wide range of coryneform taxa, that the uniqueness of three of the Schefferle strains became apparent which were subsequently described as *Brachybacterium faecium* gen. nov., sp. nov. (Collins et al. 1988). Since then, a large number of new species, well defined by DNA-DNA similarity studies and other molecular methods, as well as by metabolic

Table 14.4

Phenotypic properties distinguishing type strains of *Brachybacterium* type strains. The type strain numbers are as follows: *1 B. faecium* DSM 48100^T, *2 B. paraconglomaratum* LMG 19861^T, *3 B. conglomeratum* JCM 11608^T, *4 B. saurashtrense* JG 06^T, *5 B. fresconis* LMG 20336^T, *6 B. tyrofermentans* CNRZ 926^T, *7 B. alimentarium* CNRZ 925^T, *8 B. sacelli* LMG 20345^T, *9 B. zhongshanense* JB^T, *10 B. nesterenkovii* DSM9573^T, *11 B. rhamnosum* LMG19848^T, *12 B. muris* C3H-21^T, *13 B. squillarum* M-6-3^T, *14* B. *phenoliresistens* phenol-A^T. Data compiled from the respective species descriptions and comparative studies therein. Deviations in recorded results are indicated by a *hyphen*. The value left of the hyphen refers to the original record. All strains contain ai-$C_{15:0}$ as major fatty acids and, if investigated, diphosphatidylglycerol and phosphatidylglycerol as major polar lipids

Abbreviations: += positive, – negative, + weak, *v* variable, *nd* not determined

[a]*C* coccoid, *O to SR* ovoid to short rods, *CSR* club-shaped rods

[b]*A* aerobic, *F* facultative anaerobic, *M* microaerophilic

[c]All types refer to A4γ according to Schleifer and Kandler (1972). A more discriminating type system has been published by Schumann (2011), A31.1 (*meso*-Dpm-D-$Glu_{2)}$, A31.2 (*meso*-Dpm-D-Glu_2; α-carboxyl group of D-Glu substituted by Gly), A31.3 (*meso*-Dpm-D-Asp-D-Glu; α-carboxyl group of D-Glu substituted by Gly). See also www. peptidoglycan-types.info

[d]*MGDG* monogalactosyl diglyceride, *PGL* ninhydrin-positive phosphoglycolipid, *upL* unidentified polar lipid, *iGl* unidentified glycolipid, *uPL* unidentified phospholipid

properties, have been described, extending the range of phenotypic and habitat diversity. These are in the order of their description:

B. nesterenkovii strains, isolated from milk products (Gvozdyak et al. 1992), contain large amount of galactose, glucose, and rhamnose on their cells. The presence of rhamnose and the absence of glycine in the peptidoglycan differentiate *B. nesterenkovii* from *B. faecium* and certain other *Brachybacterium* strains (Table 14.4).

The species *B. conglomeratum, B. paraconglomeratum*, and *B. rhamnosum* were described by Takeuchi (1995). All strains contain galactose and glucose and only *B. rhamnosum* contains large amounts of rhamnose in its cell wall. The latter species can be distinguished, among other properties, from *B. nesterenkovii* by a different peptidoglycan composition.

Schubert et al. (1996) described two species from the surface of French cheese, *B. alimentarium* and *B. tyrofermentans*. These two species contain aspartic acid in the peptide subunit of their peptidoglycan (as also seen in *B. phenoliresistens*) and contain an erthrytol teichoic acid that contains the rare component diaminoglucuronic acid as a substituent. However, except for *B. faecium* (Schubert et al. 1996), teichoic acids have not been looked for in other *Brachybacterium* strains. Galactose, galactose and glucose are found as cell wall sugars in *B. tyrofermentans*. The two cheese-derived species differ in the relative proportion of the menaquinones MK-7 and MK-8.

Two novel *Brachybacterium* species, *B. fresconis* and *B. sacelli* (Heyrman et al. 2002), each comprising several strains, were isolated from medieval wall paintings. In contrast to other species of the genus, the polyamine pattern was determined for *B. muris* (Buczolits et al. 2003) as well as for *B. faecium* CCM 4372^T. Like in other members of *Propionibacteriaceae*, it consisted mainly of spermine and spermidine (Busse and Schumann 1999) and minor amounts of putrescine, but brachybacteria can be easily distinguished from propionibacteria on the basis of menaquinone and peptidoglycan composition.

The cellulolytic species *B. zhongshanense* (Zhang et al. 2007), *B. phenoliresistens* (Chou et al. 2007), and *B. squillarum* (Park et al. 2011a) do not display specific features except for *B. squillarum* that was tested as being catalase-negative. The species *B. saurashtrense* (Gontia et al. 2011) is the only species for which nitrogen fixation has been reported. It grows in nitrogen-free medium, produces indol-3-acetic acid and siderophores, and utilizes 1-aminocyclopropane1-carboxylate (ACC) as the sole source of nitrogen and possesses ACC deaminase enzymes. On NFb semisolid medium and on nutrient broth medium, growth was observed at NaCl concentrations of 4% and 15% (w/v), respectively. The type strain possesses monogalactosyl diglyceride as polar lipids, not found in other (Table 14.4).

Dermabacter Jones and Collins 1988, 54^{VL}, Validation List N^o. 28

Der.ma.bac'ter. Gr.n. *derma* skin; M.L. masc.n. *bacter* the masculine equivalent of the Gr.neut.n. *bactrum* a rod.

Strains of *D. hominis* are part of the healthy skin flora of humans but can act as opportunistic pathogens as well, see below and Funke et al. (1994); Gruner et al. (1994). Strains resemble members of *Corynebacterium* and *Brevibacterium* but can be distinguished chemotaxonomically from these by the lack of mycolic acids and dehydrogenated menaquinones, respectively.

Helcobacillus Renvoise et al. 2009, 2349^{VP}

Hel.co.ba.cil'lus. Gr. n. *helkos*, wound; L. masc. n. *bacillus*, rod; N.L. masc. n. *Helcobacillus*, a rod found in wounds.

Chemotaxonomically, *H. massiliensis* is defined by the presence of phosphatidylethanolamine and phosphatidylcholine, absent in other members of the family. Whole cell sugars are predominantly galactose and ribose. It grew between 25 °C and 44 °C, as well as under microaerophilic conditions and in the presence of 5 % CO_2. Anaerobic growth was weak. Non-hemolytic after 24 h, but alpha-hemolytic after 48 h. As compared to its closest phylogenetic neighbor, *D. hominis*, it is characterized by a higher mol% DNA G+C content of almost 7 % and a higher amount of ai-$C_{15:0}$ fatty acids.

Devriesea Martel et al. 2008, 2209^{VP}

De'vrie.se.a. N.L. fem. n. *Devriesea* referring to the veterinary microbiologist L. A. Devriese.

This monospecific genus with *D. agamarum* as the type species is inasmuch unique as it comprises isolates which were exclusively found to be involved in skin infections of agamid lizards (see clinical significance). All strains are phenotypically and metabolically almost identical, and they grew well under aerobic, microaerophilic, and anaerobic conditions on Columbia agar with 5 % sheep blood, with colonies surrounded by a narrow zone of hemolysis.

Isolation, Enrichment, and Maintenance Procedures

Considering the wide range of habitats and the number of research groups involved in the isolation procedures, it is not surprising that strains were isolated and maintained by almost as many methods as there are type strains. Most isolates were recovered from serial dilutions, but some strains were obtained from culture collections without reference of the isolation procedure. As indicated by Jones (1975), the type strain of *Brachybacterium faecium* and other "coryneform" organisms grew on neopeptone (Difco), 2–5 g; yeast extract (Difco), 2.5 g; glucose, 2.5 g; Tween 80 I g; agar 15 g; soil extract, 250 ml; and distilled water to a final volume of 1 litre, pH 6.8. The soil extract was prepared by suspending 500 g air-dried garden soil in 1 l of tap water and autoclaving at 120 °C for 15 min. After sedimentation of the larger particles, the hot supernatant was decanted

and clarified by filtration through paper pulp in a Buchner funnel until the soil solution was clear. Clinical isolates of *Dermacoccus hominis* (Funke et al. 1994), *Helcobacillus massiliensis* (Renvoise et al. 2009) as well as *Devriesea agamarum* (Martel et al. 2008) were grown on Columbia agar with 5 % sheep blood with and without a 5 % CO_2 atmosphere, or, for dermacocci, on heart infusion agar with 5 % rabbit blood (Gruner et al. 1994). Strains of *Dermabacter* were also isolated from blood cultures on pre-enriched *Bartonella* growth medium (Cadenas et al. 2007). Chemotaxonomic and metabolic testing of some *Brachybacterium* type strains (Collins et al. 1988; Takeuchi et al. 1995; Schubert et al. 1996; Heyrman et al. 2002) was done with cells grown in tryptone, trypticase soy agar, and peptone-yeast extract medium for 2 days at 28–30 °C, sometimes supplemented with brain heart infusion. Other *Brachybacterium* strains were cultivated on beef extract agar (Gvozdyak et al. 1992), while marine agar was used for the isolation of *B. phenoliresistens* (Chou et al. 2007) *B. squillarum* (Park et al. 2011a) and for the maintenance of strains from medieval wall paintings (Heyrman et al. 2002). *B. muris* was isolated in *Brucella* broth (Buczolits et al. 2003) and grew best in an anaerobic jar on sheep blood agar and in *Brucella* broth supplemented with 8 % fetal bovine serum in an atmosphere of 90 % N_2, 5 % CO_2, 5 % H_2 and residual oxygen. *B. zhongshanense* (Zhang et al. 2007) was recovered from congo red agar medium (gl^{-1}: KH_2PO_4, 0.5; $MgSO_4$ $7H_2O$, 0.25; cellulose powder, 1.88; gelatin, 2.0 and agar, 16; Hendrick et al. 1995) after 7 days at 30 °C. The isolation of *B. saurashtrense* from roots of *Salicornia brachiata* was done on nitrogen-free semisolid NFb medium (Baldani and Döbereiner 1980).

Most strains grow on DSMZ medium 92, i.e., trypticase soy yeast extract medium (gl^{-1}: trypticase soy broth, 30.0; yeast extract 3.0; agar 15.0; pH 7.0–7.2). A few *Brachybacterium* strains require DSM medium 514, i.e., Bacto Marine broth (DIFCO 2216). *Devriesea* can be grown and maintained on DSM medium 215, i.e., brain heart infusion (Difco).

No difficulties in short- or long-term maintenance have been reported and isolates can be stored at 4 °C as 20 % (v/v) glycerol suspensions. Long-term storage includes lyophilization or in straws under N_2 vapor.

Ecology

As mentioned above, members of the family have been isolated from a wide range of habitats but their function and interactions in the environment are hardly known. *Dermacoccus* and *Helcobacillus* seem to be part of the skin flora but can turn into opportunistic pathogens (the case is not clear for *H. massiliensis*); also *Devriesea agamarum is* responsible for dermatitis and septicemia, but the only reports are from lizards. Due to the higher number of species in *Brachybacterium*, the range of habitats is significantly broader, ranging from soil, sediment, and poultry litter to medieval paints, milk and milk products, corn steep liquor, and the rhizosphere. Besides the original species descriptions coverage of family members in the literature is sparse, concentrating on *Dermabacter hominis* as pathogen (see below; one rare report lists *Dermacoccus* spp. as part of the microflora involved in coffee cherry maturation [Silv et al. 2000]). Reports on *Brachybacterium* ssp. reinforces the widespread occurrence of these organisms, mainly in the marine environment, e.g., associated with a sea urchin (Huang et al. 2009) and a sea anemone (Xiao et al. 2009), as an oil-degrader in the Atlantic ocean (Wang et al. 2010), or as a manganese-oxidizing/-removing strain from a Pacific deep-sea Mn nodule sediment (Wang et al. 2009). Strains of *Brachybacterium* were among the isolates retrieved from aerial spraying of bovine slurry waste (Murayama et al. 2010) and in a freshwater lake sediment (Krett and Palatinszky 2009). *Brachybacterium conglomeratum* was among the most resistant bacteria surviving on copper surfaces (Santo et al. 2010).

BLAST search analysis of 16S rRNA gene sequences similarities slightly expends the spectrum of habitats. Several entries with high BLAST scores between 99 % and 96 % are listed, reinforcing the role of *Dermacoccus* and *Helcobacillus* as pathogens (see below). By far the highest number of sequences highly related to *Dermacoccus hominis* originate from large sequencing studies from human skin (Kong et al. unpublished) and the microflora of the human mucosa-associated ileum (Li et al. unpublished). There are a few closely moderately related non-pathogenetic relatives of *Helcobacillus*: two sequences with 96 % identity which are endophytes from Chinese cabbage and young radish (accession numbers EU373383 and EU373420, respectively; Cho et al. unpublished) and an entry indicating the presence of dermabacters in house dust (Taubel et al. 2009), indoor environment (Rintala et al. 2008), clean rooms (Probst et al. 2010) and urban aerosols (Brodie et al. 2007). No close relatives of *Devriesea* are recorded. A large number of sequences of cultured and uncultured organisms with high BLAST identities (98–99 %) are related to *Brachybacterium* supporting the abundance of members of this genus in a wide range of habitats.

Pathogenicity: Clinical Relevance

The clinical significance of strains related to *Dermabacter hominis* is known since the 1970s when "coryneform" isolates from blood or normally sterile body sites were collected in the Center of Disease Control and Prevention, Atlanta, Ga. as CDC group 3 and group 5. In the 1990s, many of these strains were affiliated to *D. hominis* by polyphasic studies (Funke et al. 1994; Gruner et al. 1994), a taxon that consisted of human cutaneous strains only. Since the description of this species, the literature shows a number of reports which clearly identifies *D. hominis* as an opportunistic pathogen: the finding of *D. hominis* strains in a cerebral (Bavbek et al. 1998) and in a recurrent abscess (Martin et al. 2009), in a peritoneal dialysis-associated peritonitis (Radtke et al. 2001), in blood cultures of patients with chest diseases (Babay and Kambal 2004) in bacteremia (Goméz-Garcés et al. 2001), in fatal septicemia (Lee et al. 2011), and from aseptically obtained human blood (Cadenas et al. 2007).

Antibiotic sensitivity testing (MIC 90 % values) revealed that rifampicin showed excellent activity, while resistance was observed against penicillin and especially chloramphenicol, erythromycin, and clindamycin (Funke et al. 1996; Troxler et al. 2001). Though also listed as being almost resistance to cefuroxime in vitro (Funke et al. 1996; Radtke et al. 2001), the peritonitis patient could be cured by this cephalosporin antibiotic (Radtke et al. 2001).

The clinical significance of *Devriesea agamarum* is restricted to proliferative dermatitis and septicemia in desert lizards of the genera *Uromastyx*, *Pogona*, and *Agama*, notably to cheilitis in Pogona. Koch's postulates were fulfilled using the bearded dragon *P. vitticeps* as a test object (Hellebuyck et al. 2009). Survival of the bacterium on dry surfaces is limited, but it persists and remains viable for up to two months in dermal crust and up to five months in moist sand or distilled water (Hellebuyck et al. 2011).

15 The Family *Dermacoccaceae*

Erko Stackebrandt · Peter Schumann
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The family *Dermacoccaceae*, a member of the order *Micrococcales*, comprises eight genera and 14 species. Irrespective of the algorithm used for the generation of 16S rRNA gene sequence trees, *Kytococcus* does not cluster with the other members of the family but shows a closer relationship to members of the family *Intrasporangiaceae*. Chemotaxonomic evidence supports the phylogenetic separateness of the genus *Kytococcus*. *Dermacoccaceae* genera, except *Kytococcus*, will be referred to as authentic members of the family in the following. Neighbor-joining (NJ) and maximum likelihood (ML) dendrograms do not agree in their clustering of the authentic members of *Dermacoccaceae*. While they constitute a coherent cluster in the NJ tree, four lineages emerge from the ML analysis. In this tree, the genera *Serinicoccus* and *Ornithinimicrobium*, though defined by a different, ornithine-based instead of lysine-based peptidoglycan type (Groth et al. Int J Syst Evol Microbiol 51:81–87, 2001; Hana et al. Int J Syst Evol Microbiol 54:1585–1589, 2004), cluster with certain genera of *Dermacoccaceae*.

Taxonomy: Historical and Current

Dermacoccaceae Stackebrandt and Schumann 2000; emend. Zhi et al. 2009; emendRuckmani et al. 2011.

The family contains the type genus *Dermacoccus* (Stackebrandt et al. 1995) and the genera *Demetria* (Groth et al. 1997), *Luteipulveratus* (Ara et al. 2010), *Yimella* (Tang et al. 2010), *Calidifontibacter* (Ruckmani et al. 2011), *Branchiibius* (Sugimoto et al. 2011), *Flexivirga* (Anzai et al. 2011), and *Kytococcus* (Stackebrandt et al. 1995).

In contrast to the emended family description by Ruckmani et al. (2011), the one given here does not include characteristics which are considered genus or species specific and may change readily with more taxa added to the family (e.g., NaCl tolerance, Tween hydrolysis, antibiotic sensitivity and resistance, and sugar oxidation reaction). The main diagnostic properties are indicated in *Table 15.1*.

Gram-positive, mainly coccoid to short rods, sometimes comma shaped or in irregular clusters. Nonmotile and nonencapsulated. Endospores are not formed. Cells rarely longer than 3.0 μm. One species forms a rudimentary aerial mycelium. Aerobic to microaerophilic, most strains are catalase-positive. Chemoorganotrophic. Mycolic acids and teichoic acids are absent. Non-acid fast. The peptidoglycan variation is of the A4α type with lysine at position 3 of the peptide side chain and an interpeptide bridge containing mono- and a dicarboxylic amino acids. The fatty acid composition is variable and includes iso-methyl and anteiso-methyl branched types as well as monounsaturated chain fatty acids. Phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol are present; other polar lipids may occur. The menaquinones are either partially hydrogenated or completely unsaturated (genus *Kytococcus*). When tested, muramic acid is acetylated. The pattern of 16S rRNA signatures will not be shown here as the set defined for the family (Zhi et al. 2009) still included sequences of *Kytococcus* species but lacked the sequences of taxa described after 2009. The DNA G+C content ranges between 66 % and 77 % (T_m, HPLC).

A member of the order *Micrococcales*, class *Actinobacteria*. The type genus is *Dermacoccus*.

Phylogenetic Structure of the Family and Its Genera

Comparative analysis of the 16S rRNA gene sequences of *Micrococcus* species led to the dissection of the genus, leaving only *M. luteus* and *M. lylae* as authentic members of the genus (Stackebrandt et al. 1995). Though morphologically resembling authentic *Micrococcus* species, the phylogenetic distance of the other species was so large and the chemotaxonomic differences so profound that it was justified to reclassify, among others, *M. nishinomiyaensis* as a member of *Dermacoccus* and *M. sedentarius* as a member of *Kytococcus*.

[g]Concluded from the amino acid composition indicated by the authors of the respective publication

When the family *Dermacoccaceae* (Stackebrandt and Schumann 2000) was described, it was placed in the suborder *Micrococcineae* (Stackebrandt et al. 1997), originally established on the basis of 16S rRNA gene sequence signatures. This suborder has recently been elevated to the order level (Ludwig et al. 2012). The genera *Dermacoccus* and *Kytococcus*, described as members of the family *Dermatophilaceae* (Austwick 1958[AL], emend. Stackebrandt et al. 1997), as well as the genus *Demetria* (Groth et al. 1997) were transferred into *Dermacoccaceae* when the topology of the enlarged 16S rRNA gene tree required readjustment of taxa above the genus level. As the overall degree of sequence similarity shared between type strains of genera of *Micrococcineae* is high and the inclusion of novel type strains frequent, the topologies of phylogenetic trees are prone to the number and selection of sequences of the order and of outside reference organisms. Also, in none of the 16S rRNA trees displaying the position of novel species, all type strains of the order are included but only subsets of sequences, subjectively based upon sequence similarity values and systematic consideration. More recently, the membership of *Kytococcus* is under discussion. The LTP 16S rRNA tree (Yarza et al. 2010) clearly sees *Kytococcus* species branching outside the authentic members of *Dermacoccaceae*, grouping with some genera of the paraphyletic family *Intrasporangiaceae* (*Fig. 15.1*). The argument to retain *Kytococcus* within the family *Dermacoccaceae* in the last edition of *Bergey's Manual of Systematic Bacteriology* (Ludwig et al. 2012) is that some chemotaxonomic properties (menaquinone composition and peptidoglycan type), which are unique for *Kytocoocus*, are absent from the other authentic members as well as from members of the family *Intrasporangiaceae* (Kageyama et al. 2008). The logic conclusion would be the description of a family of its own, *Kytococcaceae*, but in the absence of a formal description, we will also discuss properties of *Kytococcus* and its species within the scope of this chapter.

In addition to the three genera of the family described between 1995 and 1997, several monospecific genera were added to the family since 2010: *Luteipulveratus* (Ara et al. 2010), *Yimella* (Tang et al. 2010), *Branchiibius* (Sugimoto et al. 2011), *Flexivirga* (Anzai et al. 2011), and *Caldifontibacter* (Ruckmani et al. 2011). Interestingly, all trees published in the original description to depict the position of the respective new type strain included members of *Kytococcus* and in each case, members of this genus branched either within the radiation of *Dermacoccaceae* type strains or as their nearest neighbor. According to the phylogenetic branching of actinobacterial type strains in the RaxML 16S rRNA gene tree of the Living Tree Project (Yarza et al. 2010) (*Fig. 15.1*), the family is not a coherent taxon but its members are found in four different lineages. One major cluster contains all genera but *Kytococcus* which is a neighbor of *Marihabitans asiaticum* and more closely related to *Intrasporangiaceae* (which do not appear as a coherent family, either). The second group contains members of *Dermacoccus*, while *Calidifontibacter, Yimella, Branchiibius* (the species *B. cervicis* has not been included because of its recent description), *Flexivirga*, and *Luteipulveratus* define the third group. *Demetria terragena* branches between the *Serinicoccus*/*Ornithinimicrobium* group and species of group three. This situation is not seen in the neighbor-joining (NJ) tree (not shown), in which the *Serinicoccus*/*Ornithinimicrobium* lineage and the *Dermacoccus* cluster are sister clades. The NJ tree, too, sees *Kytococcus* species clustering apart from authentic dermacocci but with *Marihabitans asiaticum*. Chemotaxonomically, *Serinicoccus* (Yi et al. 2004) and *Ornithinimicrobium* (Groth et al. 2001) species contain ornithine as the diagnostic amino acid of the peptidoglycan belonging to the A4β or to a new type. Only *Serinicoccus chungangensis* (Traiwan et al. 2011) has been reported to contain *meso*-diaminopimelic acid, otherwise not found in any member of *Serinicoccus*, *Ornithinimicrobium*, or *Dermacoccaceae*. With respect to the composition of polar lipids, menaquinones and major fatty acids members of all these taxa (except for *Kytococcus*) are similar.

Molecular Analyses

DNA-DNA Hybridization Studies

DNA reassociation studies (DDH), mostly done with the microplate method of Ezaki et al. (1989), have only been performed between type strains of the genera *Dermacoccus* and *Kytococcus* (Pathom-aree et al. 2006a, b; Becker et al. 2003; Kämpfer et al. 2009). The phylogenetic distance among the monospecific genera and among these and type strains of *Dermacoccus* and *Kytococus* was below 96 % 16S rRNA gene sequence similarity, making it unnecessary to perform hybridization studies (Stackebrandt and Goebel 1994). The DDH values obtained for the pairwise analysis of the four closely related *Dermacoccus* species (above 98.5 % 16S rRNA gene sequence similarity) ranged at most between 7 % and 25 % DNA similarity; even the genomes of type strains of *D. barathri* and *D. profundi*, sharing 99.9 % 16S rRNA gene sequence similarity, did not hybridized higher than 25 % (Pathom-aree et al. 2006b). The genomes of the three *Kytococcus* type strains, sharing gene sequence similarities between 97.9 % and 98.6 %, were less than 46 % similar by DDH analysis (Becker et al. 2003; Kämpfer et al. 2009). The two type strains of *Branchiibius* (99.6 % sequence similarity) share <35 % DDH similarity (Tomida et al. 2011). All values were clearly below the threshold values for the delineation of genospecies (Wayne et al. 1987).

RiboPrinting

Though *Pvu* II is generally suited for generating multiband RiboPrint patterns of members of the order *Micrococcales*, only few members of the family *Dermacoccaceae* could be cut successfully with this restriction enzyme (*Fig. 15.2*). The patterns of the type strains of *Dermacoccus abyssi* and *Dermacoccus profundi* are highly similar and agree in major

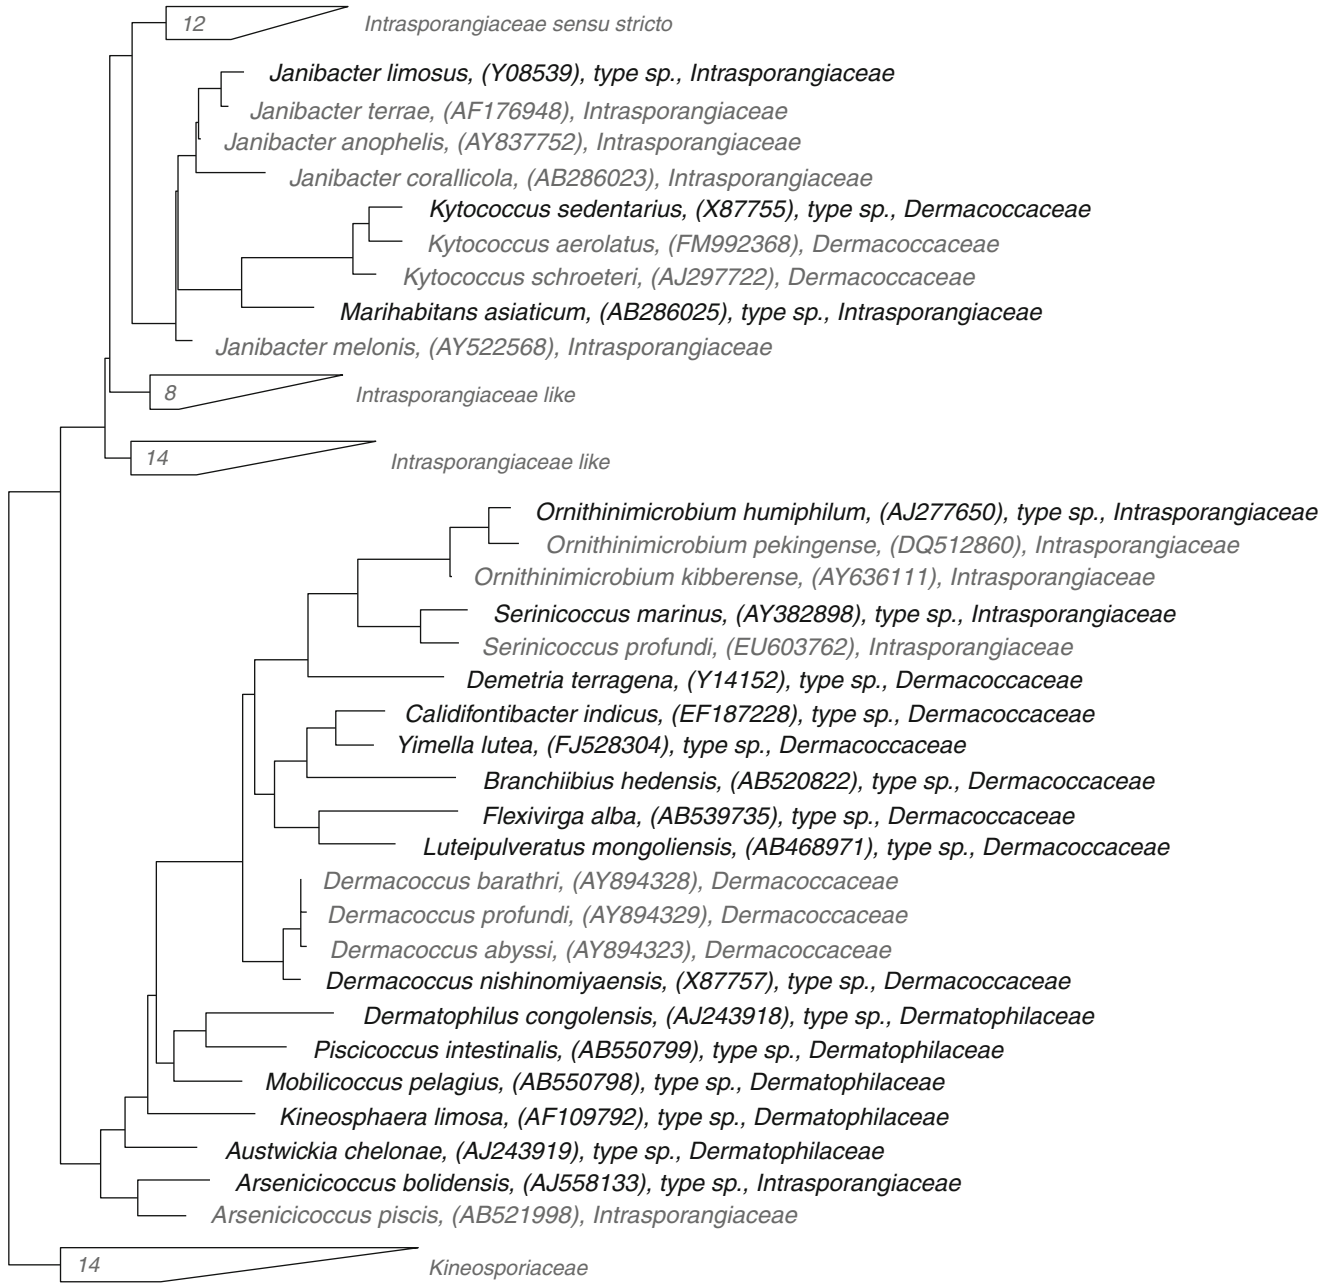

Fig. 15.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the family *Dermacoccaceae* and some neighboring taxa present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences. List of type strains used for dendrogram construction: *Dermacoccus nishinomiyaensis* DSM 20448^T, *D. abysii* MT1.1^T, *D. barathi* MT2.1^T, *D. profundi* MT2.2^T, *Demetria terragena* HKI 0089^T, *Luteipulveratus mongoliensis* MN07-A0370^T, *Flexivirga alba* ST13^T, *Branchiibius hedensis* Mer 29717^T, *Calidifontibacter indicus* PC IW02^T, YIM 45900^T, *Kytocoocus sedentarius* DSM 20547 T, *K. schroeteri* Muenster 2000, *K. aerolatus* 02-St-019/1^T

bands with the pattern of *Dermacoccus barathri* DSM 17574^T. This finding confirms the high relationship of these three *Dermacoccus* type strains as detected by 16S rRNA gene sequence comparison and MALDI-TOF mass spectrometry (See *Figs. 15.1* and *15.3*).

MALDI-TOF

The dissimilarity of whole-cell MALDI TOF mass spectra of almost all type strains indicates that this method is appropriate for identification of species of this family. Only the mass spectra

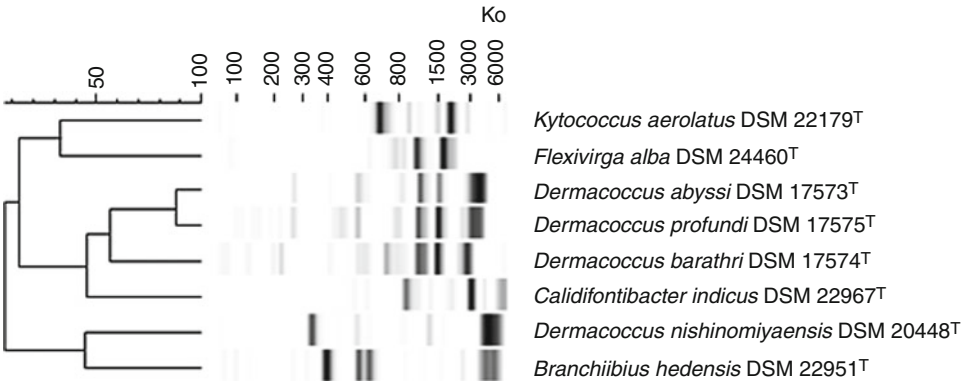

Fig. 15.2

RiboPrint patterns of those type strains of the family *Dermacoccaceae* which are cut by *Pvu*II. The dendrogram has been generated with the BioNumerics software (Applied Math, Kortrijk, Belgium)

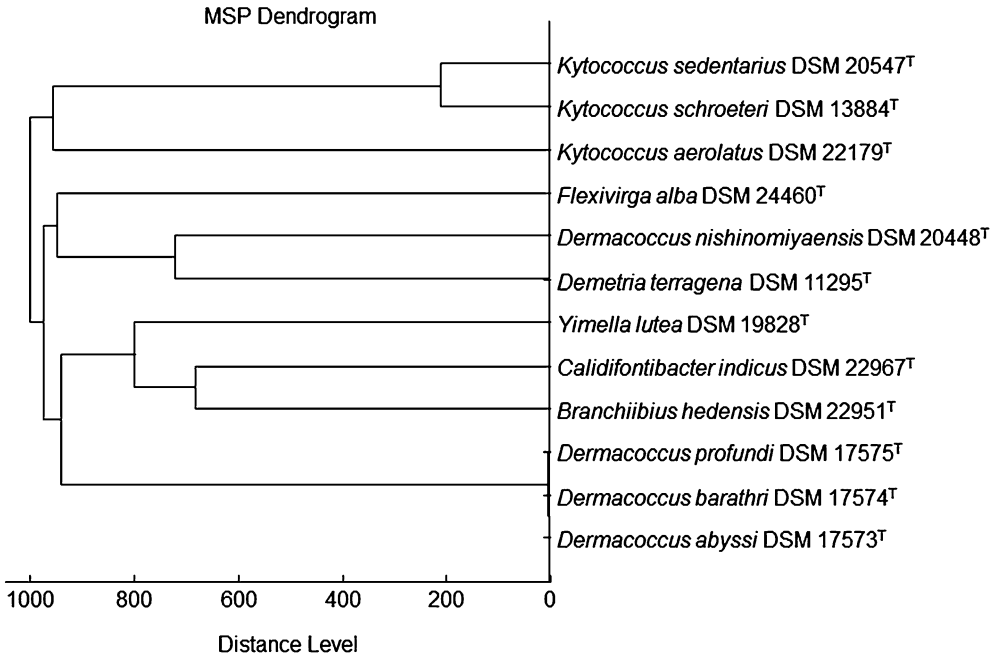

Fig. 15.3

Score-oriented dendrogram generated by the BioTyper software (version 2.0, Bruker Daltonics) showing the similarity of MALDI-TOF mass spectra of cell extracts of selected type strains of the family *Dermacoccaceae*

of the type strains of *Dermacoccus abyssi, Dermacoccus barathri*, and *Dermacoccus profundi* are almost identical (Fig. 15.2). While *Kytococcus* type strains cluster together, apart from other members of the family, *Dermacoccus nishinomiyaensis* DSM 20448^T groups with *Demetria terragena* and not with other members of the genus.

Genome Analysis

Presently the only available complete genome sequence of a member of *Dermacoccaceae* is that of *Kytococcus sedentarius* DSM 20547^T (accession number CP001686) (Sims et al. 2009), selected by the Genomic Encyclopedia of Bacteria and Archaea (GEBA) project for its production of oligoketide antibiotics as well as for its role as an opportunistic pathogen (see below). The single replicon genome is 2,785,024-bp long, annotated to contain 2,639 protein-coding, among these 1,948 with function, 1,851 of which were assigned to COGs: 64 RNA genes and only two rRNA operons are present. The mol% G+C of DNA is 71.63 % GC content which is slightly higher than that determined by the thermal denaturation method (Kloos et al. 1974). In accordance with the report Pospišil et al. (1998) on the production of polyether antibiotics (monensins), the genome contains genes involved in the synthesis of antibiotics, such as polyketide cyclases, putative exporters of

polyketide antibiotics, genes involved in polyketide biosynthesis, antibiotic biosynthesis monooxygenes, and ABC-type bacteriocin/antibiotic exporter with N-terminal double-glycine peptidase domain. Additional information can be retrieved from the JGI/DOE webpage http://img.jgi.doe.gov/cgi-bin/geba/main.cgi?section=Taxon-Detail&taxon_oid=644736380

Phenotypic Analyses

The main features of members of *Dermacoccaceae* are listed in *Tables 15.1* and *15.2*. Most of the phenotypic information is restricted to the type strain of a species. It is thus questionable whether these reactions are indeed species specific. Though membership of genera to the family has been acknowledged in the descriptions of new genera, a broad spectrum of neighboring type strains was included in hardly any of the recent descriptions, except for *Caldifontibacter indicus* (Ruckmani et al. 2011). The use of different approaches to analyze metabolic properties, except for API Zyme reactions, and the failure to perform tests used before for the characterization of other type strains results not only in the presence of many undetermined (or unrecorded) properties but also in a high number of conflicting reactions (See *Table 15.2* for some prominent examples). The recommendation of an ad-hoc committee for the reevaluation of the species definition in bacteriology (Stackebrandt et al. 2002) to obtain diagnostic or differentiating properties by comparable methods applied to reference strains of closely related taxa was in most cases ignored, making it almost impossible to find family-specific metabolic traits. In contrast, chemotaxonomic properties are evaluated by more standardized methods and chemical constituents are less subject to subjective interpretation. The exception is the fatty acid composition, especially their minor components, which differ among all studies due to differences in the growth conditions of reference material and to different designation of gas chromatographic peaks with IUPAC or trivial names. As the listing of the range of minor fatty acid components obtained in individual species descriptions is outside the scope of the chapter, the indication of fatty acids is restricted to major components as listed in *Table 15.1*. Additional data on colony morphology and colors, production of soluble pigments, acidification of growth media, antibiotic resistance and susceptibility as well as utilization of substrates for growth, acid formation, and enzymatic activities are given in the respective original descriptions and are not listed in detail.

Dermacoccus Stackebrandt et al. 1995, 689^{VP}, emend Ruckmani et al. 2011.

Der.ma.coc´cus. N.L. n. *derma*, skin: Gr. n. *coccus*, a grain, berry: M.L. masc. n. *Dermacoccus*, coccus living on skin).

In addition to properties listed in *Tables 15.1* and *15.2*, cells are nonhalophilic and mesophilic. The cytochromes are cytochromes *aa*3, *c*549, *c*555, *b*559, *b*564, and *d*626 (one type strain analyzed; Faller et al. 1980). Iso-branched saturated and monounsaturated fatty acids with 16 and 17 carbon acids dominate the cellular fatty acid profile. If present, the long-chain aliphatic hydrocarbons are C22 and C23 hydrocarbons, as well as minor amounts of C25, C26, and C27 hydrocarbons (Kloos et al. 1974).

Metabolic properties of diagnostic value of type strains of the four species are indicated in *Table 15.2*. The most extensive study on *D. nishinomiyaensis* isolates have been performed by Kloos et al. (1974), Kocur et al. (1975). D. *abysii* MT1-1^T grows well at 40 Mpa and can be considered a piezotolerant actinobacterium. At this pressure, strains of *D. nishinomiyaensis* showed a decrease in cell numbers (Pathom-aree et al. 2006a); information of the other two type strains are not available (Pathom-aree et al. 2006b). All strains grow on complex organic media but poorly only on inorganic nitrogen agar. Most auxotrophic *D. nishinomiyaensis* strains required cysteine or methionine and niacin, and were further stimulated by tryptophan, valine, aspartic acid, glutamic acid, proline, and lysine (Kloos et al. 1974). If indicated, growth occurs at 10 °C and 37 °C with an optimum of 28 °C.

The type species is *Dermacoccus nishinomiyaensis*, the type strain is DSM 20448^T, ATCC 29093^T.

Demetria Groth et al. 1997, 1132^{VP}

De.me.tria Gr. M. n. Demeter, Greek female god of agriculture and wives; -ia, M.L. fem., *Dernetria*, a bacterium being responsible for fertility.

This genus has been described on the basis of the phylogenetic distance to neighboring taxa, the presence of aspartic acid instead of glutamic acid in the peptidoglycan and menaquione MK-8(H_4) instead of MK-8(H_2), found in the most closely related taxon (at the time of the original description), *D. nishinomiyaensis*. This taxon is the only one in the family for which phosphatidylethanolamine (PE) has been reported. Metabolic differences, obvious at the time of its description, became blurred with more descriptions of *Dermacoccaceae* species being published.

The type species is *Demetria terragena*, the type strain is HKI 0089^T.

Luteipulveratus Ara et al. 2010, 578^{VP}

Lu.te.i.pul.ve.ra'tus. L. adj. *luteus* yellow; L. part. adj. *pulveratus* scattered with dust; N.L. masc. n. *Luteipulveratus* a bacterium forming white powdery aerial mycelium on yellow colonies.

This taxon is the only one within the family that produces an abundant grayish white, powdery, and sterile aerial mycelium-like structure on ISP media 3, 5, and 7, even a rudimentary aerial mycelium on ISP medium 4. Metabolic properties fall into the range of those reported for other members of the family (*Table 15.2*).

The type species is *Luteipulveratus mongolensis*, the type strain is MN07-A0370^T.

Yimella Tang et al. 2010, 662^{VP}

Yi.mel'la. L. fem. dim. suff. -ella; N.L. fem. dim. n. *Yimella* arbitrary name formed from the acronym of Yunnan Institute of Microbiology, YIM, where the first taxonomic studies of this taxon were performed.

This taxon differs from other members by a number of chemotaxonomic features, such as the presence of anteiso-C17:0 fatty acid, glycine bound to the α-carboxyl group of

[c]Ruckmani et al. (2011), Pathom-aree et al. (2006a,b)
[d]Ruckmani et al. (2011), Kämpfer et al. (2009)
[e]Becker et al. (2002), Ruckmani et al. (2011)

D-glutamic acid of the peptide subunit of peptidoglycan, fucose as whole-cell sugar and a glucosamine-containing phospholipid.

The type species is *Yimella lutea*, the type strain is YIM 45900^T.

Flexivirga Anzai et al. 2011, 616. Validation List N^o 143 in IJSEM online.

Fle.xi.vir'ga. L. adj. *flexus*, bent; L. fem. n. *virga*, a rod; N.L. fem. n. *Flexivirga*, a bent rod.

Besides the formation of comma-shaped cells seen on ISP medium 2, it is mainly the distinct phylogenetic position and the combination of chemotaxonomic properties that distinguished this taxon from other members of the family.

The type species is *Flexivirga alba*, the type strain is ST13^T.

Calidifontibacter Ruckmani et al. 2011, 2422^{VP}.

Ca.li.di.fon.ti.bac'ter. L. adj. *calidus* hot; L. n. fons, *fontis* spring, fountain; N.L. masc. n. bacter a rod;N.L. masc. n. *Calidifontibacter* a rod isolated from hot spring.

The main distinguishing properties of this taxon are the markedly higher DNA G+C content of 77 % and the presence of phosphatidylserine (disregarding strains of *Kytococcus*) and phosphatidylinositol mannosides. The considerable amount of the fatty acid iso-C16:1H (17.2 %), reported to be a discriminating feature is found at even higher amounts in three species of *Dermacoccus*. Though isolated from a warm spring (though the term, "hot" is a component of the genus name), the type strain does not grow at 42 °C.

The type species is *Calidifontibacter indicus*, the type strain is PC IW02^T.

Branchiibius Sugimoto et al. 2011, 199^{VP}.

Bran.chi.i.bi'us. L. pl. n. *branchiae* the gills of fish; N.L. masc. n. *bius* (from Gr. masc. n. bios) life; N.L. masc. n. *Branchiibius* a life existing in gills of fish.

The presence of L-serine at position 1 of the peptide subunit of the peptidoglycan (the other members of the family possess L-alanine) and arabinose as whole-cell sugar are the chemotaxonomic peculiarities of this taxon, consisting of two species. Menaquinone MK-8(H_6) and unknown branched-chain (other than 10-methyl, iso, and anteiso) fatty acids have only been reported for *Branchiibius cervicis* (Tomida et al. 2011).

The type species is *Branchiibius hedensis*, the type strain is Mer 29717^T.

Kytococcus Stackebrandt et al. 1995, 687^{VP}.

Ky.to.coc´cus. Gr. neut. n. *kytos*, skin; Gr. masc. n. *kokkos*, a grain; M.L. masc. n. *Kytococcus*, a coccus from skin.

Phylogenetic and chemotaxonomic evidence speak against the inclusion of this genus into the family *Dermacoccaceae*. Above all, the menaquinones are fully unsaturated and the peptidoglycan variation is different from all other family members. The original description of this species was reported by ZoBell and Upham (1944) and was based on one strain, designated 541. Many strains were subsequently isolated from the skin of humans and the study of Kloos et al. (1974) gives the most comprehensive view on the properties and the variation on strains labeled *Kytococcus* [*Micrococcus*] *sedentarius*.

Abbreviations: See *Table 15.3*

Table 15.3 serves for comparison of properties (excluding those which are shown in *Table 15.2*), reported to distinguish the type strains of the three species. According to the study of Kämpfer et al. (2009), Kloos et al. (1974, for *K. sedentarius*), strains are inactive in acid production from carbohydrates. *K. aerolatus* only uses a few carbon sources.

The type species is *Kytococcus sedentarius*, the type strain is strain 541^T, DSM 29547^T, ATCC 14392^T.

Clinical Significance

A few members of *Dermacoccaceae*, especially *Kytococcus schroeteri* and *K. sedentarius*, have clinical significance. The latter species is described to be a causative agent of pitted keratolysis of the foot (Nordstrom et al. 1987). This species, however, has also been discussed in a case of endocarditis (Old and McNeill 1979) and reports indicate its likely cause of airway illnesses (Savini et al. 2011). It has been identified in a case of peritoneal dialysis-associated peritonitis (Chaudhary and Finkle 2010) and in bacteremic (Mohammedi et al. 2005) and hemorrhagic pneumonia, assuming that in immunocompromised patients, this commensal may act as an opportunistic pathogen once it has spread through the blood stream (Levenga et al. 2004; Hodiamont et al. 2010; Blennow et al. 2012). More reports are available for the involvement of *K. schroeteri* in bacterial infections of blood in patients with endocarditis in both children and adults (Becker et al. 2003; Mnif et al. 2006; Aepinus et al. 2008; Renvoise et al. 2008; Jourdain et al. 2009; Yousri et al. 2010) and in shunt infection (Leport et al. 1989). The species has also been found to cause spondylodiscitis (Jacquier et al. 2010) and the formation of crusted erythematous papules in the groin of a man with acute myelocytic leukemia (Nagler et al. 2011).

Recently, strains of the novel species *Branchiibius cervicis* have been isolated from the skin of the neck of atopic dermatitis patients (Tomida et al. 2011).

Treatment of kytococci infections was successfully achieved with vancomycin or a combination of vancomycin, rifampicin, gentamicin, or pristinamycin (Mnif et al. 2006; Aepinus et al. 2008; Jourdain et al. 2009; Savini et al. 2011). Blennow et al. (2012) successfully treated a *Kytococcus* infection with linezolid and trimethoprim-sulfamethoxazole. Hodiamont et al. (2010) report that *Kytococcus* strains are often resistant to penicillin, while Szczerba (2003) indicates that micrococcal isolates, including dermacocci and kytococci, are resistant to ampicillin and erythromycin. Several descriptions of type strains, indicating resistance and susceptibility patterns, confirm these findings. *K. schroeteri* is susceptible to chloramphenicol, ciprofloxacin, gentamicin, tetracycline, vancomycin, teicoplanin, and bacitracin but resistant to penicillin, oxacillin, nitrofurantoin, and erythromycin (Becker et al. 2002). A few of these antibiotics only have been tested for the type strains of *Dermacoccus*, *Kytococcus*, *Demetria*, and *Calidifontibacter* (Ruckmani et al. 2011): The reaction toward rifampicin and ciprofloxacin is strain dependent and all dermacoccus type strains are sensitive to oxacillin.

In contrast, reports on the presence of *Dermacoccus* species in the vascular system are rare. A single study (Marques da Silva et al. 2006) reports the presence of oral bacteria, including *Dermacoccus* spp., in several 16S rRNA gene clone libraries obtained from arterial walls of aortic anaeurysms.

Isolation, Enrichment, and Maintenance Procedures

Due to the broad range of isolation sources, the isolation procedures for members of the family differed widely. *Kytococous sedentarius* and *Dermacoccus nishinomiyaensis* have been isolated frequently from the mouth

(Szczerba and Krzeminski 2001) and the skin of healthy people (Kloos et al. 1974) The nonselective medium had the following composition per liter: peptone (Difco), 10 g; yeast extract (Difco), 5 g; sodium chloride, 5 g; glucose, 1 g; agar (Difco), 15 g; distilled water, 1,000 ml, supplemented with cycloheximide (50 μg/ml). This agar was also used for the maintenance and propagation of all strains.

The other three *Dermacoccus* species (Pathom-aree et al. 2006a, b) were isolated from a 2-ml sediment sample from the Mariana Trench (Challenger Deep). A suspension of the sample (sent to the UK at 4 °C) was plated onto raffinose-histidine agar plates (Vickers et al. 1984), supplemented with cycloheximide and nystatin. Cultures were maintained on glucose-yeast extract agar plates (Gordon and Mihm 1962).

Demetria terragena (Groth et al. 1997) was isolated from a frozen compost sample on nutrient agar, containing per liter: peptone, a pancreatic digest of meat of fish, 20 g; NaCl, 5 g; agar, 15 g.

Yimella lutea (Tang et al. 2010) was isolated as a contaminant of ISP medium 5 and maintained on ISP 2 agar (Shirling and Gottlieb 1966).

Luteipulveratus mongoliensis (Ara et al. 2010) has been recovered from soil which has been dried at room temperature for 5–7 days, then rehydrated, and centrifuged (Hayakawa et al. 2000). The organism was isolated on humic acid-vitamin agar (Hayakawa and Nonomura 1987) containing 20-mg trimethoprim and 10-mg nalidixic acid per liter. Maintenance was on Bennet agar (Jones 1949).

The *Branchiibius* strains were isolated from eukaryotic specimen. *B. hedensis* was recovered from a Japanese codling (Sugimoto et al. 2011) by spreading dilutions of grind branchia onto humic acid-vitamin agar. Incubation was for 21 days at 28 °C. Maintenance was on ISP 2 medium. *B. cervicis* strains were isolated from the neck of patients with atopic dermatitis and grown on tryptic soy agar (Difco) for 1–3 days at 30 °C (Tomida et al. 2011).

Strains of *Kytococcus schroeteri* were isolated from blood of a patient with endocarditis, using the Bactec9240 System (Becton Dickinson). Growth occurred after 24 h. *K. aerolatus* was isolated from a gelatin filter set up to recover organisms from a room with walls colonized with molds (Kämpfer et al. 2009). The filter was placed on ISP3 agar medium and a colony of the species recovered after 2 weeks at 28 °C. Maintenance was on medium 79 containing (per liter) 10 g of dextrose, 10 g of Bacto Peptone (Difco), 2 g of Casamino Acids (Difco), 2 g of yeast extract (Serva), and 6 g of NaCl (pH 7.5) (Prauser and Falta 1968).

The organisms can be cultivated on the following media numbers as indicated in the DSMZ catalog of strains (http://www.dsmz.de/catalogues.html): strains of *Dermacoccus* and *Kytococcus*: (53 and 92), *Demetria* (736), *Yimella* (65), *Branchiibius* and *Calidifontibacter* (92). Strains are on a medium-term maintained as glycerol suspensions (20 %, v/v). Long-term preservation is by lyophilization in skim milk or under N_2 atm. at −196 °C.

Ecology

Habitat

As indicated in the Isolation subchapter, the habitat of type strains of *Dermacoccaceae* is broad, ranging from soil, sea sediment (Pathom-aree et al. 2006c), and compost to the branchia of fish and the skin and blood of humans. Obviously, *D. nishinomiyaensis* and *K. sedentarius*, originally isolated from water used for brewing sake (Oda 1935) and from sea water (ZoBell and Upham 1944), respectively, are part of the normal skin microflora as indicated by the studies of Kloos and Musselwhite (1975) and of Kloos et al. (1974) who found that of 115 human skin samples, 13 % and 28 % contained *K. sedentarius* and *D. nishinomiyaensis* strains, respectively. *Dermacoccus* spp. have also been isolated from salt used in the production of Spanish dry-cured ham (5.4 % of 369 strains isolated) (Cordero and Zumalacarregui 2000). As these findings conflict with the lack of growth of *D. nishinomiyaensis* strains in 7.5 % NaCl (Kocur et al. 1975), it can be assumed that either the Spanish isolates belong to a new taxon (only this species was described in the year 2000) or these organisms are transient but not actively growing on the surface of salted ham. BLAST search for the presence of *Dermacoccaceae*-related 16S rRNA sequences in public databases resulted in only few hits with high BLAST scores: Isolates have been reported in a soil sample of a dairy research station in Victoria, Australia (Ellin 185, accession number AF409027, Schoenborn et al. 2004), in soil of Barrientos Island, Antarctica (JF905611, Lee et al. unpublished), in the phyllosphere of apple trees (AB697155, He and Sano unpublished) and as a rhizosphaere strain (JN585681, Sanadhya and Jha unpublished). A *Dermacoccus*-related clone has also been identified in a 16S rRNA clone library obtained from microorganisms associated with the leaf-cutting ant *Acromyrmex* spp. (Haeder et al. 2009).

The sequence of a strain tentatively named "*Barrientosiimonas humi*" is close to that of *Demetria terragena* (JF346171, Lee et al. unpublished); another entry, close to *D. terragena*, lists the invalid name "*Demetria marina*," isolated from seawater (FM882229, Lee unpublished). *Kytococcus* isolates with 99 % BLAST scores to *K. sedentarius* were reported, among other entries, from sediments of the eastern Arabian Sea (Divya et al. 2010), Bay of Bengal (JQ068781, Kumar unpublished) and from the intertidal zone around the Republic of Palau (Gontang et al. 2007), among pelagic bacteria from the east coast of South Korea (Bhattarai et al. 2006), in association with a marine sponge (FJ999585, Liu et al. 2008) and in nonsaline groundwater environment (one strain, Tiago et al. 2004). The clinically relevant species *Kytococcus schroeteri* has also been detected among airborne isolates collected by the BioCapture BT-550 device (Mesosystems Technology Inc., Kennewick, WA, USA) during commercial airline flights (Osman et al. 2008), as well as member of the midgut microbial community of *Culex* spp. mosquitoes (Chandel et al. unpublished). Not unexpectedly, a high number of 16S rRNA clone sequences related to *Kytococcus* originate from the NIH Intramural Skin

Microbiome Consortium/NISC Comparative Sequencing Program (Kong et al. unpublished).

Application

The finding that several strains of *Kytococcus sedentarius* and *Dermacoccus nishinomyaensis* from the Czech Culture Collection of Microorganisms (CCM, Brno) produce monensins (Pospišil et al. 1998) stimulated the search for other secondary metabolites. During an isolation campaign for novel actinomycetes from Challenger Deep sediment of the Mariana Trench (Pathom-Aree et al. 2006c), 38 isolates were recovered, 19 of which belonged to *Dermacoccus* (among others *D. abysii, D. barathri*, and *D. profundi*). Screening of culture filtrates resulted in the detection of metabolites identified as phenanzine compounds, named dermacozines after high-resolution mass spectrometry and structural elucidation. Seven structures of these compounds with antitumor, antiprotozoal, and free radical scavenging activities (Abdel-Mageed et al. 2010) have been identified. As outlined by Goodfellow and Fiedler (2010), knowledge about proper taxonomic diversity and phylogenetic relationships at the species level can guide the search for new metabolites though the outcome of these studies cannot be predicted as secondary metabolites are often strain specific, rather than species specific. Nevertheless, attempts to improve classification and identification, hence nomenclature, by providing an array of genomically stable criteria have always been the goal (though not always achieved) of systematics. Secondary metabolites have rarely been included in species descriptions because of the unknown genomic stability of genes involved in their synthesis. Experience, however, has shown that phylogenetic and chemical diversities by and large mirror each other and knowledge about properties even not used in species description but in characterization can support chemists to specifically target potentially valuable biological resources.

A second example for an application is the production of keratinases from *Kytococcus sedentarius*. Two keratin-degrading serine proteases have been isolated from strain NCIMB 40287 that independently biodegrade a range of keratin polymers, including insoluble human callus (Longshaw et al. 2002). The two proteins differ in that one is constitutive while the other was highly produced under low growth rate but not under high growth rates. Maximum proteinase production occurs between pH 8.0 and 9.0. This strain is specifically mentioned in US patent (5.213.978) for a process for degradation of keratin, keratinaceous material, collagen, and collagenaceous material.

16 The Family *Dermatophilaceae*

Konstantina Kagia · Wen-Tso Liu
Department of Civil and Environmental Engineering, 3207 Newmark Civil Engineering Laboratory, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Abstract
The family *Dermatophilaceae* embraces Gram-positive, high G+C, facultative anaerobic or strictly aerobic chemoorganotrophic bacteria with a wide range of habitats such as animal and human skin, fish guts, and wastewater treatment reactors. Up to date, it consists of five genera: *Dermatophilus*, *Austwickia*, *Kineosphaera*, *Mobilicoccus*, and *Piscicoccus*. Its first member, *Dermatophilus congolensis*, was isolated as the causative agent of bovine streptotrichosis, at the time named dermatose contagieuse. The disease can be described as an acute or chronic exudative dermatitis, affecting a wide range of animals and man. It has been known with a variety of names throughout time, mostly depending on the host animal, but all of them will hereafter be called under the broader name dermatophilosis. With its complex life cycle, unique morphology, and pathogenicity, *D. congolensis* has led to significant turmoil in the history of the taxonomic placement of itself and its relatives. *Austwickia chelonae*, which was originally thought to belong to the genus *Dermatophilus*, was recently reclassified as a new genus within the *Dermatophilaceae* family. *Kineosphaera limosa* was isolated from a deteriorated enhanced biological phosphorus removal reactor, and is able to accumulate polyhydroxyalkanoates. *Mobilicoccus pelagius* and *Piscicoccus intestinalis* constitute the latest additions to the family and were both isolated from the intestinal tracts of two species of fish. Thus, it can be concluded that members of the family *Dermatophilaceae* constitute a phenotypically versatile group.

Taxonomy: Historical and Current

The family *Dermatophilaceae* was first proposed by Austwick (1958) and subsequently emended a number of times (Hamada et al. 2010; Zhi et al. 2009; Stackebrandt and Schumann 2000; Stackebrandt et al. 1997; Gordon and Edwards 1963). It was originally classified in the order *Actinomycetales* and consisted of only the genus *Dermatophilus* and three species, i.e., *Dermatophilus congolensis*, *Dermatophilus dermatonomus*, and '*Dermatophilus pedis*'. The three species differed mainly on their respective hosts and the type of lesions they exhibited, a fact that rendered the rightness of their taxonomic differentiation doubtful and finally led to their grouping into one species under the name *Dermatophilus congolensis* (Gordon 1964). *Geodermatophilus obscurus*, a soil-isolated microorganism, was erroneously assigned to the *Dermatophilaceae* family based mainly on morphological characteristics (Luedemann 1968), but its chemotaxonomic characteristics led to its reclassification as a member of the *Geodermatophilaceae* family (Stackebrandt 1983; Samsonoff 1977a).

Based on the phylogeny tree (*Fig. 16.1*) constructed using 16S rRNA gene sequences, the family *Dermatophilaceae* was reclassified into the class *Actinobacteria*, subclass *Actinobacteridae*, order *Actinomycetales*, suborder *Micrococcineae* (Stackebrandt et al. 1997). It contained the type genus *Dermatophilus* and the genera *Kytococcus* and *Dermacoccus*. Using a set of signature nucleotides, the genera *Kytococcus* and *Dermacoccus* were proved to cluster separately from the genus *Dermatophilus*, leading to the division of the three genera into two families: *Dermatophilaceae* with *Dermatophilus* as the sole genus and *Dermacoccaceae*, embracing the genera *Dermacoccus*, *Kytococcus* and *Demetria* (Stackebrandt and Schumann 2000). The higher taxonomic levels were left unchanged. *Austwickia chelonae*, which was originally assigned to the genus *Dermatophilus* based mainly on growth and biochemical characteristics and molecular analysis (Masters et al. 1995; Trott et al. 1995), was reclassified outside of the *Dermatophilus* genus based on 16S rRNA sequence analysis and chemotaxonomic characterization (Hamada et al. 2010; Stackebrandt and Schumann 2000). With the isolation of

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_177,

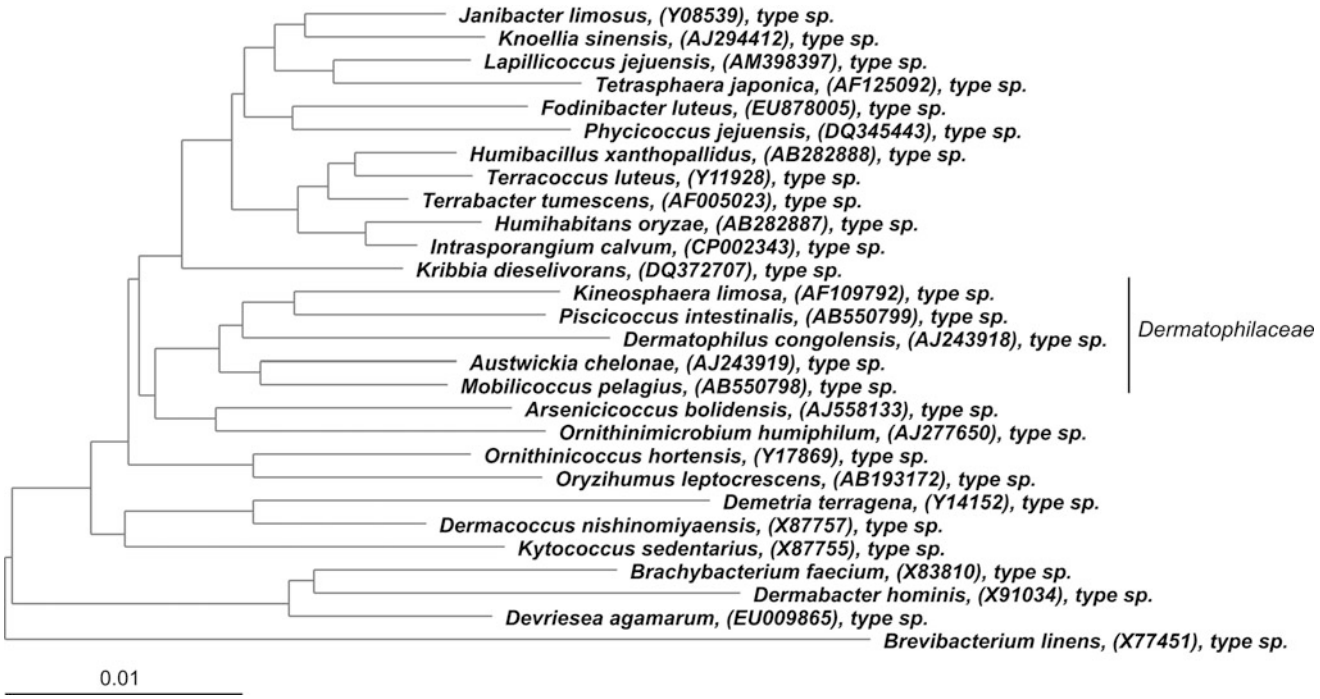

Fig. 16.1

Phylogenetic reconstruction of the family *Dermatophilaceae* based on 16S rRNA gene sequences, created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010); http://www.arb-silva.de/projects/living-tree. The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

K. limosa, *M. pelagius*, and *P. intestinalus*, the family was further emended to form the new genera/species and reclassify *Dermatophilus chelonae* as *Austwickia chelonae* (Hamada et al. 2010; Zhi et al. 2009). The distinction between *D. congolensis* and *K. limosa* was supported by the presence of signature nucleotides within the 16S rRNA gene sequence, in addition to chemotaxonomic and morphological characteristics (Stackebrandt et al. 1997).

Molecular Analyses

D. congolensis is the most well-studied member of the family *Dermatophilaceae*. Its clinical relevance has led to the application of a number of molecular techniques (i.e., sodium dodecyl sulfate polyacrylamide gel electrophoresis, western blotting, multilocus enzyme electrophoresis, restriction enzyme analysis, random amplified polymorphism DNA, and pulsed field gel electrophoresis), aiming to elucidate the variation among *D. congolensis* strains and their infective routes (Larrasa et al. 2004; Larrasa et al. 2002; Makinde and Gyles 1999; Trott et al. 1995; Gogolewski et al. 1992). They all revealed that significant genetic differences exist among *D. congolensis* isolates that do not correlate with geographic origin but sometimes correlate with host animal and properties such as hemolytic or phospholipase activity. Such methods, though effective in typing different *D. congolensis* strains, are of little use to bacterial taxonomy. Taxonomic characterization via molecular techniques such as DNA-DNA hybridization or genome comparisons has not been reported in the literature. Whole genome sequence projects have been undergone for *D. congolensis*, *A. chelonae*, *K. limosa*, and *M. pelagius*, but the results are not published yet.

Phages

Phage pDM1 was isolated from infected wool samples in Western Australia and was shown to possess a *D. congolensis*–specific lytic activity (Patten et al. 1995). The optimal medium for phage propagation is unsupplemented bovine blood agar, and clear circular plaques (1-mm diameter) are consistently produced. Chloroform, thymol, hydrogen peroxide, and ethanol, all result in significant reduction of the plaque-forming units, indicating the sensitivity of the phage to these compounds. Its lytic activity is applicable to isolates from various locations and host animals and does not extend outside the *Dermatophilus* genus level. Concurrent inoculation of the host and the phage results in the greatest reduction, indicating that early developmental stages of *D. congolensis* might be more susceptible.

Table 16.1
Major phenotypic characteristics of members of the family *Dermatophilaceae*

	D. congolensis	*A. chelonae*	*K. limosa*	*M. pelagius*	*P. intestinalis*
Oxygen relationship	Facultative anaerobic	Facultative anaerobic	Strictly aerobic	Facultative anaerobic	Facultative anaerobic

Major fatty acids[c]	$C_{17:1}$ - $C_{15:0}$ - $C_{14:0}$ - $C_{16:0}$	$C_{15:0}$ - $C_{17:1}$ - $C_{17:0}$ - $C_{16:0}$	$C_{16:0}$ - $C_{17:1}$ - $C_{18:1}$ - $C_{17:0}$	$C_{17:1}$ - $C_{15:0}$	$C_{17:1}$ - iso-$C_{16:0}$ - iso-$C_{14:0}$
Major menaquinone	MK-8(H_4)	MK-8(H_4)	MK-8(H_4)	Exclusively MK-8(H_2)	MK-8(H_4)

[a]*NA* not available, + positive, – negative
[b]*PG* phosphatidylglycerol, *DPG* diphosphatidylglycerol, *PI* phosphatidylinositol *PE* phosphatidylethanolamine, *lyso-PE* lyso-phosphatidylethanolamine, *PC* phosphatidylcholine
[c]Fatty acids are listed in order of decreasing abundance

The specificity of the phage further enhances its potential as a biological control agent. However, the in vitro results need to be examined in vivo before its large-scale application, as environmental conditions (e.g., temperature, physical and chemical parameters) may alter its effectiveness. No phages infecting other members of the family have been reported so far.

Phenotypic Analyses

All genera of the *Dermatophilaceae* family are aerobic, and most of them are facultatively anaerobic, Gram-positive, and catalase-positive cocci with a high G+C content (57–72 %). The family embraces both sporulating and non-sporulating members that have MK-8 as the dominant respiratory quinone, $C_{17:1}$ as a major fatty acid, and a cell wall peptidoglycan of the A1γ type. The major phenotypic characteristics of the type species in the family are summarized in *Table 16.1*.

Dermatophilus congolensis

Etymology: *Dermatophilus*: dermato from the Greek word *derma* skin, phil from the Greek word *philos* friend, loving, *congolensis*: because it was first found in Belgian Congo.

D. congolensis colonies, depending on growth conditions, are observed as being moist and dominated by coccoid cells or dry and dominated by filamentous ones (Roberts 1957a). Intra- and inter-strain variations in the colony morphology (i.e., shape and consistency) of *D. congolensis* were confirmed by obtaining isolates from different hosts (El-Nageh 1971). Stained smears, depending on age and staining process, can exhibit a variety of cell morphologies, including lots of coccoid spores, cocci at the stage of germination (alone or in clusters), branching mycelia in the segmentation process, non-mucoid clusters, or any combination of the above (Gordon 1964). Each cell can have a few to more than fifty flagella, 8–9 μm in width (Richard et al. 1967).

The differences in colony and cell morphology can be attributed to the complex life cycle of *D. congolensis* (Roberts 1961),

which largely depends on growth conditions (temperature, oxygen supply, and nutrient availability). In brief, motile cocci (zoospores) that are reproductively inactive lose their motility and start enlarging. The cell wall yields to accommodate a bud, and the hyphae extension starts and carries on with a continuous process of division by transverse septation. Lateral bud appearance can also occur, leading to a branching pattern. If nutrients become limiting, the extension ceases and division throughout the mycelium becomes quicker. In the next step, septum formation stops, each segment starts enlarging and division in planes parallel to the hypha's axis (or also perpendicular if no physical restrictions apply) commences. The occurring cocci are not motile, and each one can go through the whole aforementioned germination process upon nutrient supplementation. At some point, division stops and a new round of enlargement of the cocci begins. Finally, cocci regain their mobility and escape (zoospores). If the growth medium is nutritionally restricted in the first place, the zoospores will not go through the germination process, while, in case nutrients are not enough for the completion of all the life cycle stages, the mycelium dies before giving rise to a new zoospore generation.

D. congolensis is an aerobic or facultatively anaerobic bacterium. Its growth substrates include fructose, glucose, and laevulose, but not adonitol, dulcitol, glycerin, inositol, lactose, mannitol, mannose, raffinose, saccharose, salicin, sorbitol, and sucrose, and transient acid production from galactose has been reported (El-Nageh 1971; Gordon 1964; Roberts 1957a). Most *D. congolensis* isolates can hydrolyze casein and digest BCP milk, and some differ in gelatin liquefaction capability and proteolytic properties. The organism is Gram-positive, catalase-positive, methyl red- and indole-negative; does not reduce nitrate to nitrite; and hydrolyzes urea and starch but not tyrosine or xanthine (Gordon 1964; Roberts 1957a). The cell-wall peptidoglycan is of the A1γ type, the major menaquinone is MK-8(H_4), the dominant polar lipids are phosphatidylglycerol, phosphatidylinositol, and lyso-phosphatidylethanolamine, and cellular fatty acids are predominantly unsaturated and straight-chain saturated ones (Hamada et al. 2010). The G+C content ranges from 57.4 to 59.8 mol% (Hamada et al. 2010; Samsonoff 1977b).

D. congolensis exhibits hemolytic activity, and its hemolytic complex is suggested to comprise of at least two components (Skalka and Pospísil 1992). *D. congolensis* can produce extracellular serine proteases with maximum activity in the pH range of 7–10 and variation between isolates seems to be host-specific (Ambrose et al. 1998).

The type strain is *Dermatophilus congolensis* DSM 44180^T (=NBRC 105199^T = ATCC 14637^T = JCM 8106^T = NCTC 13039^T = NRRL B-2350^T = DSM 44180^T).

Austwickia chelonae

Etymology: *Austwickia:* in honor of Peter K. C. Austwick who proposed the family *Dermatophilaceae*, *chelonae* from the Greek word *chelona* turtle.

Like *D. congolensis*, members of the genus *Austwickia* go through life cycle stages ranging from coccoid zoospores to branching mycelia exhibiting transverse and longitudinal septum formation, but zoospores exhibit poor motility (flagella number ranging from zero to six) (Masters et al. 1995). They are facultative anaerobic and Gram-positive. The peptidoglycan components are alanine, glutamic acid, and meso-diaminopimelic acid (molar ratio of 2.0:1.0:0.7), proving the cell-wall peptidoglycan to be of the A1γ type. The major menaquinones are MK-8(H_4), MK-8, and MK-8(H_2). The dominant polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and lyso-phosphatidylethanolamine. Cellular fatty acids are predominantly unsaturated and straight-chain saturated ones (Hamada et al. 2010).

The type species *A. chelonae* (former *Dermatophilus chelonae*) grows optimally at 27 °C, and exhibits different hemolytic patterns based on growth conditions (bovine, ovine, or equine blood agar). Its colonies produce a distinctive putrid odor. Its growth substrates include glucose and often fructose and galactose, but not dulcitol, lactose, mannitol, salicin, sorbitol, sucrose, or xylose. *A. chelonae* hydrolyzes casein and gelatin; is catalase-positive and indole- and methyl red-negative; does not always produce urease; and exhibits a weak reduction of nitrate to nitrite. Additionally, *A. chelonae* shows chondroitinase activity with chondroitin 4-sulfate but not with chondroitin 6-sulfate and in vitro collagenase activity (Masters et al. 1995). Its major cellular fatty acids are $C_{15:0}$, $C_{17:1}$ ω9, $C_{17:0}$, and $C_{16:0}$, and its G+C content is 66.5 mol% (Hamada et al. 2010).

The type strain is *A. chelonae* W16 (=NBRC 105200^T = ATCC 51576^T = CCUG 47447^T = CIP 104541^T = DSM 44178^T = JCM 9706^T = DSM 44178^T).

Kineosphaera limosa

Etymology: *Kineosphaera*: kineo- from the Greek word *kino* = move, -sphaera from the Greek word *sphera* = sphere, *limosa* from the Latin word *limosus*: muddy because of the connection to sludge.

The genus *Kineosphaera* embraces bacteria that are strictly aerobic, non-spore-forming, Gram-positive motile cocci with a diameter ranging from 2 to 3 μm. The cocci can grow singly, in pairs, or in clusters. Members of the genus are catalase-positive, oxidase-negative; do not produce nitrite from nitrate; and have a DNA G+C content of 71 mol%. The major diaminoacid is meso-diaminopimelic acid, the cell-wall peptidoglycan is of the A1γ type, and the dominant respiratory quinone is MK-8 (H_4). The dominant fatty acids are unsaturated and straight-chain saturated ones.

The type strain *K. limosa* is Neisser-negative and can accumulate polyhydroxyalkanoates (PHAs) up to approximately 13 % in dry cell weight with 3-hydroxybutyrate and 3-hydroxyvalerate as the major monomers. Its growth temperature range spans from 10 °C to 35 °C, with an optimum

at 30 °C. Its pH range is from 6.0 to 10.2, with an optimum at 7.0. It can grow in a NaCl concentration up to 3 % (w/v). Its growth substrates include *N*-acetyl-D-mannosamine, adenosine, D-arabitol, dextrin, fructose, α-D-glucose, glycerol, γ-hydroxybutyric acid, maltose, D-mannose, 3-*O*-methylglucose, methyl β-D-glucoside, methylpyruvate, palatinose, propionic acid, psicose, salicin, D-sorbitol, succinamic acid, succinic acid, sucrose, trehalose, D-trehalose, turanose, Tween 40, Tween 80, and xylitol. Its major fatty acids include $C_{16:0}$, $C_{17:1}$, $C_{18:1}$, $C_{17:0}$ and $C_{16:1}$. The polar lipid profile comprises of phosphatidylglycerol, phosphatidylinositol, diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidylcholine.

The type strain is *K. limosa* Lpha5^T (=JCM 11399^T = DSM 14548^T).

Mobilicoccus pelagius

Etymology: *Mobilicoccus*: mobile- from the Latin word *mobilis* = mobile, -coccus from the Greek word *kokkos* = grain, *pelagius* from the Greek word *pelagos* = sea.

Members of the genus *Mobilicoccus* are Gram-positive, aerobic or facultatively anaerobic, non-spore-forming, motile cocci with peritrichous flagella. Peptidoglycan is made of D-alanine, D-glutamic acid, and meso-diaminopimelic acid (molar ratio of 1.6:1.0:0.7), suggesting the cell-wall peptidoglycan as the A1γ type. Only menaquinone MK-8(H_2) is detected, and the dominant polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. The dominant fatty acids are unsaturated and straight-chain saturated ones, and major cell wall sugars are ribose and mannose.

The type species *M. pelagius* can grow between 10 °C and 37 °C, with an optimum around 28 °C. It has a pH range from 6.0 to 9.0, with an optimum around 7.0 and a NaCl range from 0% to 7 % (v/w) with an optimum around 1 %. No growth is observed above 10 % NaCl. Its colonies are smooth and orange-yellow in color, with an approximate size of 1–2 mm, while the cell size range is 0.7–1.2 μm in diameter. It is catalase-positive and oxidase-negative. Its growth substrates include N-acetyl-glucosamine, fructose, galactose, glucose, inositol, maltose, mannose, ribose, sucrose, and trehalose but not adonitol, amygdalin, arabinose, arabitol, arbutin, cellobiose, dulcitol, erythritol, fucose, gentiobiose, gluconate, glycerol, inulin, 2-keto-gluconate, 5-keto-gluconate, lactose, lyxose, mannitol, melezitose, melibiose, methyl-α-D-glucopyranoside, methyl-α-D-mannopyranoside, methyl-β-D-xylopyranoside, raffinose, rhamose, salicin, sorbitol, sorbose, starch, tagatose, xylitol, and xylose. In terms of enzymatic activities, alkaline phosphatase, α-glucosidase, leucine arylamidase, and pyrazinamidase are detected, while acid phosphatase, N-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase lipase (C8), α-fucosidase, α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, lipase (C14), lysine decarboxylase, α-mannosidase, ornithine decarboxylase, phosphohydrolase, pyrrolidonyl arylamidase, trypsin, tryptophan deaminase, and valine arylamidase are not. The species is indole-negative, produces acetoin but not H_2S, reduces nitrate, and does not hydrolyze urea, gelatin, or esculin. Its dominant fatty acids are $C_{17:1}$ ω9 and $C_{15:0}$, and its DNA G+C content is 71.6 mol%.

The type strain is *M. pelagius* Aji5-31^T (=NBRC 104925^T = DSM 22762^T).

Piscicoccus intestinalis

Etymology: *Piscicoccus*: pisci- from the Latin word *piscis* = fish, -coccus from the Greek word *kokkos* = grain, *intestinalis*: from the Latin word *intestinum* = gut, intestine.

Members of the genus *Piscicoccus* are Gram-positive, aerobic or facultatively anaerobic, non-spore-forming and nonmotile cocci, growing in clusters of cuboid or coccoid shape. Peptidoglycan components are D- and L-alanine, D-glutamine, and meso-diaminopimelic acid (molar ratio of 1.7:1.0:0.7), suggesting the cell-wall peptidoglycan as the A1γ type. Menaquinones MK-8(H_4) and MK-8(H_6) are detected in a ratio of 96:4, and the genus's dominant polar lipids are phosphatidylglycerol, phosphatidylinositol, and lyso-phosphatidylethanolamine. The dominant fatty acids are unsaturated, iso-branched saturated, and straight-chain saturated ones, while the major cell wall sugars are ribose and mannose.

The type species *Piscicoccus intestinalis* can grow between 10 °C and 37 °C, with an optimum around 28 °C. It has a pH range from 5.0 to 9.0, with an optimum around 6.0–7.0 and a NaCl range from 0 % to 5 % (v/w), with an optimum around 0–1 %. No growth is observed above 7 % NaCl. Its colonies are rough and orange-yellow in color, ranging from 0.7 to 1.0 μm in diameter. Its growth substrates include arbutin, fructose, galactose, glucose, maltose, mannose, raffinose, sucrose, and trehalose, but not N- acetyl-glucosamine, adonitol, amygdalin, arabinose, arabitol, cellobiose, dulcitol, erythritol, fucose, gentiobiose, gluconate, glycogen, inositol, inulin, 2-keto-gluconate, 5-keto-gluconate, lactose, lyxose, melezitose, melibiose, methyl-α-D-mannopyranoside, methyl-β-D-xylopyranoside, rhamose, ribose, sorbitol, sorbose, starch, tagatose, xylitol, and xylose. In terms of enzymatic activities, acid phosphatase, alkaline phosphatase, β-galactosidase, α-glucosidase, β-glucosidase, leucine arylamidase, and pyrazinamidase are detected, while N-acetyl-β-glucosaminidase, arginine dihydrolase, α-chymotrypsin, cystine arylamidase, α-fucosidase, α-galactosidase, β-glucuronidase, lipase (C14), lysine decarboxylase, α-mannosidase, ornithine decarboxylase, phosphohydrolase, pyrrolidonyl arylamidase, trypsin, tryptophan deaminase, and valine arylamidase are not. The species is indole-negative, does not produce H_2S, hydrolyzes esculin but not urea or gelatin, and is able to reduce nitrate. The dominant fatty acids include $C_{17:1}$ ω9 iso-$C_{16:0}$ and iso-$C_{14:0}$. The DNA G+C content is 71.5 mol%.

The type strain is *P. intestinalis* Ngc37-23^T (=NBRC 104926^T = DSM 22761^T).

Isolation, Enrichment, and Maintenance Procedures

Dermatophilus congolensis was first isolated as the causative agent of bovine streptotrichosis (Van Saceghem 1915). It was later isolated from cases of mycotic dermatitis and strawberry foot rot–infected sheep without knowing that it was the same microorganism (Coleman 1967; Thompson 1954). *D. congolensis* can be readily isolated from infected skin. The adjacent material is ground in broth, resulting in suspensions containing a lot of cocci and sometimes also fragments of branched mycelia. Plating this suspension on blood agar and incubating at 37 °C leads to the growth of mostly pure cultures of branching filaments (Roberts 1957a).

Suitable culturing media for *D. congolensis* are blood agar, Brain Heart Infusion (BHI) agar, Tryptone Broth (1 % Difco Tryptone, 0.5 % NaCl, pH 7.2), and beef infusion peptone (F5A) broth. Growth in all of them is observed under aerobic conditions at 36 °C and changing the environment to anaerobic (brewer jars with illuminating gas and varying CO_2 content at 37 °C) leads to substantial but much less growth (Gordon 1964). Growth has also been reported on sheep blood agar containing 3.9 % w/v Columbia agar base and 6.7 % v/v defibrinated sheep blood (Oxoid) in an environment containing 5 % CO_2 and 95 % air at 37 °C for 48 h (Ambrose et al. 1998) as well as on BHI agar plates in a candle jar at 37 °C for 48 h (Larrasa et al. 2002). No growth was observed on Sabouraud Dextrose Agar (Difco), Potato Dextrose, Czapek's solution, and tomato paste oatmeal agar (Pridham et al. 1957). Growth can also be achieved in DSM medium 535 (30-g Trypticase Soy Broth, 15-g agar 15.0, and 1,000-ml distilled water) with 5 % (v/v) blood at pH 7.3 and 37 °C.

For maintenance purposes, serial transfers on BHI Agar slants can be employed under aerobic incubation at 36 °C for 3–7 days, followed by storage at room temperature. In this method, survival time varies from a few weeks to 2 years, and the maximum time is achieved at room temperature. For long-term storage, cultures grown for 4 days in F5A broth (0.1 % glucose, 0.5 % NaCl) can be lyophilized in skim milk suspension. Easy recovery from lyophilization can be achieved in F5A broth (Gordon 1964). Maintenance for about 1 year has been reported (Richard et al. 1967) with semimonthly transfers in 10 % (v/v) serum broth. Long-term storage can also be achieved at −80 °C in 20 % (v/v) glycerol if isolates are first grown on 8 % sheep blood agar for 2 days at 37 °C and then sub-cultured in BHI broth for 18 h at 37 °C (Gogolewski et al. 1992). Alternatively, isolates can be stored at −20 °C in BHI/neutralized soya peptone broth with 15 % glycerol (Ambrose et al. 1998). For recovery from freeze-dried isolates, dissolution of the freeze-dried ampoule in 1 mL of BHI broth and culturing for 24–48 h at 37 °C on blood agar in 5 % CO_2 in humidified conditions has been proposed (Makinde and Gyles 1999).

Austwickia chelonae has been isolated from the nose scab of a snapping turtle, an abscess in a tortoise, and from skin lesions on a turtle, all from the Perth zoo in Western Australia (Masters et al. 1995). It has also been isolated from an infected king cobra at the Central Florida Zoo, Florida, USA (Wellehan et al. 2004). *A. chelonae* has been successfully cultured on 9 % bovine blood agar (Oxoid Columbia agar base no. 2), in the presence of 10 % CO_2 for 2–3 days at 37 °C, or in the ambient atmosphere at 27 °C for the same amount of time (Masters et al. 1995). Growth was also reported on polymyxin B blood agar (1,000 IU/mL) at both 27 °C and 37 °C, but it seemed to always be faster at 27 °C. Growth can also be achieved in DSM medium 535 (see *D. congolensis* media) with 5 % (v/v) blood at pH 7.3 and 37 °C.

Other successful growth conditions tested were inoculation of tryptose-phosphate-10 % bovine serum broth with a dense zoospore suspension (observation after 3 days of incubation at 37 °C and after additional incubation at room temperature), incubation in thioglycollate broth (Oxoid) at 37 °C for 3 days, and incubation at 37 °C and 27 °C for 2–3 days on bovine, bovine, and equine agar media (Masters et al. 1995). In the last three types of media, various hemolytic patterns could be observed based on both temperature and media type. No long-term preservation processes were reported.

Kineosphaera limosa has only been isolated from an engineered environment (a deteriorated enhanced biological phosphorus removal activated sludge reactor) enriched with PHA-accumulating microorganisms. In the beginning of each cycle, the reactor was supplemented with substrate composed of acetate, peptone, and other nutrients. The isolation process consisted of taking samples from the end of the aerobic phase, washing them two to three times with 0.5 % NaCl solution by natural settling, adjusting the biomass to 500–1,000 mg/L, dispersing the sludge flocs with an ultrasonicator, serially diluting the dispersed sludge (10^{-2}–10^{-8}), and plating onto solid growth media. Specifically, GM1 medium in distilled water at pH 7 was used, with the following composition per liter: 0.50-g glucose, 2.00-g $NaCH_3COO{\cdot}3H_2O$, 0.50-g peptone, 0.50-g yeast extract, 0.44-g KH_2PO_4, 0.50-g $MgSO_4{\cdot}7H_2O$, 0.50 g $(NH_4)_2SO_4$, 10-mL vitamin solution, 100-mL autoclaved and filtered sludge extract, and 16-g agar. For maintenance and growth purposes, broth medium was used. Cultures were incubated for 1–3 weeks at room temperature, random colonies were picked and screened for polyphosphate (Neisser staining) and PHA (PHB dyes) inclusions, and the positive ones were further purified at least once on GM1 media (Liu et al. 2000). Growth can also be achieved in DSM medium 776 (0.5-g glucose, 0.5-g peptone, 0.5-g yeast extract, 0.5-g Na-glutamate, 0.5-g KH_2PO_4' 0.1-g $(NH_4)_2SO_4$, 0.1-g $MgSO_4 \times 7H_2O$ and 1,000-ml distilled water) at pH 7.0 and 28 °C. No long-term preservation processes were reported.

Mobilicoccus pelagius **and** ***Piscicoccus intestinalis*** have only been isolated from the intestinal tracts of two species of fish (*Trachurus japonicus* and *Repomucenus richardsonii*, respectively) from Kyonan Beach, Tokyo Bay, Japan (Hamada et al. 2010). The intestinal tract suspensions were serially diluted in saline (10^{-1} to 10^{-10}), and 0.1-mL of each dilution was spread on LYPm agar and incubated at room temperature for a minimum of 1 month in a sealed nylon bag containing an O_2-absorbing and CO_2-generating agent (Hamada et al. 2009). The LYPm medium contained 10-g α-lactose, 10-g yeast extract,

20-g NaCl, 5-g polypeptone, 0.025-g Tween 80, 5-ml salts solution, and 1,000-ml distilled water, while the salts solution comprised of 40-g $MgSO_4 \times 7H_2O$, 2-g $MnSO_4 \times 4H_2O$, 2-g $FeSO_4 \times 7H_2O$, and 2-g NaCl in 1,000-ml distilled water (Iino et al. 2007). Colonies were then transferred to new LYPm agar plates, and the process was repeated several times to obtain pure cultures. Subsequently, NBRC medium 802 was used for further study (general cultivation, morphology, optimal growth parameters). The medium contained 1.0 % polypeptone (Wako), 0.2 % yeast extract (Difco), 0.1 % $MgSO_4 \cdot 7H_2O$ with the addition of 1.5 % agar if solid media were required and it had a pH of 7.0 (Hamada et al. 2009). Growth can also be achieved in DSM medium 514 (5.00-g Bacto peptone, 1.00-g Bacto yeast extract, 0.10-g Fe(III) citrate, 19.45-g NaCl, 5.90-g $MgCl_2$, 3.24-g Na_2SO_4, 1.80-g $CaCl_2$, 0.55-g KCl, 0.16-g $NaHCO_3$, 0.08-g KBr, 34.00-mg $SrCl_2$, 22.00-mg H_3BO_3, 4.00-mg Na-silicate, 2.40-mg NaF, 1.60-mg $(NH_4)NO_3$, 8.00-mg Na_2HPO_4, and 1,000-ml distilled water) at pH 7.0 and 25 °C. No long-term preservation processes were reported.

Ecology

D. congolensis in nature is found on the site of infection of animals (and man) suffering from dermatophilosis. The disease is distributed worldwide, but is most intense in regions with high humidity and a tropical or subtropical climate (Zaria 1993). Humidity can play a dual role. Water can serve as a medium for zoospore transmission and/or promote leaching of the skin's protective wax barrier and bacteriostatic substances. In both cases, *D. congolensis* infection is facilitated (Zaria 1993; Kingali 1990; Roberts 1967b). *D. congolensis* has not been found in the soil, probably indicating its inability to grow outside of the conditions provided by an infected host (Roberts 1967a).

D. congolensis is not only isolated from cattle, sheep, goats, and horses, but also from a wide range of animals, such as mules, donkeys, pigs, deer, raccoons, giraffes, antelopes, buffaloes, zebras, rodents, monkeys, snakes, lizards, polar bears, cats, dogs, and even more (Amor et al. 2011; Shaibu et al. 2011; Hamada et al. 2010; Stackebrandt and Schumann 2000; Zaria 1993). In order for it to thrive, it must penetrate the skin protective barriers, such as sebaceous wax and stratum corneum (Roberts 1963). Multiplication begins deep in the epidermis, resulting in infiltration with exudate, which leads to the dermis/epidermis layers separation and is followed by sequential cycles of bacterial proliferation, leading to the formation of thick superficial scabs (Gogolewski et al. 1992; Hyslop 1979). If hair follicles rupture as a result of infection, *D. congolensis* might also penetrate the dermis. The hyphal developmental stage is considered to be particularly invasive in terms of epidermal cell penetration (Roberts 1965).

The natural habitat of *A. chelonae* is the skin of chelonids, where it forms scabs (Wellehan et al. 2004; Masters et al. 1995). *A. chelonae* type strains DSM 44178^T and NBRC 105200^T (Hamada et al. 2010; Stackebrandt and Schumann 2000) were isolated from nose scabs on a snapping turtle (*Chelydra serpentine*), and another strain was isolated from a subcutaneous mass in a male king cobra (*Ophiopagus hannah*) (Wellehan et al. 2004).

K. limosa is isolated from a deteriorated EBPR reactor wastewater treatment process. Its ability to accumulate PHA but not cellular polyphosphate suggests that *K. limosa* can compete with polyphosphate-accumulating organisms (PAOs) for carbon substrates, and can play an important role in phosphorus removal processes. In addition, one *Kineosphaera* species was isolated from *Homo sapiens* sputum, but was not associated with human disease (Keller et al. 2010).

M. pelagius has so far only been isolated from fish intestinal tracts (*Trachurus japonicas*), and no additional ecology-relevant reports have been published on this species (Hamada et al. 2010). On the contrary, more information is available on the ecology of *P. intestinalis*, the type species of which was also isolated from fish guts (*Repomucenus richardsonii*) (Hamada et al. 2010; Anceno et al. 2009; Nasidze et al. 2009; Xin et al. 2008).

Pathogenicity: Clinical Relevance

D. congolensis is not highly pathogenic by itself, and is proposed most likely as an opportunistic pathogen (Ambrose et al. 1999; Zaria 1993). Infection likelihood can be significantly enhanced by malnutrition, stress, damaged/traumatized skin, or immune deficiency (Ambrose et al. 1999; Zaria 1993; Abu Samra 1981; Stewart 1972; Egerton 1964; Memery 1961; Hudson 1937). Up to date, no single treatment is widely accepted. Generally, the treatment approaches can be grouped into three major categories, i.e., topical medication, systemic medication, and biological approach. None of them have however gained wide acceptance (Zaria 1993). Because of the large scale of dermatophilosis infection in cattle, a prospective treatment needs to be easy to apply, rapid, and economical in order for cattle owners to be likely to use it (Coleman 1967). The thus far existing approaches do not fully satisfy one or all of these requirements.

The sensitivity of *D. congolensis* to antibiotics is important in the search of a dermatophilosis treatment. It exhibits a slight sensitivity to kanamycin and no sensitivity to polymixin, ampicillin, amoxicillin, gentamycin, cefoperazone, and negram. It is sensitive to tetracyclin, terramycin B, erythromycin, chloromycetin, neomycin, chloramphenicol, sigmamycin, natromycin, septrin, stapylomycin, and oxytetracyclin. There are contradictory results on the sensitivity to penicillin and streptomycin (Kaya et al. 2000; El-Nageh 1971; Roberts 1957b).

No vaccine has been developed due to variation in host response and strain virulence, as well as because of dosage and environmental factors (Zaria 1993). *D. congolensis* virulence is connected to its lipases and proteases, which may aid in penetration of the skin barrier (Ambrose et al. 1998). Recently, caprylic acid was proposed as a means to treat dermatophilosis, as it seems to disrupt the plasma membrane through binding on aromatic amino acids on membrane proteins (Valipe 2011).

Dermatophilosis is reported to be closely connected to infestations with *Ambylomma variegatum*, an ixodid tick. Resistance to *A. variegatum* seems to be correlated with dermatophilosis resistance. Specifically, *A. variegatum* is suggested to have a systemic effect on dermatophilosis and this effect seems to be present only for infestation with adult ticks (Ambrose et al. 1999; Ambrose 1996; Lloyd and Walker 1993; Walker and Lloyd 1993).

There is little pathogenicity-relevant information on *A. chelonae*. The species also causes scabs and lesions on chelonids, and it is resistant to polymyxin B, streptomycin, neomycin, and sensitive to penicillin G, tetracycline, chloramphenicol, and sulfafurazole (Masters et al. 1995).

There is no report on the pathogenicity of the other members of the *Dermatophilaceae* family.

Application

The only member of the family *Dermatophilaceae* with important economic ramifications is *D. congolensis*. Dermatophilosis is listed as one of the top three cattle affecting diseases in the tropics (DeRyke et al. 1991). Losses in hides/skin and decrease in meat production are the major dermatophilosis-related economic impacts, while secondary ones include lower milk production, wool devaluation, and difficulties in upgrading breeds (Zaria 1993).

Dermatophilosis causes local weaknesses at the site of infection, devaluating skin quality. After tanning, there appear to be lower quality fibers, resulting in rejection by exporters (Zaria 1993; Gbolagunte and Mshelbwala 1991).The local nature of the disease on the epidermis has no direct effect on meat quality, but the indirect consequences are pronounced. Infected animals can have a significant loss of weight and subsequently die. In such a case, the owners prefer to cull or sell the animals when they are still young, before full market price is reached (Zaria 1993). Losses as high as 20 % have been reported in milk production (Nobel et al. 1976). Moreover, the disease poses a restriction in upgrading lower productivity–infected breeds by cross-breeding them with more productive exotic ones (Zaria 1993). Finally, dermatophilosis also affects wool production (Zaria 1993). Apart from wool devaluation, significant losses may also stem from problems caused to shearing machines by scabs on animals suffering from the disease (Austwick and Davies 1958).

Numerical estimates of dermatophilosis associated losses are scarce, but it has been estimated that, in 1984–1985, more than $2 million were lost due to dermatophilosis in Western Australia (Edwards et al. 1986). It is thus important to develop an effective, quick, and economical treatment for *D. congolensis* infections.

17 The Family *Dietziaceae*

Rüdiger Pukall
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
Members of *Dietziaceae*, actinomycetes characterized by the presence of mycolic acids, especially high molecular weight 3-hydroxy fatty acids substituted in the two positions with a long alkyl branch, have previously been classified in the suborder *Corynebacterinae*. The suborder *Corynebacterinae* was originally placed in the order *Actinomycetales*. According to Bergey's road map of the Actinobacteria, the six families *Corynebacteriaeceae*, *Tsukumarellaceae*, *Mycobacteriaceae*, *Nocardiaceae*, *Segniliparaceae*, and *Dietziaceae* were removed from the order *Actinomycetales* and assigned to the order *Corynebacterales*. The family *Dietziaceae* comprises solely the genus *Dietzia* which consists of 13 species with validly published names. The morphology and physiology of *Dietzia* species is similar to that of *Rhodococcus equi*, which in the past often led to misidentification of *Dietzia* strains by traditional identification techniques. Nowadays molecular based methods like 16S rRNA gene sequencing can be used to discriminate *Dietzia* strains from the type strain of *Rhodococcus equi*. This is of ecological significance, as members of *Dietzia* have been isolated from diverse environments including clinical specimens, which led to conclusion that *Dietzia* species may act as an opportunistic pathogen.

Taxonomy: Historical and Current

Short Description of the Family and the Genus *Dietzia*

Dietziaceae Rainey, Ward-Rainey and Stackebrandt 1997, 486[VP], emend. Zhi, Li and Stackebrandt 2009, 595[VP]

N.L. fem. n. *Dietzia*, type genus of the family; -aceae, ending to denote a family; N.L. fem. pl. n. *Dietziaceae*, the *Dietzia* family.

The family *Dietziaceae* was proposed by Rainey et al. (1997) in the course of the hierarchical classification system of the *Actinobacteria*. The family description was mainly based upon the phylogenetic position and the presence of defined 16S rRNA gene sequence signature oligonucleotides. Rainey and colleagues defined the following 16S rRNA signatures for members of the genus *Dietzia* (Rainey et al. 1995), the only genus within the family: positions 70–98 (U-A), 293–304 (G-U), 307 (U), 418–425 (U-A), 508 (U), 614–626 (U-G), 631 (G), 661–744 (A-U), 771–808 (A-U), 824–876 (C-G), 825–875 (G-C), 843 (C), 1049–1198 (U-A), and 1122–1151 (A-U). In 2009, an emended description of the family was published by

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_188,

Zhi et al. (2009) by extending the signature oligonucleotides considering all species of the genus *Dietzia* for which the names were validly published at that time. The pattern was specified for the following positions: 241 : 285 (U–G), 250 (U), 316 : 337 (C–G), 418 : 425 (U–A), 599 : 639 (C–G), 662 : 743 (C–G), 987 : 1218 (A–U), 1000 : 1040 (A–U), 1059 : 1198 (U–A), and 1115 : 1185 (C–G).

Type genus: *Dietzia*, Rainey et al. 1995, 33^{VP,} emend. Kämpfer et al. 2010, 394^{VP}

Diet'zi.a. M.L. dim. ending –ia,; M.L. fem. n. *Dietzia*, in honor of Alma Dietz, an American microbiologist.

Type species: *Dietzia maris* (Nesterenko et al. 1982; Rainey et al. 1995).

The taxon proposed by Rainey et al. 1995 was originally described as "*Flavobacterium maris*" (Harrison 1929) and later assigned to the genus *Rhodococcus* as *Rhodococcus maris* (Nesterenko et al. 1982). The type strain of the species has probably been isolated from soil and others strains from intestinal tract of carp (*Cyprinus carpi*).

Members of the genus *Dietzia* are aerobic, non-acid fast, non-spore-forming Gram-positive bacteria. They are mostly characterized by cocci that germinate into short rods or rod-shaped cells which may produce V-shaped forms and exhibit snapping division. Strains are chemoorganotrophic. Circular, convex yellow to orange or reddish to pink colonies are formed on agar media. The diagnostic amino acid of the A1γ type peptidoglycan is meso-diaminopimelic acid. The major cell wall sugars are arabinose and galactose. Short chain mycolic acids are present and have 34–40 carbon atoms. The long-chain cellular fatty acids are predominantly straight-chain saturated and monounsaturated fatty acids. Tuberculostearic acid is present. Polar lipids of most species consist of diphosphatidylglycerol (DPG), and/or phosphatidylglycerol (PG). A few species have phosphatidylethanolamine (PE) available and others are characterized by the presence of phosphatidylinositol (PI) or phosphatidylinositol mannoside (PIM).

The predominant dehydrogenated menaquinone with eight isoprene units is MK-8(H_2). Minor amounts of MK-7(H_2) or MK-9(H_2) were also detected in some of the *Dietzia* species. Phylogenetically, the genus is placed into the family *Dietziaceae*. According to Bergey's road map of the Actinobacteria, the six families *Corynebacteriaeceae*, *Tsukamurellaceae*, *Mycobacteriaceae*, *Nocardiaceae*, *Segniliparaceae*, and *Dietziaceae* were transferred from the order *Actinomycetales* to the new order *Corynebacterales* (Ludwig et al. 2012). The order *Actinomycetales* is now restricted to members of the family *Actinomycetaceae*. The DNA G+C content of *Dietziaceae* strains varies between 64 and 73 mol%. They have been isolated from various environmental habitats as well as from clinical specimen.

Phylogenetic Structure and Molecular Analyses

At present thirteen species with validly published names are included in the genus *Dietzia*. Representatives of the genus share 16S rRNA gene sequence similarity values of 99.8–98.0 % as compared to the type species *Dietzia maris*, with the exception of the type strains of the species *D. timorensis* and *D. papillomatosis*, which are distantly related to *D. maris* only, showing similarity values of 96.89 % and 96.52 %, respectively. As shown in Fig. 17.1, the three species *D. maris*, *D. schimae*,

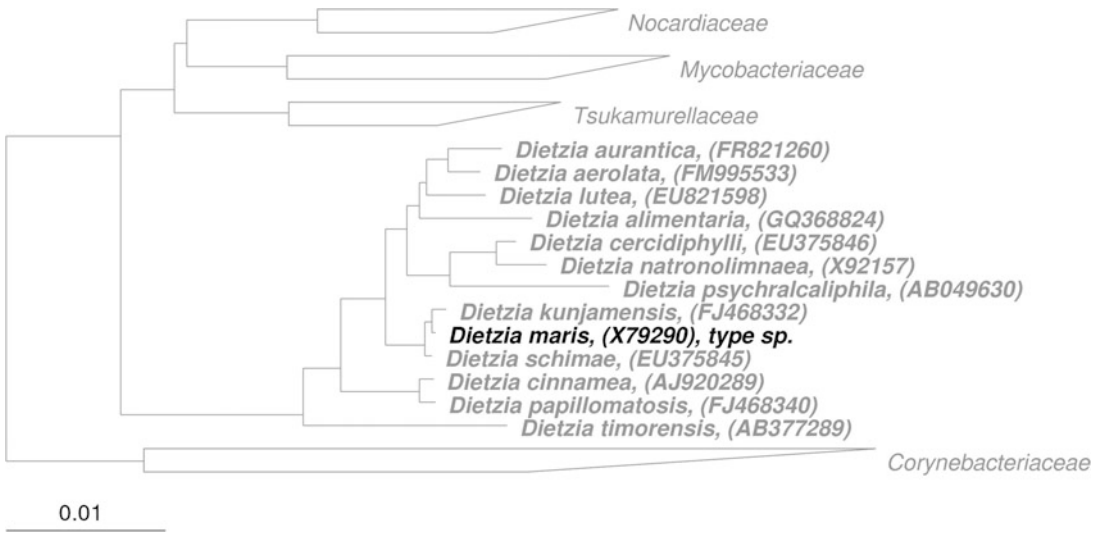

Fig. 17.1

Phylogenetic reconstruction of the family *Dietziaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. Scale bar indicates estimated sequence divergence

and *D. kunjamensis* are closely related. The 16S rRNA gene sequence of *D. schimae* differs only at three nucleotide positions as compared to that of *D. maris*. The sequence from the type strain of *D. kunjamensis* (AY972480) shows 14 additional nucleotides in the second part of the sequence and likely contains several sequencing errors. Analyses of two additional sequences, available at Genbank, confirmed the close relationship of *D. kunjamensis* to *D. maris* and *D. schimae*. However, *D. kunjamensis* could clearly be differentiated from *D. maris* and *D. schimae* by *gyr*B sequence analysis (Niwa et al. 2012). The *gyrB* protein sequence from *D. schimae* differs from *D. maris* at one position only, at which the amino acid alanine is replaced by valine. The genomic relatedness of *D. schimae* and the related phylogenetic neighbors *D. maris* and *D. kunjamensis* was determined by DNA:DNA reassociation studies (Li et al. 2008). DDH displayed low levels of DNA-DNA relatedness to both species (42.1 % and 44.0 %, respectively) and confirmed their separate species status. Further, a DNA-DNA relatedness value of 59.2 % between *D. kunjamensis* and *D. maris* was described by Mayilraj et al. (2006), as determined by the membrane filter method.

Figure 17.1 indicated also the close relationship of the two species *D. natronolimnaea* and *D. cercidiphylii*. Their 16S rRNA gene sequences are nearly identical (99.5 %), and the protein sequences of the DNA gyrase subunit B, as published by Niwa et al. 2012, also showed 100 % identity. However, DDH was determined according to a modified fluorometric micro-well method (He et al. 2005; Li et al. 2008) and led to detection of a low level relatedness (27.8 %) for *D. cercidiphylii* and *D. natronolimnaea*.

A third cluster is noticeable in *Fig. 17.1* which consists of *D. cinnamea* and *D. papillomatosis*. The 16S rRNA gene sequence of the type strain *D. papillomatosis* N1280 is accessible in Genbank as AY643401. The sequence shows several differences to *D. cinnamea*, especially behind the stretch >900 bp. The sequence of strain N1280 was reanalyzed in 2010 and submitted to Genbank again as FJ468340. This sequence showed significant differences to the original sequence (AY643401) and did not possess the various differences in the backmost part of the sequence and was found to be closely related to *D. cinnameae*. The close relationship was confirmed by *gyr* B sequence analysis (Niwa et al. 2012). The protein sequences of the DNA gyrase subunit B from both strains are nearly identical, but differ at one position, where isoleucine is replaced by valine. DDH studies have not been performed in order to confirm the separate species status of the type strains N1280 and IMMIB RIV-399.

Genome Analysis

Draft genome sequences from *Dietzia alimentaria* 72^{T} and *Dietzia cinnamea* strain P4 have been published in 2011 and 2012, respectively. *Dietzia alimentaria* strain 72 was originally derived from a traditional fermented Korean food called clam jeotgal. The genome of strain 72 has a G+C content of 67.34 % (Kim et al. 2011b). The genome sequence data are accessible via the SEED viewer (www.theseed.org, Overbeek et al. 2005). The 3,352,817 bp long genome includes 3,178 predicted protein-coding sequences, and 51 rRNA genes. The distribution of genes into subsystem categories shows that the highest numbers of genes are involved in carbohydrates (281), followed by genes coding for amino acid and derivatives (261), cofactors, vitamins, prosthetic groups, pigments (230) and fatty acids, lipids, isoprenoids (159). The whole-genome shotgun project has been deposited in GenBank under the accession number AGFF01000000.

The draft genome sequence of strain *Dietzia cinnamea* strain P4 has been deposited in GenBank under the accession number AEKG00000000. The 3,555,295 bp long genome contains 55 rRNA genes, including 50 tRNA genes. The G+C content is 70.96 %. In total, 3,593 genes were predicted, of which 3,538 were protein-coding genes: 62.82 % of the genes could be assigned to a putative function, and 72 % of these could be assigned to clusters of orthologous groups 2,587 protein coding genes with COGs are indicated in the Integrated Microbial Genomes platform (IMG, Markowitz et al. 2009). The highest number of genes is involved in amino acid transport and metabolism (220), followed by genes coding for lipid transport and metabolism (216), energy production and conversion (213), inorganic ion transport and metabolism (189). *Dietzia cinnamea* P4 derived from a study on hydrogen carbon degraders in tropical rainforest soil. A third draft genome sequence became available in 2013 (Diep et al. 2013). Strain *Dietzia* UCD-THP has originally been isolated from a residential toilet handle and shows the largest genome with 3,915,613 bp and a G+C content of 69.5 %. The whole-genome shotgun project has been deposited in GenBank under the accession number AOSR00000000: 3,614 protein-coding sequences and 50 non-coding RNAs were predicted within the RAST-Server-based annotation (Aziz et al. 2008).

Phenotypic Analysis

Phenotypic properties that distinguish *Dietzia* species from another are indicated in *Table 17.1*. Characteristics specific for the genus have been listed above.

Dietzia maris Rainey, Klatte, Kroppenstedt and Stackebrandt 1995, 33^{VP}; *Rhodococcus maris* Nesterenko, Nogina, Kasumova, Kvasnikov and Batrakov 1982, 11

mar'is. L. gen. n. *maris*, of the sea.

Gram-positive coccoid cells which germinate into short rods. Cells may exhibit snapping division and V-forms. Cells are 0.6–1.0 μm in diameter and 1.0–2.0 μm in length. Colonies grown on nutrient agar are raised, butyrous, glistening, and circular with an entire edge. Catalase activity is detectable.

Strains: *D. aerolata* Sj14a^T (Data from Kämpfer et al. 2010); *D. alimentaria* 72^T (Kim et al. 2011); *D. aurantiaca* CCUG 35676^T (Kämpfer et al. 2012); *D. cercidiphylli* YIM 65002^T (Kim et al. 2011b); *D. cinnamea* IMMB RIV-399^T (Yassin et al. 2006); *D. kunjamensis* K30-10^T (Mayilraj et al. 2006); *D. lutea* YIM 80766^T (Li et al. 2009); *D. maris* IMV 195^T (Nesterenko et al. 1982; Rainey et al. 1995, Lie et al. 2008); *D. natronolimnaea* 15LN1^T (Duckworth et al. 1998; Kim et al. 2011b); *D. papillomatosis* N 1280^T (Jones et al. 2008); *D. psychralcaliphila* ILA-1^T (Yumoto et al. 2002; Koerner et al. 2009); *D. timorensis* ID05-A0528^T (Yamamura et al. 2010)

+, positive; –, negative; *nd* not determined. Some characteristics may differ from the original description of the strain, due to variation within the methods used for biochemical testing as published in other studies (see below)

Does not attack casein, cellulose, hypoxanthine, starch, tyrosine, and xanthine are not affected, but tween 80 is decomposed. Able to reduce nitrate. Acid is produced from glycerol, but not from galactose, inositol, mannitol, sorbitol, sorbose, and xylose. Additional properties are shown in Table 17.1. Utilizes butyrate, fumarate, and succinate in addition. Able to grow with C8 and C13 *n*-alkanes. Composition of whole cellular fatty acids is listed in Table 17.2. The type strain was originally deposited as strain IMV 195 = DSM 43672 = ATCC 35013.

Dietzia aerolata Kämpfer, Langer, Martin, Jäckel and Busse 2010, 395[VP]

ae.ro.la'ta. Gr. n. *aer* air, L. fem. part. adj. *lata* carried; N.L. fem. part adj. *aerolata*, airborne.

Gram-positive coccoid cells, 1.0–1.5 μm in diameter. Positive for catalase and oxidase activity. Phenotypic properties and other characteristics are summarized in Table 17.1. Menaquinone MK-9(H_2) is detectable in minor concentrations only (~2 %). Does not contain phosphatidylethanolamine within the polar lipid profile. The polyamine pattern consists of spermin and spermidine. Composition of whole cellular fatty acids is given in Table 17.2. The type is strain Sj14a = DSM 45334 = CCM 7659.

DNA:DNA hybridization experiments against the type strains of the species *D. schimae* DSM 45139, *D. cercidiphylii* DSM 45140, and *D. maris* DSM 43672 resulted in a relatedness value of 28, 19, and 26 %, respectively.

Dietzia alimentaria Kim, Roh, Choi, Jung, Nam, Kim, Park, Shin and Bae 2011, 2255[VP]

a.li.men.ta'ri.a. L. fem. adj. *alimentaria*, pertaining to food.

Gram-positive, nonmotile rods, 1.0–1.5 μm in length. Catalase activity positive, but oxidase negative. No growth occurred at 45 °C. Hydrolysis of Tween 20, 40, 60, and 80 is positive, but casein and starch are not hydrolyzed. Other enzyme activities with positive reactions (Api ZYM) are esterase (C4), alkaline phosphatase, esterase lipase, and naphthol-AS-BI-phosphohydrolase. Additional characteristics are indicated in Table 17.1. Also able to utilize the following substrates as tested in the API 50CH kit: methyl β-D-xylopyranoside, L-sorbose, L-rhamnose, dulcitol, arbutin, aesculin, salicin, inulin, starch and glycogen. Assimilates adipic acid, malic acid, and trisodium citrate (API 20NE). Composition of whole cellular fatty acids is listed in Table 17.2. The type strain is 72^T = JCM 1630 = KACC 21126.

DNA-DNA hybridization experiments (microarray technique) showed low level relatedness to the type strains of *D. maris* JCM 6166 (17.8 %), *D. schimae* DSM 45139 (18.5 %), *D. psychralcaliphila* DSM 44820 (21.3 %), *D. kunjamensis* JCM 13325 (17.0 %), *D. cercidiphylii* DSM 45140 (26.7 %), *D. natronolimnaeae* JCM 11417 (9.6 %), and *D. cinnamea* JCM 13663 (21.9 %).

Dietzia aurantiaca Kämpfer, Falsen, Frischmann and Busse 2012, 486[VP]

au.ran.ti.a'ca N.L. fem. adj. *aurantiaca*, orange-colored

Gram-positive coccid cells up to 1.5 μm in diameter. Oxidase and catalase activity is positive. Colonies grown on TSA are circular, convex, and pigmented. Phenotypic properties are shown in Table 17.1. Utilizes ribose, acetate, azelate, fumarate, glutarate, hydroxybutyrate, DL-lactate, malate, and pyruvate in addition. Composition of whole cellular fatty acids is listed in Table 17.2. The quinone system also consists of MK-9(H_2) ~ 2 %. The type strain is CCUG 3576 = JCM 17645.

DNA:DNA reassociation experiments with the following type strains were performed: *D. aerolata* Sj14a (15 %), *D. schimae* DSM 45139 (26 %), *D. cercidiphylii* DSM 45140 (34 %), *D. maris* DSM 43672 (28 %).

Dietzia cercidiphylli Li, Zhao, Zhang, Klenk, Pukall, Qin, Xu and Li 2008, 2552[VP]

cer.ci.di.phyl'li. N.L. gen. n. *cercidiphylli* of the plant genus *Cercidiphyllum*, isolated from root sample of *Cercidiphyllum japanicum*.

Gram-positive short rods. Colonies on TSA are circular, smooth, opaque, and reddish orange. Cells may exhibit snapping division and V-forms. Positive for catalase activity, oxidase negative. Hydrolyses Tween 20, 40, 80 and urea, but not gelatin or starch. H_2S production and nitrate reduction negative. Biochemical characteristics and other properties are given in Table 17.1. Utilizes the following substrates in addition: arbutin, D-lyxose, D-mannose, potassium 5-ketogluconate, D-tagatose, and turanose. The whole cellular fatty acid profile is listed in Table 17.2. The type strain is YIM 65002 = CCTCC AA 207016 = DSM 45140.

DNA:DNA hybridization experiments displayed the following values for reassociation to. *D. kunjamensis* K30-10 (59.6 %), *D. psychralcaliphila* ILA-1(42.7 %), *D. natronolimnaea* CBS 107.95 (27.8 %), and *D. maris* DSM 43672 (32.9 %).

Dietzia cinnamea Yassin, Hupfer and Schaal 2006, 644[VP]

cin.na.me'a. L. fem. adj. *cinnamea* of/from cinnamon referring to the color of the cellular biomass.

Gram-positive, rod-shaped cells with snapping division and V-forms. Colonies on BHI agar are smooth, and yellow pigmented. Catalase activity present, oxidase activity absent. Hydrolyzes testosterone and urea, but does not attack casein, gelatin, xanthine, hypoxanthine, or tyrosine. Comparative properties of the strain are indicated in Table 17.1. Assimilates acetate, 1, 2 propanediol as carbon source in addition. The fatty acid profile is shown in Table 17.2. Phosphatidylethanolamine is the diagnostic polar lipid. Type strain is strain IMMIB RIV-399 = DSM 44904 = CCUG 50875.

Strains: *D. aerolata* Sj14a^T (Data from Kämpfer et al. 2010); *D. alimentaria* 72^T (Kim et al. 2011); *D. aurantiaca* CCUG 35676^T (Kämpfer et al. 2012); *D. cercidiphylli* YIM 65002^T (Li et al. 2008); *D. cinnamea* IMMB RIV-399^T (Yassin et al. 2006; Li et al. 2009); *D. kunjamensis* K30-10^T (Mayilraj et al. 2006; Li et al. 2009); *D. lutea* YIM 80766^T (Li et al. 2009); *D. maris* IMV 195^T (Rainey et al. 1995; Lie et al. 2009); *D. natronolimnaea* 15LN1^T (Li et al. 2009); *D. papillomatosis* N 1280^T (Jones et al. 2008); *D. psychralcaliphila* ILA-1^T (Yumoto et al. 2002; Li et al. 2009); *D. timorensis* ID05-A0528^T (Yamamura et al. 2010)

For some species, the values differ within the publications cited; so, differences are indicated in brackets

DNA:DNA hybridization studies revealed low levels of DNA relatedness to *D. natronolimnaea* DSM 44860 (34.2 %), *D. psychralcaliphila* DSM 44820 (35.7 %), and *D. maris* DSM 43672 (40.3 %).

Dietzia kunjamensis Mayilraj, Suresh, Kroppenstedt and Saini 2006, 1670[VP]

kun.ja.men'sis. N.L. fem. adj. *kunjamensis* pertaining to Kunjam Pass of the cold dessert of the Indian Himalayas.

Gram-positive, aerobic, nonmotile cells, which are coccoid or rod like. Cells are 1.0–1.2 in diameter and 1.1–2.0 μm in length. Colonies on TSA are small, smooth, glistening, and convex. Optimal growth temperature is 25 °C. Oxidase activity present, positive for nitrate reduction. Does not hydrolyze gelatin or urea. Acid is produced from mannitol. Phenotypic characteristics and other properties are given in Table 17.1. The following substrates can be utilized as carbon source as tested with the Biolog GP2 microplate system in addition: dextrin L-fucose, gentobiose, maltotriose, turanose, D-xylose, hydroxybutyric acid, L-asparagine, L-glutamic acid, glycerol, thymidine, and D-fructose-6-phosphate. The type strain is strain K30-10 = MTCC 7007 = DSM 44907.

DNA:DNA hybridization (membrane filter method) was performed against *D. maris* MTCC 7011, and the DNA relatedness was determined as 59.2 %.

Dietzia lutea Li, Chen, Zhao, Klenk, Pukall, Zhang, Tang, and Li 2009, 122[VP]

lu.te'a. L. fem. adj. *lutea*, orange-yellow colored.

Gram-positive, aerobic nonmotile cells which are coccoid or short rods (1.0–1.2 by 1.1–2.4 μm). Cells exhibit snapping division and V-forms. Colonies on TSA are circular, smooth, opaque, and convex. Catalase activity is positive, but negative for oxidase. Hydrolysis of Tween 20, 40, 80 is positive. API ZYM testing showed positive enzyme reactions for alkaline phosphatase, α-galactosidase, β-glucuronidase, and α-glucosidase. Utilizes the following substrates from the API 50CH kit: D-arabinose, aesculin, galactose, glycerol, inositol, D-lyxose, D-mannitol, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, L-rhamnose, D-ribose, L-sorbose, D- and L-xylose. Additional characteristics are shown in Table 17.1. The major fatty acids are given in Table 17.2. The type strain is strain YIM 80766 = KCTC 19232 = DSM 45074 = CCTCC AA 207008.

DNA:DNA hybridization experiments (fluorometric micro-well method) showed low level DNA relatedness to *D. maris* DSM 43672 (49.4 %), *D. kunjamensis* K30-10 (44.8 %), *D. natronolimnaea* CBS 107.95 (21.1 %), *D. psychralcaliphila* ILA-1 (30.2 %), *D. schimae* YIM 65001 (57.6 %), and *D. cercidiphylii* YIM 65002 (39.6 %).

Dietzia natronolimnaea Duckworth, Grant, Grant, Jones and Meijer 1998, 365[VP]; corrig. Duckworth et al. 1999

na.tro.no.lim.na'e.a. N.L. n. *natron* (arbitrarily derived from the Arabic n. natrun or natron) soda, sodium carbonate; N.L. fem. adj. *natronolimnaea*, of or from a soda lake (marsh).

Gram-positive, nonmotile rods (0.9–1.1 μm by 1.2–2.3 μm). Catalase activity is detectable, but oxidase activity not. Rod-shaped cells may exhibit snapping division and V-forms. Growth occurs in BHI medium and also on alkaline agar media. Colonies are circular, convex, glistening with entire margin. Optimal pH for growth is pH 9.0. Under neutral conditions, the following substrates are utilized within the API ATB 32N panel: acetate, fumarate, glutamate, succinate, mannitol, propionate, suberate, valerate, hydroxybutyrate, citrate, glycogen, L-serine, L-proline, L-asparagine, L-arginine, methionine, phenylalanine, L-glycine, and L-valine. Under alkaline conditions, fumarate, D-fructose, D-lactose, and D-xylose are not utilized. The following enzyme activities are detectable with the Api Zym kit: alkaline phosphatase, esterase (C4), esterase/lipase (C8), leucine arylamidase, cysteine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, and α-glucosidase. Additional characteristics are given in Table 17.1 including data from Li et al. 2009, which derived from API 50CH testing. Positive reactions also occurred for amygdalin, glycerol, D-melezitose, D-melibiose, and methyl α-D-glucopyranoside. Whole cellular fatty acid profile is shown in Table 17.2. The type strain is strain 15LN1 = CBS 107.95.

DNA:DNA reassociation experiment against *D. maris* was performed with the membrane filter method using [35S] dCTP labeled DNA and revealed a low DNA relatedness of 8 %.

Dietzia papillomatosis Jones, Koerner, Natarajan, Perry and Goodfellow 2008, 71[VP]

pa.pil.lo.ma.to'sis. N.L. gen. n. *papillomatosis*, of papillamatosis.

Gram-positive, aerobic nonmotile rods or coccoid cells that show snapping division and V-forms. Colonies on modified Bennett's agar are convex, shiny, and pigmented. Tween 20, 40, and 80 are attacked, but not adenine. Degrades chitin and L-tyrosine. Utilizes isoamylalcohol as sole carbon source. Biochemical and other characteristics are listed in Table 17.1. Fumaric acid, hydroxyl benzoic acid, β-hydroxybutyric acid, sodium acetate, sodium benzoate, sodium *n*-butyrate, sodium propionate, sodium pyruvate, and sodium DL-malate are also used as carbon sources. Whole cellular fatty acid composition is given in Table 17.2. Growth is inhibited in the presence of bacitracin (10U), ciprofloxacin (5 μg/mL), cotrimoxazole (25 μg/mL), fusidic acid (10 μg/mL), and penicillin (1 μg/mL).

The type strain is strain N 1280 = DSM 44961 = NCIMB 14145.

Dietzia psychralcaliphila Yumoto, Nakamura, Iwata, Kojima, Kusumoto, Nodasaka and Matsuyama 2002, 89[VP]

psy.chral.ca.li.phil'a. Gr. adj. *psychros* cold; N.L. *alcali* alkali, from Arabic *alqali* potash soil; Gr. adj. *philos* friendly to; N.L. fem. adj. *psychralcaliphila* loving cold, alkaline environments.

Gram-positive, nonmotile rods. Cells are 0.8–1.0 μm in diameter and 1.0–2.2 μm in length. Cells may exhibit snapping division. Colonies are circular, glistening, and convex. Catalase and oxidase activity is present. Negative for indole or H_2S production, and hydrolysis of urea. Tween 20, 40, 60, and 80 can be hydrolyzed, but not casein, gelatin, or starch. Utilizes propionate, valerate, hydroxybutyric acid, pyruvate, acetate, *n*-butyrate, isobutyrate, ethanol, *n*-tridecane, *n*-pentadecane, *n*-hexadecane, *n*-eicosane, *n*-tetracosane, and pristine in addition to the substrates listed in ❯ *Table 17.1*. Composition of cellular fatty acid is given in ❯ *Table 17.2*. The type strain is strain ILA-1 = JCM 10987 = IAM 14896 = NCIMB 13777.

The level of DNA-DNA relatedness to *D. maris* and *D. natronolimnaea* was determined as 38.4 % and 49.7 %, respectively.

Dietzia schimae Li, Zhao, Zhang, Klenk, Pukall, Qin, Xu and Li 2008, 2552[VP]

schi'ma.e. N.L. gen. N. *schimae* of the plant genus *Schima*, isolated from stem of *Schima* sp.

Gram-positive, aerobic, and nonmotile rod-shaped cells which exhibit snapping division and V-forms. Catalase activity present, but negative for oxidase. Negative for hydrolysis of gelatin, urea, and starch, but able to hydrolyze Tween 20, 40, and 80. Positive for nitrate reduction. Utilizes aesculin, glycerol, in addition to the substrates listed in ❯ *Table 17.1*. The fatty acid composition of the type strain is shown in ❯ *Table 17.2*. The type strain is strain YIM 65001 = CCTCC AA 207015 = DSM 45139.

The type strain displayed low levels of DNA-DNA relatedness to *D. maris* DSM 43672 (42.1 %), *D. cercidiphylii* YIM 65002 (43.2 %), *D. kunjamensis* K30-10 (44 %), *D. natronolimnaea* CBS 107.95 (53.3 %), *D. psychralcaliphila* ILA-1 (51.1 %).

Dietzia timorensis Yamamura, Lisdiyanti, Ridwan, Ratnakomala, Sarawati, Lestari, Triana, Kartina, Widyastuti and Ando 2010, 452[VP]

ti.mo.ren'sis. N.L. fem. adj. *timorensis* pertaining to West Timor, Indonesia, from where the organism was first isolated.

Gram-positive, aerobic, nonmotile coccoid to rod-shaped cells. Colonies are circular, convex, and glistening. Aesculin is hydrolyzed; arbutin and urea are not hydrolyzed. Adenine, casein, elastin, hypoxanthine, testosterone, tyrosine, uric acid, and xanthine are not attacked. Utilizes the following substrates within the Api 50 CH-Kit: aesculin, glycerol, amygdalin, L-arabitol, D-arabitol, arbutin, dulcitol, erythrol, L-fucose, D-fucose, D-galactose, gentobiose, glycogen, inositol, inulin, D-lyxose, D-mannitol, melezitose, melibiose, methyl α-D-glucopyranoside, methyl β-D-glucopyranoside, methyl α-D-mannopyranoside, methyl β-D-xylopyranoside, potassium gluconate, potassium 2-ketogluconate, potassium 5-ketogluconate, L-rhamnose, D-ribose, salicin, D-sorbitol, L-sorbose, starch, D-tagatose, xylitol, L-xylose, and X-xylose. Additional characteristics are indicated in ❯ *Table 17.1*. Whole cellular fatty acid profile is summarized in ❯ *Table 17.2*.

Isolation, Enrichment, and Maintenance Procedures

Isolation and Enrichment

Dietzia maris IMV 195^T (Rainey et al. 1995), classified by Nesterenko et al. 1982 as *Rhodococcus maris*, and originally known as *Flavobacterium maris*, was isolated from soil. Additional strains have also been isolated from skin and intestinal tracts of carp (*Cyprinus carpio*). Growth occurs on nutrient agar, trypticase soy broth agar, or ISP2 medium (Shirling and Gottlieb 1966) incubated at 28 °C.

Dietzia natronolimnaea 15LN1^T (Duckworth et al. 1998) was isolated from littoral sediment of the East African soda lake (Lake Oloidien; little lake Naivasha), which is a moderately saline and alkaline soda lake with a pH of. 8.5. Strain 15LN1 was enriched in alkaline broth which contained the following compounds (g per liter): glucose 10.0, peptone 5.0, yeast extract 5.0, KH_2PO4 1.0, $MgSO_4 \times 7\ H_2O$ 0.2, NaCl 40.0, and Na_2CO_3 10.0. The strain grows also well on brain-heart-infusion agar (pH 9.0) incubated at 30 °C.

Dietzia psychralcaliphila ILA-1^T (Yumoto et al. 2002) was isolated from a drain of a fish egg processing plant. The strain represents a cold-adapted alkaline bacterium that utilizes petroleum hydrocarbons and was isolated on AT-medium that consisted of (g/L): KNO_3 5.0, KH_2PO_4 0.5, $MgSO_4 \times 7H_20$ 0.5, $FeSO_4 \times 7H_20$ 0.01, $CaCl_2 \times 2H_2O$ 0.02, $MnSO_4 \times n\ H_2O$ 0.001, $ZnSO_4 \times 7H_2O$ 0.0005, and agar 15.0 in 1 L 100 nM $NaHCO_3/Na_2CO_3$ buffer, supplemented with vaporized *n* -tetradecane as sole carbon source. Strain ILA-1 was isolated from AT medium after 1 month of aerobic incubation at 4 °C. The strain is also able to grow on R agar (pH 9.0) at 27 °C.

Dietzia cinnamea IMMB RIV-399^T (Yassin et al. 2006) was isolated from a perianal swab of a patient with a bone marrow transplant. Strain IMMB RIV-399 is able to grow on Columbia blood agar (5 % sheep blood), GPHF medium or brain-heart-infusion agar, incubated at 37 °C under aerobic conditions. GPHF medium (g/L): glucose 10.0, peptone from Casein 5.0, yeast extract (Oxoid) 5.0, beef extract (Oxoid) 5.0, $CaCl_2 \times 2H_2O$ 0.74, agar (Oxoid) 15.0; distilled water 1,000 mL, pH 7.2.

Dietzia kunjamensis K30-10^T (Mayilraj et al. 2006) was isolated from cold dessert soil, 45 cm below an ice glacier at 4,200 m at Kunjam Pass, Himachal Pradesh, India. Strain K30-10 was enriched on tryptic soy agar medium (TSA) incubated at 25 °C.

Dietzia papillomatosis N 1280^T (Jones et al. 2008) was isolated on glucose-yeast extract agar from skin scrapings of a patient suffering from confluent and reticulated papillomatosis. The strain is also able to grow on ISP2 agar or modified Bennett's agar after 5 days of incubation at 30 °C.

Dietzia cercidiphylli YIM 65002^T and *Dietzia schimae* YIM 65001^T (Li et al. 2008) were isolated from surface sterilized roots of *C. japanicum* and surface sterilized stem of *Schima* sp., respectively. Both strains were maintained on trypticase soy agar medium (TSA) at 28 °C.

Dietzia lutea YIM 80766^T (Li et al. 2009) was isolated from a soil sample collected from the Eastern dessert of Egypt. The soil sample was diluted in sterile water and after vigorous shaking for 30 min, an aliquot of the sample was spread-plated onto Horikoshi agar. Plates were incubated at 28 °C for 2 weeks. Strain YIM 80766 is also able to grow on tryptic soy agar medium (TSA).

Dietzia aerolata Sj14a^T (Kämpfer et al. 2010) was isolated on tryptone soy agar (TSA) at 26 °C from the air collected in a duck barn. Good growth occurs also on R2A agar and nutrient agar.

Dietzia timorensis ID05-A0528^T (Yamamura et al. 2010) was isolated from a soil sample collected under mahogany trees (*Swietenia mahogany*) in West Timor, Indonesia. After pretreatment with SDS yeast extract, the strain was enriched on Humic acid vitamin agar, but the strain is also able to grow on modified Bennett's agar incubated at 28 °C for 14 days or on trypticase soy broth agar.

Dietzia alimentaria 72^T (Kim et al. 2011a) was isolated on marine agar from a salt-fermented seafood sample, which was made by fermented clams mixed with rock salt. Growth occurs also on tryptic soy agar, incubated up to 5 days at 30 °C.

Dietzia aurantiaca CCUG 35676^T (Kämpfer et al. 2012) was isolated on blood agar from a cerebrospinal fluid sample from a 24-year-old woman in Gothenborg, Sweden. The strain grows also on tryptone soy agar, nutrient agar, or R2A agar.

Maintenance

Standard procedures can be applied for members of the genus *Dietzia*. Serial transfer of subcultures grown on appropriate media (every 6–8 weeks) is possible. Strains can also be achieved in glycerol stocks (50 % (v/v) stored at −20 °C or for better survivability at −80 °C). For long-term storage, freeze drying or storage in liquid nitrogen should be used. Detailed protocols are given in the Cabri guidelines, accessible at www.cabri.org.

Ecology and Pathogenicity

Strains from the genus *Dietzia* have been isolated from various environmental habitats around the world, but increasing numbers of isolates were also obtained from clinical specimen. *Dietzia maris* strains or its DNA were often detectable in soil and sediment, including petroleum- or oil-contaminated habitats (sequence accession numbers KC189154, KC514120, JF727664, EF619406; Al-Awadhi et al. 2012), were found in seawater, associated with red algae, the dinoflagellate *Pyrodinium bahamense*, soft corals or fishes, in spring water or activated sludge (HQ425656, EF469496, JF792051, Azanza et al. 2006, Ruckmani and Chakrabarti 2011, Sun et al. 2012). A few strains have been isolated from clean room environments in Brazil (FJ876398), from Phoenix associated spacecraft surfaces (USA) and also from the assembly building in Kourou (Ghosh et al. 2010; Moissl-Eichinger et al. 2012). One strain was isolated from snow and floor debris of internal surfaces from the Moon-1 Rover (JX571065). Further strains have been isolated from clinical material like blood (DQ386308, DQ286854), throat, or thoracic fluid (Niwa et al. 2012), bone biopsy (Pidoux et al. 2001) as well as from a patient with bacteremia (Dinakaran et al. 2012).

The type strain of *D. cinnamea* was isolated from a perianal swab sample of a patient with bone marrow transplant (Yassin et al. 2006), Together with *D. maris* and *D. papillomatosis*, the species *D. cinnamea* is in individual cases identified as or suspected to be an opportunistic pathogen. *D. cinnamea* was also isolated from a dog bite wound in an adult patient (Hirvonen et al. 2012). Additional strains of the species are described as hydrogen carbon degrader (von der Weid et al. 2007) or found to be associated with *Phaseolus vulgaris* (sequence accession no. HM355703) the common bean, with biofouling material (JF514328) or on fresco surface (KC429622). The type strain of *D. papillomatosis* was originally isolated from skin of an immunocompetent patient with papillomatosis (Jones et al. 2008). *D. papillomatosis* was for the first time detected in a case of infection in a 2-year-old boy with known syringomyelia (Rammer et al. 2013). Another strain affiliated to *D. papillomatosis* was originally isolated from oat bran and found to be able to produce folate (Herranen et al. 2010).

Pilares et al. 2010 have reanalyzed a set of clinical strains, which were originally identified as *Rhodococcus equi* or *Rhodococcus* like by traditional techniques using the API Coryne identification kit. Reanalysis was done by 16S rRNA sequence analysis. The study revealed that seven of the strains could be assigned to the genus *Dietzia*. Four strains were identified as *D. maris*, two strains as *D. natronolimnaea*, and one strain as *D. timorensis*. A similar study was published by Niwa et al. in 2012, reanalyzing 16 strains previously identified as *Rhodococcus equi*. Also this study showed that the strains have previously been misidentified by biochemical testing and could be assigned to the genus *Dietzia*, based on 16S rRNA – and gyrB gene sequence analysis. Most of the strains sequenced were members of the *D. cercidiphylii*/*D. natronolimnaea* cluster and five isolates were found to be related to the *D. maris*/*D. schimae* cluster. Additional reports showing that *D. cercidiphylii* strains have been isolated from humans are not available at present. The type strain of *D. natronolimnaea* has been isolated from an East African Soda Lake (Naivasha) (Duckworth et al. 1998). Additional strains have been isolated from alkaline groundwater (Tiago et al. 2004), sediment of Lonar Lake in India (Joshi et al. 2008), from waste water of a chemical plant in China (Jin et al. 2012), from soil in Japan (Ueda et al. 2001), and from reed periphyton (Rusznyák et al. 2008).

For *D. schimae* and *D. timorensis*, DNA sequences were only detectable from environmental samples (JQ282810, JQ409503, JX429817, JX429818 and HE578791). The same is true for *D. psychralcaliphia* strains, which have been isolated from deep sea sediment (Chen and Shao 2009), petroleum-contaminated soil (Mathe et al. 2012), or from canine dental plaque (Elliott et al. 2006).

Several sequences are presently available in GenBank which have not been assigned to one of the *Dietzia* species or which derived from not yet cultivable strains; these are summarized in *Table 17.3*. Many of these sequences are indicated as unpublished, but may be the data set entry was not updated from the authors.

Application

As shown above, strains of the genus *Dietzia* have mainly been isolated from various environmental habitats. They are common in soil and marine sediment and some of the strains are able to degrade hydrocarbons, which may play an important role for the bioremediation of hydrocarbon-contaminated environmental sites. *Dietzia cinnamea* P4 was isolated from tropical rainforest soil and is able to degrade hydrocarbons. In 2012, its whole genome sequence was published by Procópio et al. (2012) which offers the possibility to study the genetic background for degradation of *n*-alkanes in more detail.

As indicated in *Table 17.1*, all type strains of the genus *Dietzia* are able to produce pigments. The carotenoid canthaxanthin is responsible for the reddish color of the *Dietzia natronolimnaeae* colonies. Strain *D. natronolimnaea* HS-1 has extensively been used for optimization of canthaxanthin production in the past (Khodaiyan et al. 2007).

Abstract
The family *Frankiaceae*, within the order *Actinomycetales*, contains bacteria isolated mainly from root nodules and occasionally from soil. Members of the genus *Frankia* have been found associated with the roots of 23 genera of dicots belonging to eight families. Historically, strains isolated in pure culture were grouped into two physiological categories, those that use carbohydrates and those that do not. Newer genomic information indicated that frankiae in general differ markedly in their complements of genes. Besides physiological grouping, these isolates were placed into four plant-compatibility groups (1-infective on *Alnus* and *Myrica*, 2-infective on *Casuarina* and *Myrica*, 3-infective on *Elaeagnaceae* and *Myrica*, 4-infective only on *Elaeagnaceae*). A 16S rRNA gene-based phylogenetic study, comprising non-isolated endophytes, yielded four clusters or clades, three of which are symbiotic (1-infective on *Alnus* and *Casuarinaceae* except *Gymnostoma*, 2-non-isolated strains in nodules of *Rosaceae-Datisca-Coriaria-Rhamnaceae*, 3-infective on *Elaeagnaceae* and *Gymnostoma*) and a fourth cluster that groups non-infective and non-effective strains. These groupings have been confirmed on the whole by analysis of other loci. DNA-DNA hybridization studies have yielded 12–15 genospecies, only one of which has been named, *Frankia alni*; one *Candidatus* Frankia datiscae was recently named to accommodate the genome of an endophyte in nodules of *Datisca glomerata*.

The family *Frankiaceae* is close to *Acidothermus, Cryptosporangium, Geodermatophilaceae* (*Geodermatophilus, Modestobacter, Blastococcus*), *Nakamurella, Sporichthya*, and *Fodinicola* and was grouped into suborder *Frankineae*. A recent rearrangement has resulted in the elevation of suborder *Frankineae* to order *Frankiales* (Normand and Benson 2012b) containing families *Acidothermaceae, Cryptosporangiaceae, Frankiaceae, Geodermatophilaceae, Nakamurellaceae*, and *Sporichthyaceae* as well as the *incertae sedis Fodinicola feengrottensis*.

Introduction

Plants have developed interactions with a variety of soil microbes that are either pathogens, loosely associated rhizosphere bacteria, or in rare instances that can generate positive durable interactions, mutualisms, or symbioses, that modify the fitness of plants, allowing them to thrive in nitrogen-poor environments. Actinobacteria grouped in the genus *Frankia* comprise one of these symbiotic lineages that form root nodules in which biological nitrogen fixation takes place.

Following the first descriptions at the end of the nineteenth century of structures on roots of some plant species, including legumes and non-legumes (Woronin 1866), that were correlated with the ability to thrive in nitrogen-poor soils (Hiltner 1896) and with nitrogen fixation (Hellriegel and Wilfarth 1888), *Rhizobium* strains were rapidly cultured and studied (Beijerinck, 1888). It took however close to 90 years for the first *Frankia* isolates to become available (Callaham et al. 1978) due to a slow growth rate, inappropriate media, incomplete sterilization, and

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_183,

the likelihood that several strains may be obligate symbionts progressively evolving to have complex growth requirements that cannot be met outside root tissues.

The plants, collectively called "actinorhizal plants" that enter symbioses with *Frankia* are phylogenetically grouped within the so-called Nitrogen-Fixing Clade (NFC, Soltis et al. 1995), but as a group are more deeply diverged than is the case with those infected by "rhizobia." The first ones that were described were those growing in Europe, *Alnus* and *Elaeagnus*, about which Frank in 1887 was hypothesizing that the root "swellings" could be caused by fungi (Frank 1887). This description was followed by other scientists of plants growing in more distant locales, reaching the present number of 23 genera. There may remain a few cryptic actinorhizal plants in poorly explored regions of the world such as New Guinea, central Amazonia, or central Africa. Some plants may also harbor rhizospheric populations of frankiae as in the case of birch (Mirza et al. 2009a), a phylogenetic neighbor of *Alnus* in the *Betulaceae*. Finally, some plants may harbor endophytic *Frankia* in a manner similar to that reported for some actinobacteria such as *Micromonospora* in various plants (Zhao et al. 2011; Kim et al. 2012) including the actinorhizals *Casuarina* (Valdes et al. 2005) and *Coriaria* (Trujillo et al. 2006).

In the past, grouping of *Frankia* strains was attempted based on *in planta* morphology (Becking 1970), on plant compatibility (Baker 1987), on physiology (Lechevalier and Lechevalier 1990), on protein patterns (Gardes and Lalonde 1987) or proteomics (Hahn et al. 2011), on DNA-DNA hybridization (Fernandez et al. 1989), or using sequence comparisons of various genes. These approaches have yielded low resolution clusterings; however, an integrated vision of the structure and of evolutionary history of the genus remains incomplete.

Taxonomy: Historical and Current

Fran.ki.a'ce.ae. N.L. fem. n. *Frankia* type genus of the family; suff. -aceae ending to denote a family; N.L. fem. pl. n. *Frankiaceae* the *Frankia* family. The description is an emended version of the one given in the *Bergey's Manual*, 2nd edition (Normand and Benson, 2012a).

After several failed isolation attempts over more than 60 years (Baker and Torrey, 1979), Pommer (1956), then working at the Botanischen Institut der Technischen Hochschule in Aachen, Germany, succeeded in isolating an actinobacterial strain in pure culture. His drawings of that culture clearly depict a *Frankia* strain comprising typical features such as branched hyphae, typical vesicles, and spores arranged in multilocular sporangia that are formed by cells dividing in three planes. Unfortunately, this strain was subsequently lost. So for a long period of time, scientists interested in this interaction had to be content with studying the microbe *in planta*. Eventually, Becking (1970) created the *Frankiaceae* family containing a single genus and ten species based on cross-inoculations using crushed nodules containing unisolated symbionts and morphological description of symbiotic microbial cells. The description of the *Frankiaceae* was emended by Hahn et al. (1989) to include, besides the genus *Frankia* that contains root symbionts, the genus *Geodermatophilus* whose members thrive in soils and on rock surfaces, and an uncharacterized *Blastococcus* genus containing a single sea sediment isolate. Although its sporangia had a similar morphogenesis, the skin pathogen *Dermatophilus* was deemed too distant and not included in the family. These genera have multilocular sporangia; however, this feature was judged insufficient to warrant placing them in the same family by Normand et al. (1996), particularly considering their many ecological and biochemical differences and the fact that members of the genus *Acidothermus*, although phylogenetically closer to *Frankia* than the others as assessed by 16S rDNA similarity, did not form multilocular sporangia. The *Geodermatophilaceae* is now considered distinct from the *Frankiaceae* and treated in a different chapter of the present book. The *Frankiaceae* presently contains only one genus, *Frankia*. This situation may change since it is also known that several related, presumably slow-growing, soil-inhabiting actinobacteria exist (Normand and Chapelon 1997).

The first confirmed isolation of a *Frankia* strain in pure culture, designated CpI1 (Callaham et al. 1978), was accomplished using a complex procedure involving an enzymatic digestion of host cell wall components of nodules of *Comptonia peregrina*, 8 years after Becking's taxonomic proposals. This success paved the way for the isolation of many additional strains from several plant species using protocols that got progressively simpler. When more strains became available, it became clear that Becking's proposed species based on cross-inoculation groups were untenable. Cross-inoculations with pure cultures showed that isolated strains had broader host ranges than indicated by crushed-nodule suspensions and that *in planta* morphology was under control of the host plant (Lalonde 1979).

Signature sequences have been used to gauge the distribution of frankiae. For example, the 5′-TGCAAGTCGAGCGAGGGGCTT-3′ has been proposed as being genus-specific (Normand and Chapelon 1997), although phylogenetically related uncharacterized soil actinobacteria have been later detected by PCR using this oligonucleotide as a primer. In another approach, a Blast search of the NCBI database yielded several hits in a study targeting nitrogen-incorporating bacteria in petroleum-contaminated arctic soils using ^{15}N DNA-SIP (DNA-Stable Isotope Probing) and pyrosequencing (locus JF397791, Bell et al., unpublished) (Yergeau et al. 2012). A study of *Alnus viridis* rhizosphere using a single *Frankia*-targeted primer yielded two nearly full length 16S rRNA genes that could be from cryptic soil *Frankiaceae* (Normand and Chapelon 1997).

Type genus: *Frankia* Brunchorst 1886, 174. (Brunchorst 1886)

Genus *Frankia*

Fran'ki.a. N.L. fem. n. *Frankia* is named after Albert Bernhard Frank (1839–1900), a German plant biologist working in Leipzig

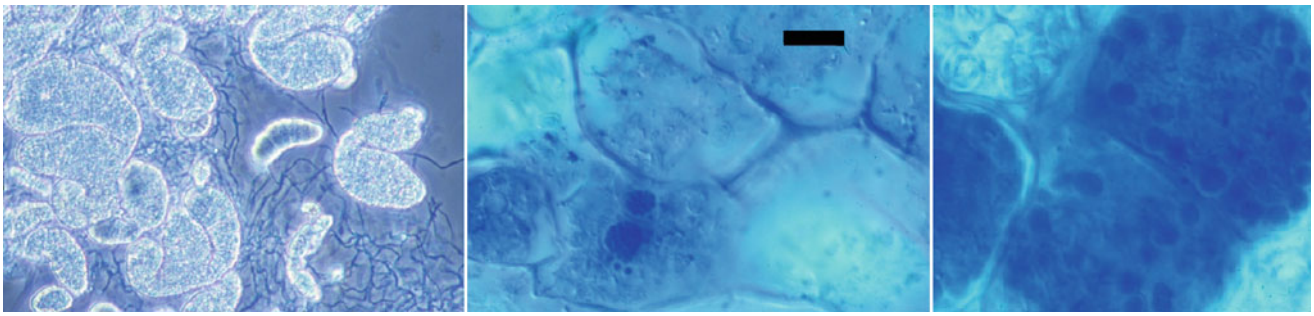

Fig. 18.1
Phase contrast micrograph of *Frankia* strain ARgP5 (clade 1b), isolated from *Alnus incana* subsp. *rugosa* (Normand and Lalonde, 1982) showing hyphae and multilocular sporangia that can reach 50 μm across (1000x). Cotton-blue stained sections of an *Alnus incana* subsp. *rugosa* old nodule induced by strain ARgP5 showing (*center*) unstained senescent vesicles in cortical cells and two stained sporangia, bar is 5 μm, and (*right*) healthy nitrogen-fixing vesicles on the periphery of cortical cells and in neighboring cells unstained amyloplasts. Photos P. Normand

and Berlin, who devoted a major part of his career, from 1877 to 1892, to the study of nitrogen nutrition in legumes and the micro-organisms that caused nodulation on roots. He is also credited with coining the term "symbiosis."

Vegetative hyphae have limited to extensive branching (*Fig. 18.1*), 0.5–2.0 μm in diameter, and occasionally wider in older cultures. No aerial mycelium is formed on solid media. Intra- and extracellular orange, red, or black pigments may be formed. Gram-positive in exponential phase cultures; Gram-variable in older cultures. Aerobic to microaerophilic, with a respiratory type of metabolism. No growth factors are required. Does not grow under anaerobic conditions. Catalase-positive due to two catalases, both expressed in pure culture at a high base level (Santos et al. 2007). Mesophilic. Chemoorganotrophic. Usually very slow-growing with doubling times of 20 h to several days. Most strains are capable of fixing N_2 both in vitro under conditions of nitrogen starvation, and *in planta*, both at atmospheric oxygen concentration and under microaerophilic conditions, a physiological adaptation that has been followed by proteomics (Alloisio et al. 2007). Nonpathogenic to humans and animals (Gordon et al. 1983). Round to irregularly shaped multilocular sporangia are borne terminally, laterally, or in an intercalary position on vegetative hyphae (*Fig. 18.1*). Lateral sporangia are usually borne on sporangiophores; some are sessile. Sporangia are up to 100 μm in length formed by septation in three planes of the cytoplasm of preexisting thin-walled swellings. Sporangiospores are nonmotile, irregular (often somewhat polygonal) in shape, usually colorless, sometimes black, showing multilamellar outer membrane–like layers in thin section. Spores are not thermally resistant. Sporangiospores usually do not develop and mature simultaneously, resulting in the presence of spores of different maturity levels in the same sporangium. Unique terminal or laterally formed "vesicles" or "diazovesicles" may be formed. These structures are terminal hyphal swellings that become increasingly septate with age. They possess envelopes with up to 90 laminated layers composed chiefly of bacteriohopanetetrol and its derivatives (Berry et al. 1993). They are the site of nitrogen fixation in cells deprived of combined nitrogen in culture and, in symbioses, where vesicles are formed (Benson and Silvester 1993). Cell walls contain meso-diaminopimelic acid (meso-DAP), glutamic acid, alanine, muramic acid, and glucosamine. No mycolates are present. Phospholipids comprise phosphatidylinositol mannosides, phosphatidylinositol, and diphosphatidylglycerol.

Vesicles occasionally form in culture, especially under low ammonium aerobic conditions where nitrogen fixation does occur. Vesicles may separate from subtending hyphae upon homogenization, and these vesiclesmay then germinate (Schultz and Benson 1989) (*Fig. 18.2*).

Fatty acids are normal, branched-chain, and mono-unsaturated. Whole-cell sugar patterns show xylose (without arabinose), madurose, or fucose or cells may contain only glucose or galactose. All tested strains contain 2-O-methyl-D-mannose, a very rare "diagnostic" sugar, and most contain rhamnose (Mort et al. 1983). Most strains are symbiotic with certain angiospermous plants, inducing nodules on the roots of suitable hosts. They may be found free-living in soil.

DNA G+C content (mol%): 70–73 (Tm) (as deduced from complete genomes analysis, *Table 18.1*).

Type species: *Frankia alni* (Woronin 1866) Von Tubeuf (1895), 118 (*Schinzia alni* Woronin (Woronin 1866), p. 6).

Species of the genus *Frankia*

1. *Frankia alni* (Woronin 1866) Von Tubeuf 1895, 118AL (*Schinzia alni* Woronin 1866, p. 6) al'ni. L. gen. n. *alni* of alder, the original source of isolation.

This is the only species designated in the genus; all other species proposed previously by Becking (1970) have been shown not to correspond to later descriptions of the genomic species (Akimov and Dobritsa 1992; Akimov et al. 1991; An et al. 1983, 1985; Bloom et al. 1989; Fernandez et al. 1989; Lumini et al. 1996). Hence, the only species still valid is the first ever described

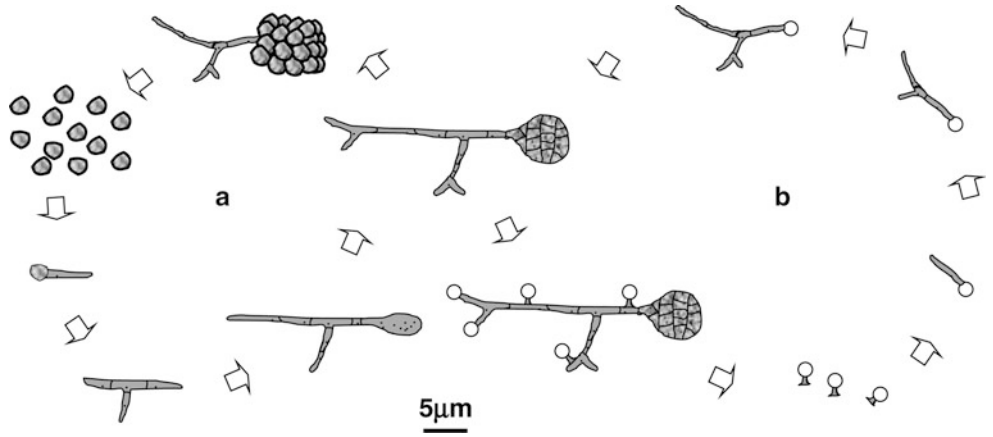

Fig. 18.2

Cell cycles of *Frankia alni*. (a) On the left from the top and counterclockwise, spores germinate and grow into a hypha that will in turn branch and divide from growth at the tip. From one hyphal tip or from an inside cell, an enlargement occurs that divides in all planes to form a sporangium from which individual spores mature. (b) Under conditions of low nitrogen solutes concentrations, vesicles appear at the tip of stalks. If the culture is homogenized, some vesicles may break free, these may germinate, form hyphae that eventually thicken and develop into sporangia. The cycle involving hyphae and spores is the dominant one while the one involving vesicles is much rarer. Drawn from Pommer (1959) and Schultz and Benson (1989)

that corresponds to the one described by Woronin (1866) as present in the roots of alder and shown later by Fernandez et al. (1989) to correspond to the numerically dominant group of strains infective on *Alnus*. Substrate hyphae, chalky white, 0.5–1.2 µm in diameter. Based on DNA-DNA hybridization and direct sequencing of 16S rDNA genes, it can be evaluated there are probably more than 20 genomic species among the isolates described so far and a similar number of unisolated strains living in the soil (Normand and Chapelon, 1997), the rhizosphere of various plants, or other environments. However, given their slow growth rates, it is likely that a rigorous species designation is still a long way in the future and may be based on genome descriptions (below). Nevertheless, 16S rRNA gene sequence characterization work continues to be carried out Clawson et al. 1998; Huguet et al. 2001; Jeong and Myrold 1999; Lumini and Bosco 1999; Navarro et al. 1999; Ritchie and Myrold 1999; Simonet et al. 1999; Wolters et al. 1997; (Clawson et al. 2004; Dai et al. 2004; Gtari et al. 2004; Huguet et al. 2004; Vanden Heuvel et al. 2004; Huguet et al. 2005b; Gtari et al. 2007b, Gtari et al. 2007a) and will be correlated with ecological investigation.

Source: root nodules of host plants belonging to families *Betulaceae* and *Myricaceae*, free-living cells may also be found in soil.

DNA G+C content (mol%): 72.8 [as determined by complete genome sequencing (Normand et al. 2007b); see the Genoscope website for details (http://www.genoscope.cns. fr/externe/English/Projets/Projet_HF/HF.html)].

Type strain: Since the publication of the Approved Lists of Bacterial Names, several strains of *Frankia alni* have been isolated. However, no type strain has been designated. The first strain isolated was HFPCpI1 (Callaham et al. 1978) with HFP standing for "Harvard Forest in Petersham" and CpI standing for "C*omptonia* p*eregrina* i*solate*"; it was deposited in the ATCC but, as is the case with several of the slow-growing *Frankia* strains, it could not be revived (although it is still available from diverse laboratories) and is no longer available there. Another strain, AvcI1 is available from the ATCC, but this strain has not been studied in much detail. For these reasons, another strain, ACN14a isolated from *Alnus crispa* growing in Tadoussac, Canada (Normand and Lalonde 1982), that has only two substitutions in the 16S rRNA gene (Normand et al. 1996) relative to HFPCpI1, has been widely distributed in different laboratories, and was chosen as model organism for whole genome sequencing. Sequence accession numbers: M88466 (16S rRNA gene; *Frankia alni* strain ACN14a), CT573213 (complete genome; *Frankia alni* strain ACN14a). More recently, the genome of cluster#1 *Alnus*-infective strain QA3 (NZ_CM001489.1) has also become available but in a non-finished state. It thus remains non-published as of August 2012 and it remains uncertain if this strain belongs to the same species as ACN14a; however, the 16S rRNA of the two strains diverges by only 1.1 % (unpublished).

There have been several studies devoted to defining genomic species among isolated strains. The first one (An et al. 1985) studied a limited number of infective strains and proposed one species with nine *Alnus*-infective isolates (cluster 1), one with a single *Elaeagnus*-infective (cluster 3) isolate and several unclustered isolates. Later, Fernandez et al. (1989) proposed 9 genomospecies among the 43 isolates analyzed, three of them in the *Alnus*-infective group of strains (cluster 1), five in the *Elaeagnus*-infective group (cluster 3), and one in the *Casuarina*-infective group (cluster 1). There were however few common strains between the two studies making it impossible to say if these numbers are to be added to those previously described except for *Frankia alni* strains CpI1 and ArI3. Lumini et al. (1996) also used this approach with *Elaeagnus*-infective

[a]Characteristics of all of the *Frankia* genome projects including published databases (Normand et al. 2007, Persson et al., 2011) and released databases that are publicly available on the Integrated Microbial Genomes (IMG) website (http://img.jgi.doe.gov) as of July 1, 2012. Several other genome sequencing programs are presently underway, targeting strains with unusual phenotypic characteristics (shaded)

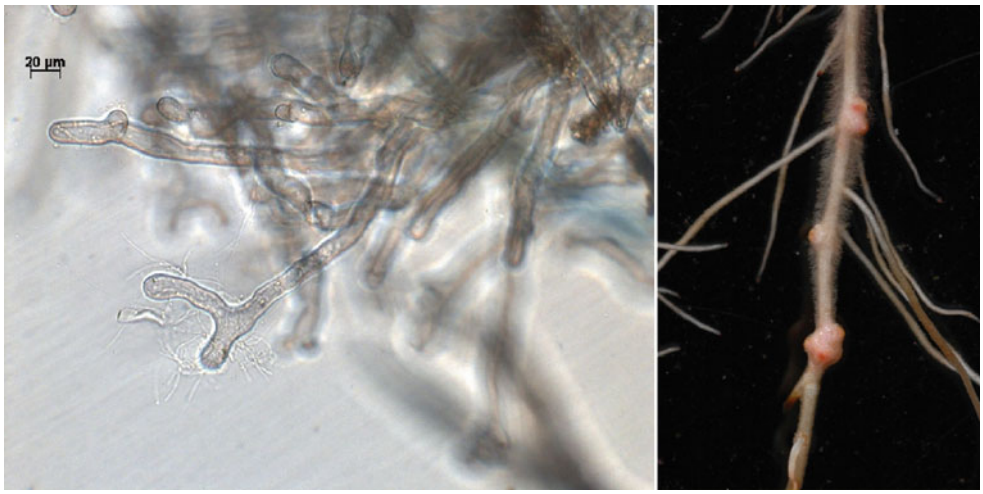

Fig. 18.3
***Alnus glutinosa* root hairs deformed and branched following inoculation (7 dpi) with *Frankia alni* strain ACN14a in growth pouches. After 3 weeks, a succession of small nodules appears on the roots; their red color is not due to hemoglobin, rather to anthocyanins. Photos courtesy of Petar Pujic, Université Lyon1**

strains, in particular those able to cross the inoculation barrier between *Elaeagnus* and *Alnus*, resulting in three further species. None of these publications used phenotypic approaches and as a consequence, none proposed naming species.

A "*candidatus*" species has been proposed for the strain present in nodules of *Datisca glomerata*, named *Candidatus* Frankia datiscae (Persson et al. 2011). Numerous isolation attempts have been made for strains of cluster 2; however, none were successful. A few attempts at cross-inoculation among potential host groups have been made, and successful nodulation of *D. glomerata* has been achieved with nodule inoculum from *Ceanothus griseus* nodules (Okubara et al. 1999).

Other species, *F. elaeagni* and subspecies *F. alni* subsp. *pommerii* and *F. alni* subsp. *vandijkii*, have been proposed by Lalonde and coworkers (1988), but these were not based on recognized approaches and have thus been abandoned.

Phylogenetic Structure of the Family and Its Genera

16S rRNA sequence analyses (*Fig. 18.3*) have resulted in genus *Frankia* being divided into four clusters with *Acidothermus* as closest neighbor and *Geodermatophilaceae* together with *Sporichthya, Nakamurellaceae*, and *Cryptosporangium* forming the Frankineae (Normand and Benson 2012b).

The cluster identified as the root of the *Frankia* lineage was #4 (non-infective, non-efficient *Alnus*-infective), then cluster #2 infective on *Rosaceae-Datiscaceae-Coriariaceae-Rhamnaceae* with clusters 3 (*Elaeagnaceae, Gymnostoma, Myricaceae*), and #1 (*Alnus, Casuarinaceae, Myricaceae*) emerging later (Normand et al. 1996). A similar topology, without considering cluster #4, was obtained by Clawson et al. (2004) using the same marker concatenated with *glnA*. A reassessment based on 16S rRNA gene and a large number of outsiders positioned cluster #4 at the root (Normand and Benson 2012b). A reassessment using the highly variable intergenic 16S-23S rRNA intergenic region also positioned cluster #4 at the root, but followed by cluster #3 and then clusters #2 and #1 (Ghodhbane-Gtari et al. 2010), a topology also recovered using a concatenate of *gyrB, nifH* and *glnII* genes (Nouioui et al. 2011). The topology obtained has been found to vary according to outgroups used, to the strains studied, to the genes regions used, and to the tree-reconstruction algorithm used. All in all, the four clusters are consistently recovered, but their respective positions vary and thus should be clarified using genome-wide approaches when a sufficiently large number of such genomes would have become available. A similar inconsistency was found to occur in the *Frankineae* forming or not a clade together comprising *Acidothermus* (*Acidothermaceae*), *Cryptosporangium* (*Cryptosporangiaceae*), *Geodermatophilaceae*, (*Geodermatophilaceae*), *Nakamurella* (*Nakamurellaceae*), and *Sporichthya* (*Sporichthyaceae*). This phylogenetic proximity between *Frankia, Geodermatophilus obscurus* and *Blastococcus aggregatus* was initially detected through reverse transcriptase sequencing and oligonucleotide cataloging of their 16S ribosomal RNA (Hahn et al. 1989). However, Barabote et al. (2009) found that although *Acidothermus* is the closest neighbor of *Frankia* when using the 16S rRNA gene sequences, BBH (Bidirectional Best Hits) protein sequences from *Acidothermus* were approximately equivalent to the more remote *Streptomyces* spp. Wu et al. (2009) studying a concatenate of 31 "universal" proteins could not recover *Frankia* and *Geodermatophilus* together in a clade. This question thus also remains open until a sufficient number of genomes from these neighbors become available.

These differences illustrate the difficulty of using a single marker to reconstruct the phylogeny of the genome as a whole, presumably because of numerous lateral transfers including those of the ribosomal genes that occur when microbes share a common niche following migrations. Presumably such transfers are more

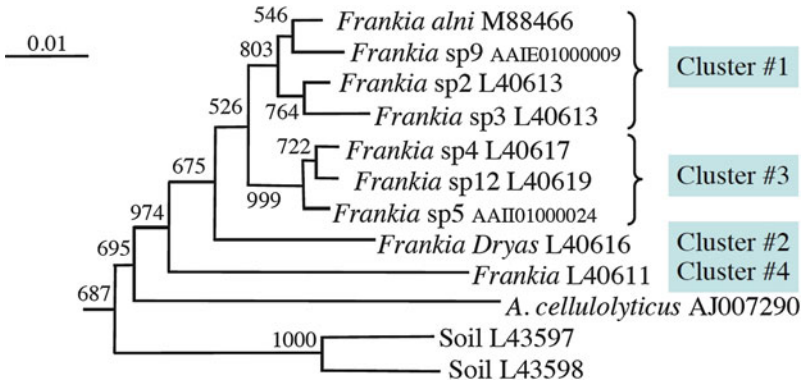

Fig. 18.4

Phylogenetic tree of *Frankia* and related taxa based on 16S analysis. The tree-reconstruction algorithm used was the Neighbor-Joining and the bootstrap results are indicated at branches (out of 1,000 replicates) and the scale bar represents 0.01 substitution per site. Unpublished

probable when genomes are large, as occurs in soil microbes. It appears inevitable that with the mounting number of genomes and with appropriate software, the complex evolutionary history of gene transfers, gene duplications, and gene loss will become clearer, although perhaps never satisfactorily. In this respect, it will be interesting to study genomes of microbes that coexist with *Frankia* in root tissues such as *Micromonospora* present in *Casuarina* (Valdes et al. 2005) and *Coriaria* (Trujillo et al. 2006).

Another marker that has been studied is the *nif* gene cluster, because it is emblematic of the symbiosis and because it is highly conserved and thus easy to recover through PCR or hybridization. NifH was used as early as 1989 to discern whether genes had been laterally transferred since the topology was distinct from that of 16S rRNA. The conclusion reached was "probably" (Normand and Bousquet 1989). A study of NifK yielded similarly uncertain results (Hirsch et al. 1995). The topology of NifH shows the gene in *Frankia* to be monophyletic, close to the Cyanobacteria while the Proteobacteria are further away and the Firmicutes even more so (*Fig. 18.4*). However, the vision that has recently emerged is that Nif determinants have undergone a complex series of events including duplications, modification of the metal cofactor (Fe, V, Mo), divergent adaptation to aerobic or anaerobic biotopes (Fani et al. 2000; Raymond et al. 2004; Boyd et al. 2011), illustrating the danger of using any single marker to infer the history of the genome as a whole. Nevertheless, the monophyly of actinobacteria and their placement as sister group to cyanobacteria appears to be a solid conclusion (Hartmann and Barnum 2010). This placement would suggest that other actinobacterial lineages have lost their *nif* genes over the time since the emergence of the Actinobacteria phylum, an event that could have happened as early as 2.4 BY ago before the rise of oxygen in the atmosphere, based on proteins molecular analyses and cell wall structure (Lake 2009), a conclusion also reached by considering physiological innovations present in actinobacteria such as the proteasome, sterol synthesis, and exospores (Cavalier-Smith 2002).

The current order *Frankiales*, as described in the latest edition of the Bergey's (Normand and Benson 2012b), thus presently comprises *Geodermatophilaceae, Nakamurellaceae, Sporichthyaceae, Acidothermaceae*, and the *Cryptosporangiaceae* as well as the *incertae sedis* species *Fodinicola feengrottensis* isolated from a medieval mine rock. The *Cryptosporangiaceae* family was previously positioned in the *Kineosporiaceae*, together with *Kineosporia* (Lilburn and Garrity, 2004) but this last family was split and the *Kineosporia* excluded to the newly created *Kineosporiaceae* together with genus *Quadrisphaera* in the latest *Bergey's Manual of Systematic Bacteriology*, 2nd edition.

Molecular Analysis

Three *Frankia* genomes sequences were published in 2007, for strains belonging to three of the known cross-inoculation groups, the first infective on *Alnus*, the second on *Casuarina* (both cluster #1), and the third on *Elaeagnus* (cluster #3) (Normand et al. 2007b). Analysis of these genomes provides some insight of these bacteria and of their evolutionary history. Besides the lack of canonical *nod* genes, a major conclusion from that study was that the three genomes had major differences in their size (5.4–7.5–9.0 Mb, see *Table 18.1*) despite having high similarity in 16S rRNA genes (1–2 % difference). Genome size correlated with host-plant range, as the genomes underwent major insertion-sequences-supported recombinations.

Since the first published report on the three *Frankia* genomes (Normand et al. 2007b), several sequencing projects on *Frankia* genomes representing the four major lineages have been initiated and are in various stages of completion including a report on a cluster 2 strain in symbiosis with *Datisca glomerata*. At present there are 11 *Frankia* genomes that have been or currently being sequenced. These sequencing projects include 3 genomes from Cluster I (ACN14a, CcI3 and QA3), 1 from Cluster II (Fd or Dg), 4 for Cluster III (EAN1pec, EUN1f, BCU110501, and BMG5.12) and 3 for Cluster IV (EuI1c, CN3 and DC12). As of July 2012, only five of these genome databases (strains ACN14a, CcI3, EAN1pec, Fd and EUI1c) have been completed and added

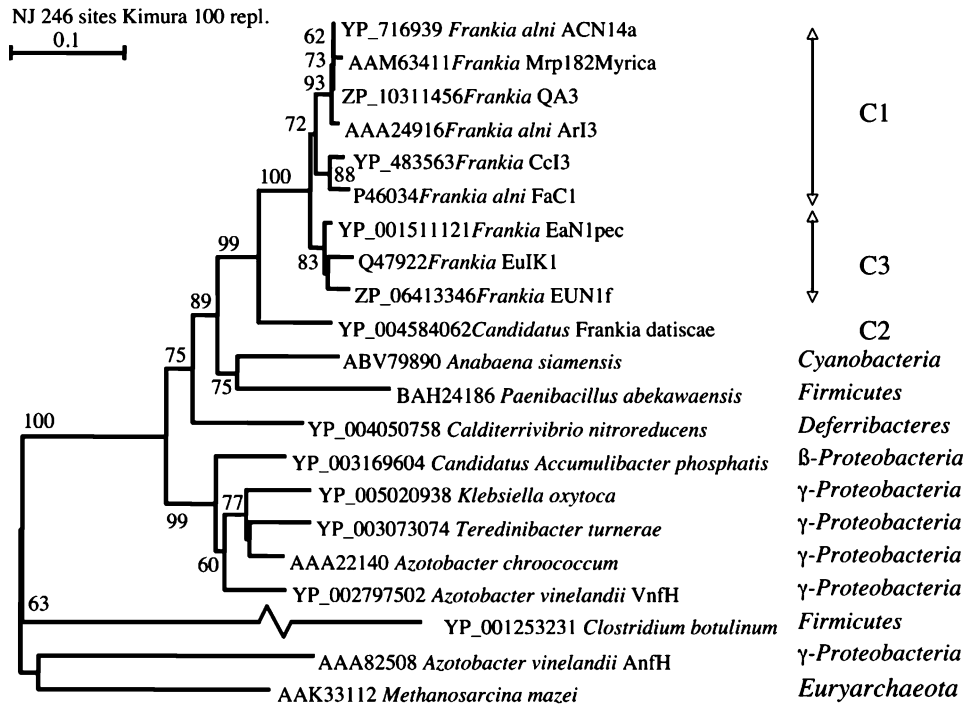

Fig. 18.5

Neighbor-Joining phylogenetic tree of NifH of *Frankia* sequences present in the NCBI data bank as well as representative sequences of other phyla. The bar represents 0.1 substitution/site. Unpublished

to the NCBI GenBank. The *Frankia* EAN1pec draft genome first reported by Normand et al. (2007) was completed and subsequently updated in GenBank. Three genomes (EUN1f, QA3, and CN3) are close to completion and have draft genome information publicly available. Two more genomes (BMG5.12 and BCU110501) are in production and the DC12 genome is in post-draft sequence finishing (*Fig. 18.5*).

An initial analysis of these eight *Frankia* genomes has provided further insight on these bacteria and their diversity. First, the correlation between host-specific range and genome size appears to be further supported. Those strains that have a wide-host-plant range had very large genomes (8.8–9.1 Mb range), while those strains with a narrow host-plant range or are potentially obligate symbionts have the smallest genomes (5.3 Mb). The medium host-range strains had a genome size that was in between the previous two (7.5 Mb). The cluster #4 strain studied had the largest genome sizes (10 Mb). Furthermore, the metabolically diverse *Frankia* groups (Cluster III and IV) were larger than the other two clusters (*Fig. 18.6*).

Five *Frankia* genomes are in databases and there should soon be about a dozen, allowing to discern better and better the core genome as new ones are added. Using the first four genomes (excluding EuI1c that does not fix nitrogen), we could extract at a threshold of 30 % of similarity in AA sequences 2,966 genes (43 %), of which 862 are characterized as "unknown function" (*Fig. 18.6*). When those genes that are also present in the 16S rRNA phylogenetic neighbors *Acidothermus cellulolyticus*, *Blastococcus saxobsidens*, *Geodermatophilus obscurus*, and *Modestobacter marinus* as well as in *Streptomyces coelicolor* are removed, the number of genes in the *Frankia*-specific core genome drops to 291 genes (4.2 %), presumably containing those genes necessary for establishment of the symbiosis and nitrogen fixation. When these are mapped onto the genome of *Frankia alni*, no strong clustering is observed (*Fig. 18.6*).

Plasmids

Prior to the genome sequencing, a few *Frankia* strains had been shown to possess plasmids (Normand et al. 1983) and several of these plasmids were sequenced (John et al. 2001; Lavire et al. 2001; Xu et al. 2002). In the post-genomic era, integrative conjugative plasmids have been identified as being present in these *Frankia* genomes (te Poele et al. 2008; Ghinet et al. 2011).

Phages

No phage has been described for the *Frankia* genomes; however, no specific work has been done for that purpose. A search in the *Frankia* genome databases for "phage" features revealed several occurrences. Since these genes are not conserved among the genomes and there is no major syntenic region, they are thus likely to represent either events that have occurred since the emergence of the different clades, or are undergoing pseudogene conversion events. The *Frankia alni* ACN14a genome has two clusters of 5–7 genes each (FRAAL 2679–2684, FRAAL 2743–51) that contain mycobacteriophage genes (*Fig. 18.6*),

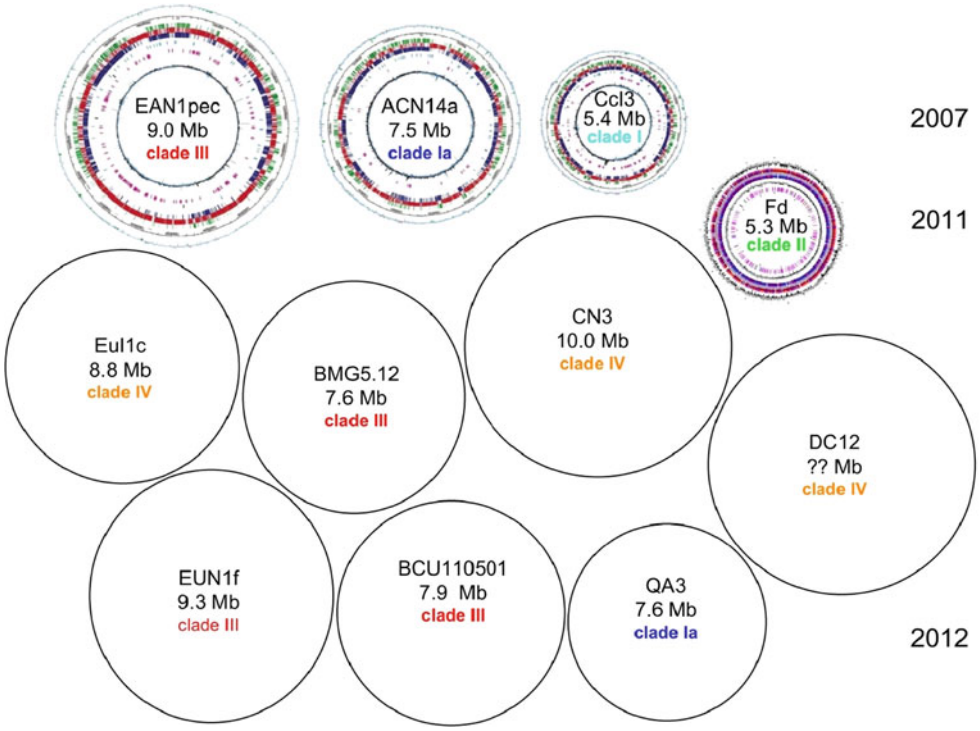

Fig. 18.6

Schematic representation of *Frankia* genomes already published in 2007 and 2011 (*top*) and those not yet published (*bottom*). The color code is clade 1 in *blue*, clade 2 in *green*, clade 3 in *red*, and clade 4 in *orange*. The size of the genomes are proportional to their real size with the largest being the clade 4 (10 Mb), followed by the clade 3 (9 Mb), the clade 1a (7.5 Mb), the clade 1 (5.4 Mb), and the smallest being the clade 2 (5.3 Mb) (Courtesy of Nick Beauchemin, University of New Hampshire, Durham, NH)

while the *Frankia* QA3 genome has one cluster (FraQA3DRAFT_2742-58) (*Table 18.2*). In the case of *Frankia* ACN14a, the similarity is low and several intervening genes are present, reducing the likelihood these clusters could be functional prophages.

The availability of genomic tools may allow an understanding how the symbiotic partners modify their expression pattern upon establishment of the symbiosis and such studies have been started. Whole genome arrays have been used on *Frankia alni* to compare symbiotic cells to in vitro grown cells, showing several clusters upregulated such as those coding for *nif*, *hup*, and *suf* (Alloisio et al. 2010).

On the host plant side, no genome project has been undertaken so far; however, an EST collection of 15,000 unigenes for both *Casuarina* and *Alnus* has permitted to compare roots to nodules 21 days after inoculation and to detect various putative symbiotic genes (Hocher et al. 2011).

Phenotypic Analysis Symbiotic Relationships

Symbiotic Relationships

Virtually all *Frankia* strains available in culture have been isolated from or described in the context of the plant hosts from which they have been isolated. Many additional strains have been identified by gene sequences obtained from field-grown root nodules during studies on strain diversity or population structure (Benson et al. 1996; Clawson et al. 1998, Clawson et al. 1999; Ritchie and Myrold 1999; Simonet et al. 1999; Huguet et al. 2001; Clawson et al. 2004; Huguet et al. 2004; Oakley et al. 2004; Vanden Heuvel et al. 2004; Huguet et al. 2005a; Huguet et al. 2005b; Mirza et al. 2009b; Welsh et al. 2009; Ghodhbane-Gtari et al. 2010; Kennedy et al. 2010; Mishra et al. 2010; Pokharel et al. 2011).

There are 23 genera of dicotyledonous plants, belonging to eight families, that have established symbiotic N_2-fixing root nodules with *Frankia* (Benson and Silvester 1993). The symbiosis is called "actinorhizal" and infected plants are referred to as "actinorhizal plants" (Torrey 1983). Suitable plant hosts (*Table 18.3*) are readily infected by most frankiae, giving rise to nitrogen-fixing (effective) nodules on the roots. Some strains give rise to non-effective nodules and still others are not infective on the host plant from which they have been isolated, under tested conditions. The latter strains are often infective on plants belonging to the family *Elaeagnaceae* (Gauthier et al. 1981; Clawson et al. 2004). Infection in the *Casuarinaceae*, *Myricaceae*, and *Alnus* takes place through root hairs (*Fig. 18.7*) after an induced deformation occurs (Callaham et al. 1979; Berry 1983; Berry and Sunell 1990; Liu and Berry 1991), whereas infection in other plants proceeds by intercellular penetration into the root (Miller and Baker 1985;

Table 18.2
Phages features in *Frankiaceae* genomes

Feature	*Fa*	*Fc*	*Fe*	*Fd*	*EuI1c*	*EUN1f*	*QA3*	*CN3*

Phage clusters	2						1	

Liu and Berry 1991). In cases where an "elaeagnus strain" infects plants from other families, the infection route is dictated by the plant be it via intercellular penetration or through root hair (Miller and Baker 1986; Racette and Torrey 1989). The molecular mechanisms whereby the plant recognizes the microbial symbiont and forms nodules are not currently known, except for the recently demonstrated expression of homologs of SymRK, the receptor-like kinase that is necessary for legume nodule and mycorrhiza formation, in nodules of *Casuarina* (Gherbi et al. 2008) and *Datisca* (Markmann et al. 2008), and the demonstration of the presence in *Alnus* and *Casuarina* transcribed genes of homologs of the whole symbiotic cascade described in Legumes (Hocher et al. 2011).

In *Frankia* genomes, canonical *nod* genes have not been identified (Normand et al. 2007a) and the factor that deforms *Alnus* root hairs, that may or not be the symbiotic effector, has only been characterized as hydrophilic, thermostable, and sensitive to some enzymes such as pronase (Ceremonie et al. 1999). This root hair deforming factor is also known to be specific to actinorhizals, as the *Rhizobium* Nod factor did not deform *Alnus* root hairs nor did the *Frankia* deforming factor deform Legumes hairs (Van Ghelue et al. 1997).

The synthesis of plant hormones such as indole-3-acetic acid or IAA (Berry et al. 1989), 2-phenylacetic acid or PAA (Hammad et al. 2003), or cytokinins (Stevens and Berry 1988) may play a role in modification of the plant root developmental program.

Lectins may help binding of the bacterial cells to the plant surfaces (Pujic et al. 2012).

The phylogenies of actinorhizal plants (Swensen and Mullin 1997) and the associated bacteria do not overlap exactly, which has led some to conclude that coevolution may have occurred (Jeong et al. 1999), especially in the case of *Casuarina*/*Allocasuarina* host plants (Simonet et al. 1999) but geographical co-occurrence may have been a major factor in the case of *Frankia* Cluster #2 strains in Western US (Oakley et al. 2004), as may also have been the case of the *Casuarinaceae Gymnostoma* nodulated by Cluster #3 *Frankia* (Navarro et al. 1997).

The time of appearance of the symbiosis has been debated and two types of evidence have been presented (Clawson et al. 2004; Swensen and Benson 2008). In the fossil record, eudicots appear before 125 Myr at the Barremian-Aptian boundary of the lower Cretaceous as triaperturate pollen grains that are diagnostic for the eudicots (Crane et al. 1995). The oldest identifiable actinorhizal lineages leading to the *Betulaceae* and *Myricaceae* occur in pollen dated 95-90MY (Thomas and Spicer 1987; Maggia and Bousquet 1994; Sims et al. 1999). Using molecular clock estimates, the Rosid I clade, containing all nitrogen-fixing lineages of Angiosperms, is thought to have radiated over a ~17 Myr period, 108–91 Myr ago (Wang et al. 2009). Given uncertainties in constructing a molecular clock, and the vagaries of the fossil record, the origin of actinorhizal plants is not readily resolvable. In a recent analysis of the origins of nodulation in the entire NFC, Doyle (2012) posits multiple origins of nodulation within the larger plant clade. Within the actinorhizal members of the NFC, the most likely scenario seems to be a single origin of the capability to nodulate (Hocher et al. 2011) followed by losses and, more rarely gains of the phenotype (Swensen and Benson 2008). As noted by Clawson et al. (1998), the lack of identifiable fossils from an actinorhizal lineage does not mean that the symbiosis did not exist prior to the deposition of fossils. Likewise, the absence of any recognizable actinorhizal lineage in the mid-Cretaceous does not mean that the ancestors of *Frankia* were not participating in plant symbioses before the lineages became established. In effect, it is difficult if not impossible to draw strong conclusions about the early evolution of the actinorhizal symbiosis.

Ecology

Natural Habitats

Actinorhizal plants generally thrive in open spaces, especially where soils are poor in nitrogen. Many of these biotopes are natural, for instance, forests after fires, beach dunes, mountain screes, glacier moraines, and volcanic lava fields (*Fig. 18.8*). Many others are man-made, for instance, road sides or rail tracks, mine spoils, rubble heaps, forests or fields after harvests, and channel banks.

Glacier Retreat

One of the best documented instances of plant succession following glacier retreat is the case of Glacier Bay, Alaska, that has been followed over close to a century (Cooper 1923; Crocker and Major 1955; Lawrence et al. 1967; Reiners et al. 1971). The recorded succession goes from pioneer species (lichens and liverworts), to nitrogen-fixing creeping shrubs such as avens (*Dryas*), to bush trees such as alders (*A. viridis* subsp. *crispa*), and finally to the climax spruce forest community over a span of

Table 18.3
Actinorhizal plant genera and associated groups of *Frankia* strains

Order	Family (nod genera/total)	Genus (# species)	Geographical distribution[1]	16S rRNA cluster[2]	Penetration mode[3]	Common English name

	Datiscaceae (1/1)	*Datisca* (2)	Western NA, South Asia	2	ICP	Durango root

The *Rhamnaceae Adolphia* has also been suggested to be actinorhizal but this report has not been confirmed. *Adolphia infesta* (Kunth) Meisn. and *Colubrina infesta* (Kunth) Schltdl. are synonymous with basionym *Ceanothus infestus* Kunth.
Notes
1-NA stands for North America, SA for South America, NZ for New Zealand, NG for New Guinea.
2-The numbers refer to those attributed by Normand et al. (1996).
3-RHI stands for "root hair deformation" and ICP for "intercellular penetration."

more than 100 years. The soil underwent a concomitant evolution, going from a nitrogen-poor sandy soil to a nitrogen-rich sandy loam. The ecological role of the nitrogen-fixing plants is considered to be that of facilitation, rather than required for succession (Chapin et al. 1994).

In that regard, other glaciers in other parts of the world have been thus studied but actinorhizals there have so far not been found to play a similar key role, for instance, in the case of the Alpine Evettes glacier (Pech et al. 2007) or the Scandinavian Svalbard glacier (Cannone et al. 2004).

Forest Fires

Forests can evolve from pioneer stages to climax, storing enormous amounts of carbon and other nutrients in their biomass and that of the fauna they shelter. They nevertheless burn following dry spells, volcanic eruptions, or even human interventions, resulting in massive loss of nitrogen from the site. If left to themselves, forests may then initiate again a drawn-out succession, that will start with pioneer plants, nitrogen-fixers being among the most successful ones. In northwestern North America, for example, sitka alder (*A. viridis* subsp. *sinuata*) is among the first species to invade following fires (Uchytil, 1989).

Volcanoes

Volcanoes have shaped our planet for millions of years and continue to do so to this day. One of the largest eruptions recorded in human history occurred on the Island Krakatau in 1883 and sent ashes into the upper atmosphere that colored the sky of the whole planet for several months. Ten years later, botanical studies showed that the actinorhizal *Casuarina* was recolonizing the island (Bordage 1916). Hawaii is an archipelago in the Pacific situated atop a hot point, resulting in the regular emission of very fluid lava that covers the ground. This nitrogen-poor substrate is presently being colonized by the actinorhizal *Myrica faya*, because native plants are too demanding to be competitive (Vitousek et al. 1987). Sakurajima in the Kagoshima Prefecture on the Japanese Southern Island of Kyūshū, Japan, is a stratovolcano that has erupted regularly and has been followed by teams of botanists, who have observed *Alnus firma* as among the first to colonize the ashes and establish thickets (Kucho et al. 2010).

Applications

Plantations

Few actinorhizal plants are large enough or solid enough to be used for furniture, although red or black alder, planted on numerous sites, are used by in the Western USA (http://redalder.net/; http://www.alibaba.com/showroom/red-alder-furniture.html).

Few actinorhizal plants produce edible parts, the exceptions being *Hippophae rhamnoides*, *Elaeagnus angustifolia* var. *orientalis*, and *Myrica rubra* that are planted on a large scale for that purpose. *H. rhamnoides* (sea buckthorn) ranges naturally from Western Europe to Japan and is planted on a large scale in Europe and North America for its fruits that are processed as juice, jelly, fruit paste, wine, or into liquor. The vitamin C, E, and A contents are high, and this constitutes a marketing argument for this health food (Beveridge et al. 1999). Various *Elaeagnus* species produce edible seeds, few of which are commercialized, except for *E. angustifolia* var. *orientalis* sold on markets in Turkey and Iran as mountain ash or Trebizond date. *M. rubra* known as Chinese bayberry or yumberry is an economically important crop in China and Japan, and is sold fresh or dried, and can be canned, pressed for juice, or for alcoholic beverages. There are also numerous websites that give long lists of health benefits proposed to be accrued from its use, ranging from antioxidants, treatment of arthritis, high blood pressure, diabetes, whitening skin, etc. A related species, *Myrica nagi*, grows in the Northeastern hills of India, producing fruits, locally called kaphal, that are harvested in the forests.

Secondary Metabolites

Although many actinobacteria have been utilized for their production of chemically diverse and biologically potent natural products, the potential of *Frankia* is only slowly being uncovered. Prior to genome analysis, only one antimicrobial agent, frankiamide, had been identified (Haansuu et al. 2001; Klika et al. 2001). Bioinformatic analysis of the first three *Frankia* genomes revealed a metabolic potential for production of novel secondary metabolites (Udwary et al. 2011). The existence of lectins in the genomes of *Alnus*-infective *Frankia alni*

Fig. 18.8
The *Elaeagnaceae* buffaloberry (*Shepherdia canadensis*) growing on a railroad track ballast alongside the St-Lawrence river in Les Eboulements, PQ, Canada. The *Myricaceae* sweet fern (*Comptonia peregrina*) growing on a beach dune in Ogunquit, ME, USA. Photos P. Normand

strain ACN14a may also find applications (Pujic et al. 2012), in particular, as some ricin-type lectins have been shown to bind viruses (Tanaka et al. 2009). The promise of this metabolic potential warrants further consideration.

The host plants also are a source of metabolites. Alder species in particular have been used traditionally for the treatment of various diseases, they have been used as an astringent, cathartic, emetic, febrifuge, hemostatic, parasiticide, skin tonic, vermifuge, etc., and were found recently to contain hundreds of metabolites causing NO and TNF-α production, HIV inhibition, antibacterial activity, antitumor activity, etc. (Sati et al. 2011).

Windbreaks

Production of fruits, vegetables, and cereals in coastal areas is hampered by salt-laden and sand-carrying winds. Windbreaks are thus often planted to shelter crops and many papers have been written to describe these assays. One site that was thus protected early is the seafront in Senegal between Dakar and St-Louis, planted over an area of 500 km by 500 m (25,000 ha) and that, to this day, is still thriving (Dommergues 1995). Similar protection has been conferred on the Southern China coast (Zhong et al. 2010) and elsewhere (Dawson 1986). At the moment, there are 300,000 ha planted in southern coastal China (Zhong et al. 2011), 500,000 ha in coastal India (Rawat et al. 2011), and 100,000 ha in coastal Vietnam (Nghia et al. 2011). These plantations that would amount to about a million hectares are also used as a source of fuel and construction wood.

Mine Spoils

Mining operations are among the most environmentally damaging industries, yielding, among other problems, spoils that affect the countryside, pollute streams, and impact and damage wildlife populations. Some places on earth have become highly impacted by toxic fumes and topsoil removal, as is the case of the nickel mining operations around Sudbury, Canada, or in New Caledonia. Alder, for instance, has been found to withstand severe soil conditions, *Alnus glutinosa* is used to establish cover on coal mine spoils in Ohio (Funk 1973), *Alnus viridis* subsp. *sinuata* on copper mine spoils in western USA (Uchytil 1989), *Alnus rubra* on coal mine spoils in Washington, and *A. viridis* subsp. *crispa* on tar sand spoils in Alberta (Roy et al. 2007). Various *Gymnostoma* species have been widely planted in New Caledonia on nickel spoils (Hery et al. 2005) and *Casuarina* and *Myrica* on bauxite spoils in Jamaica. However, no comprehensive assessment of the effect of such plantations on water quality or wildlife health or may be has been made so far.

Hydroelectric Projects

Hydroelectric dams, if they are considered on the whole environmentally friendly, are nevertheless industrial scale projects that entail moving millions of tons of rock to create dykes that in turn direct water toward turbines to generate electricity (*Fig. 18.9*). These dykes must be stabilized to ensure durability and should also be covered rapidly by vegetation for aesthetic and wildlife management purposes.

Few plants can grow on these rocky substrates at polar latitudes because they are poor in nutrients, especially in nitrogen. Yet, a few subarctic pioneer plants are known to colonize open surfaces, in particular green alder (*A. viridis* subsp. *crispa*), which is why they were used in attempts at initiating ecological successions, with more than seven million seedlings inoculated with *Frankia* and planted (Périnet and Lalonde 1983). Therefore, hundreds of thousands of nodulated seedlings were planted, for instance, in the Marguerites project where 765,000 seedlings of alder, spruce, and pine were used on the shores to speed up establishment of an extensive plant cover

Fig. 18.9
On the *left* is an aerial photo of a HydroQuebec dam in Northern Quebec (Nemaska, Cree Nation territory, James Bay area, Canada) with dykes stabilized with plantations of green alder (*Alnus viridis* subsp. *crispa*). On the *right* is a close-up of green alder seedlings planted on a nitrogen-poor rocky substrate. Photos Martin Lessard, Montreal

Ornamental Plants

Several actinorhizals are planted for ornamental purposes, especially when the soil is poor and there is little money to add topsoil. Russian olive (*Elaeagnus angustifolia*) and autumn olive (*E. umbellata*) with their lush silvery foliage are but two of the long list of species of the genus that are planted as hedges around houses, parks, and highways in Europe and North America. They thrive so well that they are now considered invasive and several US states advise their removal. *Hippophae rhamnoides* is also planted for similar reasons in Europe and in California, Oregon, and Washington; growers sell alders, bitterbrush, and ceanothus species. Italian alder (*A. cordata*) is a sturdy tree with a lush foliage and large female catkins that is planted along roads and parking lots in Europe. Casuarinas are planted for the same reason in tropical countries, for instance, *C. cunninghamiana* planted around parking lots and along highways. Several Ceanothus hybrids are sold in garden shops for planting in gardens, for instance, *Ceanothus* x *delileanus* Gloire de Versailles with its large blue inflorescences.

Construction

The city of Venice was built starting from the time of the Roman Empire over hundreds of muddy islands by driving millions of alder poles through the mud. This permitted to form piles to support construction of massive buildings that have withstood some fifteen centuries and have resisted decay to this day. The Roman architect Vitruvius thus spoke of using alder poles to establish piles in muddy soil (De Architectura, II, IX, 10 e 16 – (I sec. a.C.); http://www.turismo.ravenna.it/eng/Discover-the-area/People_-history_-traditions/Famous-personages/Strabo-and-Vitruvius) : "The alder, which grows on the banks of rivers, and is to appearance an almost useless wood, possesses nevertheless most excellent qualities, inasmuch as it contains much air and fire, not a great deal of earth, and less water. Its freeness from water makes it almost eternal in marshy foundations used for piling under buildings, because, in these situations, it receives that moisture which it does not possess naturally. It bears immense weights and does not decay. Thus we see that timber which above ground soon decays, lasts an amazing time in a damp soil....."

Conclusion

Frankia offers the curious distinction of being one of the first microbes to have been hypothesized to exist, at the end of the nineteenth century, because it caused visible nodules on the roots of *Alnus* and *Elaeagnus*, yet could not be obtained in pure culture before 1978 when the strain CpI1 was obtained and distributed worldwide to be studied (Callaham et al. 1978).

Another dubious distinction of *Frankia* is that it is probably the taxon with the lowest number of described species despite having thousands of isolated strains studied and described (Normand and Benson 2012a). This is partly due to the fact that *Frankia* contains several strains that have defied isolation in pure culture, that many isolated strains that can be cultivated nevertheless grow very slowly making these difficult to treat with approaches such as DNA-DNA hybridization and to study

phenotypically, which is recognized as the standard to define and name species.

The study of the genomes of these microbes is also hindered by the lack of a genetic transformation system. Nevertheless, as more and more strains are isolated and classified into new species, as more and more genomes are obtained, as more and more genes are studied in heterologous hosts, as several soil metagenomes are studied, we should see the evolutionary history of one of the most contrasted microbial lineage unfold.

19 The Family *Gaiellaceae*

Luciana Albuquerque[1] · *Milton S. da Costa*[2]
[1]Center for Neuroscience and Cell Biology, University of Coimbra, Coimbra, Portugal
[2]Department of Life Sciences, University of Coimbra, Coimbra, Portugal

Abstract
Gaiellaceae, a family within the order *Gaiellales*, comprises the genus *Gaiella*. The order *Gaiellales* represents a distinct phylogenetic lineage based on 16S rRNA gene sequence analysis. The Actinobacteria include several deep-branching lineages that consist of species of the genera *Rubrobacter*, *Solirubrobacter*, *Patulibacter*, *Conexibacter*, *Thermoleophilum*, and more recently *Gaiella* (Albuquerque et al. Syst Appl Microbiol 34:595–599, 2011; Reddy and Garcia-Pichel. Int J Syst Evol Microbiol 59, 87–94, 2009). This organism was isolated from a deep mineral water borehole, it is strictly aerobic, catalase- and oxidase-positive, utilizing several organic compounds. The most distinctive characteristic is the presence of iso internally branched fatty acids found in no other bacterium (Albuquerque et al. Syst Appl Microbiol 34:595–599, 2011). Since only one species is known, we will treat the order *Gaiellales* and the family *Gaiellaceae* on equal terms. The type strain is F2-233^T (=CECT 7815^T = LMG 26412^T) and strain F2-223 (=CECT 7816) is an additional strain of this species.

Taxonomy: Historical and Current

Short Description of the Order and Family

Gaiellales Albuquerque et al. 2012

Gaiellales (Ga.i.el.la'les, N.L. fem. dim. n. *Gaiella*, type genus of the order; suff. -ales, ending to denote an order; N.L. fem. pl. *Gaiellales*, the *Gaiella* order).

Members of the order *Gaiellales* are non-spore-forming. The order represents a distinct phylogenetic lineage based on 16S rRNA gene sequence analysis. The order *Gaiellales* belongs to the class *Actinobacteria*. The order contains the family *Gaiellaceae* (Albuquerque et al. 2011).

Gaiellaceae Albuquerque et al. 2012

Gaiellaceae (Ga.i.el.la.ce'a.e. N.L. fem. dim. n. *Gaiella*, type genus of the family; suff. -*aceae*, ending to denote a family; N.L. fem. pl. *Gaiellaceae*, the *Gaiella* family).

The members of the sole family *Gaiellaceae* of the order *Gaiellales* stain Gram-negative and form rod-shaped cells. These organisms are strictly aerobic and chemoorganotrophic. The peptidoglycan contains *meso*-Dpm as diagnostic diamino acid. Internally methyl-branched iso-fatty acids are present. Menaquinone 7 (MK-7) is the major respiratory lipoquinone. The type and only genus of this family is *Gaiella* (Albuquerque et al. 2011).

Phylogenetic Structure of the Order, Family, and Its Genus

Comparison of the 16S rRNA gene sequence of *Gaiella occulta* with sequences in the public data bases demonstrated that this genus represents a deep-branching lineage of the Actinobacteria that branches within the radiation of the genera *Rubrobacter* (Carreto et al. 1996; Chen et al. 2004; Suzuki et al. 1988), *Thermoleophilum* (Zarilla and Perry 1984; Zarilla and Perry 1986), *Patulibacter* (Kim et al. 2012; Reddy and Garcia-Pichel 2009; Takahashi et al. 2006), *Conexibacter* (Monciardini et al. 2003; Seki et al. 2012) and *Solirubrobacter* (An et al. 2011; Kim et al. 2007; Singleton et al. 2003). These genera currently form four orders *Rubrobacterales* (genus *Rubrobacter*), *Thermoleophilales* (genus *Thermoleophilum*), *Solirubrobacterales* (genera *Solirubrobacter*, *Conexibacter*, and *Patulibacter*), and *Gaiellales* (*Gaiella occulta*). *Gaiella occulta* shares between 87 % and 88 % pairwise 16S rRNA gene sequence similarity with the species of the orders *Thermoleophilales* and *Solirubrobacterales* and just 85 % with the species of the order *Rubrobacterales* (*Fig. 19.1*). This lack of a close relationship with these existing orders is also supported by the low bootstrap value for the branching of the *Gaiella oculta* lineage with the other deep-branching actinobacterial lineages including the order *Coriobacteriales* (Albuquerque et al. 2011).

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_394,

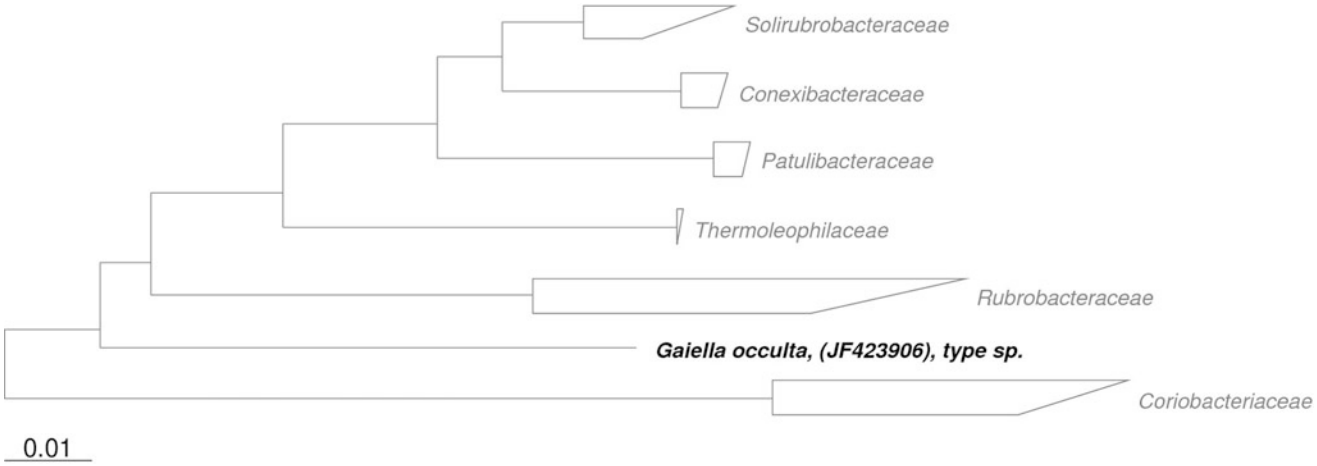

Fig. 19.1

Phylogenetic reconstruction of the family *Gaiellaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence dataset and alignment were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Phenotypic Analyses

The main features of members of the orders *Gaiellales, Solirubrobacterales, Rubrobacterales, and Thermoleophilales* are listed in *Table 19.1*.

The sole species of the order *Gaiellales* can be distinguished from the species of the other deep-branching orders of the Actinobacteria by several characteristics that seem to be order specific and to reflect the phylogeny based on 16S rRNA gene sequence analysis. For example, *Gaiella occulta* (strains F2-233^T and F2-223) are mesophilic, like the species of the order *Solirubrobacterales*, while the members of the order *Rubrobacterales* and *Thermoleophilales* are thermophilic with optimum growth temperatures ranging between about 45 °C and 60 °C. The order *Gaiellales* can be differentiated from these three orders by their novel internally branched iso-fatty acids. The species of the *Rubrobacterales* have straight chain internally branched fatty acids, namely, $C_{16:0}$ 12-methyl and $C_{18:0}$ 14-methyl instead of internally branched iso-fatty acids; the members of the order *Solirubrobacterales* possess primarily straight chain monounsaturated fatty acids. However, the fatty acids of the *Thermoleophilales* have not been examined and a full comparison of these chemotaxonomic markers cannot be made at this time. The members of the *Solirubrobacterales* possess MK-7(H_2), MK-7(H_4) or DMK-7 instead of MK-7 found in strains F2-233^T and F2-223, while the species comprising the *Rubrobacterales* possess MK-8. The peptidoglycan of *Gaiella occulta* contains *meso*-Dpm like the species of the orders *Solirubrobacterales* and *Thermoleophilales*, while species of the order *Rubrobacterales* have a different type, containing L-Lys.

Gaiella Albuquerque et al. 2012

The family *Gaiellaceae* comprises one genus composed of a sole species represented by strains F2-233^T (=CECT 7815^T = LMG 26412^T) and F2-223 (=CECT 7816) isolated from a deep mineral water aquifer in Portugal.

Gaiella [Ga.i'el.la. N.L. dim. fem. n. *Gaiella*, named after Gaia, Greek goddess of the earth, referring to the origin of the organism (i.e., the earth)]. This genus comprises one species *Gaiella occulta*.

Gaiella occulta forms nonmotile short rod-shaped cells with 1.0–3.0 μm in length and 0.3–0.5 μm in width and stain Gram-negative. The members of this species are strictly aerobic, and oxidase- and catalase-positive. The optimum growth temperature is about 35–37 °C in liquid R2A medium and the cultures are non-pigmented; growth does not occur at 15 and 45 °C. The optimum pH for growth is between 6.5 and 7.5; growth does not occur at pH 5.0 or pH 9.0. No growth occurs in media containing 1 % NaCl. Poor growth occurs on medium R2A solidified with agar. Nitrate is reduced to nitrite. Gelatine is degraded; esculin and hippurate are not degraded. Alkaline phosphatase, esterase (C 4), esterase lipase (C 8), acid phosphatase, naphthol-AS-BI-phosphohydrolase are positive in the API ZYM, other activities are negative. The organism assimilates a few sugars, as well as *myo*-inositol, organic acids, and amino acids, namely, D-glucose, D-fructose, D-mannose, D-ribose, D-xylose, α-ketoglutarate, DL-lactate, acetate, pyruvate, glutamate, L-alanine, L-asparagine, L-lysine, proline, L-glutamine, L-arginine, L-serine, and ornithine. A large number of sugars, organic acids, and amino acids are not utilized: D-galactose, L-rhamnose, L-fucose, L-sorbose, D-arabinose, L-arabinose,

[g]*MK* menaquinone, *DMK* demethylmenaquinone

sucrose, maltose, lactose, D-cellobiose, D-trehalose, D-raffinose, glycerol, ribitol, xylitol, sorbitol, mannitol, erythritol, D-arabitol, L-arabitol, succinate, malate, citrate, benzoate, fumarate, formate, D-gluconate, D-glucoronate, aspartate, glycine, L-histidine, valine, L-phenyalanine, L-leucine, L-isoleucine, methionine, and threonine. Aliphatic hydrocarbons, namely, hexane, heptane, *n*-decane, dodecane, *n*-hexadecane, petroleum ether, L-chlorobutane, and toluene, are not used either. The peptidoglycan type is A1γ' (*meso*-Dpm directly cross-linked; glycine at position 1 of the peptide subunit). Major fatty acids are iso-$C_{17:0}$ 10-methyl, iso-$C_{17:0}$, and iso-$C_{15:0}$ 8-methyl. Polar lipids consist of three unidentified phospholipids and two unidentified phosphoglycolipids. The G + C content of the DNA is 71.6 mol%. Unlike the species of the genus *Rubrobacter*, this organism does not survive exposure to a 1 kGy dose of gamma ionizing radiation (Albuquerque et al. 2011).

Isolation, Enrichment, and Maintenance Procedures

Gaiella occulta was isolated from the vent water of a deep mineral water aquifer (150 m) (Albuquerque et al. 2011). Large sample volumes (250–1,000 ml) were filtered through membrane filters (Gelman type GN-6; pore size 0.1 μm; diameter 47 mm). The filters were placed on the surface of solidified R2A agar medium. This organism grew very poorly on medium solidified with agar, growth was better in liquid R2A medium. The strain was routinely cultured in liquid R2A medium at 37 °C.

Gaiella occulta does not require special procedures for maintenance and long-term storage. Can be stored frozen at −70 °C in R2A medium containing 15 % glycerol without loss of viability. Long-term preservation is by lyophilization.

Ecology

Habitat

The only strains known were isolated from one deep aquifer in Portugal, supplying a mineral water bottling plant. The borehole water has a temperature of 28 °C, a pH of 5.9, and is very poor in mineral ions (Albuquerque et al. 2011). Other environments are unknown. *Gaiella occulta*, unlike the species of the genus *Rubrobacter*, was not resistant to 1 kGy dose of gamma ionizing radiation. Other closely related environclones (about 98 % 16S rRNA sequence similarity) have been identified in soil (EU335248), water distribution systems (JF922500, JF922567), and a shallow lake (GQ472411).

Abstract
Members of the family *Geodermatophilaceae*, order *Actinomycetales*, contain bacteria isolated mainly from soils, seawater, and stone surfaces that have been grouped into the three genera *Geodermatophilus*, *Blastococcus*, and *Modestobacter*. Members of *Geodermatophilus* have been found mainly in soils, *Blastococcus* spp. have been found in a marine sediment and in stone interiors and *Modestobacter* spp. have been found on stone surfaces and in polar regolith. Members of the genera *Geodermatophilus* and *Modestobacter* have been found to be unusually resistant to oxidative stresses while those of *Blastococcus* were found resistant to some heavy metals and metalloids. This family is close to the genera *Acidothermus, Cryptosporangium, Frankia, Nakamurella, Sporichthya*, and *Fodinicola* and was grouped with them into suborder *Frankineae*. A recent rearrangement has resulted in the elevation of suborder *Frankineae* to order *Frankiales* (Normand and Benson, Order VI. *Frankiales* ord. nov. In: *Bergey's Manual of Systematic Bacteriology*, vol 5. The Actinobacteria. Bergey's Manual Trust, Athens, pp 509–511, 2012) containing families *Acidothermaceae*, *Cryptosporangiaceae*, *Frankiaceae*, *Geodermatophilaceae*, *Nakamurellaceae*, *Sporichthyaceae*, and *Fodinicola.*

Introduction

Common sense tells us that stones are devoid of life, given there are basically no organic substrates for organotrophs and little for chemolithotrophs. Many stones also contain high concentrations of chemicals that constitute fierce challenges to microbial cells such as reactive metals and metalloids. Besides, there is, in general, little free water available to microbial life. Finally, stones have varied origins but most have undergone episodes of high pressure and/or high temperature that are adverse to most microbial taxa. Yet stones, especially sedimentary ones such as those of calcareous origin, crumble, eventually forming soils and sediments. Stone degradation is a time-requiring process that comprises colonization of outer layers, local pH modifications together with physicochemical processes such as acid secretion and exudates that attack calcium carbonate, thus forming niches for sturdy, non-demanding microbes.

Stone surfaces exposed to air constitute a biotope generally considered as punishing to microbial life. On top of being nutrient poor, they are exposed to direct or indirect solar radiations, to temperature extremes, and to desiccation cycles. Yet, there are nutrients in rain water that washes the stones, there is wind-borne carbon-laden dust, and there is some percolation from the soil solution carrying nutrients. Furthermore, the surfaces are full of micro-depressions where microbial cells can get a grip. Therefore, robust radiation-resistant microbes can colonize stone surfaces as is well known by city managers who have to fight deterioration of old stone buildings brought about by a combination of physicochemical and biological agents.

Soils in general constitute very permissive biotopes, inhabited by an extremely varied menagerie considered to be the richest

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_180,

among biotopes (Torsvik et al. 2002). However, dry desert soils are an exception to this vision as the lack of water is a strong selection factor for microbes, killing many, and also for plants. Since plants constitute the dominant source of carbon in soils, desert soils are not only dry but also carbon poor and thus select for an adapted microflora of sturdy, non-demanding microbes able to withstand long episodes of famine. Regolith, the crumbly material originating from stone flaking brought about by cycles of thawing, water infiltration, and freezing that occur under polar conditions, is also a very inhospitable biotope when compared to soil.

These three biotopes, stone interiors, stone surfaces, and desert soils, have been found to be colonized by strains phylogenetically related, belonging to the *Geodermatophilaceae*. They represent unusual examples of adaptation to extreme biotopes. They are also unusual in that they belong phylogenetically to the actinobacteria; yet, they have no or only rudimentary hyphae. Nevertheless, the three lineages are related as storms can uplift desert soils and carry particles over long distances (Chuvochina et al. 2011a, b), as stones surfaces are attacked by physicochemical factors, leading to cracks, fissures, and flaking (Gomez-Alarcon and de la Torre 1994; Welton et al. 2003; De Graef et al. 2005) and these detritus are in turn released, fall into the soil, or are carried away by winds.

Taxonomy: Historical and Current

Geo.der.ma.to.phi.la′ce.ae. N. L. masc. n. *Geodermatophilus* type genus of the family; -aceae ending to denote a family; N. L. fem. pl. n. *Geodermatophilaceae* the *Geodermatophilus* family (Modified from *Bergey's Manual*). The description is an emended version of the one given in the *Bergey's Manual*, 2nd edition (Normand and Benson 2012a).

The genus *Geodermatophilus* was grouped together with the genus *Frankia* into family *Frankiaceae* that was thus emended based on the similarity in 16S rRNA sequences as well as similarity in a morphological feature, multilocular sporangia (Hahn et al. 1989). This arrangement was maintained by subsequent works such as the second edition of *The Prokaryotes* (Akkermans et al. 1992). The family *Geodermatophilaceae* was created by default in 1996 (Normand et al. 1996) based on 16S rRNA gene analysis when the family *Frankiaceae* that initially contained *Geodermatophilus* was split to be left with only genus *Frankia*. That arrangement was maintained the following year (Stackebrandt et al. 1997) when the two families, each then containing a single genus, were pooled into a suborder, Frankinae, in the new organizational scheme proposed for the Actinobacteria. A formal description of family *Geodermatophilaceae* was finally published (Normand 2006) to contain three genera *Geodermatophilus* (Luedemann 1968) found in soils, *Blastococcus* (Ahrens and Moll 1970) found in sea sediments, and *Modestobacter* (Mevs et al. 2000) found in polar regolith, three genera that have strikingly different physiological features (*Table 20.1*).

After a long period with a modest rate of description of new species, the last two years have seen the description of several new species, most of them based on a single isolate. As this chapter goes to press, this rush of new species (three in genus *Geodermatophilus* all in the year 2012, two in genus *Modestobacter*, one in 2011 and the other in 2012) has made the task of the authors more difficult as it was impossible to get all data in time.

Genus *Geodermatophilus*

Geo.der.ma.to.phi.lus. Gr. n. *ge* earth; Gr. n. *derma*, *atos* skin; Gr. adj. *philos* loving; N.L. masc. n. *Geodermatophilus*, a group of microorganisms that live in the soil, yet that supposedly love the skin, by analogy to the genus *Dermatophilus* (*Micrococcineae*; *Dermatophilaceae*), another actinobacterial genus that causes a skin disease and has similar morphological features.

The genus *Geodermatophilus* was the first member of the family to be described by Luedemann (1968) from microbiological work on soils from the Amargosa Desert of Nevada, USA. Colonies of a black-pigmented, friable organism appeared repeatedly from cultures of such soil samples from various deserts. The name given was based on the fact the organism was from soils (Geo from the greek γή), had a morphological feature reminiscent of another actinobacterium, *Dermatophilus*, namely, multilocular sporangia and the fact its pigmentation was intense and black (*obscurus*). There were no true hyphae, only a few small fragmented filaments, cuboid cells, and motile zoospores. Division was found to occur by a budding process. The germinating spores become septate. They also produce either a short tube or longer, flexible hyphae with transverse septations.

Since *Dermatophilus* is a known animal pathogen, causing skin infections, *Geodermatophilus* was also tested on animals (Gordon and Perrin 1971). Infection studies in rabbits and guinea pigs did not permit to establish the pathogenicity of the different isolates available at the time and it is now considered nonpathogenic.

The morphology of *Geodermatophilus* is similar to that of *Dermatophilus*. It is now considered these morphological similarities constitute a case of convergent evolution of a few striking features rather than phylogenetic similarity as the genetic distance in the 16S rRNA genes between *Geodermatophilus* and *Dermatophilus* is very large, between 10 % and 12 % (unpublished). Several types of cell are found (*Fig. 20.1*).

The morphology appears to consist of two forms called R-forms (motile bud-forming rods) and C-forms (coccoids) according to Ishiguro and Wolfe (1970). The cell wall of the R-form consists of two layers with an inner transparent membranous layer (10–12.5 nm thick) and an outer dense diffuse layer (7.5–10 nm). In addition to these, the C-form has a supplementary thick fibrous layer (30 nm) over the dense layer that would act as a mortar to hold coccoid cells together. An unidentified factor present in Difco Tryptose appears necessary to maintain the cells in the C-form as well as to trigger change from the R-form to the C-form. The C-form consists of sporangia and vegetative cells that would be resting forms able

to withstand adverse conditions while the R-form is motile and dividing and would be more active (*Fig. 20.2*).

DNA G+C content (mol%): 72.9–75.9.

Type species: *Geodermatophilus obscurus* Luedemann 1968, 1857[AL].

Recently, a second species *G. ruber* was described for a single isolate obtained from the rhizosphere soil of the medicinal plant *Astragalus membranaceus* (Zhang et al. 2011) growing in Qinghai Province, in northwest China. The name chosen to designate the species was related to the most prominent distinguishing feature, colony pigmentation that was red instead of black as in *G. obscurus*. However, since this new species was based on the study of a single isolate, it remains to be seen whether this feature is constant and indeed if all features are general. In particular, *G. obscurus* was found to have higher than usual resistance to gamma irradiation (Rainey et al. 2005; Ryjenkov et al. 2005; Xiang et al. 2005; Cash et al. 2006; Chanal et al. 2006; Chevrot et al. 2006; Nakabachi et al. 2006; Amato et al. 2007a, b; Bordenave et al. 2007; Cheng and Foght 2007; Liao et al. 2007; Markert et al. 2007; Meyer and Kuever 2007; Bagwell et al. 2008; Callegan et al. 2008; Fredrickson et al. 2008; Hoehenwarter et al. 2008; Kumar et al. 2008; Lapouge et al. 2008; Manickam et al. 2008; Hervas et al. 2009; Hervas and Casamayor 2009; Yuan et al. 2009; Login et al. 2011; Gtari et al. 2012) and it should be possible to determine if this resistance is a generic feature or if it is linked to the habitat.

More recently, a third species, *G. nigrescens*, has been proposed for a single soil isolate obtained from a dry-hot river valley

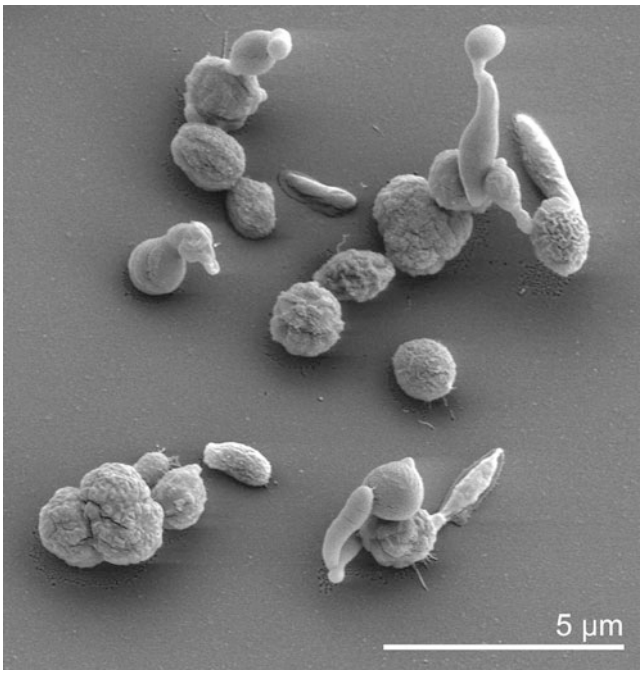

Fig. 20.1
Scanning electron micrograph of *Geodermatophilus obscurus* G-20T, courtesy of Prof. Manfred Rohde, Helmholtz Centre for Infection Research, Braunschweig, Germany (Ivanova et al. 2010)

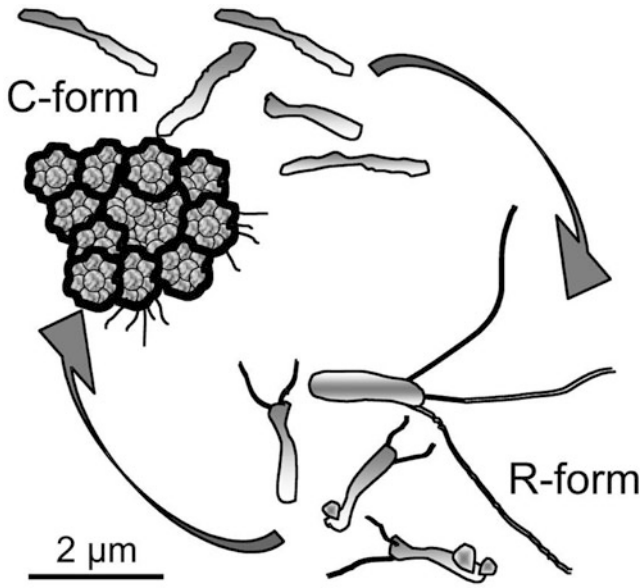

Fig. 20.2
Drawing of *Geodermatophilus obscurus* inspired from Ishiguro and Wolfe (1970) and others showing the two forms, C-forms or coccoid cells and R-forms or motile budding rods

in Dongchuan county, Yunnan province, in southwest China (Nie et al. 2012). Because once again a single isolate was studied, it is impossible to determine if the discriminating features listed are indeed common to the species as a whole. This species was proposed in the journal *Antonie van Leeuwenhoek* and later validated in the IJSEB (Official publication date 17 September 2012 Validation List N° 147 in IJSEM Online), the name is thus considered validly published.

Lastly, a fourth, a fifth, and a sixth species have been proposed by the same authors to describe isolates obtained from arid sands from the African country of Chad. Two of these species, called *G. arenarius* (Montero-Calasanz et al. 2012) and *G. siccatus* (Montero-Calasanz et al. 2013), are single-isolate species that can grow at high temperature, form pigmented colonies, and have very high G+C% with *G. arenarius* having seemingly the highest known G+C% with 75.9 %. A sixth species, *G. telluris*, DSM 45421, has been isolated from a desert soil sample and has just been accepted for publication in IJSEM (HP Klenk, pers. comm.).

Other species isolated from dry sandy soils are under study and should be published in the coming years (HP Klenk, pers. comm.).

DNA G+C content (mol%): 72.8–75.9.

Type species: *Geodermatophilus obscurus* Luedemann 1968, 1857AL (Table 20.2).

Species of the Genus *Geodermatophilus* Luedemann 1968, 1857[AL]

1. *Geodermatophilus obscurus* Luedemann 1968, 1857[AL]

ob.scur'us. L. masc. adj. *obscurus* dark, obscure, indistinct.

Black-pigmented colonies (Fig. 20.3). Gram-positive. Forming highly irregular tuber-shaped non-capsulated multilocular thalli. These structures contain highly irregular vibrioid or cuboid cells, 0.5–2.0 mm in diameter. Under favorable environmental conditions, the thalli will release individual nonmotile cells. A proportion of these cells will develop into elliptical zoospores propelled by a terminal tuft of long flagella. Mycelium is rudimentary. No aerial mycelium is produced. Cell walls contain meso-DAP as well as glutamic acid, alanine, glucosamine, and muramic acid. Aerobic. Chemoorganotrophic. Mesophilic. Thalli appear greenish-black and vary in size with the strain. Colonies after 30 day incubation at 28 °C are flat, black, (Fig. 20.3) granular, dry, with an earthy smell. Good growth on yeast extract-starch-sucrose-malt extract agar.

DNA/DNA hybridization was not minimum standard practice when the known isolates of *Geodermatophilus obscurus* were simply characterized morphologically and trophically into five subspecies: *obscurus*, *amargosae*, *utahensis*, *dictyosporus*, and *everesti* (Table 20.3).

Source: the type strain was isolated from soil of the Amargosa Desert, Nevada, USA.

DNA G+C content (mol%): 72.9–74.6 (Luedemann and Fonseca 1989).

[a]++ Strongly positive, + positive, +/− weak, − negative, *nd* not determined

Red-pigmented. Newly formed colonies are light red, becoming deeper red after growth for 4 days on complex medium agar. No diffusible pigments are produced on any medium tested. Gram-positive. Coccoid cells are motile with flagella. Mycelium is rudimentary. No aerial mycelium is produced. Cell walls contain meso-DAP. Chemoorganotrophic. Mesophilic. Colonies after 30 day incubation at 28 °C are flat, granular, and moist. Good growth on R2A agar.

Source: The type strain was isolated from a rhizosphere soil of the medicinal plant, the *Fabaceae Astragalus membranaceus* growing in the mountainous areas around Xining (37°35′N, 101°49′E; elevation 2,800 m), Qinghai Province, northwest China (Zhang et al. 2011).

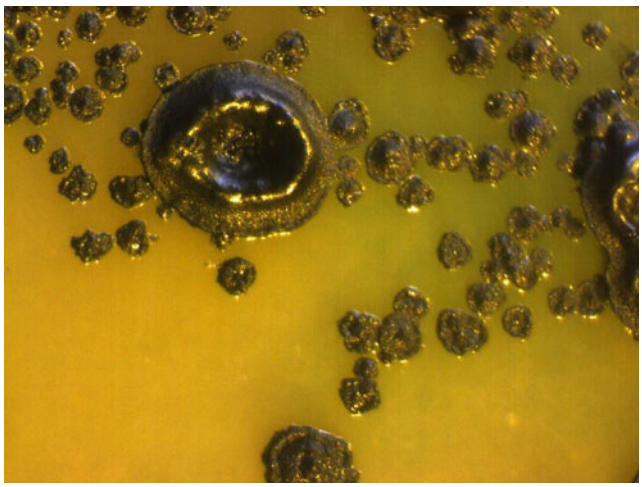

Fig. 20.3
Colonies of *G. obscurus* strain G20 growing on a complex medium with a black-pigmented shine and a concave center (Photo courtesy of Jerome Gury (Université de Pau))

DNA G+C content (mol%): 72.8 (HPLC; (Mesbah et al. 1989)).

Type strain: CPCC 201356^T.

Sequence accession no. (16S rRNA gene): EU438905.

3. *Geodermatophilus nigrescens* Nie et al. 2012, 811.

(ni.gres'cens. L. v. *nigresco* to become black; L. part. adj. *nigrescens* becoming black).

Newly formed colonies are light red, becoming black after growth on complex medium agar such as nutrient agar, Czapek, potato-glucose, yeast extract-malt ISP2 or ISP3. No diffusible pigments are produced on any medium tested. Gram-positive. Mycelium is rudimentary. No aerial mycelium is produced. Cell walls contain meso-DAP. Chemoorganotrophic. Mesophilic. Colonies after 30 day incubation at 37 °C are flat, granular, and moist. Good growth on yeast extract-malt extract (ISP2) and oatmeal (ISP3).

Source: the type strain was isolated from a soil sample collected from a dry-hot river valley in Dongchuan county, Yunnan province, southwest China (Nie et al. 2012).

DNA G+C content (mol%): 73.1 (fluorometric micro-well method, (Ezaki et al. 1989)).

Type strain: YIM 75980^T.

Sequence accession no. (16S rRNA gene): JN656711.

4. *Geodermatophilus arenarius* Montero-Calasanz et al. 2013 (Montero-Calasanz et al. 2012)

(a.re.na'rius. L. masc. adj. *arenarius* related to *arena*, sand, from which the organism has been isolated).

Light red- to brown-pigmented. Newly formed colonies are light red, turning deeper red and brown, convex with a moist surface, and an entire margin. No diffusible pigments are produced on any medium tested. Gram-positive. Coccoid cells are motile with periplasmic flagella. Mycelium is rudimentary. No aerial mycelium is produced. Cell walls contain meso-DAP.

Chemoorganotrophic. Mesophilic. Colonies after 30 day incubation at 28 °C are flat, granular.

Source: the type strain was isolated in 2007 from a Saharan desert soil collected near Ouré Cassoni in the Republic of Chad (Montero-Calasanz et al. 2012).

DNA G+C content (mol%): 75.9 (HPLC; (Mesbah et al. 1989)).

Type strain: CF5/4^T (=DSM45418^T).

Sequence accession no. (16S rRNA gene): HE654547.

5. *Geodermatophilus siccatus* Montero-Calasanz et al. 2012 (Montero-Calasanz et al. 2013)

(si.cca'tus. L. part. masc. adj. *siccatus* dried referring to the survival under xerophilic conditions).

Young colonies are light red becoming black-pigmented. Convex and circular colonies. No diffusible pigments are produced on any medium tested. Gram-positive. Catalase-positive and oxidase-negative. Circular to elliptical cells are motile with flagella. Septate mycelium from germinating zoospores is rudimentary. No aerial mycelium is produced. Cell walls contain meso-DAP. Chemoorganotrophic. Mesophilic with no growth observed below 15 °C.

Source: The type strain was isolated in 2007 from a Saharan desert soil collected near Ourba in the Republic of Chad (Montero-Calasanz et al. 2013).

DNA G+C content (mol%): 74.9.

Type strain: CF6/1^T (=DSM45419^T).

Sequence accession no. (16S rRNA gene): HE654548.

Genus *Blastococcus* Ahrens and Moll 1970, 264^{AL} emend. Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 257 emend. Lee 2006, 2394

Blas.to.coc'cus. Gr. n. *blastos* bud, shoot; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Blastococcus* budding coccus.

Gram-stain-positive, coccoid cells that occur singly or in pairs, often reproducing by budding and multiple fission, giving rise to several cell forms. Single cells may be motile rods and vibroid or nonmotile cocci that have a tendency to form aggregates. Strains may form motile zoospores. Formation of buds on rods is common, and gave the genus its name but are not universal. Membranous bodies, 1–4 per cell, that are linked to the cytoplasmic membrane, may be present. Oxidase-negative, catalase-positive, and aerobic; some strains may be microaerophilic. Strains from surfaces of marble and limestone utilize a broader spectrum of organic compounds than the only known strain from a marine sediment. Predominant fatty acids are C16:0 iso, and, in some strains, C16:1 iso,C18:1ω9c,C17:1 ω8c, C15:0 iso, and C17:0. Peptidoglycan contains meso-DAP as diagnostic diamino acid. Predominant menaquinone is MK-9(H4); MK-9 may also occur in high amounts. Polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine; phosphatidylcholine, phosphatidylethanolamine, and two unknown phospholipids may occur. Arabinose and galactose have been identified as whole-cell sugars in one species.

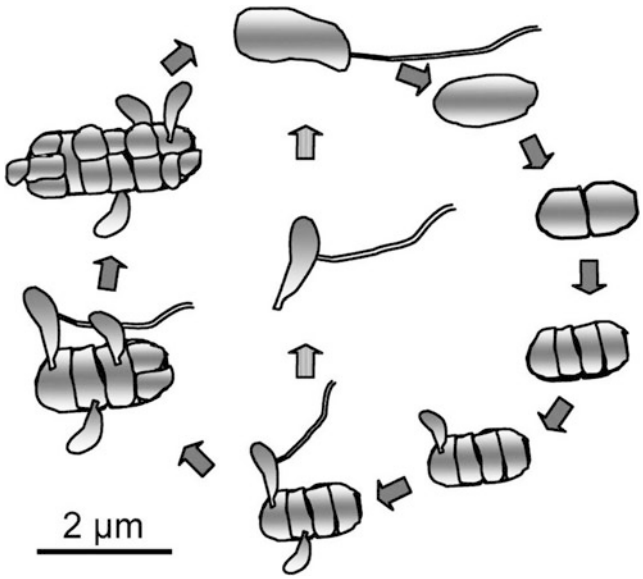

Fig. 20.4
Schematics of the life cycle of *Blastococcus aggregatus* starting at the top with a motile rod with one or two motile flagella. Motile cells lose their flagella (*clockwise*) and start dividing in several planes. At the same time, budding starts and some of the budding cells become motile and detach from the mother cell (*vertical arrows*) (Drawing from Ahrens and Moll (1970), Urzi et al. (2004))

Phylogenetically, a member of the family *Geodermatophilaceae*, genus *Blastococcus* was described as a single isolate and single species genus, containing *Blastococcus aggregatus*, an isolate obtained from sediments at the bottom of the Baltic Sea (Ahrens and Moll 1970). The colonies obtained were pigmented, divided by budding (gr. *blastos*), and formed coccoid cells (from Gr. masc. n. kokkos, grain, seed), that remained aggregated. The life cycle of this unusual bacterium has been studied by Ishiguro and Wolfe (1970) and found to consist of two types of cells, motile individual rods, and nonmotile aggregated cells (*Fig. 20.4*).

DNA G+C content (mol%): 72.3–74.

Type species: *Blastococcus aggregatus* Ahrens and Moll 1970, 264AL emend. Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 257.

Species of the Genus *Blastococcus*

1. *Blastococcus aggregatus* Ahrens and Moll 1970, 264^{AL} emend. Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 257 ag.gre.ga'tus. L. masc. part. adj. *aggregatus* added to, joined together, referring to the tendency to form coccoid aggregates.

Gram-positive, highly irregular vibroid or rod-shaped cells occurring singly or in three-dimensional coccoid aggregates. The manifestation of these stages is influenced by environmental conditions; low salt concentrations, temperatures of 5–10 °C, and microaerophilic conditions favor the motile rod stage.

Acetic acid	+	–	+
α-Ketoglutaric acid	+	–	–

[a]Data from Urzi et al. (2004) and Lee (2006)

Single cells are either motile vibroids (0.3–1.5 × 0.4–3.0 μm) or rods or ellipsoid (1.2–1.5 × 1.5–3.0 μm). Rods are often separated by disk-like septa. These motile or nonmotile rods carry 1–6 vibrioform buds, attached by a tapered pole onto the mother cell. Increased temperature and salt concentrations induce the formation of nonmotile coccoid aggregates (1.2–2.5 μm in diameter), appearing as linear, band-like, or column-like three-dimensional forms. Larger aggregates (1 mm in diameter) are separated by rectangular and/or radial partitions. Cell types of different sizes occur mostly side by side. After 5 days on peptone-yeast extract agar at 20 °C, colonies are pink, turbid, round, and convex with shiny surfaces. In liquid media, thin turbidity and formation of pink sediment are observed. Catalase-positive, oxidase-negative. No growth is observed in mineral medium; weak growth is seen in the presence of ethanol, but not with glucose, acetate, citrate, methanol, ethylamine, or paraffin. Good growth is observed in mineral medium plus peptone (0.5 %) and yeast extract (0.1 %); in these media, addition of glucose, acetate, citrate, ethylamine, or paraffin (at 1 %) reduces growth. Growth is enhanced in peptone-yeast extract medium by the addition of 1 % NaCl. Increasing the salt concentration leads to increased formation of aggregates. No acid or gas is produced from glucose, galactose, fructose, xylose, sucrose, maltose, lactose, or glycerin. Methyl red and Voges–Proskauer reactions are negative. Does not hydrolyze starch, chitin, alginate, or cellulose. Reactions toward substrates provided by the API ZYM, API 20 NE, and Biolog GP2 panels are indicated in ❯ *Table 20.4*. Peptidoglycan diamino acid, menaquinone, and polar lipids are as described for the genus. Two unknown phospholipids may occur. Major fatty acids are 14-methylpentadecanoic acid (C16:0 iso) and 14-methylpentadecenoic acid (C16:1 iso); smaller amounts of C18:0, C16:1 ω7c, C18:1 ω9c, C16:0, and C14:0 iso occur. Extinction maxima of carotenoids are at 470 and 500 nm.

Source: isolated from sediment of Station Breitengrund at a depth of 20 m in the Western Baltic Sea.

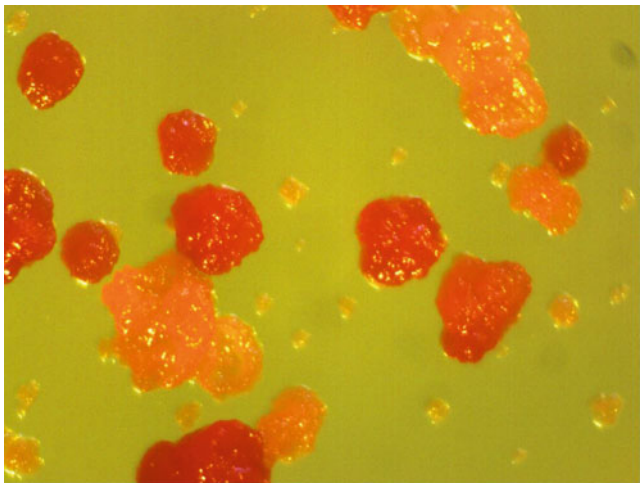

Fig. 20.5
Colonies of *Blastococcus saxobsidens* strain DD2 growing on a complex medium. Color ranges from *orange* to *red* (Photo courtesy of Jerome Gury (Universite de Pau). Source: the isolation site of the type strain was limestone sampled in Malta. Other strains were isolated from calcarenite and marble from Italy and Greece)

DNA G+C content (mol%): 73.9 (HPLC).

Type strain: DSM 4725, ATCC 25902. Sequence accession no. (16S rRNA gene): AJ430193.

A second species, *Blastococcus saxobsidens*, was created in 2004 (Urzi et al. 2004) to accommodate isolates obtained from stones around the Mediterranean.

Blastococcus saxobsidens Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 258[VP].

sax.ob'si.dens. L. neut. n. *saxum* rock; L. part. adj. *obsidens* staying, remaining, occupying; N.L. masc. part. adj. *saxobsidens* rock-occupying.

Colonies are pink-orange pigmented, irregular, and convex with a smooth to rough surface (2–3 mm in diameter) (*Fig. 20.5*). Aerobic, Gram-stain-positive. Motile and nonmotile cells (1.0–1.7 μm in diameter) are coccoid, occurring in tetrads with a tendency to remain aggregated. Sparse growth on Luedemann medium, malt agar, and yeast extract-casein hydrolyzates starch-glucose agar. No growth on potato-dextrose agar or yeast extract-glucose-glycerol agar. Grows between 20 °C and 37 °C and at pH 5–8.6; optimum growth is at 32 °C and pH 6.8. No growth in 3 % NaCl, except strain BC448, which can grow at 5 % NaCl. Catalase- and oxidase-positive. Nitrate is not reduced to nitrite. Carbon sources utilized for growth are: D-glucose, D-fructose, L-arabinose, ribose, myo-inositol, and lactose. No acid production is observed from D-fructose, myo-inositol, or lactose. Casein, gelatin, and starch are not hydrolyzed. DNA, tyrosine, xanthine, and hypoxanthine are not decomposed. Tweens 20, 40, 60, and 80 are not hydrolyzed. The peptidoglycan diamino acid, major menaquinone, and polar lipids are as described for the genus. Major fatty acids are 14-methyl-pentadecanoic acid (C16:0 iso), *cis*-9-heptadecanoic acid (C17:1 ω8c), and 13-methyl-tetradecanoic acid (C15:0 iso), with smaller amounts of C16:0, C17:0 ante, C16:1 iso, C18:1 ω9c, and C16:1 ω7c.

DNA G+C content (mol%): 72.95 (genome sequence (Chouaia et al. 2012)).

Type strain: BC444, DSM 44509, NRRL B-24246.

Sequence accession no. (16S rRNA gene): AJ296061.

A third species, *Blastococcus jejuensis*, was created in 2006 (Lee 2006) to accommodate a single isolate from a beach sediment in Korea.

Blastococcus jejuensis Lee 2006, 2395[VP]

je.ju.en'sis. N.L. masc. adj. *jejuensis* of or belonging to Jeju Island, Republic of Korea, the site from which the type strain was isolated.

Aerobic, motile, non-spore-forming, oxidase-negative, catalase-positive, Gram-positive. Cells are cocci that occur in pairs or rods. Bud formation is observed for rod-shaped cells. Colonies are circular, smooth, transparent, and apricot in color. Starch and casein are hydrolyzed, but not elastin. Hypoxanthine, tyrosine, and xanthine are not decomposed. In API 20NE tests, glucose fermentation and indole production from tryptophan are not observed. Activities of arginine dihydrolase, urease, and β-galactosidase are not present. Nitrate is not reduced to nitrite. Esculin degradation and gelatin hydrolysis are not detected. Caprate, adipate, citrate, and phenylacetate are not assimilated. In API ZYM tests, results for leucine arylamidase and α-glucosidase are positive and weakly positive, respectively, whereas results for esterase lipase (C8), lipase (C14), trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are negative. The temperature range for growth is 10–37 °C, with optimum growth at 30 °C. Growth occurs at pH 6.1–10.1, with optimum growth at pH 7.1. Growth is observed in the presence of 0–1 % NaCl, but not in 2 % NaCl. The following substrates are used as sole carbon and energy sources: mannan, *N*-acetyl-β-D-mannosamine, amygdalin, cellobiose, D-fructose, D-galactose, D-galacturonic acid, gentiobiose, myo-inositol, melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl-D-glucoside, palatinose, L-rhamnose, sedoheptulosan, D-sorbitol, sucrose, D-tagatose, turanose, xylitol, acetic acid, γ-hydroxybutyric acid, α-ketovaleric acid, D-lactic acid methyl ester, succinic acid, L-asparagine, putrescine, 2,3-butanediol, adenosine, and D-glucose 6-phosphate. Tween 40, D-ribose, a-ketoglutaric acid, and methyl succinate are not utilized. The polar lipid profile contains phosphatidylcholine, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylmethylethanolamine, and phosphatidylinositol. Mycolic acids are not present. The major cellular fatty acids are C16:0 iso, C17:1ω8c, and C15:0 iso. The predominant menaquinone is MK-9(H4). Whole-cell hydrolyzates contain meso-DAP as the diagnostic diamino acid and arabinose and galactose as diagnostic sugars.

Source: isolated from sand sediment from Gwakji beach on Jeju Island, Republic of Korea.

DNA G+C content (mol%): 72.3 (method not reported).

Type strain: KST3-10, NRRL B-24440, KCCM 42251. Sequence accession no. (16S rRNA gene): DQ200983.

Stone surfaces are likely to host *Blastococcus* lineages that remain to be described as it was recently found by studying Madrid and Mallorca stone walls comprising sandstone, granite, and slate material (Salazar et al. 2006).

Genus *Modestobacter* Mevs, Stackebrandt, Schumann, Gallikowski and Hirsch 2000, 344^{VP} emend. Reddy, Potrafka and Garcia-Pichel 2007, 2018

Mo.des.to.bac′ter. L. adj. *modestus* modest, humble; N.L. masc. n. *bacter* a rod or staff; N.L. masc. n. *Modestobacter* a rod with modest growth requirements.

Gram-positive, non-spore-forming. Short rods or cocci with a tendency to remain aggregated and form short, multiseptate filaments. These produce slender buds. Aerobic heterotrophs able to grow in oligotrophic medium. Typically psychrotolerant. Major fatty acids include C18:1, C16:0 iso, and C17:0 anteiso. The major respiratory quinone is MK-9(H4). The cell wall peptidoglycan contains meso-DAP as diamino acid, with alanine, glutamate, and meso-DAP present in a 2:1:1 stoichiometric ratio. DNA G+C content (mol%): around 70. Type species: *Modestobacter multiseptatus* Mevs et al. 2000, 344VP. Further descriptive information: The genus was created in 2000 to accommodate strains isolated from Antarctic "soil" or regolith. The morphology of the strains was found to be sufficiently special to warrant the creation not only of a novel species, but also of a new genus that was later positioned in the *Geodermatophilaceae* on the basis of its 16S rRNA gene sequence (Mevs et al. 2000). The word "soil" is debatable because the fine granular material found in the McMurdo dry valley being almost completely devoid of organic matter can better be called regolithic. The recent description of three other species, *M. versicolor* (Reddy et al. 2007), *M. marinus* (Xiao et al. 2011) and *M. roseus* Qin et al. (2013), has permitted a more elaborate description. The four species are found in markedly different biotopes and thus have a number of distinguishing features.

Modestobacter multiseptatus Mevs et al. 2000, 344^{VP} emend. Reddy et al. 2007, 2018 mul.ti.sep.ta'tus. L. adj. *multus* much; L. adj. *septatus* fenced; N.L. masc. adj. *multiseptatus* much fenced, with many septa.

Colonies are irregularly shaped, shiny, and beige to pinkish. Cells are Gram-positive, short rods, or cocci with a tendency to remain aggregated. Cells show cross and longitudinal wall growth and multiply by budding and swarmer formation. Cell sizes vary (1.0–2.8 × 1.0–3.0 μm), with a mean size of 1.7 × 1.6–1.9 μm. Slender buds may become motile. Aerobic heterotroph; can grow on oligotrophic medium PYGV (Staley 1968) or on DSMZ medium 65. Growth occurs between 0 °C and 28 °C. Can tolerate pH 3–12, with optimum growth at pH 7.5–8.5. Positive for catalase, cytochrome oxidase, phosphatase, and amylase. Shows type II restriction endonuclease activity. H_2S is not formed from cystine or sulfate. Does not utilize fructose, xylose, or trehalose, but can utilize D-glucose, D-galactose, lactose, sucrose, mannitol, succinate, and malate. Utilization of maltose, mannose, melibiose, fucose, ribose, rhamnose, sorbitol, and *N*-acetylglucosamine is variable. Adenine, hypoxanthine, xanthine, hippurate, cellulose, chitin, dextrin, xylan, arbutin, and casein are not hydrolyzed. Utilizes peptone or yeast extract as nitrogen source and reduces nitrate aerobically or anaerobically. The main respiratory quinone is MK-9(H4); MK-8(H4) and MK-9(H6) are present in small amounts. Main fatty acids are C18:1 and C16:0 iso. meso-DAP is present. Cell wall sugars are composed of galactose, glucose, and ribose.

Source: isolated from Antarctic surface "soil" from Linnaeus Terrace (1,600 m) of the Asgard Range in the Transantarctic Mountains. DNA G+C content (mol%): 68–70 (melting spectrometry; Mandel and Marmur 1968).

Type strain: AA-826, DSM 44406, CIP 106529, JCM 12207.

Sequence accession no. (16S rRNA gene): Y18646.

Species of the Genus *Modestobacter*

Modestobacter versicolor Reddy et al. 2007, 57^{VP} ver.si.co'lor. L. masc. adj. *versicolor* that changes its color, of changeable color, of various colors, particoloured.

Colonies are dark brown on oligotrophic medium and pink to white on copiotrophic medium, 1–4 mm in diameter, convex, entire, smooth to rugose, and slightly mucoid. Cells are short, small rods (straight, lightly curved, irregular, or even tapering), often developing into multiseptate cells, occurring singly or in pairs, sometimes remaining aggregated and only rarely forming filaments longer than several cells. Single rods are 0.5–1.0 × 1.0–3.0 μm. Short filaments are up to 7.0-mm long. Septation is transversal (orthogonal to the long cellular axis), and apical cells may resemble buds. Motility is variable, by means of polar flagellation. Growth is observed at 4–30 °C (but not at 37 °C) and pH 5–9, with optimum growth at 25 °C and pH 7. Produces copious amounts of melanin under oligotrophic conditions. Tolerates NaCl at concentrations less than 3 %. Cells are positive for catalase, β-galactosidase, phosphatase, urease, and lipase, but negative for oxidase, gelatinase, arginine decarboxylase, lysine decarboxylase, ornithine decarboxylase, and phenylalanine deaminase. Negative for methyl red, Voges–Proskauer and indole tests. Hydrolyzes casein and aesculin, but not cellulose or starch. Reduces nitrate to nitrite. Does not produce H_2S gas and cannot grow on DNA or Simmons' citrate test plates. Utilizes a wide variety of sugars, low-molecular-mass organic acids and amino acids, and all four nitrogenous bases. Respiratory quinones and cell-wall peptidoglycan, fatty acid, and polar lipid compositions are given in *Table 20.5*.

In the original description, the species had been proposed as dinitrogen fixer, but no experimental details have been provided and the claim should thus be seen as unconfirmed.

Source: The type strain is CP153-2T (5ATCC BAA-1040T 5DSM 16678T), it was isolated from a biological soil crust on the Colorado Plateau, USA (Reddy et al. 2007).

Modestobacter marinus Xiao et al. 2011, 1710^{VP} ma.ri'nus. L. masc. adj. *marinus* concerning the sea, the ocean, where the type strain was found.

Colonies are orange to red on copiotrophic medium at the initial stage of growth, turning black after 14 days. Colonies are dark throughout growth on oligotrophic medium. Cells are non-spore-forming, Gram-positive, short rods (straight, lightly curved, about 0.5–0.8 × 1.5–2.5 mm), motile by means of flagella. Psychrotolerant, growing at 4–35 °C (but not at 37 °C), with optimal growth at 28 °C. Tolerant of only narrow variations in pH, with fast growth occurring at pH 6–8 and very slow growth at pH 9. Tolerates NaCl at concentrations less than 5 % (w/v). Hydrolyzes casein, cellulose, and starch. Does not produce H_2S and cannot grow on DNase test plates. In API 20NE tests, positive for aesculin hydrolysis, *p*-nitrophenyl β-D-galactopyranosidase, and assimilation of L-arabinose, D-mannitol, potassium gluconate, malic acid, and phenylacetate. Negative for indole production, acid from glucose, arginine dihydrolase, urease and gelatinase. Nitrate reduction is weakly positive. Tested by the API ZYM enzyme assay, positive for alkaline phosphatase, esterase lipase (C8), leucine arylamidase, valine arylamidase, acid phosphatase, naphthol-AS-Biphosphohydrolase, α-glucosidase, and β-glucosidase; weakly positive for cystine arylamidase, trypsin, α-chymotrypsin, and β-galactosidase; negative for esterase (C4), lipase (C14), α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. In the API 50 CH test system, acids are produced from glycerol, L-arabinose, D-ribose, D-galactose, D-fructose, D-mannose, D-mannitol, aesculin, maltose, sucrose, trehalose, turanose, and L-fucose. Weakly positive for acid production from L-rhamnose, salicin, cellobiose, lactose, and D-xylose. All other API 50 CH test results are negative. The cell-wall peptidoglycan contains meso-diaminopimelic acid as the diamino acid. Major fatty acids are iso-$C_{16:0}$ and $C_{17:1v8c}$; the major respiratory quinone is MK-9(H_4). The diagnostic phospholipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, phosphatidylglycerol, and an unknown aminophospholipid (Xiao et al. 2011).

Source: The type strain, 42H12-1^T (=DSM45201^T = CGMCC 4.5581^T), was isolated from deep-sea sediment collected from the Mid-Atlantic Ocean at coordinates 14.75°N 44.97°W close to the Mid-ocean ridge (Xiao et al. 2011).

DNA G+C content (mol%): 72.3 ± 1 (HPLC; (Mesbah et al. 1989)).

Sequence accession no. (16S rRNA gene): EU181225.

Modestobacter roseus Qin et al. (2013))^{VP} ro'se.us. L. masc. adj. roseus rose-colored, pink.

As this chapter goes to press (Nov 2012), the paper describing *M. roseus* has just been accepted for publication. Colonies are rose-colored on oligotrophic and copiotrophic medium. Cells are Gram-positive, aerobic, non-spore-forming, short rods (straight, lightly curved), or cocci with a tendency to remain aggregated, motile by means of flagella. Growth is observed at 10–37 °C and pH 6–11, with an optimum at 28 °C and pH 7–8. The NaCl range for growth is 0–10 % (w/v). In API 20NE tests, positive for aesculin hydrolysis, paranitrophenyl-β-D-galactopyranosidase, assimilation of arabinose, glucose, mannitol, mannose, *N*-acetyl-D-glucosamine, maltose, malate, and gluconate. Uses L-valine and L-lysine as sole nitrogen sources. In the API 50 CH test system, acids are produced from L-arabinose, arbutin, esculin, D-fructose, glycogen, lactose, maltose, D-mannitol, D-mannose, and D-ribose. The cell wall peptidoglycan contains meso-diaminopimelic acid as the diamino acid. Major fatty acids are iso-C_{16}: 0, iso-$C_{15:\ 0}$, and $C_{17:1\omega8c}$; major respiratory quinone is MK-9(H_4). The diagnostic phospholipids are DPG, PE, PI, PIM, two unknown aminophospholipids and an unknown phospholipid.

Source: The type strain is KLBMP 1279T (=KCTC 19887T = NBRC 108673T), it was isolated from surface-sterilized roots of a coastal halophyte *Salicornia europaea* Linn. collected from the city of Nantong, Jiangsu Province, east of China. A single isolate has been studied.

DNA G+C content (mol%): 71.7 (HPLC; (Mesbah et al. 1989)).

Sequence accession no. (16S rRNA gene): JQ819258.

Phylogenetic Structure of the Family and Its Genera

The family is quite coherent, distinct from the other families in order Frankiales with a long branch length. However the three genera *Geodermatophilus, Blastococcus*, and *Modestobacter* are close to one another with short branch lengths between genera and long branch lengths within genera (Fig. 20.6).

16S rRNA sequence analyses have positioned genus *Geodermatophilus* at the root of the tree (Normand and Benson 2012b) with *Modestobacter* and *Blastococcus* in derived positions. A different topology had been obtained by Stackebrandt and Schumann (2012) with *Modestobacter* at the root of the clade. Previously, Normand and coworkers (1996), using the same marker but different outgroups, placed *Blastococcus* at the root. This last topology was obtained using a large number of conserved proteins (in preparation). This topology would be coherent with *Blastococcus* being the ancestor of the clade as its physiology is closer to that of other actinobacteria, regarding in particular resistance to reactive oxygen species. *Blastococcus* would thus have colonized stones interior as well as marine and beach sediments. Nevertheless, the uncertainties concerning the topology and the bushiness of the tree point to a rapid differentiation of the three genera. The present treatment based on the single 16S RNA gene positions *Modestobacter* at the root but this topology may not be the definite one.

A similar inconsistency was found to occur in the *Frankia-Geodermatophilaceae* forming or not a clade together with *Acidothermus, Sporichthya*, and *Cryptosporangium*. This phylogenetic proximity between *Frankia, Geodermatophilus obscurus* and a strain of "*Blastococcus*" was initially detected through reverse transcriptase sequencing and oligonucleotide cataloging

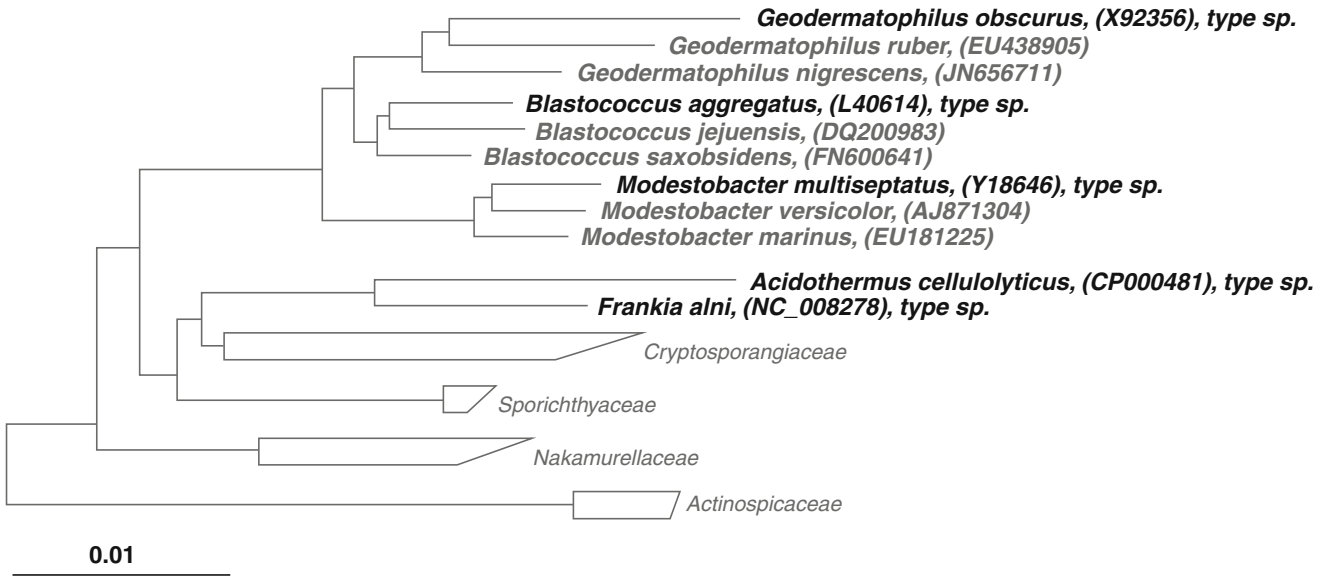

Fig. 20.6

Phylogenetic reconstruction of the family *Geodermatophilaceae* based on 16S rRNA and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence datasets and alignments were used according to the All-Species Living Tree Project (*LTP*) database (Yarza et al. 2010) (http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

of their 16S ribosomal RNA (Hahn et al. 1989). This clade was completed and confirmed with *Modestobacter* by sequencing the full 16S rRNA gene (Normand et al. 1996). However, Wu et al. (2009) studying a concatenate of 31 "universal" proteins could not recover *Frankia* and *Geodermatophilus* together in a robust clade.

These differences illustrate the difficulty of using a single marker to reconstruct the phylogeny of the genome as a whole, presumably because of numerous lateral transfers including those of the ribosomal genes that occur when microbes share a common niche following migrations. Presumably such transfers are more probable when the number of gene copies is low, as occurs in slow-growing microbes. It appears inevitable that with the mounting number of genomes and with appropriate software, the detailed evolutionary of gene transfers, gene duplications, and gene loss will be possible to recreate.

Molecular Analysis

Three genomes have been recently undertaken, one for each of the three recognized genera. The first one, that of *Geodermatophilus obscurus*, was published in 2010 (Ivanova et al. 2010) and was used to reassess by multi-genes analysis the phylogeny of bacteria (Wu et al. 2009). The second one was that of *Blastococcus saxobsidens* (Chouaia et al. 2012) and the third one was that of *Modestobacter marinus* (Normand et al. 2012), both of which were recently published allowing to define a core genome (*Fig. 20.7*, *Table 20.6*).

Phages

No phage has been described for the three genera; however, no specific work has been done for that purpose. A search in the three genomes for "phage" as keyword revealed several occurrences; however, these genes are not conserved and there is no extensive syntenic region and are thus likely to represent events that have occurred since the emergence of the three genera (*Table 20.7*).

Phenotypic Analysis

Isolation and Maintenance Procedures

Several media have been used for the isolation of the *Geodermatophilaceae*. In general, the media are based on rich organic ingredients like yeast extract, peptone, and malt extract. Among sugars, glucose is the most used. The isolation can be a relatively long process with a rather long time for the appearance of the first colonies that may be visualized on plates after 2–4 weeks. In certain cases, especially for testing at low temperatures, incubations last up to several months. In several

instances, rich but diluted media were used to simulate the oligotrophic conditions occurring in the starting source of the inocula like barren soils or stones. In other cases, standard microbiological media like TSA or R2A have been used for isolation. In several studies, considering the slow growth rate of the *Geodermatophilaceae*, antifungal compounds have been used in the medium to inhibit fungal growth and favor the *Geodermatophilaceae*.

Maintenance of the cultures can be done by storing for some weeks on slants at 4 °C, while for longer periods the cultures are

generally conserved in 20 % (w/v) glycerol suspensions at −20 °C and −80 °C in a suitable medium.

The isolation procedure to obtain the original strains is described in more detail below.

Geodermatophilus obscurus (Luedemann 1968). The isolation procedures are not described in the original study that isolated the first *Geodermaptophilaceae* species (Luedemann 1968), but *G. obscurus* was maintained on the so-called Luedemann medium consisting of 0.5 % Yeast Extract (Difco), 0.5 % NZ Amine type A, 1 % glucose, 2 % Soluble Starch (Difco), 0.1 % CaCO3, and 1.5 % agar.

Geodermatophilus arenarius (Montero-Calasanz et al. 2012) and *G. siccatus* (Montero-Calasanz et al. 2013). The isolation procedure comprised resuspension of desert sand in physiological saline, shaking for 1 h at 26 °C, keeping overnight at 4 °C, and finally shaking for 2 h before streaking the supernatant on R2A and TSA medium. Plates were incubated at 25 °C for 3–10 days. Maintenance of the isolates was originally performed by using freezing in MicrobankTM Blue Colour Beads (Pro-Lab Diagnostics, Richmond, Canada).

Geodermatophilus nigrescens (Nie et al. 2012). Two grams of air-dried soil were shaken in a flask with 18-mL sterile water and glass beads at 30 °C for 1 h. The suspension was serially diluted 100 times and 200 µL were spread on yeast extract-malt extract agar ISP2 medium (Shirling and Gottlieb 1966) supplemented with nalidixic acid (25 mg L^{-1}) and nystatin.

Geodermatophilus ruber (Zhang et al. 2011). *G. ruber* has been isolated on an R2A medium following the dilution plating method and incubating at 28 °C for 3 weeks. The isolate was maintained on R2A slant agar at 4 °C and as suspensions of cells in 20 % (v/v) glycerol.

Modestobacter marinus (Xiao et al. 2011). The isolation conditions for *M. marinus* were not reported in the original description. However, the strain was routinely cultured in liquid or solid ISP2 medium (Shirling and Gottlieb 1966) for 3–5 days at 28 °C. The strain was cultured in solid ISP2 or TSA media within 7 days.

Modestobacter multiseptatus (Mevs et al. 2000). Solid PYGV medium (pH 6.5; Staley 1968) was inoculated directly with soil particles (0.9 g) and incubated for 1–5 months at 4 or 9 °C. Pure cultures were kept on PYGV agar slants or lyophilized or frozen at −71 °C. Good growth was also observed on DSMZ medium 65.

Modestobacter versicolor (Reddy et al. 2007). The biological soil crust sample for the original isolation of *M. versicolor* was suspended in Ringer's solution and plated on oligotrophic BG11-PGY plates (10 % strength BG11 mineral medium, 0.025 % peptone, 0.025 % yeast extract, 0.025 % glucose, 1.5 % agar). BG11 mineral medium is made of $NaNO_3$ 1.5 g L^{-1}, $K_2HPO_4 \cdot 3H_2O$ 40 mg L^{-1}, $MgSO_4 \cdot 7H_2O$ 75 mg L^{-1}, $CaCl_2 \cdot 2H_2O$ 36 mg L^{-1}, citric acid 6 mg L^{-1}, ferric ammonium citrate 6 mg L^{-1}, EDTA 1 mg L^{-1}, Na_2CO_3 20 mg L^{-1}, and 1 mL L^{-1} of trace element solution.

Blastococcus aggregatus (Ahrens and Moll 1970). Peptone-yeast medium (peptone 5 g L^{-1}, yeast extract 1 g L^{-1}, $FePO_4$ 0.1 g L^{-1} in tap water, adjusted to pH 7.2) added with 0.8 % NaCl was used for the isolation. Colonies appear small (1 mm diameter after 21 days) with a pink color. The colony surface looks like an orange peel under a microscope at low magnification (Normand and Benson 2012a).

Blastococcus saxobsidens (Urzi et al. 2004). Isolation was performed by growing the cells at 28 °C after dilution plating on Bunt and Rovira medium (1955) that was modified by adding 0.5 % glucose, 0.5 % NaCl, and 0.03 % Na_2CO_3 and by setting pH at 8.6. The stone samples used for isolation were ground to a powder in a sterile mortar and suspended (ratio 1:10, w/v) in physiological saline (0.85 % NaCl). For favoring the cell detachment from the stone material, 0.001 % (w/v) Tween 80 was supplemented to the solution and the stone powder suspension was vortexed for 60 min. The isolated strain was maintained on Luedemann medium (Luedemann 1968).

Blastococcus jejuensis (from Lee 2006). *B. jejuensis* was isolated from a 1-m deep beach sediment. Samples were placed into sterile 50-mL Falcon tubes containing seawater. One gram of sand sediment was mixed with 9-mL sterile distilled water and mixed in a tube rotator for 30 min at a moderate speed. A subsample (0.1 mL) was serially diluted and transferred onto SC-SW agar plates supplemented with 60 % (v/v) sterilized natural seawater. The SC-SW agar medium contained 1 % soluble starch, 0.03 % casein, 0.2 % KNO_3, 0.2 % NaCl, 0.002 % $CaCO_3$, 0.005 % $MgSO_4 \cdot 7H_2O$, 0.001 % $FeSO_4 \cdot 7H_2O$, and 1.8 % agar in 60 % sterilized natural seawater and 40 % distilled water (pH 7.2). The isolate was maintained on ISP2 medium (Shirling and Gottlieb 1966) supplemented with 60 % sterilized natural seawater, and in a 20 % (v/v) glycerol suspension supplemented with 60 % (v/v) sterilized natural seawater, at −20 °C and −80 °C.

Biotypes and Ecology

Common characteristics of the genera in the *Geodermatophilaceae* are modest growth requirements and the ability to grow as a pioneer in biotopes commonly considered as nutrient-poor like mineral rock substrates or dry soils. The three genera have been isolated from very different regions, latitudes, and climatic conditions including desert environments, rocks, dry soils, monument surfaces, but all characterized by dry conditions and scarcity of organic matter (Taylor-George et al. 1983; Eppard et al. 1996; Garrity et al. 1996; Urzì and Realini 1998; Urzì et al. 2001; Essoussi et al. 2010). They typically grow as endoliths on and in stone materials where they contribute in forming the so-called subaerial biofilms (Gorbushina 2007).

Geodermatophilaceae have been frequently retrieved from extreme environments with very hot or cold and dry climates.

Several *Geodermatophilaceae* and in particular species of the genus *Geodermatophilus* have been isolated from sand and stones in hot deserts from different continents (Eppard et al. 1996; Garrity et al. 1996; Nie et al. 2012). Indeed the original description of the genus *Geodermatophilus* arises from isolates obtained from soil of the Amargosa desert in Nevada, US (Luedemann 1968). Recently, Montero-Calasanz et al. (2012, 2013) reported the description of two new species of *Geodermatophilus, G. arenarius*, and *G. siccatus*, isolated from Sahara sands in Chad, while *G. nigrescens* has been isolated from a dry-hot river valley in southwest China (Nie et al. 2012) and *Geodermatophilus* sp. has been isolated from the Sonoran desert in North America (Rainey et al. 2005). Of the genus *Modestobacter, M. versicolor* has been isolated from biological soil crusts of arid soils from the Colorado Plateau in USA and showed a variable pigmentation from pink to brown-black depending on the level of organic matter available (levels of carbon and nitrogen) in the medium (Reddy et al. 2007).

Besides the hot desert environments, several reports indicated that *Geodermatophilaceae* colonize dry and cold soils. Strains of the genus *Geodermatophilus* were isolated from hyperarid areas from the Qinghai-Tibet plateau in China at altitudes between 3,000 and 3,900 m (Zhang et al. 2011). Other *Geodermatophilaceae* have been isolated or detected through cultivation-independent approaches also in Antarctica like in the Asgard Range (Transantarctic Mountain) where *M. multiseptatus* has been originally isolated (Mevs et al. 2000) and in the Miers Valley where *Geodermatophilaceae* have been evidenced by PCR and sequencing (Babalola et al. 2009).

An interesting aspect of *Geodermatophilaceae* is that they are apparently capable of surviving prolonged periods in the atmosphere associated to soil dust and cover long transcontinental distances. Following a 16S rRNA-based sequence diversity survey of high altitude snows in the Alps (Col du Dome, Mt. Blanc, 4,250 m), several clones of *Geodermatophilaceae*, associated to *Geodermatophilus* and *Blastococcus* were detected and associated to depositions of Saharan dust (Chuvochina et al. 2011a, b). These observation indicates that *Geodermatophilaceae* have a large range dispersal pattern through the atmosphere that makes the family ubiquitous in different environmental conditions.

Besides extreme soils of hot and cold desert, *Geodermatophilaceae* have been also found in standard soils and rhizospheres. For instance, *Geodermatophilus ruber* has been isolated from the rhizosphere soil of the medicinal plant *Astragalus membranaceus* (Zhang et al. 2011). Some *Blastococcus* sp. strains have been proposed as endophytes being found to be associated to plant tissues of medicinal plants from the tropical rain forests of Xishuangbanna in China (Qin et al. 2013).

Another interesting biotope *Geodermatophilaceae* has been associated to the surface of stone monuments (Urzì et al. 2001; Salazar et al. 2006). In several studies, *Geodermatophilaceae* of the three genera have been isolated from monument surfaces, for instance, in the Mediterranean basin (Eppard et al. 1996; Urzì and Realini 1998; Brusetti et al. 2008). In particular, cultivation experiments evidenced the presence of *Modestobacter* and *Blastococcus* genera on calcarenite stones (Urzì et al. 2001; Brusetti et al. 2008), while *Geodermatophilus* has been recovered more from desert environments (Eppard et al. 1996; Garrity et al. 1996).

As endoliths growing in stone materials, members of *Geodermatophilus, Modestobacter* and *Blastococcus* species have evolved as parapatric taxa (ecotypes) among the family *Geodermatophilaceae*. These hypotheses about the evolutionary paths and the ecological microniches among *Geodermatophilaceae* have been formulated based on ROS-generating resistance patterns data (Gtari et al. 2012) as well as microniche colonization (Brusetti et al. 2008; Gtari et al. 2012). Whereas *Blastococcus saxobsidens* was found to be sensitive to gamma radiation (D10 = 900 Gy; 10 % survival at 900 Gy), *Modestobacter marinus* was moderately tolerant (D10 = 6,000 Gy) and *Geodermatophilus obscurus* was highly tolerant (D10 = 9,000 Gy). The high resistance to gamma ionizing radiation of *Geodermatophilus* sp. has been also reported by Rainey et al. (2005). A difference in resistance to short wavelength (254 nm) UV was shown by *B. saxobsidens*, *M. multiseptatus*, and *G. obscurus*, being sensitive, tolerant, and highly tolerant (D10 of 6, 900, and >3,500 kJ m^{-2}, respectively, Gtari et al. 2012). Tolerances to desiccation, mitomycin C, and hydrogen peroxide correlated with the ionizing radiation and UV resistance profiles of the three species as well as with the pigments synthesized. Resistance to heavy metals/metalloids did not follow the same pattern, with resistance to Ag^{2+} and Pb^{2+} being similar for *B. saxobsidens, M. marinus*, and *G. obscurus*, whereas resistance to AsO_4^{3-}, Cr^{2+}, or Cu^{2+} was greater for *B. saxobsidens* than for the other two species (Gtari et al. 2012). These distinguishable physiological features were reflected by diverse preferences of members of the three *Geodermatophilaceae* genera in colonizing stone material and to drive the stringencies caused by solar radiation, temperature, drought, and lack of nutrients. On rocks and stone materials, *Geodermatophilus* and *Modestobacter* appear as inhabitants respectively of altered and surface stone materials and are subsequently adapted to extensive environmental changes in contrast to *Blastococcus* which inhabits the deeper part of stone material and relatively stable conditions.

The original biotopes where *Blastococcus* strains were first isolated are marine biotopes. Ahrens and Moll (1970) proposed the description of the new genus *Blastococcus* and the species *Blastococcus aggregatus* following the isolation from sediments of the Baltic Sea. Other *Geodermatophilaceae* isolates derive from marine sediments: *Blastococcus jejuensis* has been isolated from beach sediments in South Korea (Lee 2006) and *Modestobacter marinus* was isolated from a 2,983-m deep-sea sediment sample collected in the Atlantic Ocean (Xiao et al. 2011). Marine sediments represent oxic/anoxic interfaces where steep gradients of oxygen exist and microaerophilic conditions may occur. The isolation of *Geodermatophilaceae* from such environment suggests an ecological assembly of *Geodermatophilaceae* selected to thrive at relatively low oxygen tensions, a concept further supported by the capability of growth under microaerophilic conditions especially within the *Blastococcus* genus (Normand 2006).

Applications

Some features of the *Geodermatophilaceae* have been studied for various applications.

The adaptations of *Geodermatophilaceae* to thrive in harsh environments characterized by low water and nutrient availability, exposure to high irradiation rates, and for strains adapted to mineral rocky substrates with exposure to heavy metals have selected features of interest for potential applications.

The capability of resistance to high irradiation rates and the tolerance to heavy metals/metalloids as reported in the previous paragraph make these bacteria potential candidates for the primary colonization of substrates with low organic inputs, for instance, in the formation of the soil-protective biological soil crusts in barren sterile soils, or for the bioremediation of polluted environments even in the presence of radiations.

Geodermatophilaceae appear equipped with robust enzymes capable of being active in relatively harsh conditions. For instance, it has been shown that the esterases (EC 3.1.1.x) of *Geodermatophilaceae*, which constitute a diverse group of enzymes that play central roles in most catalytic pathways, are highly tolerant to stressful conditions. Esterases were studied for a collection of *Geodermatophilaceae* and other actinobacteria obtained from Sahara desert stone and monument in Tunisia and Egypt (Essoussi et al. 2010, 2012). *Blastococcus, Geodermatophilus*, and *Modestobacter* are distinguishable from *Arthrobacter, Micromonospora, Actinoplanes, Kineococcus*, and *Nocardia* by a rich and particular pool of esterase activities that could be directly linked to harsh conditions characterizing their ecological habitat including high level of aridity, temperature, ionic strength, and low nutrient availability. As an example, esterases from *Geodermatophilus* strains display a high resistance to thermal inactivation and alkaline pH and retain up to 30 % of activity after heating for 20 min at 120 °C and pH 12. The activity was strongly activated in the presence of Ca^{2+} and Mg^{2+} ions and moderately by Zn^{2+} and was markedly inhibited by Cu^{2+} and Co^{2+} ions. Jaouani et al. (2012) purified an intracellular esterase from *Geodermatophilus obscurus* strain G20 of approximately 55 kDa. The enzyme was highly thermostable, with a residual activity greater than 90 % after incubation at 80 °C for more than 10 h. The enzyme showed an optimal activity between pH 8.0 and 9.0 and was stable in the pH range 7.0–10.0. This esterase showed preference for esters of *p*-nitrophenol with short chain fatty acid. When the *p*-nitrophenyl acetate (C2) was used as substrate, the Michaelis–Menten constant (Km) and maximum velocity for the reaction (Vmax) of esterase were 400 μM and 2,500 U/mg protein, respectively. The effect of phenylmethanesulfonyl fluoride (PMSF), a serine-specific inhibitor, on the enzyme activity suggested that the thermostable esterase belongs to the serine hydrolase group. The high thermostability, activity at alkaline pH, tolerance to methanol and various metal ions, and specificity for short chain fatty acids make this enzyme highly interesting for applications in biocatalysis.

Geodermatophilaceae have been also associated to negative traits. When recovered from monument stones,

Fig. 20.8
Degradation of a calcareous stone wall in Carthage, Tunisia, where several isolates of the three *Geodermatophilaceae* genera have been isolated. Biopitting and stains are associated with these bacteria

Geodermatophilaceae have been frequently associated with mechanical alterations of the stone material with biopitting and powdering and alterations of the surfaces (*Fig. 20.8*) with orange, grayish, greenish, and black spots and patinas (Urzì and Realini 1998). However, clear demonstrations of causative roles in the alterations have been not documented, and until now, the *Geodermatophilaceae* have been shown to be simply associated to the surfaces alterations.

Conclusion

Geodermatophilaceae are isolated from extreme biotopes such as polar regoliths, gamma-irradiated sands, or from the inside of stone monuments. They are also present in less extreme locales such as rhizosphere soils. However, they do not appear as dominant in molecular catalogs and thus have a selective advantage only when environmental conditions are very punitive for more common bacteria. They constitute a very coherent clade, recovered by many approaches including phylogeny of several markers and morphology.

Given the *Geodermatophilaceae* are slow growers and that they inhabit extreme environments that have been less studied through metagenomics, it is expected new taxa should be recovered soon with the constantly rising sequencing power and the numerous metagenomics programs underway. Already, hints of new lineages have been obtained through studying with 16S rRNA targeted primers the microbial diversity of stones surfaces (Salazar et al. 2006).

The study of the genomes of these microbes, only recently obtained, is not complete. It is not yet understood, for instance, how two of the three strains (*Geodermatophilus* and *Modestobacter*) could have developed such high resistance to oxidative stress (Gtari et al. 2012). It is expected that the

genomes should yield clues permitting to understand how the *Geodermatophilaceae* did adapt to their respective biotopes. As more and more strains are isolated and classified into new species, as more and more genomes are obtained, we should see the evolutionary history of some of the most contrasted microbes unfold.

21 The Order *Glycomycetales* and the Genus *Actinocatenispora*

Erko Stackebrandt
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The order *Glycomycetales* comprises the family *Glycomycetaceae* with its genera *Glycomyces*, *Haloglycomyces* and *Stackebrandtia*. Also covered in this chapter is the genus *Actinocatenispora* which, in some 16S rRNA gene sequence-based trees shows a weak affiliation to this order. The type strains were either directly isolated from soil or they were recovered as endophytes. All strains form a vegetative mycelium and some strains form an aerial mycelium on some media. Antibiotic substances have been identified in one species, and the presence of PKS I genes have been demonstrated in an unnamed species. Members of the order can be isolated routinely on standard growth media but are considered "rare actinomycetes" as their presence is hardly detected in non-culture studies.

Taxonomy, Historical and Current

Short Description of the Family

The family *Glycomycetaceae* was originally described by Stackebrandt et al. (1997) on the basis of the isolated position of the *Glycomyces* line of descent within the radiation of members of the order *Actinomycetales* and a set of 16S rRNA gene-specific nucleotides. In the same publication the suborder *Glycomycineae* was described. Since then the family *Glycomycetaceae* was emended twice. Firstly by Labeda and Kroppenstedt (2005) incorporating the new phenotypic information of the second genus of the family, *Stackebrandtia*, secondly by Zhi et al. (2009), who also emended *Glycomycineae*, after many new genera and families were added to the *Actinobacteria*, expanding the diversity of 16S rRNA gene sequences. Recently, a third genus has been added to the family, named *Haloglycomyces* (Guan et al. 2009) without additional emendation of the family. In the 2nd. edition of *Bergey's Manual of Systematic Bacteriology*, vol 5, Actinobacteria, the family *Glycomycetaceae* has been placed in the order *Glycomycetales* (Ludwig et al. 2012). Phenotypic and chemotaxonomic properties of the three genera are compiled in ❯ *Table 21.1*.

Glycomycetaceae Rainey et al. 1997, 487^{VP}, emend Labeda and Kroppenstedt 2005, emend Zhi et al. 2009.

Gly.co.my.ce.ta'ceae. N.L. masc. n. *Glycomyces* type genus of the family; -taceae ending to denote a family; N.L. fem. pl. n. *Glycomycetaceae* the *Glycomyces* family.

Aerobic. Gram-positive, non-acid-fast, non-motile actinomycetes. Branched substrate mycelium (approx. 0.35–0.5 μm in diameter) and, on some media, aerial mycelia are produced. Catalase positive. Mycolic acids are absent. Contains meso-diaminopimelic acid (A_2pm) as the diamino acid. Cell walls contain *N*-glycolylmuramic acid. When searched for, teichoic acids are present (Potekhina et al. 1993). Whole-cell sugar pattern contains ribose as a diagnostic sugar along with other genus-specific sugars. Iso(i)- and anteiso(ai)-branched fatty acids. Phospholipid content includes phosphatidylglycerol and diphosphatidylglycerol in addition to other genus-specific phospholipids (Labeda and Kroppenstedt 2005).

The 16S rRNA gene sequence pattern of 16S rRNA signature nucleotides consists of nucleotides at positions 657 : 749 (G–U), 672 : 734 (C–G), 681 : 709 (A–U), 831 : 855 (U–G), 832 : 854 (G–U), 833 : 853 (G–C), 840 : 846 (C–U), 952 : 1229 (C–G), 1064 : 1192 (G–G) and 1117 : 1183 (A–U) (Zhi et al. 2009).

The family comprises the genera *Glycomyces, Stackebrandtia* and *Haloglycomyces*.

The nomenclatural type is the genus *Glycomyces* Labeda et al. (1985).

Phylogenetic Structure of the Family and Its Genera

The position of the family in the 16S rRNA gene tree depend upon the selection of outgroup sequences used

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_192,

Table 21.1

Properties differentiating the genera *Glycomyces, Stackebrandtia and Haloglycomyces*. Properties of the distantly related genus *Actinocatenispora* is included for comparison (Data are from Labeda and Kroppenstedt (2005), Wang et al. (2009), Guan et al. (2009) and Seo and Lee (2009))

Characteristics	*Glycomyces*	*Stackebrandtia*	*Haloglycomyces*	*Actinocatenispora*
Spore –like bodies	Oval spherical, or rod-shaped spores on vegetative hyphae or chains of cylindrical spores on aerial hyphae	Non-fragmenting vegetative and aerial mycelium	Short or elongated rods on vegetative hyphae (approx 0.45 mm in diameter)	Cylindrical spores on vegetative hyphae or Chains of cylindrical spores on aerial hyphae
Aerial mycelium	On some media Two species without aerial mycelium	On some media in *S. nassauensis* No aerial mycelium in *S. albidiflava*	Well developed on most media	No aerial mycelium in *A. sera*
Diagnostic amino acid(s) in peptidoglycan	meso- A_2pm, gly[a]	meso- A_2pm	meso- A_2pm	meso- A_2pm, Gly
Major menaquinone	MK10, MK11 and/or MK12 isoprene units, but the degree of saturation varies within each species	MK10(H_4), MK10(H_6), MK11(H_4), MK11(H^6)	MK-9(H_4), MK-9(H_2), MK-8(H_4), MK-10(H_4)	MK-9(H_4). MK-9(H_6), and MK-9(H_8) are strain dependent
Presence of $C_{16:0}$ 10-methyl and iso-branched 2 hydroxy fatty acids	–	+	–	–[b]
Major polar lipids	PI, DPG, PIM, PG (some strains)[c]	PG, DPG, PE, PME[c]	PG, PE, DPG, PI, PIM[c]	PI, DPG, PE, PIM, PG[c]
Whole cell sugars	Strain specific, very variable, see Table 21.3	Rib, xyl, glu or rib, ino	Rib, xyl, glu	Ara, xyl, other sugars are strain specific
DNA mol% G+C	70–73	69–73	60.8	72–74.3
NaCl tolerance	Most strains tolerate 5 %	Up to 9 %	Up to 18 %	4 %, one strain 7 %

Abbreviations: *PIM* phosphatidylinositol mannosides, *DGP* diphosphatidylglycerol, *PE* phosphatidylethanolamine, *PME* phosphatidylmethylethanolamine, *PG* phosphatidylglycerol and additional unknown phospholipids. *ara* arabinose, *gal* galactose, *glu* glucose, *ino* inositol, *man* mannose, *rib* ribose, *xyl* xylose

[a]Glycine, as well as *N*-glycolylmuramic acid, has been determined in a few species only

[b]Fatty acid composition of strains often differs significantly in different publications

[c]Additional non-identified phospholipids, aminophospholipids and phosphoglycolipids may be present, either individually or in combination

(Labeda and Kroppenstedt 2005; Guan et al. 2009). In the maximum-likelihood and maximum-parsimony trees of Zhi et al. (2009) *Glycomycetaceae*, together with *Actinomycetaceae* and *Actinopolysporaceae*, form a clade, though with different nearest neighbors. The editors (Whitman et al. 2012) of the vol. 5 of *Bergey's Manual*, *Actinobacteria* (www.bergeys.org) elevated the former ranks of subclass and suborder to the ranks of class and order, respectively, to make the taxonomy of the *Actinobacteria* more consistent with that of other prokaryotes. In this outline *Glycomycetales* is a member of a larger clade that also includes the orders *Actinopolysporales*, *Corynebacteriales*, *Jiangellales*, *Micromonosporales*, *Propionibacteriales*, and *Pseudonocardiales*. In the curated tree of The All-Species Living Tree (http://www.arb-silva.de/fileadmin/silva_databases/livingtree/LTP_release_106/LTPs106_SSU_tree.pdf) the nearest neighbor of the *Glycomycetaceae* is the genus *Actinocatenispora* (Thawai et al. 2006; Matsumoto et al. 2007; Seo and Lee 2009). As mentioned by Ludwig et al. (2012), genera of *Glycomycetaceae* and *Actinocatenispora* have certain properties in common (Table 21.1) and the higher taxon affiliation of *Actinocatenispora* should be reconsidered once the branching position of this lineage within the actinobacterial tree has been consolidated. In contrast to the phylogeny depicted in *Bergey's Manual*, the topology of the LTP tree sees *Glycomycetaceae* to be more closely related to *Streptosporangiaceae, Nocardiopsaceae and Thermomonosporaceae*. As pointed out by Munk et al. (2009), NCBI BLAST server search of the *S. nassauensis* 16S rRNA gene sequence indicated the absence of type strains of *Glycomyces* within the 250 top hits. Reanalysis of the search in 2012 confirmed that the closest relatives of *S. nassauensis* and *S. albidiflava* are strains of *Luedemanella, Actinoplanes, Krasilnikovia, Catenuloplanes, Pseudosporangium and Catellatospora* but not the sequences of either *Glycomyces* or *Haloglycomyces* strains. Using the sequence of *Glycomyces harbinensis* as a reference, *Haloglycomyces albus* and *S. albidiflava* are among the 40 top hits while *S. nassauensis* is absent among

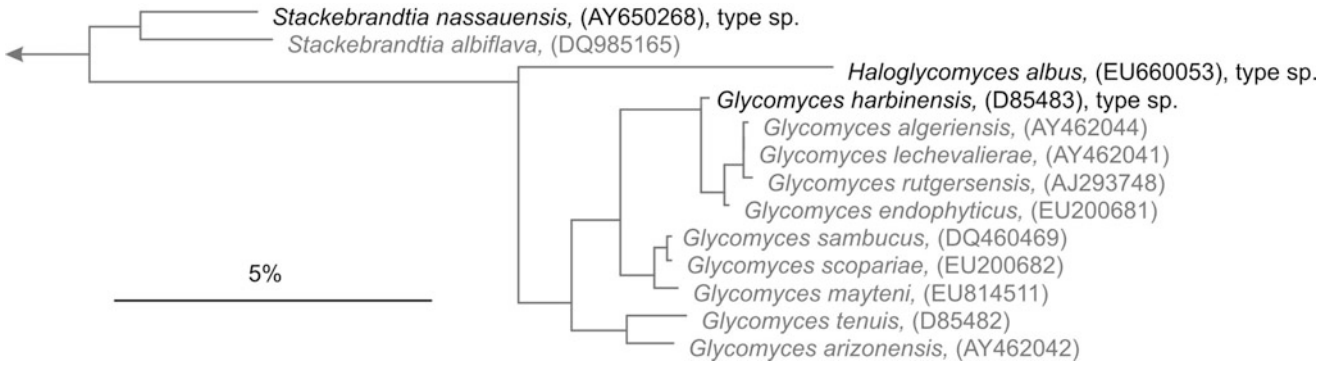

Fig. 21.1

Maximum likelihood genealogy reconstruction based on the RAxML algorithm (Stamatakis 2006) of the sequences of all members of the family *Glycomycetaceae* present in the LTP_106 (Yarza et al. 2010). The tree was reconstructed by using a subset of sequences representative of close relative genera to stabilize the tree topology. In addition, a 40 % conservational filter for the whole bacterial domain was used to remove hypervariable positions. The *bar* indicates 5 % sequence divergence. List of type strains used for dendrogram construction; *Glycomyces harbinensis* IFO (NBRC) 14487^T, *G. algeriensis* NRRL B-16327^T, *G. lechevalierae* NRRL B-16149^T, *G. rutgersensis* IMSNU 22074^T, *G. endophyticus* YIM 56134^T, *G. sambucus* E71^T, *G. scopariae* YIM 56256^T, *G. mayteni* YIM 61331^T, *G. tenuis* NBRC 15904^T, *G. arizonensis* NRRL B-16153^T, *Haloglycomyces albus* YIM 92370^T, *Stackebrandtia nassauensis* DSM 44728^T, *S. albidiflava* YIM 45751^T

the top 250 hits. Undiscovered sequence idiosyncrasies may be the reason for this unusual observation.

The intrafamily relationship sees type strains of *Stackebrandtia* as the deepest branching members, while *Haloglycomyces* and *Glycomyces* are sister lineages. *Stackebrandtia* type strains show 95.8 % 16S rRNA gene sequence similarity among each other and around 92 % similarity with type strains of the other two genera. Within *Glycomyces* the pair *G. tenuis* and *G. arizonensis* form a separate branch. In contrast to other species of the genus these two species are the only ones for which an aerial mycelium has never been observed. A second group comprises the highly related pair *G. sambucus*, and *G. scopariae* (99.7 %) and, more distantly related, *G. mayteni* (98.4–98.8 %), while a third group encompasses the close relatives *G. algeriensis*, *G. lechevalierae* and *G. rutgersensis* (>99.5 %), *G. endophyticus* and *G. harbinensis* (>98.9–99.1 %) (Fig. 21.1). *Haloglycomyces albus* branches between the two generic lineages (Fig. 21.1) and more closely to *Glycomyces* species. The two type strains of *Stackebrandtia* are moderately related among each other (95.4 %) and they are distantly related to both, *Glycomyces* (88.9–90.7 %) and *Haloglycomyces* type strains (89 %). The three *Actinocatenispora* type strains, being 97.6–99.3 % related among themselves, are slightly more close to *Stackebrandtia* strains (90.4–91.1 %) than to those of *Haloglycomyces* and *Glycomyces* (86.4–87.5 %).

Additional species names have been proposed during the deposition of 16S rRNA gene sequences in public databases but none of them have yet been validly named: "*Glycomyces mongolensis*" (Tsetseg et al. unpublished, AB367437), "*Glycomyces xinjiangensis*" from a salt field in Xinjiang, China (Shi and Tang, unpublished, HQ833642), "*Glycomyces donghensis*" and "*Actinocatenispora albus*" from a salt soil (Gorden unpublished, JN252407 and HQ412605, respectively) and "*Glycomyces albus*" (Tang unpublished GU119912). A strain of "*Glycomyces illinoisensis*" has been deposited by D. Labeda in the DSMZ as DSM 44734. It should be noted that the sequence AM980986 is entered in public data repositories as "*Actinocatenispora silicis*" and not under *A. rupis*.

Molecular Analyses

DNA-DNA Hybridization Studies

As the 16S rRNA gene sequences of several *Glycomyces* strains are highly similar, DNA-DNA hybridization (DDH) experiments were performed in order to elucidate whether or not they represent genomic species. Even at very high sequence similarities at 99.7 % sequence similarity corresponding DHH values were not higher than 58 % (Table 21.2), thus distinctly below the 70 % threshold value recommended for species delineation (Wayne et al. 1987). The only other highly related strain pair is *Actinocatenispora thailandica and A. sera* (99.3 % 16S similarity) sharing 45–475 DDH similarity (Matsumoto et al. 2007).

Genome Analysis

At present only the full genome sequence of *Stackebrandtia nassauensis* DSM 44728^T is available for members of *Glycomycetaceae*. The genome which has been sequenced within the Genomic Encyclopedia of Bacteria and Archaea project (Munk et al. 2009) has a circular chromosome of 6,841 Mb. 6.450 genes were predicted of which 6.487 code for proteins. In addition 2 rrn operons were identified and 53 genes coding for RNAs. 68 % of the protein-coding genes were associated with the

Table 21.2

Relationship between 16S rRNA gene sequence similarities (lower left triangle) and DNA-DNA reassociation values (upper right triangle) within groups of highly related *Glycomyces* species. Similarity values were calculated on the basis of the restricted set of sequences of strains: *G. algeriensis* NRRL B-16327^T; *G. lechevalierae* NRRL B-16149^T; *G. rutgersensis* IMSNU 22074^T; *G. endophyticus* YIM 56134^T; *Glycomyces harbinensis* IFO 14487^T; *G. sambucus* E71^T; *G. scopariae* YIM 56256^T; *G. mayteni* YIM 61331^T; *G. tenuis* NBRC 15904^T; *G. arizonensis* NRRL B-16153^T

general COG functional categories. The majority of these genes were annotated as belonging to transcription (13.5 %), carbohydrate- (9.0 %) and amino acid transport and metabolism (7.6 %), as well as signal transduction mechanisms (7.2 %). The mol% G + C content of 68.1 % is 4.3 % lower than that determined by HPLC (Labeda and Kroppenstedt 2005).

Phenotypic Analyses

Glycomyces Labeda et al. 1985, 419^{VP}, emend Labeda and Kroppenstedt 2004, 2345.

Gly'co.my.ces. Gr. adj. *glykus* sweet; Gr. n. *myke* fungus; N.L.n. *Glycomyces* sweet (glycolipid-containing).

The emendation became necessary with the description of four novel species (Evtushenko et al. 1991; Labeda and Kroppenstedt 2004) when the original circumscriptions of morphological and chemotaxonomic properties were too narrow. With the description of additional four species between 2007 and 2009 (Gu et al. 2007; Qin et al. 2008, 2009) an even higher variation among some of the genus-specific properties were noticed without, however, emending the genus description. Type strains of the species were not cultivated on the same range of growth media and not all morphological (e.g., spore morphology, dimension of vegetative mycelium), physiological (e.g., lysozyme sensitivity, catalase) and chemotaxonomic properties (e.g., presence of glycine in peptidoglycan, mol% G+C of DNA) were investigated for all type strains. In addition to entries listed in ❯ *Table 21.1* the range of described properties for type strains are indicated in ❯ *Tables 21.3* and ❯ *21.4*. Strains are Gram-positive, aerobic, and filamentous. The *N*-acyl group of the cell-wall muramic acid is glycolyl. All strains produce acid from L-arabinose, maltose, D-xylose as well as from D-glucose, salicin, D-mannose (*G. tenuis* not tested), and α-methyl-D-glucoside (*G. tenuis* and *G. arizonensis* not tested), but not from dulcitol. All strains decompose casein. Additional reactions which were only tested in a few species are not listed here and should be looked at in the original descriptions. The growth temperature ranges from 10 °C to 42 °C and most strains grow between 15–20 °C and 37 °C.

Genus-specific 16S rRNA gene signature nucleotides have not been determined. The type species is *Glycomyces harbinensis*.

Stackebrandtia Labeda and Kroppenstedt 2005, 169^{VP}, emend. Wang et al. 2009.

Stack.e.brandt'i.a. N.L. fem. n. *Stackebrandtia* named for Erko Stackebrandt.

Gram-positive, aerobic non-motile, filamentous. Branched and non-fragmenting substrate mycelium are produced. Catalase-positive. Growth range between 17 °C and 37 °C. The *N*-acyl group of the cell-wall muramic acid is glycolyl. Other genus-specific as well as species-specific properties are indicated in ❯ *Tables 21.1* and ❯ *21.5*. Genus-specific 16S rRNA gene signature nucleotides have not been determined. The type species is *Stackebrandtia nassauensis*.

Haloglycomyces Guan et al. 2009, 1299^{VP}

Ha'lo.gly.co.my'ces. Gr. n. *hals* salt; N.L. masc. n. *Glycomyces* a bacterial genus name; N.L. masc. n. *Haloglycomyces* a salt-(loving) *Glycomyces*-like bacterium.

Most of the salient generic features are indicated in ❯ *Table 21.1*. Aerobic, Gram-positive, halophilic and filamentous. Oxidase-negative and catalase-positive. The menaquinones

Table 21.3

Range of morphological and chemotaxonomic properties in Glycomyces type strains (Data are from Labeda et al. (1985), Labeda and Kroppenstedt (2004), Evtushenko et al. (1991), Qin et al. (2008, 2009), and Gu et al. (2007)) 1 *G. harbinensis* IFO 14487^T, 2 *G. algeriensis* NRRL B-16327^T, 3 *G. lechevalierae* DSM 44724^T, 4 *G. rutgersensis* IFO 14488^T, 5 *G. endophyticus* YIM 56134^T, 6 *G. scopariae* YIM 56256^T, 7 *G. sambucus* DSM 45047^T, 8 *G. mayteni* YIM 61331^T, 9 *G. tenuis* VKM Ac-1250^T, 10 *G. arizonensis* NRRL B-16153^T

Table 21.5

Differentiating properties of *S. nassauensis* NRRL B-16338T and *S. albidiflava* YIM 45751^T. Both type strains of *Stackebrandtia* produce acid from galactose, mannose, arabinose and cellobiose, but not from inositol, adonitol, dulcitol, melezitose or erythritol. Both strains are positive for starch, casein and gelatin hydrolysis, but negative for adenine degradation. Neither strain assimilates tartrate, benzoate or mucate (Data are from Labeda and Kroppenstedt (2005) and Wang et al. (2009) who also lists additional morphological properties and metabolic reactions)

For other abbreviations see *Tables 21.1* and *21.3*. *APL* aminophospholipid + positive, – negative, *w* weak reaction, *nd* not determined

[a]The phospholipid pattern determined for *S. nassauensis* by Wang et al. (2009) is different to that determined for the same strain by Labeda and Kroppenstedt (2005)

In addition to properties listed in *Table 21.1* morphological descriptions and metabolic reactions are indicated by Guan et al. (2009).

The type strain *H. albus* YIM 92370^T is defined by the following metabolic reactions: utilizes cellobiose, glucose, maltose, mannitol, mannose, rhamnose and sorbitol as sole carbon sources, but not D-arabinose, dextrin, fructose, galactose, glycerol, inositol, lactose, melibiose, raffinose, ribose, xylitol or xylose. Positive for gelatin hydrolysis, starch hydrolysis, milk coagulation and peptonization, but negative for urease, cellulose hydrolysis, production of H_2S and nitrate reduction. additional morphological properties and metabolic reactions.

Actinocatenispora Thawai et al. 2006, 1792^{VP}, emend Seo and Lee 2009

The genus *Actinocatenispora* is not an authentified member of *Glycomycetaceae* but included here as family *insertae sedis* because of its isolated phylogenetic position.

Ac.ti.no.ca.te.ni.spo′ra. Gr. n. *actinos* ray; L. n. *catena* chain; Gr. n. *spora* seed; N.L. fem. n. *Actinocatenispora* spore chain-producing ray (fungus).

In addition to properties indicated in *Table 21.1* Gram-positive, non-acid-fast, non-motile and aerobic organisms with branching substrate hyphae. Aerial hyphae are formed in two species. Spore chains are borne on the aerial mycelium or produced directly from the vegetative mycelium. Spores (0.4–0.5 × 0.9–1.6 μm or 0.3–0.4 × 0.5–1.0 μm) are cylindrical and the spore surface is smooth. Cell wall contains glutamic acid, glycine, alanine and *meso*-diaminopimelic acid. The *N*-acyl group of the cell-wall muramic acid is glycolyl. Mycolic acids are not detected. Habitat is soil. The type species is *Actinocatenispora thailandica*.

The three type strains of the species *A. thailandica* TT2-10^T (Thawai et al. 2006), *A. sera* KV-744^T (Matsumoto et al. 2007) and *A. rupis* CS5-AC17^T (Seo and Lee 2009) differ in the metabolic properties (*Table 21.6*) as indicated by the latter authors. Additional metabolic, chemotaxonomic and morphological characteristics are indicated in the respective species descriptions.

Isolation, Enrichment and Maintenance Procedures

Several strains were taken as freeze-dried culture from public culture collections and information about the original isolation method is not available. For the isolation of *G. arizonensis* B-16153^T, a 1 g soil sample from a kangaroo rat (*Dypodymus* sp.) burrow was suspended in 9 ml sterile tap water and shaken with two 5 mm glass beads in a 25 × 150 mm. After heating at 60 °C for 5 min and further dilutions samples were spread on the surface of Czapek's sucrose agar (Waksman 1950) amended with 50 μg each of cycloheximide and nystatin ml^{-1}, 10 mg streptomycin ml^{-1} and 25 mg novobiocin ml^{-1}. Antibiotics were also

+ positive, – negative, *w* weak reaction

used in the isolation of *Stackebrandtia albiflava* (raffinose-histidin agar, (Vickers et al. 1984), supplemented with cycloheximide and nyastin,50 and 25 µg ml^{-1}, respectively) and for the endophyte *G.sambucus*. This organism was obtained by placing slices of surface sterilized root samples on BL-2 agar plates containing per liter 5 g each of glucose, soluble starch, NaCl and $CaCO_3$, 2 g acid casein hydrolysate, 1 g yeast extract, 15 g agar, and 100 µg penicillin ml^{-1} (Gu et al. 2006). The organism, seen around the root sample under a light microscope, was transferred onto fresh yeast extract/malt extract (ISP medium 2) agar (Shirling and Gottlieb 1966). As an alternative, pulverized surface-sterilized roots were pulverized and tap water suspensions spread ontop of tap water/yeast extract medium (Crawford et al. 1993). Isolation of *Haloglycomyces albus* was achieved on cellulose-casein agar containing 10 g microcrystalline cellulose, 0.3 g casein, 0.2 g KNO_3, 0.5 g K_2HPO_4, 0.02 g $CaCO_3$, 0.01 g $FeSO_4$, 100 g NaCl, 30 g $MgCl_2.6H_2O$, 20 g KCl and 15 g agar per litre distilled water, pH 7.5 (Tang et al. 2008). *Actinocatenispora thailandica* was isolated on starch-casein nitrate agar. A. sera was isolated on agar media containing per litre 10 g L-proline, and 15 g agar, supplemented with the anti-fungal reagent (Benlate® 20 *m*g ml^{-1} Dupont Co., DE, USA). *A. rupis* was recovered on starch casein agar (1 % soluble starch, 0 · 03 % casein, 0 · 2 % KNO_3, 0 · 2 % NaCl, 0 · 002 % $CaCO_3$, 0 · 005 % $MgSO_4.7H_2O$, 0 · 001 % $FeSO_4.7H_2O$ and 1 · 8 % agar [pH 7 · 2]) after 2 weeks at 30 °C. Cultivation was done at about 27–30 °C for 1–4 weeks. Subcultivation and maintenance were done on a wide range of media conventionally used for the growth of streptomycetes, such as various ISP media, medium ATCC 172, Czapek agar, oatmeal agar or yeast extract-malt extract agar.

No difficulties in short or long term maintenance have been reported and isolates can be stored at 4 °C as 20 % (v/v) glycerol suspensions, freeze-dried in sterile serum at 4 °C, lyophilized or kept in straws under N_2 vapor.

Ecology

Four of the *Glycomyces* type strains are endophytes, i.e., *G. endophyticus* (Qin et al. 2008), *G. sambucus* (Gu et al. 2007), and *G. scopariae* and *G. mayteni* (Qin et al. 2009) isolated from the roots of *Carex baccans* and *Sambucus adnata*, *Scoparia dulcis* and *Maytenus austroyunnanensis*, respectively; all other type strains were soil isolates. *G. tenuis* was isolated from a sample of *Streptomyces galilaeus* which itself is a soil organisms (Evtushenko et al. 1991). The type of soil varied from greenhouse to farm soils and origin of the soils and plants from China, North Africa and the USA indicates a wide geographic distribution. Soil is also the habitat of *Stackebrandtia* (Bahamas, China), *Haloglycomyces* (China) species, the latter being isolated from a hypersaline sample, as well as of *Actinocatenispora* (soil surface of peat swamp forest, Thailand; cliff of Korean island and soil, Niigata Prefecture, Japan).

Browsing through the NCBI BLAST server only a few sequences are found which are closely to moderately related to members of the three genera. Several of the strains/DNA originate from soil but also from sediments, plant material (e.g., seagrass, Zhang et al. unpublished, GQ163474.1) and waste (e.g., composted swine manure Hayakawa et al. unpublished; AB562484). Besides strains with invalid names mentioned above, several entries do not link the origin of the habitat to the sequence information. *Glycomyces* strains have been reported from a study on rare actinomycetes from shallow water of Trondheim Fjord, Norway (e.g., EF212018, EF216364; Bredholdt et al. 2007). A large number of entries (>20, e.g., GQ262917, GQ263583) belong to *Glycomyces*-related clone sequences (97–98 % similarity) from a simulated low-level radioactive waste side in Idaho, USA (Field et al. 2010). This simulated waste layer (not soil) was covered with an overlying soil layer using local unsaturated soils. The same study also reports the presence of a single clone related to *Actinocatenispora* spp (97 % BLAST hit; GQ263629).

The only record for a sequence moderately related (95 %) to *Haloglycomyces albus* originate from a highly alkaline saline soil (Valenzuela-Encinas et al. 2009).

A few entries of as-yet uncultured strains were found to be moderately (96 %) related to *Stackebrandtia* strains such as those found in pig manure (Snell-Castro et al. unpublished AM982657), from fungus garden material of the leaf-cutter ant *Atta colombica* (Suen et al. 2010) and in a report from the NIH Intramural Skin Microbiome Consortium (Kong et al. unpublished).

Medical Relevance and Application

All members of the four genera are listed as risk group 1 organisms according to the German Technical Rules for Biological Agents and internal DSMZ assessment as indicated in the DSMZ catalogue of strains (www.dsmz.de).

Antibiotic sensitivity has only been tested for *G. tenuis* VKM Ac-1250^T (Evtushenko et al. 1991). The strain did not grow in the presence of (per ml^{-1})10 μg of streptomycin, 5 μg of tobramycin, 10 μg of erythromycin, 1 μg of ristomycin; ir is resistant to (per ml^{-1}) 5 μg of oligomycin, 1 μg of novobiocin, and the following antibiotics at concentrations less than 1 μg/ml: carbenicillin, erythromycin, streptomycin, tetracycline, rifampin, and ristomycin. No antibiotic activity is observed against *Bacillus mycoides, Escherichia coli, Staphylococcus aureus, Sarcina lutea*, and *Saccharomyces cerevisiae.*

Of the two *Glycomyces* isolates isolated from the Trondheim Fjord (Bredholdt et al. 2007) and tested for antimicrobial activity and the presence of polyketide synthase and non-ribosomal peptide synthetase genes only one strain gave a positive signal for the presence of a PKS I genes. Neither strain showed antimicrobial activity.

Screening of the complete genome of *Stackebrandtia nassauensis (accession number* CP001778) revealed several KEGG-defined entries of proteins related to polyketide synthases and non-ribosomal peptide synthetase (several for non-ribosomal peptide synthetase/polyketide synthase; several for putative exporter of polyketide antibiotics-like protein; putative cyclase/dehydrase; putatively involved in polyketide/antibiotic biosynthesis; and coronafacic acid polyketide synthase I and II). This suggests that under favorable conditions *S. nassauensis* is capable of antibiotic production, possibly including lantibiotics, as the genome analysis gave several hints for proteins involved in their synthesis such as putative lantibiotic modification protein, lantibiotic dehydratase domain protein, and other proteins involved in lantibiotic biosynthesis.

G. harbinensis is the producer of the antitumor antibiotic LL-DO5139β (Lee et al. 1987). This substance is part of the LL-D05139 complex, containing LL-DQ5139β and azaserine. Chemical analysis revealed LL-DO5139β to be *N*-L-alanyl-L-serine diazoacetate with similar but greater antibacterial activities than serine diazoacetate (azaserine). The dipeptide antibiotic is active against gram-positive and -negative bacteria and tumors. The fermentation process and antimicrobial spectrum of LL-D05139/3 and azaserine has been shown by Lee et al. (1987).

22 The Family *Iamiaceae*

Akira Yokota
Faculty of Mathematics and Natural Sciences, Department of Biology, University of Indonesia, Depok, Indonesia

Abstract
A family within the order *Acidimicrobiales* embraces the genera *Iamia* and *Ilumatobacter*. Members of the family are defined by a wide range of morphological and chemotaxonomic properties, such as isoprenoid menaquinones, fatty acids, amino acids of peptidoglycan and whole cell sugars, which are used for the delineation of genera and species. Members of the family are mainly found in marine environments, but they have been isolated from soils, activated sludge.

Taxonomy: Historical and Current

Short Description of the Family and Their Genera

I.a.mi.a'ce.ae. N.L. fem. n. *Iamia* type genus of the family; -aceae ending to denote a family; N.L. fem. N. *Iamiaceae* the family of *Iamia*.

Phylogenetically a member of the order *Acidimicrobiales* (Stackebrandt et al. 1997; Zhi et al. 2009), phylum Actinobacteria.

The family was originally proposed for the genus *Iamia* (Kurahashi et al. 2009), but nearly at the same time, a new genus *Ilumatobacter* (Matsumoto et al. 2009), which should be included in this family, was independently proposed in 2009. "*Candidatus* Microthrix parvicella" (Blackall et al. 1996) and "*Candidatus* Microthrix calida" (Levantesi et al. 2006), which has been proposed for filamentous bacteria isolated from activated sludge sewage treatment plants and their tasxonomic category not covered by the Rules of the Bacteriological Code, could be included in this family. Taxonomic characterization for these species is still incomplete (*Fig. 22.1*).

Gram-staining positive. Non-sporing and nonmotile rods. Aerial mycelium is not formed. Grow aerobically. Some species require NaCl or seawater for their growth. Diagnostic diaminoacids are either *meso*-diaminopimelic acid or LL-diaminopimelic acid. Hexadecanoic acid (C16:0) and hexadecenoic acid (C16:1) are the predominant fatty acids. Menaquinone MK-9(H_4) or MK-9(H_8) is the predominant isoprenoid quinone. The set of 16S rRNA gene sequence signature is comprised of positions 408–434 (G-C), 722–733 (G-G), 1118–1155 (U-A), 443–491 (U-A), 1165–1171 (G-C), and 1263–1272 (A-U). G+C values of DNA range between 68 and 74 mol%. Usually found in marine environments.

Phylogenetic Structure of the Family and Its Genera

According to the phylogenetic branching of actinobacterial type strains in the 16S rRNA gene tree of the Living Tree Project (Munoz et al. 2011), the family *Iamiaeae* is moderately related to the family *Acidmicrobiaceae* (Stackebrandt et al. 1997; Zhi et al. 2009). In the *Iamiaceae* cluster, genus *Iamia*, *Ilumatobacter*, "*Candidatus* Microthrix parviella" (Blackall et al. 1996), and "*Candidatus* Microthrix calida" (Levantesi et al. 2006) are included.

Molecular Analyses

Genome Comparison (Genome Analyses)

Genome sequences are not available for any strain in this family.

Phages

Any phages are not known for the strains in this family.

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_281,

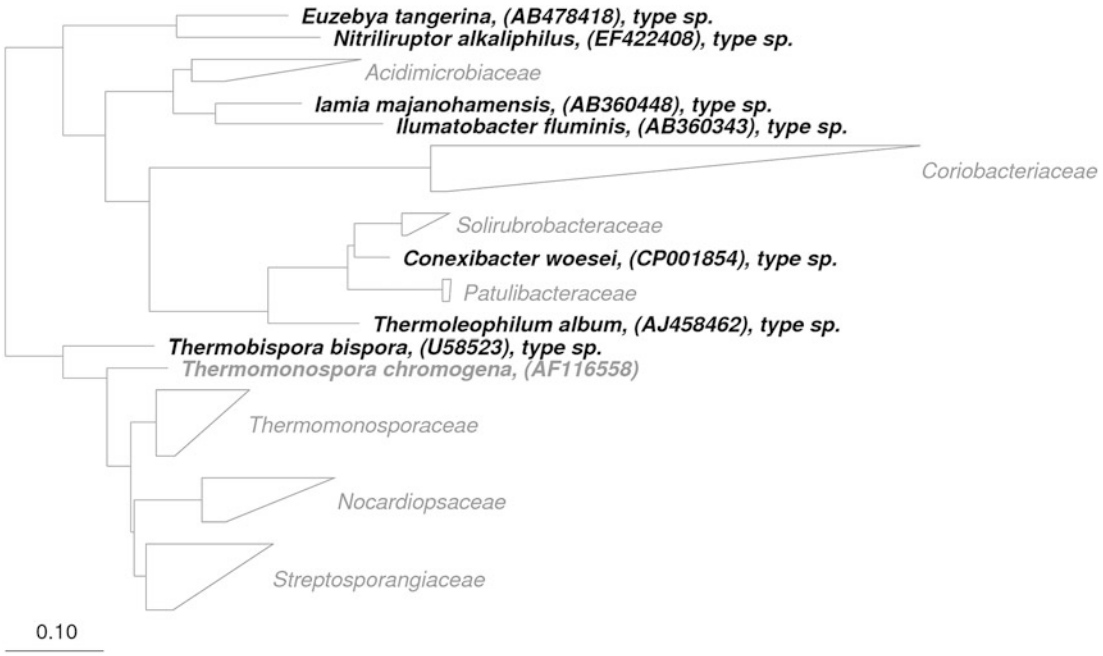

Fig. 22.1

Phylogenetic reconstruction of the family *Iamiaceae* based on 16S rRNA and created using the maximum likelihood algorithm RAxML (Stamatakis 2006). The sequence datasets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). Representative sequences from closely related taxa were used as out groups. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Phenotypic Analyses

Differentiating cultural and physiological characteristics between *Iamia* and *Ilumatobacter* and neighboring taxa are indicated in *Table 22.1*.

Iamia Kurahashi et al. 2009, 871[VP]

Iamia (I.a'mi.a. N.L. fem. N. *Iamia* arbitrary name formed from the acronym of the Institute of Applied Microbiology at the University of Tokyo, which has made significant contribution to Microbiology).

Cells are Gram-positive, non-endospore-forming rods that are nonmotile. Colonies grow aerobically, but not anaerobically. In media devoid of sodium chloride, growth is observed. Oxidase- and catalase-positive. The predominant menaquinone is MK-9(H_6). Cell wall contains glutamic acid, alanine, and *meso*-diaminopimelic acid. The peptidoglycan is presumed to be A1γ. The peptidoglycan is of the glycolyl type. The major cellular fatty acids are heptadecanoic acid (C17:0), heptadecenoic acid (C17:1ω8c), pentadecanoic acid (C15:0), and hexadecanoic acid (C16:0). The type species is *Iamia majanohamensis*.

In addition to the properties given in the genus description, the type strain of *Iamia majanohamensis* F12^T shows following characteristics: cells are 1.2–1.7 × 0.3–0.5 μm in size. Colonies on marine agar are small, white, circular, convex, smooth, shiny, and 0.2–0.3 mm in diameter after 3-week incubation at 30 °C. Optimal growth temperature is 28–30 °C. No growth occurs at temperatures above 45 °C or below 10 °C. Hydrolysis of gelatin is observed. Cell-wall sugars are rhamnose, mannose, arabinose, galactose, and xylose. Positive for catalase, oxidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, production of acetoin and gelatinase, and reduction of nitrate to N_2, but negative for β-galactosidase, urease, tryptophan deaminase, utilization of citrate, production of H_2S and indole, and assimilation of amygdalin, arabinose, D-glucose, inositol, D-mannose, melibiose, rhamnose, sucrose, and sorbitol. The DNA G+C content is 74.4 mol%.

The type strain of *Iamia majanohamensis* F12^T was isolated from the ventral epidermis of the sea cucumber *Holothuria edulis* at Aka Island, Okinawa, Japan.

Ilumatobacter Matsumoto et al. 2009[AL]

Ilumatobacter (I.lu.ma.to.bac'ter. Gr. N. *iluma* –atos, sediment deposited in water; N.L. masc. n. *bacter*, a rod, a bacterium; N.L. masc. n. *Ilumatobacter* a rod isolated from a sediment).

Cells are Gram-positive, aerobic, nonmotile rod. The cell-wall peptidoglycan contains LL-diaminopimelic

acid, glycine, alanine, and hydroxyglutamate (molar ratio, ca. 1.4: 2.4: 1.1: 1.0). The acyl type is glycolyl. Predominant menaquinone is MK-9(H_8). Mycolic acids are not detected. The major cellular fatty acids are 14-methyl-pentadecanoic acid (iso-C16:0), 15-methyl- hexadecenoic acid (iso-C17:1ω9c), 15-methyl-hexadecanoic acid (iso-C17:0), 14-methyl-pentadecenoic acid (iso-C16:1), heptadecenoic acid (C17:1ω8c), octadecenoic acid (C18:1ω7c), 16-methyl-hexadecenoic acid (iso-C18:1), and 14-methyl-hexadecanoic acid (anteiso-C17:0). The type species is *Ilumatobacter fluminis*.

In addition to the properties given in the genus description, the type strain of *Ilumatobacter fluminis* shows the following characteristics: The colonies are colorless. The cells are about 0.4–0.5 × 1.3–1.6 μm. Sea water or artificial sea water is needed for growth. The temperature range for growth is 26–31 °C. Growth occurs at pH 7–11. Alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, and β-glucosidase are present, but α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are absent. The G+C content of the genomic DNA of the type strain is 68 mol%. Habitat is marine. The type strain is YM22-133^T.

Isolation, Enrichment, and Maintenance Procedures

Iamia majanohamensis F12^T was isolated from abdominal epidermis of a sea cucumber, *Holothuria edulis*, collected at seawater off the coast of Okinawa, Japan. The medium used for isolation of the strain F12^T was SN medium, consisting of 770-mg $NaNO_3$, 15.9-mg K_2HPO_4, 5.6-mg disodium EDTA dehydrate, 10.4-mg Na_2CO_3, 1-mg vitamin B_{12}, and 1-mg Cyano trace metal solution in filtered 75 % seawater. Cyano trace metal solution is composed of 6.25-g citric acid. H_2O, 6.0-g ferric ammonium citrate, 1.4-g $MnCl_2{\cdot}4H_2O$, 0.39-g $Na_2MoO_4{\cdot}2H_2O$, 0.025-g $Co(NO_3)_2{\cdot}6H_2O$, and 0.222-g $ZnSO_4{\cdot}7H_2O$ in l L of distilled water. The isolate also grows on marine agar (MA) but very slowly, and colonies on MA after 3 weeks at 30 °C were 0.2–0.3 mm in diameter. The strain grows on a medium devoid of sodium chloride. The cultures of *Iamia majanohamensis* F12^T were maintained on marine agar (MA) at 25 °C.

Ilumatobacter fluminis YM22-133^T was isolated from the sediment of an estuary collected at the mouth of the Kuira River, Okinawa, Japan. The sample was homogenized with a glass rod, and the homogenate (50 μL) was placed on "R" medium plates, and was incubated at 25 °C for 30 days.

The isolate also grows on marine agar (MA). The strain requires seawater or artificial seawater for its growth. The culture of *Ilumatobacter fluminis* YM22-133^T was maintained on "R" medium agar at 25 °C.

Ecology

As the habitat of species of two genera in the family *Iamiaceae* is only known for mainly the type strains, information on the ecological niche and on ecological function of members of the family is lacking.

Although the members of the genus *Iamia* were isolated from sea cucumber and the type strain of *Ilumatobacter fluminis* was isolated from sediment of an estuary at mouth of river in Okinawa, Japan, soil or seawater appears to be the natural environment for the member of family *Iamiaceae*.

A high number of environmental clone sequences which are affiliated to the family *Iamiaceae* were obtained from soils and marine circumstances and listed in The NCBI taxonomy Browser (http://www.ncbi.nlm.nih.gov/guide/taxonomy/) and the Green-Gene database (DeSantis et al. 2006), e.g., from Australia caves (AF317769, Holmes et al. 2001), farm soil (AY921876, Tringe et al. 2005), Lake freshwater in Japan (AB154320), heavy oil seeps (EF157223, Kim and Crowley 2007), soil sample collected under a glacier (EU421859), and pasture soil (AY395396). Several clones from marine environments are also listed: Gulf of Mexico sediments (DQ521825, Lloyd et al. 2006), deep-sea octacoral (DQ395467), Antarctic sea water (DQ295238, Grzymski et al. 2006), marine basalt (DQ070822, Mason et al. 2007), and carbonate chimney in hydrothermal field (DQ270650, Brazelton et al. 2006).

The strain of *Iamia majanohaensis* does not require seawater or NaCl for its growth, and therefore, it could not be a marine species. As the strain of *Ilumatobacter* requires seawater for its growth, this species seems to be a marine species.

Strains of "*Candidatus* Microthrix" were isolated from industrial activated sludge wastewater treatment plants. "Microthrix" strains are known to cause solids separation problem known as foaming and bulking. A high number of uncultured clone sequences which have high similarity to "*Candidatus* Microthrix" have been isolated from many environments including soils, activated sludge, wastewater treatment, etc.

Pathogenicity: Clinical Relevance

No information on pathogenicity is available for *Iamia majanohamensis* and *Ilumatobacter fluminis*.

Application

No information on application is available for *Iamia majanohamensis* and *Ilumatobacter fluminis*.

23 The Family *Intrasporangiaceae*

Erko Stackebrandt · Carmen Scheuner · Markus Göker · Peter Schumann
Leibniz Institute DSMZ-German Collection of Microorganisms and Cell Cultures, Braunschweig, Germany

Abstract
The family *Intrasporangiaceae*, proposed on the basis of phylogenetic evidence, is a genus-rich taxon of the order *Micrococcales*, comprising more than 50 species with a wide range of phenotypic and chemotaxonomic properties and thriving in a wide range of habitats. Even at the genus level some taxa are taxonomically heterogeneous. While several genera contain more than a single species, more recently described genera are defined by only their type strain. In contrast to earlier phylogenetic analysis, recent evidence shows the polyphyletic structure of the family with some genera branching outside the core of the family. *Tetrasphaera*, *Janibacter*, and *Terrabacter* species are of ecological importance as they are involved in biological phosphate removal from wastewater and bioremediation processes. The clinical significance is low though the number of reports including members of the family being involved in infections as opportunistic pathogens is increasing.

Taxonomy, Historical and Current

The family *Intrasporangiaceae* was established on the basis of the phylogenetic position of members of the genera *Intrasporangium*, *Sanguibacter*, and *Terrabacter* and a set of unique 16S rRNA gene sequence signatures. It was placed within the suborder *Micrococcineae*, order *Actinomycetales* (Stackebrandt et al. 1997). Later, the genus *Sanguibacter* was excluded as a family of its own (Stackebrandt and Schumann 2000) and the genera *Terracoccus* and *Janibacter* were included into the emended family *Intrasporangiaceae*. Since then, a large number of newly described genera have been affiliated to the family which at the time of writing harbors 19 genera and more than 55 species. In the latest edition of *Bergey's Manual of Systematic Bacteriology* (Goodfellow et al. 2012) *Micrococcineae*, covering 16 genera, was elevated to order rank, *Micrococcales* (Busse 2012), phylum Actinobacteria. The set of signature nucleotides given originally for the family (Stackebrandt et al. 1997) was emended by Stackebrandt and Schumann (2000), Zhi et al. (2009), who also gave the signatures for the 16 genera covered. Members of the family have been isolated from sea and lake sediments, soil, ultrapure water, salt mines and mine waste, activated sludge, corals, insects, rotten melons, marine waters, and the upper stratosphere. It is therefore not surprising that the family is heterogeneous with respect to morphology (cocci, rods, rod-coccus cycle, and mycelia), relation to oxygen (aerobic to facultatively anaerobic), and the diagnostic amino acid composition of peptidoglycan

E. Rosenberg et al. (eds.), *The Prokaryotes – Actinobacteria*, DOI 10.1007/978-3-642-30138-4_176,

(meso-A_2pm [type A1γ], LL-A_2pm [A3γ], and ornithine [A4β]). The majority of strains encompass the menaquinones MK-8(H_4), but MK-10(H_4) and the fully saturated MK-8 type are also represented. The complex cellular fatty acids include iso- and anteiso-branched chain acids and monounsaturated straight-chain acids. Phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol are the major polar lipids. Table 23.1 lists all validly published species names, together with the type strain designation and their isolation source. A comparison of morphological and chemotaxonomic traits is given in Table 23.2, while Tables 23.3–23.11 compile some cultural, metabolic, and some additional chemotaxonomic data. It should be noted that several species descriptions are incomplete with respect to presenting chemotaxonomic properties as devised by Schumann et al. (2009) in the Minimal Standards list of recommended properties for characterization and differentiation of genera and species classified in the suborder *Micrococcineae* (now order *Micrococcales*).

Phylogenetic Structure of the Family and Its Genera

Phylogenetic analysis of genera based upon the RAxML algorithm (Fig. 23.1) analyses of 16 S rRNA gene sequences of nearly all type strains of the family sees a clustering of most species according to their genus affiliation. The genera, however, do not cluster exclusively according to the diagnostic amino acid of peptidoglycan: *Terrabacter* (note that *T. aeriphilus* appears to be more closely related to *Terracoccus luteus*), *Terracoccus*, *Humibacillus*, and *Intrasporangium* all contain LL-A_2pm, but *Lapillibacillus*, also possessing LL-A_2pm, groups with genera containing meso-A_2pm. *Phycicoccus* is not a coherent genus, as the type species *P. jejuensis* groups with *Ornithinibacter aureus* and *Fodinibacter luteus*. Members containing ornithine in their peptidoglycan are found at different positions in the dendrogram. This relationship, however, is not supported by chemotaxonomic evidence (Table 23.2). The family *Intrasporangiaceae* appears not to be a coherent taxon: both RAxML and NJ (not shown) analyses see the family to consist of two sister clades, the first one embracing the majority of genera and the second one not only containing the pairs *Ornithinimicrobium* and *Serinicoccus* and *Marihabitans* and *Arsenicicoccus*, but also, in addition, members of the families *Dermacoccacea* and *Dermatophilaceae*. The relationship of one or more members of *Intrasporangiaceae* to *Dermatophilus* and *Dermacoccus* has been noted before in the literature, e.g., Stackebrandt (2012), in the original description of *Arsenicicoccus piscis* (Hamada et al. 2009), and the phylogenetic closeness between *Intrasporangiaceae* and *Dermatophilaceae* with *Marihabitans* clustering with members of the latter family is also obvious in the dendrogram shown by Schumann et al. (2009). *Arsenicicoccus* and *Marihabitans* contain A_2pm isomers as diagnostic amino acids of peptidoglycan, while *Ornithinimicrobium* and *Serinicoccus* possess ornithine. Members of *Dermacoccaceae* contain L-Lys at position 3 of the peptidoglycan subunit, and the interpeptide bridge contains a dicarboxyl amino acid, while *Dermatophilus* contains meso-A_2pm, like some other members of *Intrasporangiaceae* which cluster in the main clade. From the viewpoint of phylogenetic consistency either families *Dermacoccaceae* and *Dermatophilaceae* need to be included in *Intrasporangiaceae*, or a new family could be created for the genera *Ornithinimicrobium* and *Serinicoccus* (which would be supported by chemotaxonomic evidence), *Arsenicicoccus* could be described as a member of *Dermatophilaceae*, while *Marihabitans* would constitute a family of its own. Family-specific 16S rRNA signature nucleotide sets would have to be searched for in order to support this decision.

A more detailed view of the relationship among species is depicted in Fig. 23.2.

Molecular Analyses

DNA-DNA Hybridization (DDH) Studies

This method has been used extensively to delineate novel strains from validly named species (<70 %) and to allocate strains to the same species (>70 %). The latter tests included, among others, strains of *Kribbia dieselivorans* (Jung et al. 2006), *Oryzihumus leptocrescens* (Kageyama et al. 2005), *Janibacter melonis* (Yoon et al. 2004), *Tetrasphaera jenkinsii* (McKenzie et al. 2006), and *Janibacter terrae* (Lang et al. 2003). A wide range of DDH methods has been used which explains the lack of correlation between DHH values and 16S rRNA gene sequence similarity values. Two main DDH methods dominate, the fluorimetric method of Ezaki et al. (1989) and the thermal reassociation method of De Ley et al. (1970), modified by Huss et al. (1983). Other methods were the radioactive filter method of Seldin and Dubnau (1985), the membrane filter method of Tourova and Antonov (1987), the method of Takahashi et al. (1993), the modified hydroxyapatite method of Ziemke et al. (1998), and the genome-based microarray approach (Bae et al. 2005).

The intraspecific relatedness of *Tetrasphaera jenkinsii* was also determined by 16-23S RNA intergenic fingerprinting (McKenzie et al. 2006). *rpoC1* gene analysis was performed on some *Tetrasphaera* type strains (McKenzie et al. 2006). In situ FISH probes have been designed on the basis of strains described by Maszenan et al. (2000) and are useful to detect these strains in wastewater and to differentiate them from related, yet undescribed members of the genus (Kong et al. 2005).

Riboprinting

The restriction enzyme *Pvu*II is superior to *Eco*RI in generating multiband patterns for members of the family *Intrasporangiaceae*. However, DNA may remain partially undigested, causing the band at ca. 50 kbp in some patterns (see Fig. 23.2).

Table 23.1

Alphabetical list of genera and species, designated type strains, effective publication, and the habitat of type strains

Genus and species	Type strain	Authors	Habitat of isolation
Aquipuribacter hungaricus	IV-75^T	Tóth et al. (2012)	Ultrapure water, power plant purification system, Hungary
Arsenicicoccus bolidensis	CCUG47306^T	Collins et al. (2004)	Lake mine waste sediment, Boliden, Sweden
Arsenicicoccus piscis	Kis4-19^T	Hamada et al. (2009)	Intestinal tract of Japanese fish
Fodinibacter luteus	YIM C003^T	Wang et al. (2009)	Wall of a salt mine, Yunnan, China
Humibacillus xanthopallidus	KV-663^T	Kageyama et al. (2008a)	Paddy field soil, Saitama Prefecture, Japan
Intrasporangium calvum	7KIP^T	Kalakoutskii et al. (1967)	Air in a school dining room, Russia
Intrasporangium chromatireducens	Q5-1^T	Liu et al. (2012a)	Manganese mine soil, Hunan, China
Intrasporangium mesophilum	YIM 49065^T	Yang et al. (2012)	Soil, *Jatropha curcas*, Yunnan, China
Intrasporangium oryzae	KV-657^T	Yang et al. (2012)	Soil, paddy field, Saitama, Japan
Janibacter alkaliphilus	SCSIO 10480^T	Li et al. (2012)	Gorgonian coral *Anthogorgia* sp., Weizhou Island, China
Janibacter anophelis	H2.16B^T	Kämpfer et al. (2006)	Midgut of *Anopheles arabiensis*, Kenya
Janibacter corallicola	04PA2-Co5-61^T	Kageyama et al. (2007)	Hard coral *Acropora gemmifera*, Angauru, Palau
Janibacter hoylei	PVAS-1^T	Shivaji et al. (2009)	40–41.4 km altitude, Hyderabad, India
Janibacter limosus	HKI 83^T	Martin et al. (1997)	Wastewater sludge, Jena, Germany
Janibacter melonis	CM2104^T	Yoon et al. (2004)	Spoiled oriental melon, Korea
Janibacter terrae	CS12^T	Yoon et al. (2000)	Soil from around a wastewater treatment plant in Korea
Knoellia aerolata	5317S-21^T	Weon et al. (2007a)	Air sample, Suwon, Korea
Knoellia flava	TL1^T	Yu et al. (2012)	Pig manure, Wuhan, China
Knoellia locipacati	DMZ1^T	Shin et al. (2012)	Soil sample, demilitarized Zone, Korea
Knoellia sinensis	HKI 0119^T	Groth et al. (2002)	Soil from a cave, Guilin, China
Knoellia subterraneae	HKI 0120^T	Groth et al. (2002)	Soil from a cave, Guilin, China
Kribbia dieselivorans	N113^T	Jung et al. (2006)	Tidal flat sediment, Kwangyang, Korea
Lapillicoccus jejuensis	R-Ac013^T	Lee and Lee (2007)	Stone from agricultural field, Jeju, Korea
Marihabitans asiaticum	HG667^T	Kageyama et al. (2008b)	Surface seawater, Kesennuma port, Japan
Ornithinibacter aureus	HB09001^T	Xiao et al. (2011a)	Seawater South China Sea, Hainan, China
Ornithinimicrobium humiphilum	HKI 0124^T	Groth et al. (2001)	Garden soil, Giessen, Germany
Ornithinimicrobium kibberense	K22-20^T	Mayilraj et al. (2006)	Soil, Lahaul-Spiti Valley, Himalayas, India
Ornithinimicrobium murale	01-Gi-040^T	Kämpfer et al. (2013)	Mold-colonized cellar wall, Giessen, Germany
Ornithinimicrobium pekingense	LW6^T	Liu et al. (2008)	Activated sludge from a sequential batch reactor
Ornithinicoccus hortensis	HKI 0125^T	Groth et al. (1999)	Garden soil, Giessen, Germany
Oryzihumus leptocrescens	KV-628^T	Kageyama et al. (2005)	Paddy field soil, Saitama Prefecture, Japan
Phycicoccus aerophilus	5516 T-20^T	Weon et al. (2008)	Air sampler, Taean region, Korea
Phycicoccus bigeumensis	MSL-03^T	Dastager et al. (2008)	Soil sample, Bigeum Island, Korea
Phycicoccus badiiscoriae	Sco-B23T	Lee (2013)	Scoria layer, Darangshi Oreum mountain, Jeju, Korea
Phycicoccus cremeus	V2M29^T	Zhang et al. (2011)	Forest soil, Changbai Mountains, China
Phycicoccus dokdonensis	DS-8^T	Yoon et al. (2008)	Soil, Dokdo, Korea
Phycicoccus ginsenosidimutans	BXN5-13^T	Wang et al. (2011)	Soil of ginseng field, Baekdu Mountain, Korea
Phycicoccus jejuensis	KSW2-15^T	Lee, (2006)	Dried seaweed, Gwakji beach, Jeju, Korea
Serinicoccus chungangensis	CAU 9536^T	Traiwan et al. (2011)	Tidal flat sediment, Seogmo Island, Yellow Sea, Korea
Serinicoccus marinus	JC1078^T	Yi et al. (2004)	Surface sea water, East Sea, China
Serinicoccus profundi	MCCC 1A05965^T	Xiao et al. (2011b)	Deep sea sediment (5,368 m), Indian Ocean
Terrabacter aeriphilus	5414 T-18^T	Weon et al. (2010)	Air sampler, Taean region, Korea
Terrabacter aerolatus	5516 J-36^T	Weon et al. (2007b)	Air sampler, Jeju, Korea

Table 23.1 (continued)

Genus and species	Type strain	Authors	Habitat of isolation
Terrabacter carboxydivorans	PY2^T	Kim et al. (2011)	Soil sample, Yonsei University, Seoul, Korea
Terrabacter ginsenosidimutans	Gsoil 3082^T	An et al. (2010)	Soil of ginseng field, Korea
Terrabacter lapilli	LR-26^T	Lee et al. (2008)	Stone from agricultural field, Jeju, Korea
Terrabacter terrae	PPLB^T	Montero-Barrientos et al. (2005)	Soil mixed with Iberian pig hair, Spain
Terrabacter terrigena	ON10-^{T}	Yoon et al. (2009)	Soil around a wastewater treatment plant, Korea
Terrabacter tumescens	NCIB 8914^T	Collins et al. (1989)	Soil, Australia Jensen (1934, 1933)
Terracoccus luteus	IMET 7848^T	Prauser et al. (1997)	Bank of duck pond, Hiddensee, Germany
Tetrasphaera australiensis	Ben 109^T	Maszenan et al. (2000)	Activated sludge, Glenelg, Australia
Tetrasphaera duodecadis	IAM 14868^T	Ishikawa and Yokota (2006)	Arable soil
Tetrasphaera elongata	Lp2^T	Hanada et al. (2002)	Activated sludge reactor, Japan
Tetrasphaera japonica	T1-X7^T	Maszenan et al. (2000)	Activated sludge, Japan
Tetrasphaera jenkinsii	Ben 74^T	McKenzie et al. (2006)	Activated sludge, Glenelg, Australia
Tetrasphaera remsis	3-M5-R-4^T	Osman et al. (2007)	Life support module simulator, Pasadena, USA
Tetrasphaera vanveenii	Ben 70^T	McKenzie et al. (2006)	Activated sludge, Carrum, Australia
Tetrasphaera veronensis	Ver 1^T	McKenzie et al. (2006)	Activated sludge, Verona, italy

Table 23.2

Morphological and chemotaxonomic characteristics of genera of *Intrasprongiaceae*. Following the type genus *Intrasporangium* the order of other genera is according to peptidoglycan types: *Arsenicoccus* (Collins et al. 2004), *Terracoccus* (Prauser et al. 1997), *Humibacillus* (Kageyama et al. 2008a), *Lapillicoccus* (Lee and Lee 2007), *Terrabacter* (Collins et al. 1989), *Janibacter* (Martin et al. 1997), *Fodinibacter* (Wang et al. 2009), *Knoellia* (Groth et al. 2002), *Tetrasphaera* (Maszenan et al. 2000), *Phycicoccus* (Lee 2006), *Marihabitans* (Kageyama et al. 2008b), *Kribbia* (Jung et al. 2006), *Aquipuribacter* (Tóth et al. 2012), *Oryzihumus* (Kageyama et al. 2005), *Ornithinibacter* (Xiao et al. 2011a), *Ornithinicoccus* (Groth et al. 1999), *Ornithinimicrobium* (Groth et al. 2001), and *Serinicoccus* (Yi et al. 2004). Major polar lipids and fatty acids are those common to all species of the respective genus, as compiled (with the exception of compilations for *Ornithinimicrobium* and *Terrabacter* species) from the original species descriptions. Species-specific variations are listed in *Tables 23.3–23.10* and in the original genus descriptions

Properties	*Intrasporangium*	*Arsenicicoccus*	*Terracoccus*	*Humibacillus*	*Lapillicoccus*
Number of species	4	2	1	1	1
Morphology	Branching mycelium	Cocci, clusters	Cocci, singly or packets	Irregular rods	Cocci
Metabolism	Aerobic	Facultative anaerobic	Aerobic	Aerobic	Aerobic
Peptidoglycan type according to Schleifer and Kandler (1972) (nomenclature according to www.peptidoglycan-types.info)	A3γ (A41.2)	A3γ (A41.1)	A3γ (A41.2)	A3γ (no term available)	A3γ (ND)
Diagnostic peptidoglycan diamino acid-interpeptide bridge[a]	LL-A_2pm–Gly_3 (α-carboxyl group of D-Glu substituted by Gly)	LL-A_2pm-Gly	LL-A_2pm-Gly_3 (α-carboxyl group of D-Glu substituted by Gly)	LL-A_2pm-Gly_2	LL-A_2pm-ND
Major polar lipids[b]	PG, DPG, PI, PIM	PG, DPG, PI, PE[c]	PG, DPG, PI, PE	ND	DGP, PI
Major fatty acids (>10 %) common to all members of the genus[d]	i-$C_{15:0}$, ai-$C_{16:0}$, i-$C_{16:0}$	i-$C_{15:0}$, i-$C_{16:0}$, i-$C_{14:0}$	i-$C_{15:0}$, ai-$C_{15:0}$, $C_{16:0}$	i-$C_{15:0}$	i-$C_{16:0}$, i-$C_{15:0}$, $C_{17:1}\omega$8c

Cell-wall/whole-cell sugars[e]	ND	Glc	Glc, Ara, Xyl[c]	Glc, Rib[c]
G+C content	70	72	69–71	72–74

Symbols and abbreviations: + positive, − negative, *w* weakly positive, nd not determined, *v* variable

[a] A_2pm, diaminopimelic acid; Gly, glycine; Asp, aspartic acid; Orn, ornithine. The interpeptide bridge composition has not always been investigated

[b] *PG* phosphatidylglycerol, *DGP* diphosphatidylglycerol, *PI* phosphatidylinositol, *PIM* phosphatidylinositol mannoside, *PE* phosphatidylethanolamine, *u* unknown, *GL* glycolipid, *PL* phospholipid, *PGL* phosphoglycolipid

[c] Not all species investigated

[d] A number before a colon indicates the number of carbons; the number after the colon is the number of double bonds; iso- indicates a methyl branch at the iso position; anteiso- indicates a methyl branch at the anteiso position

[e] Ara, arabinose; Gal, galactose, Glc, glucose; Man, mannose; Rha, rhamnose; Rib, ribose; Xyl, xylose

[f] *meso*-A_2pm and 3-hydroxy *meso*-A_2pm as well as aspartic acid as constituent of the interpeptide bridge were reported by Ishikawa and Yokota (2006)

[g] *S. chungangensis* displays the peptidoglycan type A1γ (A31) according to Traiwan et al. (2011)

[h] *O. pekingense* contains lysine as additional diamino acid according to Liu et al. (2008) and *O. murale* contains no aspartic but glutamic acid in the interpeptide bridge (Kämpfer et al. 2013)

[i] Data from Kämpfer et al. (2013) who compared all four species in a single study

[j] MK-8 in *I. calvum* was reported by Collins et al. (1984) and Kageyama et al. (2007), while Yang et al. (2012) found MK-8(H_4); see section Genus *Intrasporangium* Kalakoutskii et al. (1967)

The *Pvu*II RiboPrint patterns served for the classification of eight dibenzofuran-degrading strains that agreed in their *Pvu*II RiboPrint patterns with this of *Janibacter brevis* DSM 13953^T (Lang et al. 2003). Though the species *Janibacter brevis* and *Janibacter terrae* were considered synonymous due to agreement in phenotypic characteristics and a high DNA-DNA similarity value, RiboPrinting revealed that their type strains are not identical and differ in their strain-specific patterns from one another and both from this of *Janibacter limosus* DSM 11140^T (Lang et al. 2003; *Fig. 23.2*). However, the type strains of *Janibacter terrae* DSM 13876^T and *Janibacter anophelis* DSM 18333^T (98.4 % 16S rRNA gene sequence similarity) display almost identical *Pvu*II RiboPrint patterns (*Fig. 23.2*).

MALDI-TOF

The MALDI-TOF mass spectra of species of the family *Intrasporangiaceae* differ sufficiently to be well suited for their identification. The most similar spectra were obtained for the type strains of the synonymous species *Janibacter terrae* and *Janibacter brevis* which share 80.6 % DNA-DNA similarity (Lang et al. 2003) but differ in their *Pvu*II RiboPrint patterns (*Fig. 23.3*; Lang et al. 2003). Though there are several exceptions, most spectra of type strains of *Intrasporangiaceae* species cluster according to their genus affiliation (*Fig. 23.4*). The MALDI-TOF mass spectra of *Terrabacter*, *Terracoccus*, *Intrasporangium*, and *Humibacillus* species cluster together in agreement with the respective

Table 23.3

Additional properties apt to differentiate type strains of *Intrasporangium* species (see Table 23.1). 1. *I. calvum*; 2. *I. mesophilum*; 3. *I. oryzae*; 4. *I. chromatireducens*

Properties	1	2	3	4
Morphology	Branching and fragmenting mycelium	Branching and fragmenting mycelium	Fragmentary vegetative mycelium	Branching hyphae

[a]Fatty acid data of *I. calvum*, *I. mesophilum*, and *I. oryzae* from Yang et al. (2012) and Kageyama et al. (2007), data of *I. chromatireducens* from Liu et al. (2012a)

clustering in Fig. 23.2 though MALDI-TOF mass spectrometry does not demonstrate the total phylogenetic structure of the family *Intrasporangiaceae* when compared to the 16S rRNA sequence-based dendrograms (Fig. 23.4 vs. Figs. 23.1 and 23.2).

Genome Comparison

As of January 2013, the Genomes OnLine Database (Pagani et al. 2012) contained 26 registered genome projects of *Intrasporangiaceae*, *Dermacoccaceae*, and *Dermatophilaceae*. Thereof, genome sequences of nine species were available with protein sequences in GenBank with seven type strains among them. These and the outgroup (*Kineococcus*) genomes were *Austwickia chelonae* NBRC 105200^T (BAGZ00000000), *Dermacoccus* sp. Ellin185 (AEIQ00000000), *Intrasporangium calvum* DSM 43043^T (Del Rio et al. 2010; CP002343), *Janibacter hoylei* PVAS-1^T (Pawar et al. 2012; ALWX00000000), *Janibacter* sp. HTCC2649 (Thrash et al. 2011; AAMN00000000), *Kineosphaera limosa* NBRC 100340^T (BAHD00000000), *Kytococcus sedentarius* DSM 20547^T (Sims et al. 2009; CP001686), *Mobilicoccus pelagius* NBRC 104925^T (BAFE00000000), *Serinicoccus profundi* MCCC 1A05965^T (Xiao et al. 2011c; AFYF00000000), and *Kineococcus radiotolerans* SRS30216^T (Bagwell et al. 2008; CP000750-CP000752). The genome sequences were phylogenetically investigated as described in Spring et al. (2010),

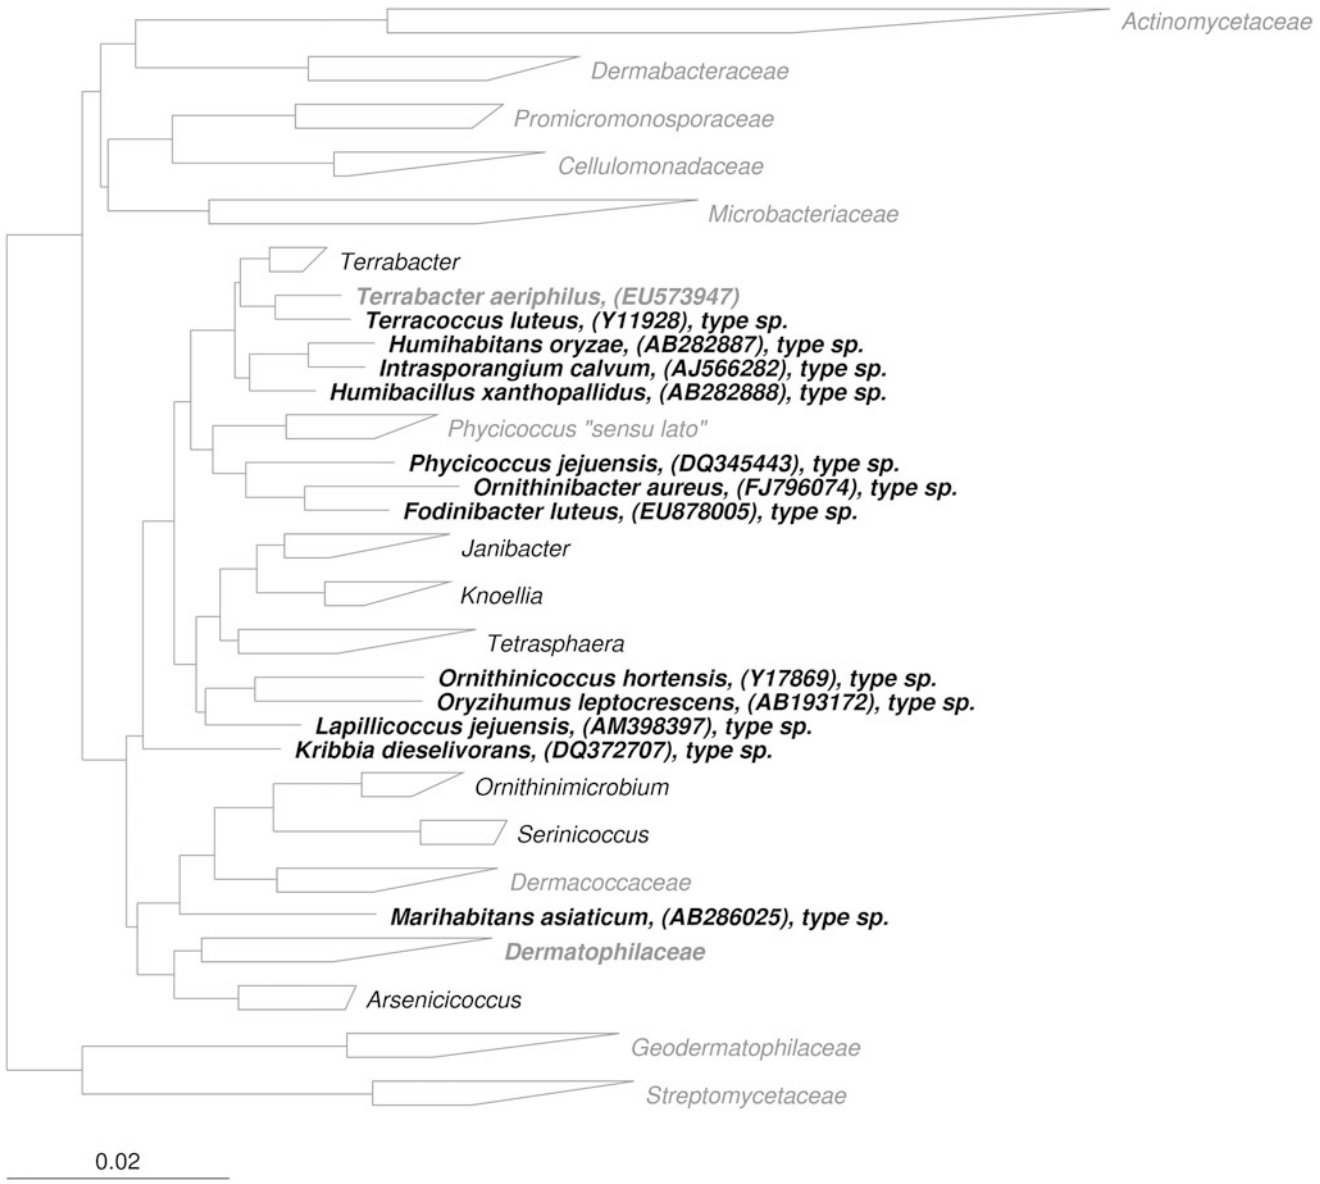

Fig. 23.1

Phylogenetic reconstruction of the family *Intrasporangiaceae* and related families based on16S rRNA gene sequences and created using the neighbor-joining algorithm with the Jukes-Cantor correction. The sequence data sets and alignments were used according to the All-Species Living Tree Project (LTP) database (Yarza et al. 2010; http://www.arb-silva.de/projects/living-tree). The tree topology was stabilized with the use of a representative set of nearly 750 high-quality type strain sequences proportionally distributed among the different bacterial and archaeal phyla. In addition, a 40 % maximum frequency filter was applied in order to remove hypervariable positions and potentially misplaced bases from the alignment. Scale bar indicates estimated sequence divergence

Anderson et al. (2011), Göker et al. (2011), and Abt et al. (2012). That is, maximum likelihood (ML) and maximum-parsimony (MP) phylogenetic trees were inferred from two distinct supermatrices (concatenated alignments), a "full" matrix using all alignment comprising at least four sequences and a matrix using the "core genes" only, i.e., those alignments containing 10 sequences, as well as from the ortholog-content and from the gene-content matrix.

The "full" supermatrix contained 2,778 genes and 847,312 characters, whereas the core-gene supermatrix comprised 744 genes and 229,331 characters. Both matrices were analyzed under ML with the suggested model, PROTGAMMAJTTF. The resulting trees had an identical topology, which is shown in *Fig. 23.5a* together with ML and MP bootstrap support values. The best MP core-gene tree was topologically identical to the ML trees, whereas the MP tree inferred from the "full" supermatrix positioned the clade comprising *Kytococcus sedentarius* DSM 20547^T and *Serinicoccus profundi* MCCC 1A05965^T as sister clade of the other ingroup organisms and grouped *Dermacoccus* sp. Ellin185 as sister taxon to the

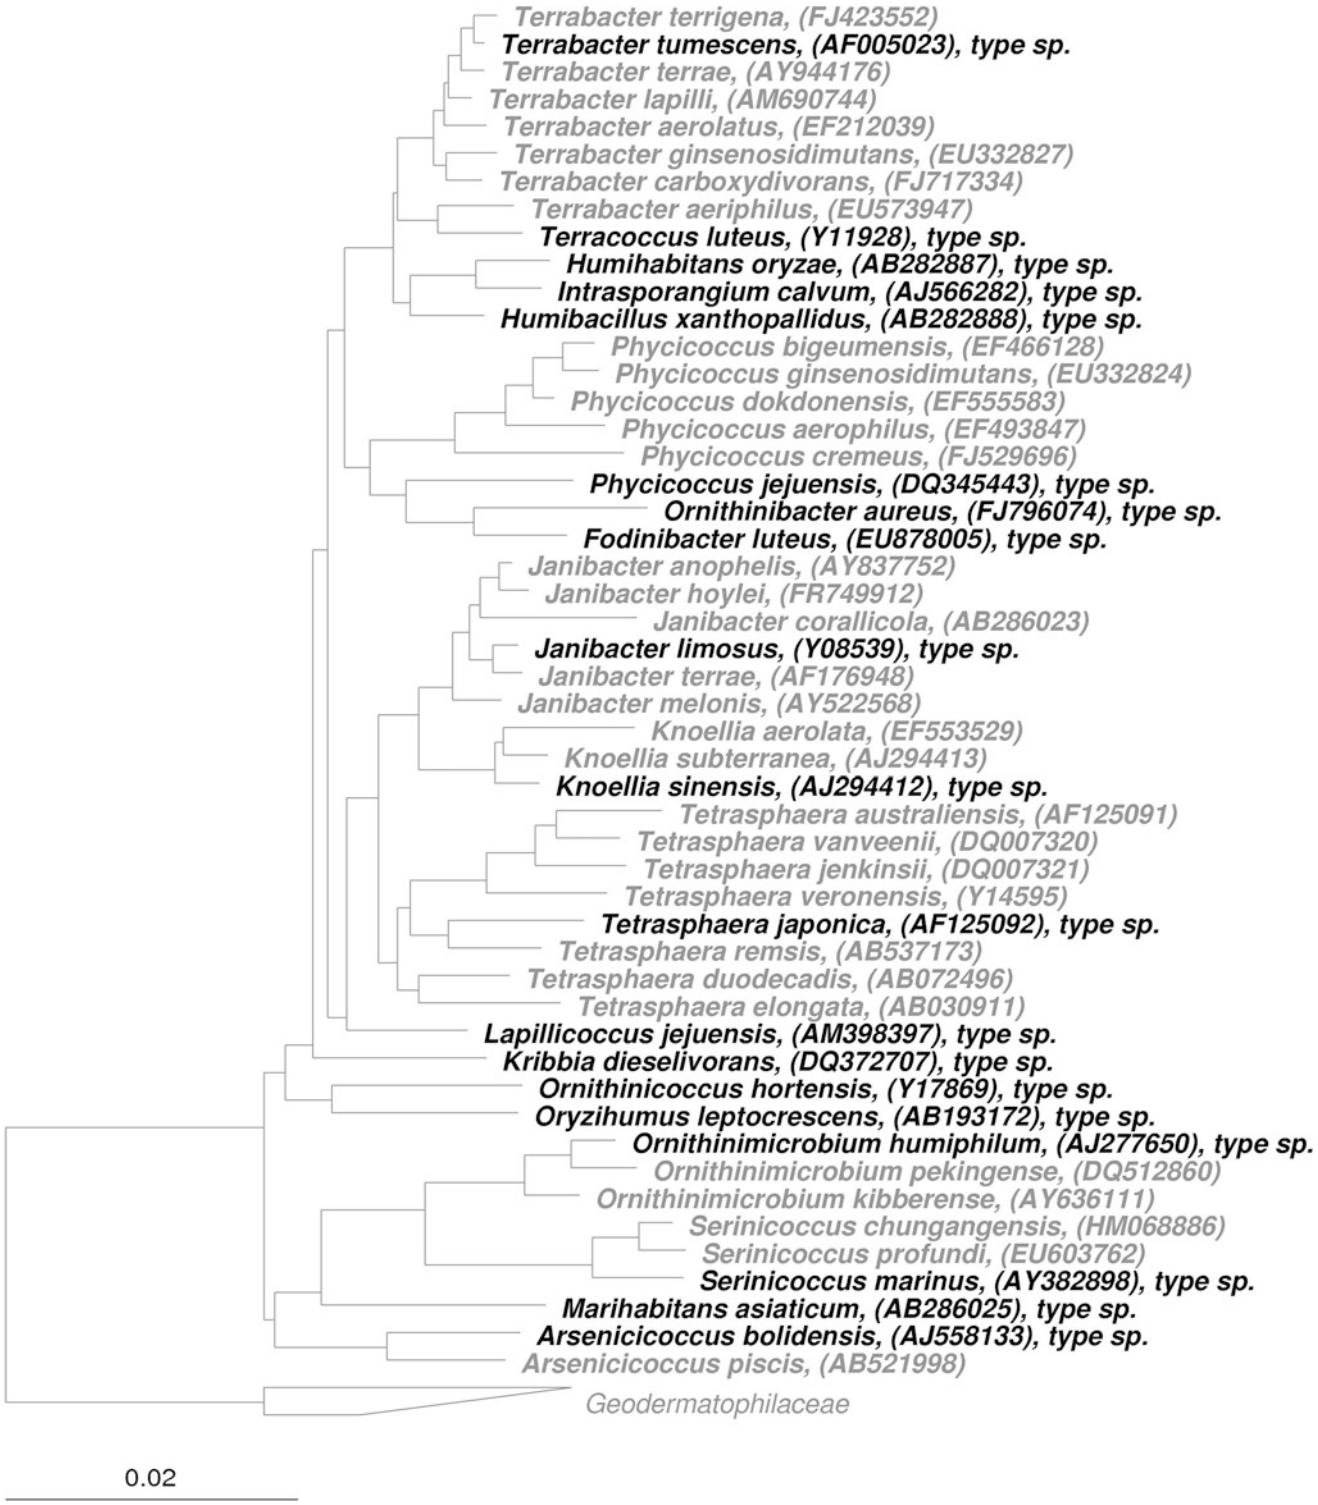

Fig. 23.2

Phylogenetic reconstruction of *Intrasporangiaceae* species based on16S rRNA gene sequences and created using the neighbor-joining algorithm with the Jukes-Cantor correction. For details of tree generation, see legend to *Fig. 23.1*

other ingroup clades except the previously described one (data not shown). Support was maximum (100 %) for all branches except for the two previously described branches under ML and MP (*Fig. 23.5a*).

The gene-content matrix comprised 8,499 characters, the ortholog-content matrix 11,943 characters. For both matrices, the BINGAMMA model was used as implemented in RAxML (Stamatakis 2006). ML and MP trees from both matrices were

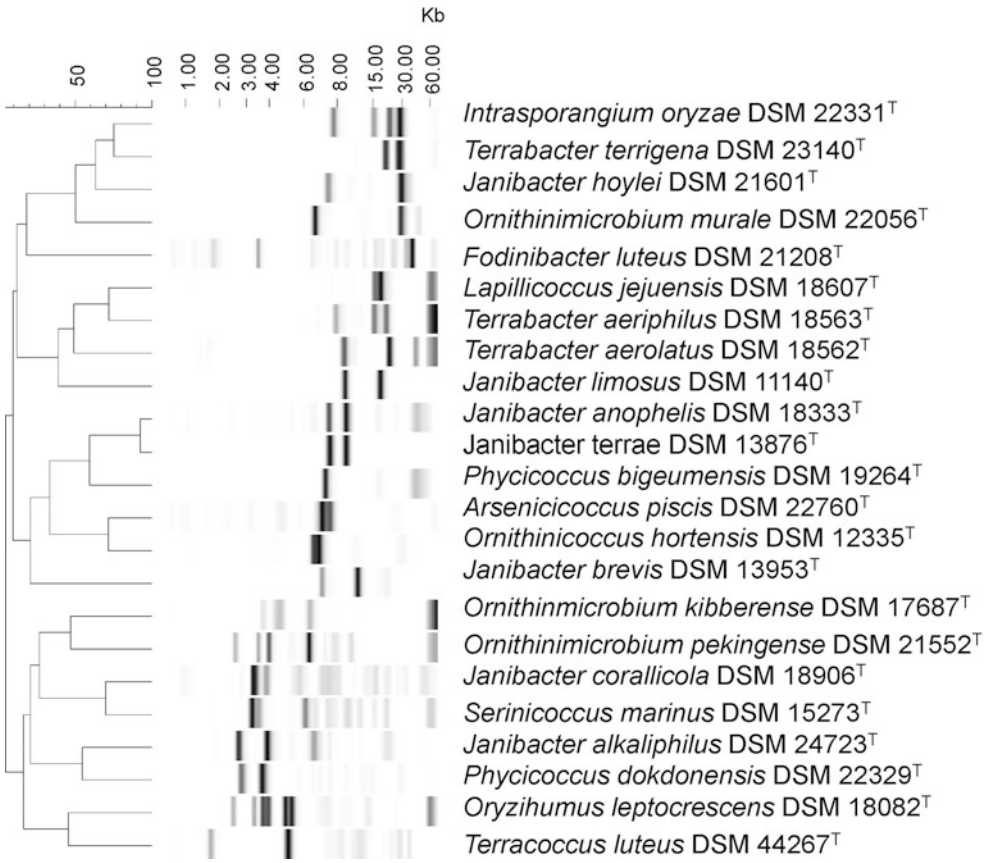

Fig. 23.3

***Pvu*II RiboPrint patterns of selected type strains of *Intrasporangiaceae* species. The dendrogram has been generated with the BioNumerics software (Applied Math, Kortrijk, Belgium)**

topologically identical and are shown in *Fig. 23.5b* with bootstrap support values. In contrast to the supermatrix trees, a maximally supported clade comprising *Janibacter* sp. HTCC2649 and *Intrasporangium calvum* DSM 43043^T was revealed.

Both phylogenetic trees (*Fig. 23.5a*, *b*) support the monophyly of *Dermatophilaceae* (which are, however, only represented by *Mobilicoccus pelagius* NBRC 104925^T, *Kineosphaera limosa* NBRC 100340^T, and *Austwickia chelonae* NBRC 105200^T), whereas the family *Intrasporangiaceae* did not form a monophyletic group in either tree. Rather, they clustered into two distinct clades, each together with *Dermatococcaceae* species, confirming the 16S rRNA analysis shown above.

FISH Probes

An oligonucleotide probe, combined with microautoradiography and histochemical staining, was designed to monitor the diversity of *Tetrasphaera* strains in wastewater treatment systems with enhanced biological phosphorus removal (EBPR). Quantitative FISH analyses showed that the *Tetrasphaera*-specific probe displayed different morphologies, and positively reacting cells constituted up to 30 % of the total biomass (Xia et al. 2008).

Phages

Using the type strains of *Tetrasphaera elongata, T. japonica, T. australiensis*, and *T. jenkinsii* as target strains, a plaque was observed on *T. jenkinsii* lawn using an enriched sample from the wastewater treatment plant in Carrum (Victoria, Australia). The phage TJE1, belonging to the *Caudovirales*, produced lytic plaques on *T. jenkinsii* DSM 17519^T but not on the other tested strains of *Tetrasphaera*, nor on any of the other 65 actinobacterial cultures screened. The complete genome sequence of 49,219 bp and 66 putative open reading frames could be divided into three functional modules comprising (i) a DNA modification, replication, and cell lysis, (ii) a DNA packaging and structure, and (iii) a module encoding host interacting proteins. Only 16 ORFs (24 %) could be assigned a putative function on the basis of their amino acid identity with other proteins in the GenBank database or by the presence of functionally conserved motifs (Petrovski et al. 2012).

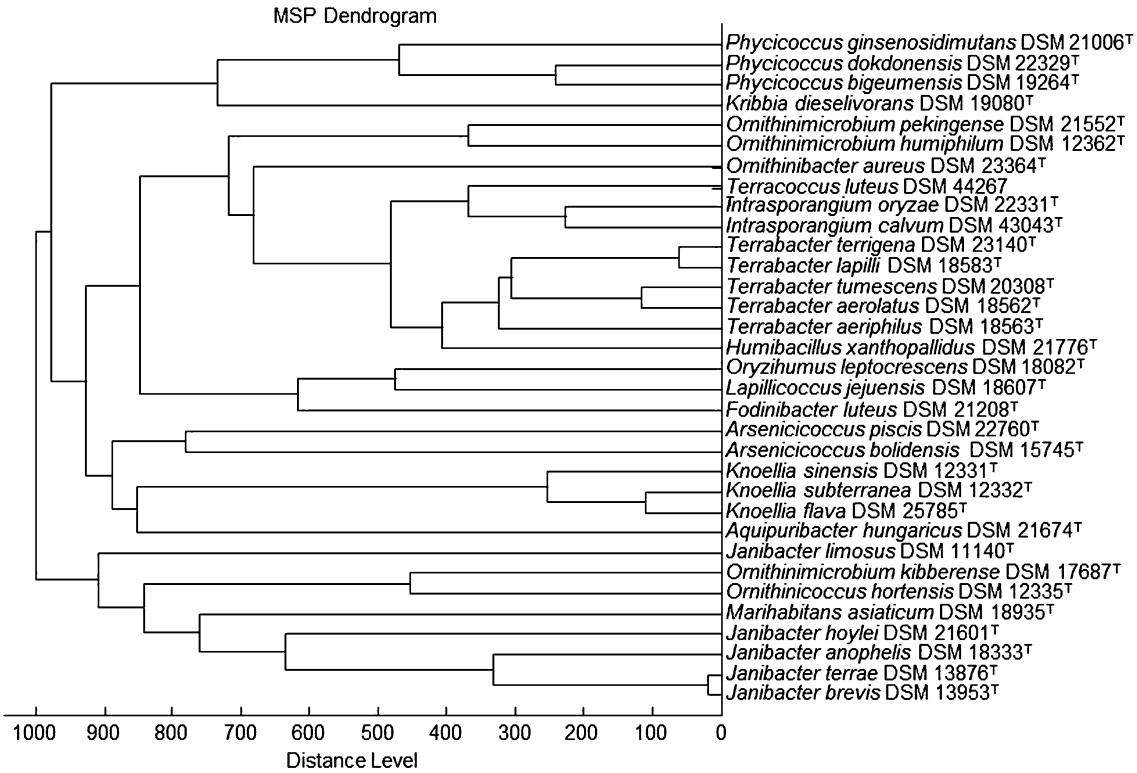

Fig. 23.4

Score-oriented dendrogram generated by the BioTyper software (version 2.0, Bruker Daltonics) showing the similarity of MALDI-TOF mass spectra of cell extracts of selected type strains of the family *Intrasporangiaceae*

Phenotypic Analyses

The main features of members of *Intrasporangiaceae* are listed in Table 23.2. Rather than giving detailed phenotypic traits, only properties used in the differentiation of species within individual genera and some common properties are given in Tables 23.3–23.11. The original descriptions are indicated in Table 23.1.

Genus *Intrasporangium* Kalakoutskii et al. 1967

In.tra.spo.ran'gi.um. L.prep. *intra* within; Gr. n. *spora* a seed; gr. h. *angelon* a vessel; N.L. neut. N. *Intrasporangium* a name coined to emphasize the possibility of intercalary formation of sporangia in mycelium filaments.

The genus includes the species *Intrasporangium calvum* (Kalakoutskii et al. 1967), *Intrasporangium mesophilum* (Yang et al. 2012), *Intrasporangium chromatireducens* (Liu et al. 2012a), and *Intrasporangium oryzae* (Yang et al. 2012), the latter resulting from the reclassification of the species *Humihabitans oryzae* (Kageyama et al. 2007). Menaquinone MK-8(H_4) was detected as major isoprenoid quinone in *I. chromatireducens*, *I. mesophilum*, and *I. oryzae*. However, there are conflicting data on the major menaquinone of the type strain of *I. calvum*: While Kalakoutskii (1989), Collins et al. (1984), and Kageyama et al. (2007) agreed in reporting MK-8 as menaquinone of the type strains *I. calvum* KIP 7^T, IMET 7816^T, and NBRC 12989^T, Yang et al. (2012) found MK-8(H_4) as the major menaquinone of the type strain *I. calvum* DSM 43043^T. The latter observation and additional information on the fatty acid and polar lipid composition gave rise to the emendation of the description of the genus *Intrasporangium* (Yang et al. 2012). A recent reexamination of the menaquinone compositions by HPLC and mass spectrometry of *I. calvum* type strains with identical 16S rRNA gene sequences from different culture collections by Hamada and Schumann (unpublished) confirmed the presence of MK-8(H_4) as the major menaquinone in the type strains *I. calvum* DSM 43043^T and NRRL B-3866^T. However, after cultivation under the same conditions, MK-8 was the predominant menaquinone in *I. calvum* NBRC 12989^T, while ca. 70 % MK-8 and 30 % MK-8(H_4) co-existed in strain IMET 7816^T that represented the oldest genuine deposition of the type strain KIP 7^T in a service culture collection (IMET Jena, German Democratic Republic) and had been maintained as stab culture above liquid nitrogen since 1966. This study supports the view that the type strain of *I. calvum* has the potential to produce both menaquinones MK-8 and MK-8(H_4) and it might depend on the way of long-term storage and reactivation in which menaquinone occurs as the major component. Additional data than those shown in Table 23.3 are listed in the original species descriptions.

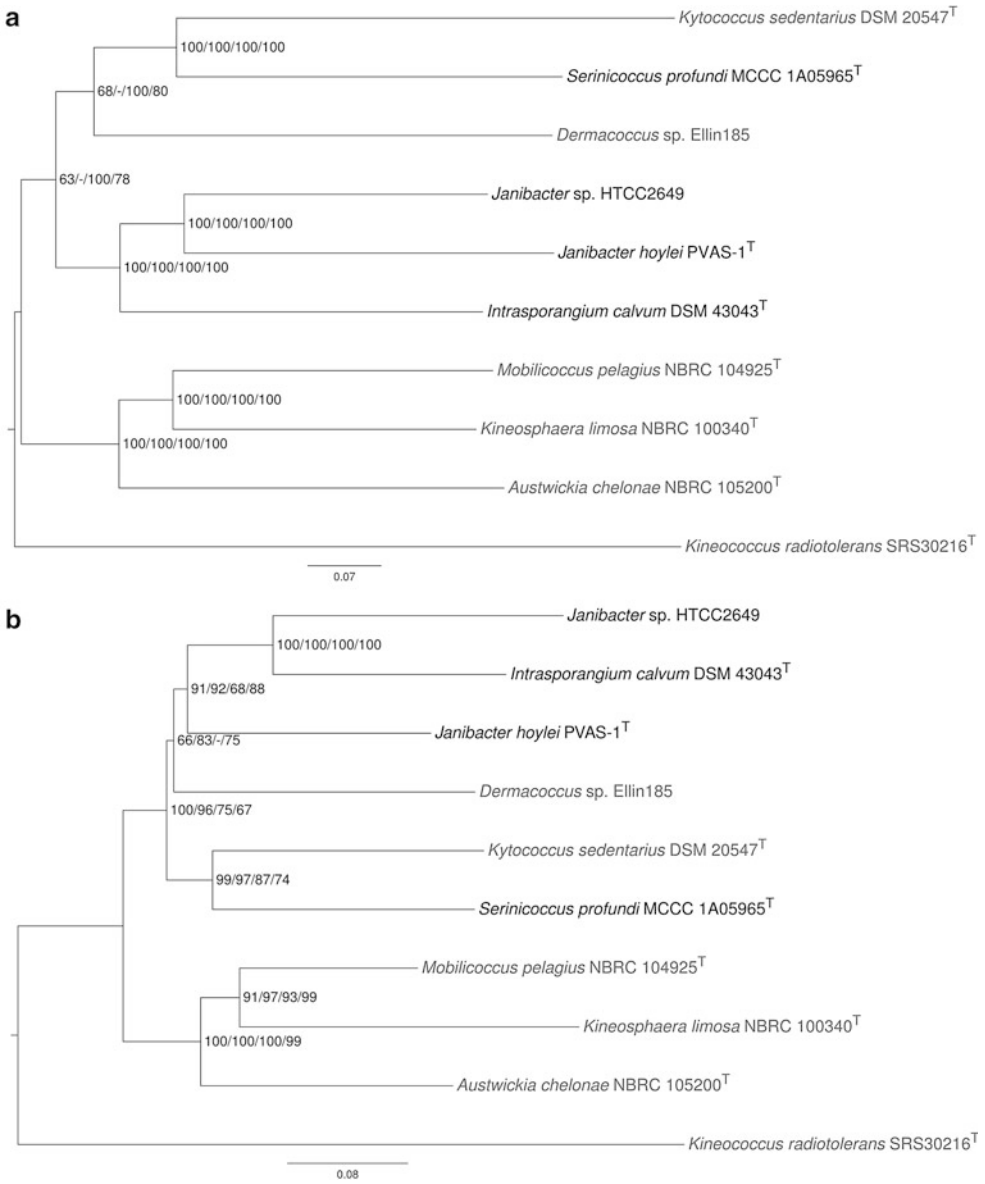

Fig. 23.5

(a) Phylogenetic tree inferred from the ''full'' matrix under the maximum likelihood (ml) criterion and rooted with kineococcus radiotolerans srs30216t. The branches are scaled in terms of the expected number of substitutions per site. Intrasporangiaceae are labelled in black, other taxa in grey. Numbers on the nodes (from left to right) are bootstrapping support values (if larger than 60 %) from (i) ml ''full'' supermatrix, (ii) maximum-parsimony (mp) ''full'' supermatrix, (iii) ml core genes, and (iv) (mp) core-gene analysis. (b) Phylogeny inferred from the gene-content matrix under the maximum likelihood (ml) criterion and rooted with kineococcus radiotolerans srs30216t. The branches are scaled in terms of the expected number of substitutions per site. Intrasporangiaceae are labelled in black, other taxa in grey. Numbers on the nodes (from left to right) are bootstrapping support values (if larger than 60 %) from (i) ml gene-content matrix, (ii) mp gene-content matrix, (iii) ml ortholog-content matrix, and (iv) mp ortholog-content matrix analysis

Genus *Janibacter* Martin et al. 1997

Ja.ni.bac'ter. L. n. *Janus*, a god in roman mythology, who is said to have had two faces; M. L. masc. n. *bacter*, a rod; L. n. *Janibacter*, referring to the changing morphology of the microorganisms.

Table 23.4 lists some properties useful to differentiate among species. Additional data other than those shown in *Table 23.4* are listed in the original species descriptions. The study of Kageyama et al. (2007) compiles the fatty acid profiles of five species performed under the same conditions. By and large the profiles agree with those listed in the original species description though some deviations are obvious (e.g., the presence of 10-methyl-$C_{17:0}$ in *J. terrae*, the absence of ai-$C_{17:0}$ in *J. terrae*, or the absence of $C_{17:1}$ in *J. limosus*).

[a]Six type strains were analyzed in parallel for the composition of fatty acids (Weon et al. 2010), which may differ from that given in the original decriptions

[b]i-C15:0 2OH/C16:1ω7c

cocci of Gram-positive and Gram-negative staining cells were observed on glucose sulfide (GS) medium. These strains, belonging to the cultured organisms of the "*Candidatus* Nostocoida limicola" taxon. (Blackall et al. 2000), were described as members of the species *T. jenkinsii*, *T. vanveenii*, and *T. veronensis* (McKenzie et al. 2006).

All members of the genus (excepting *T. duodecadis* and *T. remsis*) store polyphosphate either as granules (grown on R2A) or throughout the trichomes (grown on GS).

Table 23.6 lists some properties useful to differentiate among species. Additional data than those shown in *Table 23.6* are listed in the original species descriptions.

Genus *Knoellia* Groth et al. 2002

Knoell'i.a. N.L. fem. n. *Knoellia* after Hans Knöll (1913–1978), a German pioneer in antibiotic research.

Table 23.7 lists some properties useful to differentiate among species. Additional data than those shown in *Table 23.7* are listed in the original species descriptions. Yu et al. (2012) compared the fatty acid patterns of four species, grown under the same condition. Significant differences in both quality and quantity are obvious when compared to the patterns listed in the original description, e.g., the presence of i-C14:0 and C17:1ω9c in *K. sinensis* and *K. subterraneae* and absence of i-C17:1 in *K. sinensis*.

Genus *Phycicoccus* Lee 2006

Phy.ci.coc'cus. L. n. phycos -i from Gr. n. phukos seaweed; N.L. masc. n. coccus from Gr. n. kokkos a grain or berry; N.L. masc. n. *Phycicoccus* coccus from seaweed).

*Phycicoccus ochan*gensis (Kim et al. 2012) and *Phycicoccus badiiscoriae* (Lee 2013) have been effectively published but are not yet validated. *Phycicoccus aerolatum*, isolated from air, has been mentioned in public databases (EF493848; Weon, unpublished) but is not validly named.

Table 23.8 lists some properties useful to differentiate among species. Additional data than those shown in *Table 23.8* are listed in the original species descriptions. All strains are nonmotile and positive for catalase reaction and assimilation of glycogen, sucrose, β-galactosidase, β-glucosidase, and urease. All strains are negative for indole production, acid production from glucose, and assimilation of L-arabinose, adipate, caprate, citrate, phenylacetate, lipase (C14), valine arylamidase, trypsin, β-glucuronidase, *N*-acetyl-b-glucosaminidase, and α-fucosidase. Other reaction are listed in *Table 23.2* and in the original species descriptions. Wang et al. (2011) compared the fatty acid composition of four species performed under the same conditions. As in other such studies, remarkable differences in the composition are found when compared to the original descriptions, e.g., the presence of significant amounts of $C_{17:0}$ in *P. dokdonensis* and of $C_{15:0}$, $C_{16:0}$, and ai-$C_{15:0}$ in *P. aerophilus*.

Genus *Serinicoccus* Yi et al. 2004

Ser.in'i.coc.cus. N.L. n. *serinum* serine; N.L. masc. n. coccus from Gr. masc. n. *kokkos* a grain, seed; N.L. masc. n. *Serinicoccus* a coccus with serine in the cell wall.

Table 23.9 lists some properties useful to differentiate among species. Additional data than those shown in *Table 23.9* are listed in the original species descriptions. All strains are positive for catalase and negative for oxidase. Nitrate is reduced to nitrite. All strains show esterase (C4) and valine arylamidase activity but are negative for α-mannosidase and urease and negative for the utilization of L-arabinose, D-mannitol, and *N*-acetylglucosamine.

Genus *Ornithinimicrobium* Groth et al. 2001

Or'ni.thi.ni.mic.ro.bi.um. Gr. n. *ornithos* bird, ornithine an amino acid named after birds; Gr. adj. *micros* small; Gr. masc. n. *bios* life; N.L. neut. n. *Ornithinimicrobium* a microbe with ornithine.

Table 23.10 lists some properties useful to differentiate among species. Additional data than those shown in *Table 23.10* are listed in the original species descriptions.

Genus *Arsenicicoccus* Collins et al. 2004

Ar.sen.i.ci.coc'cus. L. n. arsenicum arsenic;N.L. masc. n.coccus berry; N.L. masc. n. *Arsenicicoccus* arsenic coccus, because the type species was recovered from an arsenic enrichment.

Table 23.11 lists some properties useful to differentiate among species. Additional data than those shown in *Table 23.11* are listed in the original species descriptions.

The two species share many metabolic properties (Hamada et al. 2009), such as presence of β-galactosidase, α-glucosidase, and β-glucosidase and hydrolysis of aesculin and gelatin. Acid is produced from D-fructose, D-galactose, D-glucose, glycogen, D-maltose, D-mannose, D-melibiose, D-raffinose, starch, D-sucrose, and D-trehalose. They differ from each other in that *A. bolidensis* produces acids from *N*-acetyl-glucosamine, arbutin, D-cellobiose, gentobiose, D-mannitol, and salicin, while *A. piscis* does not, but produces acid from D-ribose. The latter species is positive for alkaline and acid phosphatase, α-chymotrypsin, phosphohydrolase, and pyrazinamidase, while *A. bolidensis* reacts negatively. Both type strains grow in the presence of 0.45 mM arsenic.

The following genera contain a single species only. Their main phenotypic properties are indicated in *Tables 23.2* and *23.11*. Other metabolic traits are indicated in the original species descriptions. The composition of fatty acids may vary when the type strains have been included in comparative analysis with newly described species. The origin of the species is compiled in *Table 23.1*.

Table 23.6

Properties apt to differentiate type strains of *Tetrasphaera* species (see Table 23.1). 1. *Tetrasphaera japonica*; 2. *Tetrasphaera remsis*; 3. *Tetrasphaera duodecadis*; 4. *Tetrasphaera elongata*; 5. *Tetrasphaera jenkinsii*; 6. *Tetrasphaera vanveenii*; 7. *Tetrasphaera australiensis*; 8. *Tetrasphaera veronensis*

Properties	1	2	3	4	5	6	7	8

Isolation, Enrichment, and Maintenance Procedures

Considering the large number of species, isolation sources, and laboratories involved in isolation, isolation and enrichment strategies differ widely. Most studies used 10^{-5} dilutions or standard dilution techniques, mixing soil samples or crushed and grinded stones or corals in water or phosphate buffer. In rare

cases, the material was spread directly on enrichment plates (e.g., *Aquipuribacter hungaricus* and *Marihabitans asiaticum*). Techniques and media used can be grouped into categories. R2A medium was used widely, either undiluted (e.g., *Aquipuribacter hungaricus, Janibacter alkaliphilus, Tetrasphaera jenkinsii*) and with the addition of 200 µg cycloheximide for air-sampled organisms (*Terrabacter aeriphilus, Knoellia aerolata, Phycicoccus aerophilus, Janibacter hoylei*) or at different dilutions, e.g., 10× (*Kribbia dieselivorans, Phycicoccus bigeumensis*) or 5× (e.g., *Terrabacter ginsenosidimutans*). Marine agar (MA2216, Difco) was used for *Marihabitans asiaticum* (10× diluted), *Fodinibacter luteus, Janibacter corallicola* (supplemented with 1 % $CaCO_3$), *Serinicoccus marinus*, and *S. profundi*. Other studies used peptone-yeast extract/brain heart infusion agar (Yokota et al. 1993) (*Knoellia subterranea, Ornithinicoccus hortensis, Ornithinimicrobium humiphilum*), WAT agar (Li et al. 2002) (*Phycicoccus jejuensis, Terrabacter lapilli*), TSA (*Knoellia locipacati, Ornithinimicrobium kibberense*), glucose-yeast extract agar (*Serinicoccus chungangensis*), nutrient agar (Difco) (*Janibacter melonis, Terrabacter terrigena, Phycicoccus dokdonensis* [10× diluted]), LB agar (*Ornithinimicrobium pekingense, Intrasporangium chromatireducens*), and various other, more specialized media, such as mineral medium (Kim and Hegeman 1981), V2M (Zhang et al. 2010), xylan-nutrient agar (Wang et al. 2011), GS agar (Maszenan et al. 1997), feather agar (Williams et al. 1990), GMP agar (for the isolation of *Oryzihumus leptocrescens* with the addition of superoxide dismutase) (Takahashi et al. 2003), starch-casein agar (Küster and Williams 1964), basal salt medium (Collins et al. 2004), casein-mineral medium (Altenburger et al. 1996), LYPm medium (Iino et al. 2007), or R medium (Yamada and Komagata 1972). Several type and non-type strains of *Tetrasphaera* were isolated by micromanipulation (Skerman 1968) from activated sludge biomass and cells enriched on GS or R2A agar Plates. *T. duodecadis* (formerly *Arthrobacter duodecadis*) was isolated on medium containing vitamin B12 as essential growth factor (Lochhead 1958).

Long-term preservation followed routine techniques, e.g., at −20 °C, −70 °C, or −80 °C in 20 % glycerol, or in liquid nitrogen in the presence of 5 % DSMO (w/v).

Pathogenicity, Clinical Relevance

None of the *Intrasporangiaceae* strains is considered obligatory pathogenic for humans, though several reports are available that indicate the involvement of members of the family in clinical cases. Clones related to *Terracoccus luteus* were found in children with atopic dermatitis (Kong et al. 2012), and a clone related to *Janibacter* spp. was found among the microorganisms determined in the inflammation of the ileal pouch (McLaughlin et al. unpublished). A strain of *Ornithinimicrobium pekingense* was reported to be involved in an eye infection (Borsali et al. 2011) and a *Terrabacter* strain was detected in infectious endophthalmitis (Aarthi et al. 2012). An undescribed strain of *Janibacter* was identified in the blood of a patient with acute myeloid leukemia (Loubinoux et al. 2005), and *J. melonis* was described to cause bacteremia (Elsayed and Zhang 2005). Antibiotic sensitivity testing has been performed on a few type strains, i.e., *Phycicoccus dokdonensis, Serinibacter profundus, Ornithinimicrobium humiphilum, Knoellia sinensis, K. subterranea, Ornithinibacter aureus*, and *Ornithinicoccus hort*ensis, but not all of these species have been tested against the same set of antibiotics. Five of the seven species (two were not tested) are sensitive towards lincomycin, polymyxin B, rifampicin, and streptomycin. Most of the species are also sensitive towards choramphenicol, erythromycin, gentamicin, and neomycin (*O. aureus* is resistant against each of these) and resistant against oxacillin. Reactions against ampicillin, kanamycin, penicillin G, and tetracycline vary.

Habitat

While the habitat of type strains is shown in ❯ *Table 23.1*, information on additional habitats is available following BLAST analysis of 16S rRNA gene sequences deposited in public databases. The following listing on cultured and not-yet cultured stains with 98–99 % BLAST sequence similarity to type strains is not extensive, and the reader is encouraged to search for the most recent entries. In some cases organisms from different genera were found in the same habitat, i.e., in Australian soil, uranium-contaminated soil, and on skin of children with atopic dermatitis. Soil and the marine environment appear to be the main habitats.

Cultured strains, related to *Janibacter* species, were from alkaline groundwater (Tiago et al. 2004), fermented onions (HM439458; Park and Sa, unpub.), leaves of *Phaseolus vulgaris* (Lopez-Lopez et al. 2010) and the midgut of *Culex quinquefasciatus* (JN644568; Chandel et al. unpub.), and from deep sea sediment (HM222674; Luo et al. unpub.). Clone sequences originate from seahorses (Balcazar et al. 2010), pouchitis microflora (GQ158446; McLaughlin et al. unpub.), and arctic sea ice (Yu et al. 2009).

Knoellia-related isolates and clones originated from urban aerosols (Brodie et al. 2007), marine sediment (Bredholdt et al. 2007), plant leaves (Lopez-Lopez et al. 2010), and Caribbean sponges (Tabares et al. 2011).

Arsenicicoccus-related sequences were retrieved from a strain isolated from a salt mine (DQ358660; Xiao et al. unpub.); from glaciers (JX949811; Liu and Xin, unpub.), marine sediment (HQ858012; Dastager, unpub.), cellulose or xylan/pectin enrichments, and pig feces (JQ607653; Ziemer et al. unpub.); and from uncultured soil (Joseph et al. 2003). A clone sequence was obtained from material of an indoor environment (Rintala et al. 2008). An *Ornithinicoccus* strain was among a wide range of bacteria associated to root nodules collected from legumes (Zakhia et al. 2006).

Isolates related to *Serinibacter* species originate from marine sediments (Gontang et al. 2007) and other marine environments (DQ985072; Wang and Jiao, unpub.), sea sponges (JX007966; Sun and Li, unpub.; JN128293; Su et al. unpub.), and fermented seafood (JN187087; Jeon and Jung, unpub.) and as for

Table 23.12

Summary of *Intrasporangiaceae* strains with bioremediating capacities

Species and strain	Gene/protein	Function	Comment	Reference
Terrabacter sp. strain DBF63	dbfA and dbfBC fln-dbfA, pht, and pca gene clusters	Dibenzofuran degradation utilization of fluorene	DfdA dioxygenase degrades dibenzo-p-dioxin, carbazole, dibenzothiophene, anthracene, phenanthrene, and biphenyl	Kasuga et al. (2013)
Terrabacter sp. strain DBF63	DbfA1, DbfA2	Dibenzofuran 4,4a-dioxygenase	The DFDO system converts dibenzofuran to 2,2′,3-trihydroxybiphenyl	Takagi et al. (2005)
Terrabacter sp. strain DBF63	DbfA	Fluorene degradation to phthalate	Fluorene and 9-fluorenone are degraded to 9-fluorenol and 1,1a-dihydroxy-1-hydro-9-fluorenone, respectively	Habe et al. (2004)
Terrabacter sp. strain DBF63	flnD1 and ORF16	Fluorene degradation to phthalate. Class III two-subunit extradiol dioxygenase	9-Fluorenol and 1,1a-dihydroxy-1-hydro-9-fluorenone are degraded to 9-fluorenone and 2′-carboxy-2,3-dihydroxybiphenyl, respectively	Habe et al. (2004)
	FlnE	Serine hydrolase	Phthalate formation	
Terrabacter sp. strain FLO	ND	Aromatic-ring-hydroxylating dioxygenase	Biodegradation of polycyclic aromatic hydrocarbons to transform phenanthrene, fluorene, pyrene, and fluoranthene into the cis-dihydrodiol metabolites	Zhou and Zhou (2007)
Terrabacter spp.	PAH-RHDalpha	Alpha subunit of the PAH-ring hydroxylating dioxygenase	PCR primer set to amplify narAa, phdA/pdoA2, idA/pdoA1, nidA3/fadA1	Cébron et al. (2008)
Janibacter terrae XJ-1	dbdA	Dibenzofuran dioxygenase	Dibenzofuran is degraded to 2,2′,3-trihydroxybiphenyl, salicylic acid, gentisic acid, and other metabolites	Jin et al. (2006)
Janibacter sp. TYM3221	Gene cluster bphAaAbAcAd	1,1-Dichloro-2,2-bis(4-chlorophenyl)ethylene degradation	End product 4-chlorobenzoic acid	Nguyen et al. (2011b)
Janibacter strain YA	ND	Mono-chlorinated dibenzo-p-dioxin degradation: 1-chloro-dibenzo-p-dioxin (1-CDD) and 2-chloro-dibenzo-p-dioxin	2-chloro-2′,6-dihydroxydiphenylether as metabolite	Iwai et al. (2005)
Janibacter strain YY-1	ND	Growth on fluorene and dibenzothiophene cometabolization of dibenzo-p-dioxin, phenanthrene, and anthracene	2,3,2′-Trihydroxybiphenyl, biphenyl-dihydrodiol, dibenzothiophene 5-oxide, and coumarin as major metabolites	Yamazoe et al. (2004)
Terrabacter ginsenosidimutans strain Gsoil 3082^T	bgpA	Ginsenosidase type III	Hydrolyzes 3-O-glucoside of multi-PPD-type ginsenosides. 3-O-β-D-(1− > 2)-glucopyranosyl of Rb1 is hydrolyzed to gypenoside XVII, and the 3-O-β-D-glucopyranosyl of gypenoside XVII is hydrolyzed to gypenoside LXXV. Glucopyranosyls linked to the 3-O-position of Rb2, Rc, Rd, Rb3, and Rg3 are hydrolyzed	Jin et al. (2012)

ND not determined

Terracoccus luteus from skin of children with atopic dermatitis (Kong et al. 2012).

Several sequences of isolates and clones are reported for *Ornithinimicrobium* species, such as oyster shells (Islam et al. 2009), garbage composter (Narihiro et al. 2004), and leachate sediment (Liu et al. 2011). Several clones were obtained from skin of children with atopic dermatitis (Kong et al. 2012), and they were detected in a study on the synecology of the primary and secondary feedlot habitats of *Escherichia coli* O157:H7 (Durso et al. unpub.).

Uncultured strains moderately related to described *Tetrasphaera* species originate not only from wastewater

(HQ010781; Ji and Chen 2010) and activated sludge (EU104275; Brown and Turner, unpub.), have been found also in clean room environments (accession number EU071503; Nellen et al. unpub.), from a siliceous sedimentary rock (AB179506, Yoshida et al. unpub.), and the human skin (Grice et al. 2009). Several isolates (Ellin strains) were recovered from soil (Schoenborn et al. 2004).

Sequences of uncultured strains, related to *Terrabacter* species, originate not only from house dust (FM872945; Taubel et al. 2009), rhizosphere of Phragmites (AB240275; Nakamura et al. unpub.), apple phyllosphere (Yashiro et al. 2011), and freshwater (Baik et al. unpub.), but also some from Australian soil (Ellin strains) (Schoenborn et al. 2004).

Clone sequences related to *Terracoccus luteus* were found on the skin of children with atopic dermatitis (Kong et al. 2012), while *Intrasporangium calvum* shared close relatedness with uncultured microorganisms involved in anaerobic benzene degradation (Kunapuli et al. 2007) and in soil heavily contaminated with uranium (Brodie et al. 2006).

Phycicoccus-related bacteria were reported by Mitsui et al. (1997) and uncultured strains were mainly identified in soil samples, such as in potassium rich soil (JF428901; Huang and Sheng, unpub.), an unidentified soil (EF688365; Jia et al. unpub.), uranium-contaminated soil (Brodie et al. 2006), soils of the Tianshan Glacier No. 1 (JN662535; Wu et al. unpub.), volcanic ash (FN386744; Lee and lee, unpub.), and unvegetated soil (Sattin et al. 2009). Only two clone sequences were related to *Ornithinibacter aureus*, both from a wastewater treatment plant (HM773480; Lee et al. unpub.; Liu et al. 2012b). *Fodinibacter luteus* is related to an uncultured marine bacterium (AB522645; Kasai et al. unpub.).

Application

Especially members of *Tetrasphaera* are intrinsic members of wastewater treatment plants, and, except for *T. duodecadis* and *T. remsis*, all species accumulate polyphosphate granules (Maszenan et al. 2000; Hanada et al. 2002; McKenzie et al. 2006).

The culture extract of a *Janibacter limosus* strain showing a high biological activity against bacteria and fungi was found to contain two natural products, i.e., helquinoline (4-methoxy-2-methyl-1,2,3,4-tetrahydroquinoline-8-carboxylic acid) and *N*-acetylkynuramine (Asolkar et al. 2004).

Waste Treatment and Removal

Members of the genus *Tetrasphaera* are considered to be polyphosphate accumulating organisms (PAOs) in enhanced biological phosphorus removal (EBPR) from wastewater in which they may play a dominating role (Liu et al. 2001; Eschenhagen et al. 2003; Kong et al. 2005; Nguyen et al. 2011a). None of the type strains accumulates polyhydroxyalkanoates (Liu et al. 2001; Maszenan et al. 2000). Analysis of the annotated genome of *T. australiensis, T. japonica, T. elongata*, and *T. jenkinsii* allowed the elucidation of key features of organisms thriving under the alternating anaerobic/aerobic conditions encountered in EBPR systems. It was postulated that under anaerobic conditions these PAOs take up glucose (but also amino acids and acetate), fermenting it to succinate and other components. Glycogen is synthesized as a storage polymer, using energy generated from the degradation of stored polyphosphate and glucose fermentation. Under aerobic conditions the stored glycogen is catabolized to provide energy for growth and used to replenish the intracellular polyphosphate pool needed for the subsequent anaerobic metabolism. Denitrifying abilities were also recognized among the *Tetrasphaera* strains (Kristiansen et al. 2013). *Tetrasphaera* strains seem to occupy a slightly different ecological niche compared with "*Candidatus* Accumulibacter" contributing to a functional redundancy and stability of the EBPR process (Xia et al. 2008).

Bioremediation

Using a microcosm enrichment approach to enrich bacteria which are representative of long-term biphenyl-adapted microbial communities resulted in the isolation of more than 150 biphenyl-degrading strains. Based upon characterization of fatty acid methyl ester (FAME) analysis and 16S rRNA gene sequence comparison, one minor cluster was assigned to *Terrabacter* sp. (Wagner-Döbler et al. 1998).

Terrabacter sp. strain DBF63 is capable of degrading fluorene (FN) to intermediates of the tricarboxylic acid cycle via phthalate and protocatechuate. Genes were identified for the protocatechuate branch of the beta-ketoadipate pathway (pcaR, pcaHGBDCFIJ) by sequence analysis of a 70 kb DNA region of the FN-catabolic linear plasmid pDBF1 (Habe et al. 2004, 2005). The dbfA1A2 cistron and pht operon of *Terrabacter* sp. DBF63 were located on the two linear plasmids, pDBF1 (160 kb) and pDBF2 (190 kb), while dbfBC genes were located on the chromosome (Nojiri et al. 2002). Another *Terrabacter* strains capable of degrading dibenzofuran by the plasmid-borne dioxygenase dfdA1 gene was strain YK3 (Iida et al. 2002). *Table 23.12* gives an overview of strains and their bioremediating capacities.
